As a separation method, chromatography has a number of advantages over older techniques—crystallization and distillation, for example (see the section *Chemical separations and purifications* above). It is capable of separating a multicomponent chemical mixture without requiring an extensive foreknowledge of the identity, number, or relative amounts of the substances present. It is versatile in that it can deal with molecular species ranging in size from viruses composed of millions of atoms to the smallest of all molecules—hydrogen—which contains only two; furthermore, it can be used with large or small amounts of material. Some forms of chromatography detect substances present at the picogram (10^{-12} gram) level, thus making the method a superb analytical technique. It is also effective as a large-scale preparative method. Its resolving power is unequalled among separation methods; more than 100 constituents can be isolated from complex mixtures such as gasoline.

Chromatography is carried out by utilizing a gas or liquid (the mobile phase) flowing over or through an adsorbing material (the stationary phase) of high surface area. When the components of the mixture to be separated are introduced into this system, they migrate in the direction of the flow at different rates, which are determined by their relative distributions between the mobile and stationary phases. Chromatography is thus a differential migration technique, along with electrophoresis (separation in an electrical field) and sedimentation (separation in a gravitational field). It depends for its separating ability on differential retardation, or retention, caused by the unequal degree of adsorption of the solutes washed along by the fluid stream.

HISTORY

The first purely pragmatic applications of chromatography can be traced to the early dye chemists, who tested their dye mixtures by dipping strings or pieces of cloth or filter paper into the dye vat. The dye solution migrated up the inserted material by capillary action, and the dye components separated into bands of different colour. In the 19th century, several German chemists carried out deliberate experiments to explore the phenomenon. They observed, for example, the development of concentric, coloured rings by dropping solutions of inorganic compounds onto the centre of a piece of filter paper; a treatise was published in 1861 describing the method and giving it the name "capillary analysis." For the following 50 years, the technique was used for the analytical separation of a large variety of materials, including biological samples.

The discovery of chromatography, however, is generally attributed to the Russian botanist Mikhail S. Tsvet (also spelled Tswett) because he recognized the physicochemical basis of the separation and applied it in a rational and organized way to the separation of plant pigments, particularly the carotenoids and the chlorophylls. Tsvet's book, published in 1910, described a technique that is used today in essentially the same form. A vertical glass column is packed with an adsorptive material, such as alumina or powdered sugar; a solution of the plant pigments is added to the top of the column, and the pigments are washed through the column with an organic solvent. The pigments separate into a series of discrete coloured bands on the column, divided by regions entirely free of pigments. After the column of adsorptive material is extruded carefully from the tube, the different zones of pigments are isolated by cutting the material into sections. Pigment is then washed off each section with a solvent. Because Tsvet worked with coloured substances, he called the method chromatography (from Greek words meaning colour writing). About 1900 an American chemist sepa-

Discovery of chromatography

rated the components of crude oil by passing the sample through a column of fuller's earth; he was well aware of the analytical importance of this process, but his work was not widely followed outside the petroleum field. Tsvet's development of chromatographic procedures also was generally unknown to chemists in the Western world because he published either in German botanical journals or in Russian works. In 1931 chromatography emerged from its relative obscurity when the German chemist Richard Kuhn (who later received the Nobel Prize for Chemistry) and coworkers reported the use of this method in the resolution of a number of biologically important materials. Ten years later, two British chemists, A.J.P. Martin and R.L.M. Synge, began a study of the amino-acid composition of wool. Their initial efforts, in which they used a technique called liquid-liquid countercurrent distribution, failed to give them adequate separation; they conceived, therefore, of an alternative method, in which one liquid was firmly bound to a finely granulated solid packed in a glass tube and a second liquid, immiscible with the first, was percolated through it. Silica gel served as the granular solid, and Martin and Synge pictured the gel as composed of water tightly bonded to the crystals of silica; the mobile phase was chloroform. Their work with this technique was remarkably successful. Although their method was mechanically identical with the method of Tsvet, it was innovative in that it involved the concept of a stationary liquid (water) supported on an inert solid (silica), with the result that the solute molecules partitioned between the stationary liquid and a separate mobile liquid phase (chloroform). The new technique was called partition chromatography, and in 1952 Martin and Synge were awarded the Nobel Prize for their work.

The initial partition-chromatography system presented difficulties because of lack of reproducibility in the properties of the silica gel and lack of uniformity in the packing of columns. Partly for this reason, Martin, Synge, and their coworkers worked out a new procedure in which the stationary medium consisted of a sheet of filter paper. The paper was thought of as consisting of water bonded to cellulose, giving another partition method. The technique gave the desired reproducibility, and beginning in the 1940s paper chromatography found wide application in the analysis of biologically important compounds, such as amino acids, steroids, carbohydrates, and bile pigments. In this field it has replaced, to a large extent, the column technique initiated by Tsvet.

Motivated probably by the same drawbacks to column chromatography, two Russian pharmacists developed a technique for distributing the support material as a thin film on a glass plate. The plate and support material could then be manipulated in a fashion similar to that of paper chromatography. The results of the Russian studies were reported in 1938, but the potential of the method was not widely realized until 1956, when intensive research on its application was begun. The new chromatographic system became known as thin-layer chromatography.

Still another chromatographic technique, gas chromatography, was first carried out in Austria, but the first extensive exploitation of the method was made by Martin and A.T. James in 1952, when they reported the elution gas chromatography of organic acids and amines. In this work, small particles of support material were coated with a non-volatile liquid and packed into a heated glass tube. Mixtures injected into the inlet of the tube and driven through by compressed gas appeared in well-separated zones. This development was immediately recognized by petroleum chemists as a simple and rapid method of analysis of the complex hydrocarbon mixtures encountered in petroleum products. A major advance came with the elimination of the support material and the coating of the liquid on the wall of a long capillary tube. With this development, it has become possible to carry out such extraordinary separations as the identification of 350 different components of coffee flavour in a single chromatographic experiment.

In the years since the rediscovery of chromatography by Kuhn, chromatographic separations have contributed greatly to many fields and possibly have been the greatest single cause of the dramatic acceleration that occurred in

Discovery of gas chromatography

biochemical research during this period. Discovery of the structure of insulin, for example, was made possible when the British biochemist Frederick Sanger rationally and methodically applied chromatography to the fragments of the ruptured insulin molecule. He received the 1958 Nobel Prize for Chemistry for his work.

METHODS

Classification. Classification of the various chromatographic techniques is somewhat confusing because the descriptive terms used may refer to the state of the adsorptive material, the nature of the adsorptive force, the nature of the mobile phase, the method of termination, the method of solute introduction, and the presence or absence of gradients. In column chromatography, the adsorptive material is placed in a column of glass or metal, generally long and narrow in form. The adsorbent may be granular and fill the column (packed column), or it may be a liquid coating the inside column wall (capillary column). The mobile phase is drawn through the column by gravity or forced through by pumps. In paper and thin-layer chromatography, the adsorptive material consists, respectively, of a sheet or a thin film. In either case, liquid is drawn over the initially dry film by capillary action.

Adsorption
chroma-
tography

If the adsorptive force is provided by molecules attaching to the surface of a solid that is packed in a column, spread as a thin film on a glass or plastic sheet, or coated on the inside walls of a tube, the method is termed adsorption chromatography. If the solid is a polymeric material containing attached ions that can be exchanged for ions in the solution mixture, the method is termed ion-exchange chromatography (see CHEMICAL REACTIONS: *Ion-exchanging reactions*). If the adsorptive force is provided by the molecules dissolving in a liquid coated on a granular solid or on the walls of a column, the method is termed partition chromatography (meaning that the solute is partitioned between two liquid phases; in this case the term adsorption might be considered something of a misnomer). If the molecules diffuse into narrow pores within a solid, the process is termed molecular sieving, gel filtration, or gel-permeation chromatography. (Again, in these cases, it is questionable whether true adsorption is involved.) Regardless of the mechanism involved, in all types of chromatography the material that takes up the solute remains fixed and is called the stationary phase.

The method is further classified by the nature of the mobile phase. When this is a gas, the method is called gas chromatography; when it is a liquid, liquid chromatography. Adsorption chromatography, then, can be either gas-solid chromatography or liquid-solid chromatography, depending upon whether the mobile phase is a gas or a liquid. Similarly, partition chromatography can be gas-liquid or liquid-liquid chromatography.

Chromatographic methods also can be classified according to the method used to terminate a single chromatographic procedure, or "run." In development chromatography, the flow of the mobile phase simply is halted after a certain time interval. Because the average velocities of the solutes differ, depending upon their retardation, each is displaced a different distance. The distance moved by a solute relative to the distance moved by the solvent is a measure of the retention and is called the R_f value. Slightly retained solutes move a large distance (that is, have a large R_f value), whereas strongly retained solutes remain close to the site of sample introduction (that is, have a small R_f value). In elution chromatography all of the solutes migrate through the entire adsorptive bed and appear at its terminus at different times. Solutes that are slightly retained by the stationary phase have small retention times, whereas those more tenaciously retained have large retention times. (Retention times can be converted to retention volumes by multiplying the times by the volumetric flow rate of the mobile phase.)

Frontal
analysis

In zonal chromatography, the most common form, the mixture of solutes to be separated is introduced as a narrow zone, or spot, either added to the incoming mobile phase or applied directly to the adsorptive material. In the method called frontal analysis, by contrast, the mixture to be resolved is introduced as a continuous stream or

"train." If the letters A , B , and C represent the solutes in order of increasing affinity for the stationary phase, then the first zone to appear is the front of the A solute train, the second zone consists of part of the A train and the front of the B train, and the final zone contains the remainder of all three solute trains. The zones are contiguous.

When A , B , and C are strongly retained, and a large, but discrete, sample of the mixture is placed at the top of an adsorptive bed, the solutes come to occupy contiguous bands. The top band is almost exclusively C because it has the greatest affinity for the adsorptive sites and is concentrated enough to displace the more weakly adsorbed A and B from these sites. The next band consists almost exclusively of B , for the same reasons. The lowest band consists of A . If a fourth substance, D , which is the most strongly adsorbed of all, then is introduced continuously into the column, it displaces C , which in turn displaces B , which displaces A . The zones then migrate through the medium in this order. This procedure is called displacement chromatography. It is not widely used because there is no space between zones and it is, therefore, difficult to achieve separations.

Quite often, gradients—smooth changes in temperature or in composition of the mobile phase—are used in elution chromatography to speed up sluggish zones. If temperature is varied steadily during the run, the process is called programmed temperature chromatography. If mobile-phase composition is changed, it is gradient elution chromatography.

Technique. *Gas chromatography.* In gas chromatography, helium, hydrogen, nitrogen, or some other inert gas is employed as the mobile phase. With gas-solid chromatography, a stationary phase of an adsorptive solid, such as carbon, alumina, or silica, either is packed in the column as small particles or is coated on the inside wall as a film. Retention, in either case, is by weak adsorptive forces between the solute molecules and adsorptive sites on the solid material. The solid support also can be a porous, relatively nonadsorptive material, as is the case with the so-called molecular sieves, and the molecules then are separated on the basis of molecular size rather than degree of adsorption. Small molecules diffuse preferentially into the small regular pores of the sieve and thus are retarded relative to larger molecules, which are not so trapped. In gas-liquid chromatography, a nonvolatile liquid is coated on a finely divided solid, the support, and these particles are packed in the column, or the liquid may be coated on the inside wall of a small diameter tube. The stationary liquids include high-molecular-weight hydrocarbons and complex polymers, such as the polyesters.

An important consideration in gas chromatography is detection of the material as it comes off the column in the carrier gas. Thermal-conductivity detectors compare the heat-conducting ability of the exit gas stream to that of a reference stream of pure carrier gas. To accomplish this, the gas streams are passed over heated filaments in thermal-conductivity cells. Measured changes in filament resistance of the cells reflect temperature changes caused by increments in thermal conductivity. This resistance change is monitored and registered continuously on a recorder. An alternate type of detector is the flame-ionization detector, in which the gas stream is mixed with hydrogen and burned. Positive ions and electrons are produced in the flame when organic substances are present. The ions are collected at electrodes and produce a small, measurable current. The flame-ionization detector is highly sensitive to hydrocarbons, but it will not detect carrier gases, such as nitrogen and oxygen, or highly oxidized materials, such as carbon dioxide, carbon monoxide, sulfur dioxide, and water. In another device, the electron-capture detector, a stream of electrons from a radioactive source is produced in a potential field. Materials in the gas stream containing atoms of certain types capture electrons from the stream and measurably reduce the current. Most important of the capturing atoms are the halogens—fluorine, chlorine, bromine, and iodine. This type of detector, therefore, is particularly useful with chlorinated pesticides. Other important detector systems are: the helium-ionization detector, the flame-photometric detector, and the micro-

Methods of
detection

coulometric detector. The effluent gas from the gas chromatograph also can be led directly to the inlet port of a mass spectrometer, a device that separates materials on the basis of their masses. This procedure not only tells when materials come off the column, but also identifies them.

Liquid-solid chromatography. Liquid-solid chromatography is carried out with a liquid mobile phase and a solid stationary phase. In liquid-solid chromatography, as it is generally practiced, the solid is packed into a vertical tube, the sample is introduced onto the top of the packing bed, and a solvent is added continuously to the top of the column to wash the mixture through by gravity flow. Results from gas chromatography suggested that separation could be improved in liquid chromatography if the diameter of the tube and the sizes of the solid particles were reduced and if the pressure driving the liquid through were increased. A number of instances of improved separations using long, narrow columns and high inlet pressures, in fact, have been reported. The capacity of such columns is reduced, however, and sensitive detectors must be employed to locate the small amounts of material in the effluent.

If the solute components are coloured, their position on the column, or their appearance in the effluent, is easily determined. In early work employing development chromatography with colourless solutes, the column packing was extruded to yield a long cylinder; a colour-developing reagent was then streaked along the column to indicate the presence of a solute band. In elution chromatography, successive samples of the effluent are collected in tubes held in a mechanically driven rotating tray, called a fraction collector. Reagents are added to the sequential fractions to determine the presence of a solute, perhaps by producing a coloured product or a precipitate; or the fractions can be examined by a spectrophotometer, which detects substances by their light-absorption properties. This time-consuming process has now been automated. With solutes (such as amino acids) that respond to the chemical reagent ninhydrin the effluent is automatically mixed with the colour-developing reagent, and the solution continuously passed through a spectrophotometer cell. The absorption of light is recorded on a photoelectric tube connected to a recorder. A tracing then records the solutes as they pass off the column. Solutes absorbing light in the ultraviolet region can be similarly monitored. In another detection method, dissolved solutes produce a change in the refractive index of the effluent, another light effect that can be continuously monitored.

Popular adsorbents for liquid chromatography are alumina and silica. Ion exchange columns employ both positively charged (cationic) and negatively charged (anionic) exchangers. The column may be packed with a porous polymer, a porous glass, or a gel (modified cellulose or agarose) for molecular-sieve chromatography.

Thin-layer chromatography. In thin-layer chromatography, the adsorbent is mixed with a binder, such as calcium sulfate, and a slurry of adsorbent, binder, and water is coated on a glass plate. As the plate dries, the binder and adsorbent particles together form a thin film. The thin-layer plate is then heated to drive off water and activate the adsorbent. The sample mixture is placed on one edge of the plate as a spot, a row of spots, or a continuous streak. The plate is clamped vertically between two other glass plates with the lower edge of the adsorbent exposed in a trough of solvent. The solvent rises up through the adsorbent by capillary action to produce the mobile-phase flow. Alternatively, the loaded edge can be placed in the upper position and solvent can be fed to the plate by wick systems, with the result that flow is downward by gravity, as well as by capillary action. In any case, flow is normally halted before the solvent progresses to the other edge. For uncoloured solutes the plate is sprayed with a colour-developing reagent, or the presence of solutes is detected by ultraviolet absorption or fluorescence. No matter which method is used, the result is a series of spots or bands arranged in the direction of flow.

Liquid-liquid chromatography. In liquid-liquid chromatography, both the stationary and mobile phases are liquid. When hydrated silica gel and powdered cellulose

are used in columns, the stationary phase, in both cases, is presumed to be water bonded to the solid support. The mobile phase is normally a liquid immiscible with water. Sheets of filter paper are used in the same manner as that described for thin-layer chromatography, but, in this case, the stationary material is the liquid (water) bonded to the cellulose support. This is paper chromatography. Reversed-phase paper chromatography involves impregnation of the paper with an organic fluid, which adheres firmly to the paper. The mobile phase is then water or a water-miscible liquid. Paper also can be chemically modified so that it acts as an ion exchanger, or it can be impregnated with a liquid exchanger. Another technique sometimes used consists of passing a solution of two liquids through a column packed with a solid. One of the liquids shows preferential adsorption to the solid, with the result that there are effectively two liquid phases, the adsorbed liquid and the equilibrium solution that remains unadsorbed.

THEORETICAL CONSIDERATIONS

Retention. The rates of migration of substances in chromatographic procedures depend on the relative affinity of the substances for the stationary and the mobile phases. Those solutes attracted more strongly to the stationary phase are held back relative to those solutes attracted more strongly to the mobile phase. The forces of attraction are usually selective; that is, stronger for one solute than another. At least one of the two phases must exert a selective effect, and very often both phases are selective. In gas chromatography, the mobile phase is ordinarily a gas that exerts essentially no attractive force on the solutes at all. In this case the mobile phase is entirely nonselective.

The forces attracting solutes to the two phases are the normal forces existing between molecules—intermolecular forces. There are five major classes of these: (1) the universal, but weak, interaction between all electrons in neighbouring atoms and molecules, called dispersion forces; (2) the induction effect, by which polar molecules (those having an asymmetrical distribution of electrons) bring about a charge asymmetry in other molecules; (3) an orientation effect, caused by the mutual attraction of polar molecules resulting from alignment of dipoles (positive charges separated from negative charges); (4) hydrogen bonding between dipolar molecules bearing positive hydrogen ions; and (5) acid-base interactions in the Lewis acid-base sense; that is, the affinity of electron-accepting species (Lewis acids) to electron donors (Lewis bases). In the special case of ions, a strong electrostatic force exists, in addition to the other forces; this electrostatic force attracts each ion to ions of opposite charge. This is an important element of ion-exchange chromatography.

In studies of chromatographic behaviour, the retention ratio, the relative speed of solute and mobile phase, is a quantity of major significance. It is approximately equal to the experimentally determined R_f value described above. Its value never exceeds one, because the solute can never move faster than the mobile phase that carries it along. The retention ratio is inversely related to the distribution coefficient, a factor that describes the relative distribution of solute between the mobile and the stationary phases. The precise relationship of the retention ratio and the distribution coefficient is expressed in the following equation: $R = (1 + K V_s / V_m)^{-1}$, in which R is the retention ratio, K is the distribution coefficient, and V_s / V_m is the ratio of the amount of stationary phase present (V_s) to the amount of mobile phase (V_m).

The versatile operation of chromatography requires that solute velocity, and thus the retention ratio, be subject to control. As the above equation suggests, partial control can be gained by altering the ratio of stationary phase to mobile phase (V_s / V_m). Greater control can be gained by manipulating the distribution coefficient (K), because there are many factors that affect it. Changes in the chemical nature of the stationary and mobile phases, for example, alter the distribution coefficients of different solutes in the solvent system. This provides selectivity control; that is, it makes it possible to separate solutes by changing solvent systems. Changes in the chemical nature of the phases also cause gross shifts in individual distribution coefficient,

operations

because the intermolecular forces involved are altered. Increased temperature generally decreases the distribution coefficient, drastically so in gas chromatography, in which a 20° C rise in temperature may halve the distribution coefficient and, as a consequence, double the retention ratio. Variations in mean pressure affect the distribution coefficient if they are large enough—tens and hundreds of atmospheres of pressure are necessary to influence gas and liquid chromatography, respectively.

Local changes in distribution coefficient may occur as “pulses” of solute in high concentration appear. Very low solute concentrations do not affect the distribution coefficient, but at high concentrations solute molecules interact with one another as well as with the constant background presented by the mobile and stationary phases. In adsorption chromatography, the interaction takes the form of a competition for adsorption sites on the stationary phase. The limited sites available accommodate only limited amounts of solute and, as these sites are filled, the amount adsorbed finally becomes independent of the amount present. For all such interactions, the distribution coefficient changes with concentration in a nonlinear fashion. In modern chromatographic practice, nonlinear distribution is avoided when possible, because it distorts and broadens chromatographic zones, making separations less sharp.

Resolution. Chromatography separates complex mixtures into individual solute zones; a written, or traced, record of a chromatographic procedure is a chromatogram. For development chromatography, as in paper chromatography, the final chromatogram consists of a series of spots or zones arranged along the migration coordinate. In elution chromatography, when a detector is used, the chromatogram is a trace on a recorder chart of the solute concentration plotted against the time. This yields a concentration profile, exhibiting discrete peaks at points where zones of solute appear. A similar profile can be produced from a development chromatogram by recording the concentration of the solute along the migration path, using a radioactive detector or an optical densitometer (a device that is used for detecting solutes optically).

There are two features of the concentration profile important in the separation or resolution of solute zones. Peak position, the first, refers to the location of the maximum concentration of a peak. To achieve satisfactory resolution, the maxima of two adjacent peaks must be disengaged. Such disengagement depends upon the identity of the solute and the selectivity of the stationary and mobile phases.

The second feature important to resolution is the width of the peak. Peaks in which the maxima are widely disengaged still may be so broad that the solutes are incompletely resolved. For this reason, peak width is of major concern in chromatography. It is infrequently measured as such, however, but rather is reflected in a quantity called the plate height, or the height equivalent to a theoretical plate. (These phrases are borrowed from the separation procedure called fractional distillation, in which separation is achieved by distillation and condensation on obstructions called plates.)

Chromatographic peaks ordinarily are bell-shaped. Mathematically, they present the profile shown in Figure 1. The so-called standard deviation (represented by sigma,

σ) is one-quarter of the baseline width (w) between lines drawn tangent to the points of inflection of the peak. Either the standard deviation or the baseline width may be taken as a measure of peak width in comparing peaks for various purposes.

In chromatography, peak width increases in proportion to the square root of the distance that the peak has migrated. Mathematically, this is equivalent to saying that the square of the standard deviation is equal to a constant times the distance travelled. The height equivalent to a theoretical plate is defined as the proportionality constant relating the standard deviation and the distance travelled. Thus, the defining equation of the height equivalent to a theoretical plate is as follows: $HETP = \sigma^2/L$, in which HETP is the height equivalent to a theoretical plate, σ is the standard deviation, and L the distance travelled. The use of the plate height is superior to the use of peak width in evaluating various chromatographic systems, because it is constant for the chromatographic run, and it is nearly constant from solute to solute.

In elution chromatography, in which the peak develops on a time scale, an equivalent form of the above equation is: $HETP = L \sigma^2/t_r^2$, in which L is now the column length, t_r the time of retention of the peak by the column, and σ the standard deviation of the peak in time units. (Several other equivalent equations exist, some of them using the baseline width rather than the standard deviation of the peak.)

Three basic processes contribute to plate height (HETP): (1) Molecular diffusion, in which solute molecules diffuse outward from the centre of the zone. This effect is inversely proportional to the flow velocity, because rapid flow reduces the time for diffusion. Mathematically, the contribution to plate height of this factor is expressed B/v in which B is a constant. (2) Eddy diffusion, in which solute is carried at unequal rates through the tortuous pathways of the granular bed. The contribution to plate height is a constant factor, A , independent of velocity. (3) Nonequilibrium or mass transfer, in which the slowness of diffusion in and out of the stationary and mobile phases causes fluctuations in the times of residence of the solute in the two phases and a consequent peak broadening. The effect is proportional to velocity and is expressed as $C_s v$ and $C_m v$, in which C_s and C_m are constants relating to the stationary and mobile phases, respectively.

The function of chromatographic theory has been twofold: (1) to evaluate B , A , C_m , and C_s in terms of underlying diffusivity and flow processes, and (2) to assemble them into a total plate height equation.

The general equation used is $HETP = A + B/v + C_s v$. This is inadequate at high velocities, however, and is replaced by the equation

$$HETP = (1/A + 1/C_m v)^{-1} + B/v + C_s v.$$

Knowledge of the component terms in such equations allows one to optimize chromatographic operating conditions.

Chromatographic columns are often characterized by the total number of theoretical plates, N , often also called column efficiency. This is defined as $N = L/HETP$. Typically, the total number of theoretical plates (N) is about 10^2 , but it ranges from 10 to 10^6 .

APPLICATIONS

Chemical separation problems are enormous in scope. More than 1,000,000 known chemical compounds exist and are found primarily in the form of mixtures; these must be separated if the individual components are to be either characterized or utilized. In biological systems alone, thousands of known compounds, and undoubtedly thousands more that are unknown, require separation if they are to be detected and isolated in a pure state for characterization. Chromatography bears the main burden of such separations. The multitude of possible chromatographic techniques, and the variations possible within each technique, provide the flexibility needed to meet extreme demands. A few general principles govern the strengths and weaknesses of the various techniques and determine their suitability for different applications.

Advantages of gas chromatography

As pointed out earlier, gas chromatography is faster than liquid chromatography, separation times usually being seconds or minutes with the former and minutes or hours with the latter. Detection sensitivity also is superior with gas chromatography. The fundamental limitation of the method, however, is that solutes must be reasonably volatile, so that a finite fraction of solute is distributed in the gaseous phase. For organic substances, volatility is rarely adequate if the molecular weight of the compound exceeds 500. High temperatures, often up to 300° C (572° F), enhance volatility, but decomposition of the substance can result. High pressures, ranging from 50 to 1,000 atmospheres, also enhance volatility, but this technique is not widely used. Nonvolatile compounds often are converted to volatile derivations so that they can be separated by gas chromatographic techniques. Fatty acids, for example, are converted to their volatile methyl esters for gas chromatography. These considerations generally make gas chromatography the method of choice for most organic substances used and produced in industry and research. Common solvents, petroleum products, flavours, pollutants, and insecticides are examples (see Figure 2 for an example of a practical separation achieved with this technique). Gas chromatography also has invaded biochemistry, serving ideally for small- and medium-sized molecules, such as amino acids, fatty acids, essential oils, simple sugars, steroids, and alkaloids. For larger molecules (many steroids and some alkaloids), and particularly for natural and synthetic macromolecules (polymers), gas

chromatography is entirely inappropriate. In these fields, liquid chromatography comes into widest use.

In gas chromatography, the partition method (gas-liquid chromatography) is generally chosen over the adsorption method (gas-solid chromatography). A bigger sample capacity, an improved reproducibility, and a wider range in solute type and molecular weight are possible with the former method. Gas-solid chromatography, however, often is more selective in separating molecules with only slight geometrical differences. Analysis of complex samples of natural products with a wide range of molecular weights is generally carried out using programmed-temperature gas-liquid chromatography in order to hasten the elution of retarded components.

Molecules of moderately large size can be treated conveniently by either liquid-liquid chromatography or liquid-solid chromatography. Ion-exchange chromatography is generally applied to substances with ionic groups. As molecular size increases, retention becomes more difficult to regulate by the partition and adsorption methods. Gel-permeation and gel-filtration methods are then preferred. Macromolecules, such as synthetic polymers and proteins, are separated mainly by these techniques.

Column chromatography has a better inherent resolution than does thin-layer or paper chromatography. Nonetheless, the latter methods are widely used for biochemical applications because of their speed, convenience, and low cost.

Partition method

SPECTROSCOPY

Spectroscopy is the study of the absorption and emission of light and other radiation, as related to the wavelength of the radiation. Light from natural sources (such as the Sun, stars, fireflies, flames, and lightning) and from man-made sources (such as incandescent lamps, arcs, lasers, and fluorescent lamps) is generally composed of many colours. This composite nature of light is not usually evident to the casual observer, but it can be shown by passing light through a prism or other device that splits it into its constituent colours. A display or description of these colours emitted by a source of light is called the spectrum (plural: spectra) of the source (see Figure 3).

Spectroscopy is the science that deals with the sources, measurements, analyses, and uses of spectra. It has practical application in almost every technical field, especially for identifying constituents and processes in any source that emits light. With spectroscopic methods, one can analyze in the laboratory, for example, the composition of

a small amount of material with an accuracy and speed that cannot be achieved by chemical processes. Samples can be compared to test their identity. A continuous flow of products can be monitored for variations or pollutants. Apparatus to measure temperatures in controlled thermonuclear fusion (the uniting of certain atoms so that part of their mass is converted to energy) is another special application of spectroscopy. Still another type of spectroscopic observation makes possible detailed studies of atomic and molecular structures. In astronomy, solar magnetic storms can be predicted and the chemical constitution of stars can be analyzed by spectroscopy.

electric and magnetic fields without the transfer of matter. Light is properly designated as that range of electromagnetic radiation that is visible to the human eye, although the term sometimes is used to include regions that are invisible.

Light, as well as other electromagnetic radiation, has a wave character, and specification by wavelength (distance between successive crests of a light wave) can be made far more precisely than specification by colour. In early spectrometers, each wavelength absorbed or emitted by a source was displayed as the image of a slit, with images side by side for many wavelengths; such images are called lines, and so each line represents a wavelength or frequency, and the series of lines is called a spectrum. Some modern spectrometers use electrical devices for detectors, and the spectrum is displayed as a series of peaks on a graph of line intensity versus wavelength; these peaks by convention are also called lines.

Because the shortest wavelengths of electromagnetic radiation are on the order of atomic diameters, special units are employed to specify them. The angstrom unit, symbolized by Å, named after a Swedish physicist, Anders Jonas Ångström, is equal to 10⁻¹⁰ metre; and one nanometre, abbreviated nm, is equal to 10⁻⁹ metre. The micrometre, or micron, symbolized by the Greek letter mu, μ, is equal to 10⁻⁶ metre (equal to 10,000 Å or 1,000 nm) and is frequently used in the infrared region. Visible light has a wavelength range of about 400 nanometres (violet) to 700 nanometres (deep red).

It is often convenient to specify an electromagnetic wave by the frequency at which it oscillates, or vibrates, rather than by wavelength. Frequency (ν) and wavelength, symbolized by the Greek letter lambda, λ, are inversely proportional to one another, and their product is equal to a

constant (νλ = c), in which ν is defined as the frequency, or number of oscillations per second, usually expressed in hertz (Hz), one hertz being equal to one cycle per second, or megahertz (1,000,000 Hz). The constant, c, is equal to the speed of light in a vacuum, 2.997925 × 10⁸ metres per second. Electromagnetic phenomena with their approximate wavelength and frequency ranges are shown in Table 3.

Basic properties of atoms. An isolated atom can exist as a stable structure only in certain discrete (distinct) states, called energy states or stationary states, and a measurement of the energy of the atom will result in one of the values characteristic of that atom. In principle, the so-called allowed states for any atom can be found from the laws of quantum mechanics. Under ordinary conditions, an atom is almost always in its lowest possible energy state (its ground state, in which it possesses the minimum possible energy). Energy can be added only in those amounts that will just raise the energy to one of the other allowed values. The atom will not absorb an amount of energy

Meaning of spectral lines

Table 3: Electromagnetic Phenomena

	approximate wavelength range (metres)	approximate frequency range (hertz)
Radio waves	10-1,000	3 × 10 ⁵ -3 × 10 ⁷
Television waves	1-10	3 × 10 ⁷ -3 × 10 ⁸
Microwaves, radar	1 × 10 ⁻³ -1	3 × 10 ⁸ -3 × 10 ¹¹
Infrared	8 × 10 ⁻⁷ -1 × 10 ⁻³	3 × 10 ¹¹ -4 × 10 ¹⁴
Visible light	4 × 10 ⁻⁷ -7 × 10 ⁻⁷	4 × 10 ¹⁴ -7 × 10 ¹⁴
Ultraviolet	1 × 10 ⁻⁸ -4 × 10 ⁻⁷	7 × 10 ¹⁴ -3 × 10 ¹⁶
X-rays	5 × 10 ⁻¹² -1 × 10 ⁻⁸	3 × 10 ¹⁶ -6 × 10 ¹⁹
Gamma rays (γ rays)	1 × 10 ⁻¹³ -5 × 10 ⁻¹²	6 × 10 ¹⁹ -3 × 10 ²¹
Cosmic rays	less than 1 × 10 ⁻¹³	greater than 3 × 10 ²¹

Figure 4: Emission and absorption spectra of various X-ray and radio-frequency sources. (A) X-ray emission from an X-ray tube with a rhodium anode operated at three different voltages, showing characteristic spectrum (α and β lines) of rhodium superimposed upon broad continua due to bremsstrahlung. (B) The absorption of magnesium versus incident X-ray photon energy, showing the abrupt increase in absorption as the energy becomes sufficient to remove an electron from the L shell. (C) Characteristic fluorescence line spectrum of tungsten, recorded with a bent crystal spectrometer. (D) Radio-frequency spectrum of centre of Orion Nebula; centre of largest peak is at frequency of 5008.9 MHz, which corresponds to a hydrogen transition.

that would make its final energy some intermediate value. An atom that has absorbed energy and is in one of its higher states is said to be in an excited state. The energy levels are identical for identical atoms; allowed energies of a particular atom of silver are the same as those for any other atom of the same isotope of silver (isotopes are all atoms of an element that have unequal mass but the same atomic number).

Other small systems, including molecules, ions (charged atoms or molecules), atomic nuclei, and elementary (subatomic) particles, have discrete allowed energies.

If an atom in its ground state is given some amount of energy so that it then exists in an excited state, the atom will give off that extra energy spontaneously as it moves back into lower states, ending in the ground state again. The energy is often emitted as electromagnetic radiation, hence it appears as light if the wavelength falls within the appropriate range. In the process of a single transition from some upper state to a particular lower state the energy given off is found from the combination principle: emitted energy (E) equals upper state energy minus lower state energy; this energy is usually carried by a single group of light waves (a photon) having a frequency (ν) in which photon energy (E) is equal to a constant times the frequency, or, $E = h\nu$, in which h is Planck's constant, which is defined as a unit of action (work times time), 6.6256×10^{-34} joule second. This relationship determines frequencies (and wavelengths because $\lambda = c/\nu$) of light emitted by atoms if the energies of the states are known; conversely, the relationship allows finding the energy states of an atom from measurements on the spectrum of that atom. The allowed energies of an atom are discrete and therefore its spectrum consists of discrete wavelengths. Because of the appearance of a given wavelength when seen through a prism or grating spectroscope, these discrete emitted (or absorbed) wavelengths are called spectral lines (see Figures 3 and 7).

Historical survey. The basis for spectroscopic research and for analytical spectroscopy is the discovery, made by

a German physicist, Gustav Kirchhoff, in 1859, that each pure substance has its own characteristic spectrum. Another German physicist, Joseph von Fraunhofer, repeating more carefully an earlier experiment by an English scientist, William Hyde Wollaston, had shown in 1814 that the spectrum of the Sun's electromagnetic radiation does not grade smoothly from one colour to the next but is crossed by many dark lines, indicating that light is missing at certain wavelengths because of absorption (see Figure 3 above). These lines are still called Fraunhofer lines, and the spectrum containing them is called a darkline, or absorption, spectrum. The spectra of some metals and compounds when heated in flames and the spectra obtained from electric discharges in gases were studied by many scientists during the 18th and 19th centuries; these spectra were seen to be composed of numerous bright discrete lines indicating that only certain wavelengths were present in the emitted light. These are called brightline, or emission, spectra. Although the possibility of the existence of characteristic spectra, a spectrum unique for each chemical element, had been considered by numerous investigators, the early studies were hampered by the difficulty of obtaining relatively pure substances and the fact that even slightly impure substances could yield many spectra simultaneously. By using carefully purified substances, Kirchhoff demonstrated characteristic spectra and initiated the technique of spectroscopic analysis of the chemical composition of matter. The technique was applied by Kirchhoff and his colleague Robert Bunsen in 1861 to the analysis of the Sun's electromagnetic spectrum and the identification of the chemical elements in the Sun.

Before the 20th century, there was no theory that could explain satisfactorily how spectra are formed or why different elements have different spectra. Some of the principal discoveries leading to present understanding of spectra were: the discovery of infrared radiation by an English astronomer, William Herschel, in 1800 and of ultraviolet radiation by a German physicist, Johann Wilhelm Ritter, in 1801; the recognition of a series in the spectrum of hy-

The combination principle

drogen in 1885 by a Swiss scientist, Johann Jakob Balmer; the discovery of the electron, the basic negatively charged constituent of atoms, by a British physicist, Joseph John Thomson, in 1897; the beginnings of quantum theory by a physicist in Germany, Max Planck, in 1900; the formulation of the combination principle; the experimental proof that atoms are composed of tiny, massive, positively charged nuclei surrounded by electrons, by a British physicist, Ernest Rutherford, in 1911; the first theoretical calculations of the discrete energy states of atoms and the wavelengths of light given off by atoms, by the Danish physicist Niels Bohr in 1913. Quantum mechanics was developed by the physicists Erwin Schrödinger and Werner Karl Heisenberg of Germany to describe the detailed properties of atoms. This theory, extended by the physicists Wolfgang Pauli of Austria and Paul Adrien Maurice Dirac of England, and others, now provides methods for calculating energy states and spectral lines emitted by atoms, ions, and simple molecules.

Applications. In chemistry and physics, spectroscopy is used as a tool for studying the structures of atoms and molecules. The large number of wavelengths emitted by these systems makes it possible to check theories of their structure in detail, including the electron configurations of ground and various excited states.

Spectroscopy provides a precise analytical method for finding the constituents in material having unknown chemical composition; in typical analyses, a concentration of a few parts per million of a trace element in a material can be detected when the material is vaporized and caused to emit light (as in an electric arc) to produce an emission spectrum, the bright lines that identify the element causing the spectrum. The absorption spectra of solutions containing inorganic or organic chemicals show dark lines and bands (close groups of lines) characteristic of the molecules, radicals (molecular fragments), and ions present in the solution. Emission and absorption spectra of the atmosphere are thus used for monitoring trace elements and compounds (e.g., mercury or the compound dichlorodiphenyltrichloroethane [DDT]) in pollution control, the sensitivity of these techniques sometimes approaching a few parts per 1,000,000 in concentration.

In astronomy, the spectra of the Sun and other stars show lines characteristic of the atoms, ions, and radicals in them, plus lines characteristic of materials in the nearby empty space between the source and the Earth, and materials in the Earth's atmosphere. Spectra of the light reflected from planets other than the Earth show, in addition, lines caused by absorption by their atmospheres. Thus chemical analyses can be made of these distant objects. (For detailed coverage of the topic, see the section *Astronomical spectroscopy* below).

Data on spectroscopic properties of atoms, ions, and molecules are used in the design of lasers (devices that operate on the principle of stimulating the emission of stored energy in atoms), which have wide scientific, industrial, and military application. Fluorescent lamps make practical use of the absorption of ultraviolet radiation with subsequent emission of visible light. High-purity spectral lines are used in metrology (the science of measurement), particularly for measurement of fundamental physical constants, such as the electron's charge and mass; the fundamental metric unit of length, the metre, is in fact defined as 1,650,763.73 wavelengths of a particular unperturbed line in the spectrum of krypton gas. Spectroscopic analyses are used in criminology, archaeology, medicine, agriculture, the biological sciences, and engineering.

PRACTICAL CONSIDERATIONS

General methods of spectroscopy. Production and analysis of a spectrum usually require four components: (1) a source of light (or other electromagnetic radiation), (2) a disperser to transmit different wavelengths differently, (3) a detector to sense the presence of light where it appears after dispersion, and (4) a recorder to make a spectrogram, a temporary or permanent copy of the spectrum.

An apparatus intended to accept light, separate it into its component wavelengths, and detect the spectrum is called a spectrometer; a spectrograph is a spectrometer

that also records spectra. A spectroscope is a combination of disperser and associated optics for visual observation of spectra. A monochromator consists of a disperser and associated optical components arranged to accept light from an external source and transmit only a small range of wavelengths. A spectrophotometer is a spectrometer used to record quantitatively the amount of light emitted or absorbed by a sample of material according to the wavelength.

Processes in spectral sources and types of spectra. Two kinds of electromagnetic spectra can be distinguished: emission spectra, which show one or more bright lines or bands on a dark background, and absorption spectra, which have a continuously bright background except for one or more dark lines (Figure 3).

A spectral line is emitted from atoms (or other particles) when they are excited by some means to the upper energy state responsible for the transition and then decay to the lower energy state. The required initial excitation can be accomplished in a variety of ways. A collision between an electron with high energy (energetic electron) and an atom can impart energy to the atom to elevate it to an excited state. Electron impact is the principal basis for excitation in electric discharges (see below *Laboratory sources of spectra*). Excitation of atoms to higher energy states can also be accomplished by irradiating atoms with electromagnetic radiation that the atoms can absorb. Fluorescence spectra are produced when atoms become excited by absorbing radiation (often in the ultraviolet region) and then emit radiation as the atoms decay to lower states. Impacts on atoms by energetic atomic nuclei, ions, and molecules produce excited atomic states in special applications.

An incandescent liquid or solid, such as a lamp filament, emits a broad, continuous range of wavelengths. In these sources, the atoms may be excited both by electron and by atom impact. Because the atoms are packed closely, their individual energy levels merge together into overlapping levels; the emitted lines then overlap and merge into a continuous—i.e., nondiscrete—spectrum. Similar phenomena occur in the interiors of stars and in high-pressure arcs, in which broadening of spectral lines occurs because of the high collision rates.

So-called bound-free or free-free transitions occur, with resulting emission of radiation, when an electron makes a transition in its energy level to an unbound state from a bound or from another unbound state. These transitions also give rise to continuous spectra.

Before radiation reaches an observer, it may pass through a medium, usually consisting of a vapour of unexcited atoms (or ions or molecules), in which specific wavelengths are absorbed; these absorbed waves correspond to transitions by the vapour atoms from their ground states to higher states. As a result, the absorbed wavelengths are missing in the spectrum of radiation transmitted through the vapour. This phenomenon is the origin of the Fraunhofer lines in the solar spectrum; light emitted by the hotter, deeper layers within the Sun is partially absorbed by atoms in the cooler, outer layers before it reaches Earth. Flames are often used as sources of spectra. Temperature and composition vary throughout a flame; hence flames can be used as absorption sources or as emission sources.

An emitting atom moving toward an observer (or instrument) compresses the light waves emitted in that direction. The light then has shorter wavelengths than it would have if the emitter were at rest; i.e., its spectrum is shifted toward the blue. Similarly, light emitted by atoms moving away from the observer has longer wavelengths, hence appears redder. This phenomenon is called the Doppler effect. As a result, light that would have a well-defined wavelength if emitted by atoms at rest has a spread or broadening caused by their ordinary random thermal motion toward and away from the observer. This Doppler broadening restricts the useful resolving power (ability to distinguish between two adjacent lines) of spectroscopic instruments. The average speeds of atoms in a source increase with temperature; so the widths of spectral lines indicate the temperature of the source. The shifts of spectra with relative velocities of source and observer are sometimes used

tool

to measure velocities of sources, especially in astronomical spectra.

Laboratory sources of spectra. In atomic spectroscopy, a few sources of spectral emission lines serve for most purposes. These sources are: the hollow cathode; the Geissler tube invented by Heinrich Geissler, a German physicist; carbon arc; sparks; electrodeless lamps; and flames (see Figure 5).

The hollow cathode discharge lamp (Schüler tube after Hermann Schüler, a German physicist) consists of two electrodes mounted inside a glass or ceramic envelope. The cathode (negative electrode) is usually formed as a cup or hollow cylinder constructed of, or coated with, the material the spectrum of which is to be investigated. The gas within the envelope is usually one of the inert gases—helium, neon, or argon—at a pressure of roughly 1 torr (the torr is a unit commonly used in specifying gas pressures; sea-level atmospheric pressure is approximately 760 torr). A direct electric current, typically one to 100 milliamperes, at several hundred volts, is passed through the tube; the spectrum appears most brightly within the cathode.

The Geissler discharge tube, the archetype of the neon signs used extensively in advertising, consists of a sealed, hollow glass tube having an electrode at each end and filled with a gas at pressure typically 0.1–10 torr. Often a portion of the glass tube is constricted to provide greater current density (hence greater brightness) in that region. Electric transformers operating typically at voltages from 1,500–10,000 volts and currents from 10–50 milliamperes, alternating current (ac), power these tubes. A modification of the Geissler tube is used to provide the metric standard of length.

Electrodeless lamps consist of glass tubes, usually about one centimetre in diameter and a few centimetres long, filled with a gas at 0.1–10 torr pressure. Spectra of materials other than gases can be obtained by adding to the gas a few milligrams of a volatile compound containing the element of interest; *e.g.*, uranium chloride for the spectrum of uranium. The power source is a high-frequency oscillator, typically 25–2,500 megahertz. (Current within the lamp may be induced by wrapping wires leading from the oscillator around the lamp or by placing the lamp inside an appropriate resonant cavity connected to the oscillator.)

For rapid spectroscopic processing and analysis of solid

Figure 5: Sources of laboratory spectra.

All of these sources, except for the X-ray tube, generate visible and ultraviolet light.

materials, arcs are convenient sources. Graphite and copper are typical electrode materials. A small amount of the material of interest may be powdered, mixed with powdered electrode material, and pressed into a shape convenient for use as one electrode of an arc. Other methods can be used to incorporate the material within an electrode. Arcs can be run with a wide range of voltages (perhaps 10–100 volts) and currents in the range of 1 to 100 amperes, in an atmosphere of air or some other gas. Usually the current is direct current (dc), with the powdered material in the cathode. Effective temperatures in arcs often range from 3,500° to 5,000° C (6,300° to 9,000° F). At such temperatures, little ionization of the atoms occurs, and mainly the spectra called the first, or neutral, spectra of elements are observed.

Figure 6: Refraction of light by a prism having index n_2 immersed in a medium having refractive index n_1 . The angles i and r that the rays make with the normal are the angles of incidence and refraction. Because n_2 depends upon wavelength, the incident white ray separates into its constituent colours upon refraction, with deviation of the red ray the least and the violet ray the most.

Spark sources are often used when higher excitation is required than is available in an arc. The simplest spark source consists of the discharge of a strong current at a potential of around 5,000 volts across a gap between two electrodes. Effective temperatures for these sources can range into the tens of thousands of degrees Celsius; the materials within the spark are often ionized, sometimes highly so, and the dominant spectra are the second (II, singly ionized, or one electron missing from each atom), third (III, doubly ionized, or two electrons missing from each atom), etc., depending upon the power released in the spark, the materials and spacings of the electrodes, and the surrounding atmosphere.

The first man-made spectroscopic sources consisted of flames to which small amounts of substances were added, to be vaporized and excited by collisions with the constituents of the flame. Flame sources are used extensively in analytical chemistry; in these, the materials are formed into an aerosol so that they can be injected into the flame conveniently at a controlled rate.

Transparent chambers or containers with windows at both ends serve as absorption cells for the production of absorption spectra. Light having a continuous distribution of wavelength is passed through the cell. When a gas or vapour is introduced into the cell, the change in the transmitted spectrum can be interpreted as the absorption spectrum of the gas. Often, absorption cells are enclosed in ovens because many materials of spectroscopic interest vaporize significantly only at high temperatures.

Methods for dispersing spectra. Refraction. Historically, glass prisms were first used to break up or disperse light into its component colours. The path of a light ray bends (refracts) when it passes from one transparent medium to another; *e.g.*, from air to glass. Different colours (wavelengths) of light are bent through different angles; hence a ray leaves a prism in a direction depending upon its colour (see Figure 6). The amount of bending of a ray at each interface can be found from Snell's law (Willebrord van Roijen Snell of Holland, *c.* 1600), which states that if n_1 and n_2 are the refractive indices of the medium outside the prism and of the prism, respectively, and the angles i and r are the angles that the ray of a given wavelength makes with a line at right angles to the prism face, as shown in Figure 6, then the equation $n_1 \sin i = n_2 \sin r$ is obtained for all rays. The refractive index of a medium, indicated by the symbol n , is defined as equal to the speed of light in *vacuo* divided by the speed of light in the medium. Typical values for n range from 1.0003 for air at 0° C (32° F) and atmospheric pressure, to 2.3 for thin layers of zinc sulfide.

For typical optical glasses, the refractive index is in the neighbourhood of 1.5–1.9 and varies by 2 to 4 percent across the visible spectrum, with the refractive index greater for violet light than for red light. Because the variation of the refractive index is small, the spectrum is spread over a relatively small range of angles; thus prism instruments are generally used in applications for which low spectral resolution (ability to separate wavelengths) is sufficient.

In order for a prism to produce a large number of exit light beams having different, well-defined wavelengths, it is necessary that the incident light beam composed of these same wavelengths falls upon the prism as a set of

The hollow cathode discharge lamp

Use of spark sources

The refracting prism

Camera
lens

parallel rays. This condition is conveniently accomplished by a collimator, a combination of lens and aperture (in this case a slit). Light rays from the source pass through the slit at the focus of the collimator lens, which then renders the rays nearly parallel (see Figure 7). After the light is refracted by the prism, it is focussed by a lens, usually called the camera lens; if a viewing screen is placed at the focus, an image of the slit is seen for each wavelength of light present. Because the image of a slit is a line, each wavelength forms its own line. The lines can be observed by the eye or by placing photographic or photoelectric detectors at the focal position.

There are other devices besides prism instruments that can be used to break up light into its constituents. A collimated beam of light may be considered as a collection of parallel wave fronts advancing in the direction of travel of the light. Just as a water wave breaks up into ripples moving in all directions when it strikes a barrier, a light wave breaks up into waves travelling in all directions when it meets a barrier. This is the phenomenon of diffraction. Where the sizes of optical components approach the wavelength of light, diffraction phenomena become predominant.

Diffraction. Diffraction gratings are composed of closely spaced transmitting slits on a flat surface (transmission gratings) or alternate reflecting and nonreflecting grooves on a flat or curved surface (reflection gratings). A typical grating might be ruled on an aluminum coating on a piece of glass having dimensions from 2×2 centimetres (0.8×0.8 inches) up to 15×30 centimetres (6×12 inches) and consist of equally spaced parallel lines, as few as 100 lines per millimetre of width or as many as 6,000 lines per millimetre. The close spacing of lines requires that the wave picture of light be used to describe the interaction of light with a grating.

Secondary
waves

If collimated light falls upon a transmission grating, the wave fronts, or crests, successively pass through and spread out as secondary waves from the transparent parts of the grating. Most of these secondary waves, when they meet along a common path, interfere with each other destructively, so that light does not leave the grating at all angles. At some exit angles, however, secondary waves

Figure 7: Principles of a prism spectrograph.

Light from a point on entrance slit (illuminated by a light source) is formed into parallel rays by the collimating lens. The light is refracted by the prism, then focussed by the camera lens. Violet light from the point is brought to focus; the slit is imaged as a line at the focal surface. Red light from slit is imaged as a different line. A spectrum thus appears at the focal surface.

from adjacent slits of the grating are delayed by exactly one wavelength, and these waves reinforce each other when they meet; that is, the crests of one fall on top of the other. In this case, constructive interference takes place and light can leave the grating. Constructive interference occurs also for delays of 0, 2, 3, 4... wavelengths. The grating equation describes this phenomenon for both the transmission and reflection grating and gives the relationship between the incident angle, i ; exit, or reflection angle, r ; spacing between grating slits, d ; wavelength, λ ; and the integer, m (usually called the order of interference): the product of order and wavelength is equal to the product of slit spacing and the difference between the sines of the angle of incidence and exit; i.e., $m\lambda = d(\sin i - \sin r)$. If light having several constituent wavelengths falls upon a grating at a fixed angle, i , different wavelengths are diffracted in slightly different directions and can be observed and recorded separately. Each wavelength is also diffracted into several orders (or groupings); gratings are usually blazed (engraved) so that a particular order will be

the brightest. A lens or concave mirror can then be used to produce images of the spectral lines.

A simplification is obtained when a concave grating is used as a disperser. This device is formed by ruling on a concave mirror parallel lines equally spaced along a geometrical chord of the surface. Because a concave mirror has focussing properties, it can replace both collimator and camera lens (see Figure 8). Henry Augustus Rowland, a physicist in the United States, showed (1882) that if entrance slit, grating, and photographic plate lie on a circle the diameter of which is equal to the radius of curvature of the grating, all spectral lines can be made to focus. Many large, high-resolution grating spectrographs have been built on the basis of the Rowland circle, and most tabulated data on wavelengths have been obtained with such instruments.

In any grating spectrometer, if a slit aperture is moved along the surface where the spectral lines are focussed, the lines are transmitted successively through the aperture. A detector placed behind the aperture then responds to the spectrum, line by line; the output of such a detector can then be amplified and recorded. These scanning techniques have some advantages over photographic recording: because the detection efficiencies of some electrical detectors (see below *Detectors*) are greater than efficiencies of photographic detectors, the method provides greater sensitivity and greater speed. Many photoelectric detectors respond nearly linearly—i.e., with response proportional to the amount of light received—so the recorded brightness is simply related to the characteristics of the source.

In some arrangements, it is more convenient to tilt the grating (or prism) about its axis that is parallel to the slit than to move the slit. Typically, the grating may be rotated so that the angles of incidence and diffraction change, hence changing the wavelength of light reaching the fixed exit slit.

Interference. A third class of devices for dispersing spectra consists of interferometers, which divide a wave front by semitransparent surfaces, allow the beams thus produced to travel different paths, and then recombine the beams. Variants of this method are used in testing of optical components. In spectroscopy, the principal interferometers are those developed by a United States physicist, A. A. Michelson (1881), in an attempt to find the luminiferous ether—a hypothetical medium then thought to pervade all space—and by two French physicists, Charles Fabry and Alfred Pérot (1897), specifically for high-resolution spectroscopy (see Figure 9).

In the Michelson interferometer, an incident beam of light strikes a tilted semitransparent mirror and divides, weaker waves being reflected and transmitted. These continue to their respective mirrors, are reflected, and return to the semitransparent mirror. The two waves finally moving toward the observer have travelled different path lengths, hence interfere and are transmitted preferentially only if their path difference is 0, 1, 2, 3, ... wavelengths. This device then acts as a filter that transmits preferentially certain wavelengths and reflects others back to the

light source, resulting in a visible interference pattern. The Fabry-Pérot interferometer (Figure 9A) consists of two parallel glass plates coated with highly reflecting, slightly transparent films on their inner faces. When the interferometer is placed in a beam of light from a spectrometer, multiple reflections take place between the two faces, producing concentric interference rings. Even if there are two spectral lines so close together that they cannot be resolved by an ordinary spectroscope, the Fabry-Pérot interferometer will produce rings of slightly different radii, depending on the wavelengths of the two lines, which can be distinguished from one another.

Instruments for obtaining high resolving power often use interferometers in series with grating instruments. The grating preselects the line or lines of interest, which are further analyzed by the interferometer.

Beginning about 1960, instruments known as multiplex spectrometers found considerable use, especially in recording astronomical infrared spectra. The prototype of this kind of instrument is the Michelson interferometer (Figure 9B), with one mirror mounted upon a carriage so that length of the light path in that branch of the light path can be varied. A spectrum is obtained by recording photoelectrically the light intensity of the interference pattern as the carriage is moved. Little preselection of wavelength is done, and so the resulting signals, contain-

Multiplex spectrometers

ing information simultaneously about many wavelengths, are complicated. A mathematical transformation (called a Fourier transform) must be performed on the data to yield the spectrum (see OPTICS). The principal advantage of this method is that the entire spectrum is recorded simultaneously with one detector. With the use of these Fourier spectrometers and other types of multiplex spectrometers, the spectra obtained are less affected by electronic noise originating in the detectors than are the spectra obtained by conventional scanning spectrometers.

Detectors. The principal detection methods used in spectroscopy, to be described below, are: photographic (plates and films), photoemissive (photodiodes, photomultipliers, image tubes), radiometric (bolometer, thermocouple, thermopile, Golay cell), and semiconductor (photoconductive and photovoltaic cells).

In most investigations before about 1940, and in many current applications, a strip of photographic film or a photographic plate records the pattern of spectral lines. This method has several advantages over other methods of recording: the source brightness need not be constant; information over the entire spectrum is recorded simultaneously; a permanent record results, detailed studies of which can be made later.

Photoemissive detectors have replaced photographic plates and films in many applications. When a photon (quantum of light) having sufficient energy strikes a metal surface, it can cause the ejection of an electron from the surface. A stream of photons releases a series of electrons, hence produces an electric current. A photoemissive diode (photodiode) consists of a surface (the cathode) appropriately treated to permit the ejection of electrons and

a separate electrode (the anode) on which electrons are collected, both often sealed within an evacuated glass envelope. A photomultiplier (or multiplier phototube) has a cathode, a series of electrodes (dynodes), and an anode sealed within a common evacuated envelope. Some photoemissive detectors use continuous-strip or continuous-tube dynode structures. Appropriate voltages applied to the cathodes, dynodes, and anode cause electrons that are ejected from the cathode to make collisions with the dynodes in succession, knocking out more electrons upon each collision. The current is thus multiplied by the tube and is then more easily amplified and recorded. A single photon ejecting a single electron from the cathode can be detected as a pulse of 100,000 to 10,000,000 electrons at the anode; for some applications, these single pulses are counted directly. Photomultipliers are useful primarily in the wavelength range 1,050–12,000 angstroms, from far ultraviolet to near infrared; the lower wavelength limit is set by light-transmission properties of optical materials, whereas the upper limit is set by the requirement that the photon must have enough energy to eject an electron from the cathode.

Image intensifier tubes contain a sensitive photocathode and provision for accelerating the ejected photoelectrons so that they strike a phosphor screen, causing many photons to be emitted; alternatively, the electron may pass through a thin film, ejecting more electrons, which are accelerated in turn and detected, or may strike a photographic plate, causing its exposure. Such devices are often used in night-vision devices. They have found some application in spectroscopy because they maintain to some extent the sensitivity of photoelectric detection while preserving the information about the location at which the initial photon arrived.

A bolometer is a device the electrical resistance of which changes when it becomes warmer as a result of its absorbing light. A thermocouple junction is a junction between dissimilar metals. If an electrical circuit is made using two dissimilar metals, and if the junctions are at different temperatures, current flows in the circuit. A junction that absorbs light can thus be used as a detector, because its temperature generally increases when it absorbs light. A thermopile is a set of thermocouples mounted in series in order to obtain sensitivity greater than that obtained with a single junction. Golay cells detect light by the expansion of a gas when it is warmed by incident radiation. The four detectors described here have the common characteristic of responding to incoming energy of any wavelength; hence they can be used for detection in the far infrared where photographic and photoemissive detectors are insensitive.

Photoconductive cells contain thin semiconductor layers in which electrical resistance varies with illumination. Geiger-Müller tubes, proportional counters, and ionization chambers that depend on the release of electrons by incoming photons are used for detecting radiation from far ultraviolet to gamma rays (see below *X-ray detectors*).

When a spectrum is detected photographically, the spectrogram serves also to record the results. In order to produce a nonphotographic permanent record, as with a scanned spectrum, the output signal current or voltage from the detector may be amplified and fed into an auxiliary output device. The simplest such device is a galvanometer that deflects an amount proportional to the input signal; a chart recorder can be used to draw an ink record of deflection versus wavelength on a moving strip of paper, or the amplified signal may be digitized and printed or recorded on magnetic tape, paper tape, or punched cards for later handling by computer.

Recording of spectra

Foundations of atomic spectra

BASIC ATOMIC STRUCTURE

Because the emission of spectral lines depends on the electron structure of atoms, it is apropos here to show how the periodic table of elements is organized. This will require definitions of the following quantum numbers: principal, orbital, spin, and magnetic. An atom, the smallest stable particle of neutral matter, has a diameter of approximately 2×10^{-10} metre. It consists of a core, or nucleus, which

contains most of the mass of the atom, and a collection of electrons surrounding the nucleus. The nucleus contains a certain number (Z) of protons and a generally different number (N) of neutrons; the diameter of a nucleus depends upon the number of protons and neutrons and is typically in the range 1.5 to 10×10^{-15} metre (.000015 to .0001 angstrom); *i.e.*, much less than an atomic diameter. Each proton has one unit of positive electric charge ($+e$). Because each electron carries the basic unit of negative electric charge, and because opposite charges attract one another, in a neutral atom the total charge of the nucleus, $+Ze$, is balanced by Z electrons surrounding the nucleus. An atomic ion is an atom having either more or fewer electrons than protons (*i.e.*, more or fewer than Z electrons); an ion thus has a net negative or positive electric charge.

The chemical and spectroscopic properties of atoms and ions are primarily determined by their electronic structures; *i.e.*, by the numbers and arrangements of electrons surrounding their nuclei. Typical energies of electrons within an atom range from a few electron volts (eV) to a few thousand electron volts. (One electron volt, equal to 1.60×10^{-19} joule, is the kinetic energy gained by an electron when it is accelerated by a one-volt potential difference.) Chemical reactions and other processes occurring in spectroscopic sources usually involve energy exchanges of this order of magnitude. Processes that occur within nuclei to produce electromagnetic radiation and other forms of radioactivity typically involve energies ranging from thousands to millions of electron volts; hence nuclei are nearly unaffected by the usual processes occurring in chemical reactions, light absorption, and light sources.

The forces holding an atom together are primarily electrostatic—*i.e.*, the mutual attractive electric force between the positive charges in the nucleus and the negative charge of each electron. Because like charges repel one another, there is a significant amount of electrical repulsion of each electron by the others. Also, two principles not usually apparent in the macroscopic world of everyday experience become important in atomic phenomena. The Pauli exclusion principle (1925) states that no two electrons can exist in the same energy state. The Heisenberg uncertainty principle (1925) predicts that it is impossible to measure accurately both the position and momentum of an electron simultaneously. A more useful approximate picture of an atom is that of a massive nucleus concentrated at a point surrounded by an electron mist or cloud, the density of which is proportional to the probability that an electron can be found there.

To a rough approximation, the electrons within an atom or ion move independently of one another. It is often possible first to calculate the properties of an atom on the basis of independent motions of the electrons rather than to make corrections for the correlations in electron motion caused by their forces on each other. Calculations begin with finding the possible states of atoms (and ions) that have just one electron outside a closed shell (see below *The periodic table*)—*i.e.*, hydrogen-like atoms and ions. The electron states in a complex atom are built up of electrons in these “one electron” states, and then corrections are made for the interelectronic forces.

HYDROGEN ATOM STATES

Principal quantum number. A hydrogen atom is composed of a nucleus (a proton) and a single external electron. The electron has wave properties in addition to particle properties. (Experiments show that atoms, molecules, and other microscopic particles also have wave properties.) Its wavelength is specified by the de Broglie relation (1924): particle wavelength, symbolized by the Greek letter lambda, λ , is equal to Planck's constant, h , divided by momentum (mass times velocity), or $\lambda = h/p$, in which p is the momentum of the particle. This wave then travels around the nucleus of the atom. In order that the wave not cancel itself, it must travel at the appropriate distance from the nucleus so that the circumference of the orbit is equal to n times the electron wavelength, in which n is a positive integer equal to 1, 2, 3, The electron wave will then be stable. The motion of the electron is also limited by the

requirement that the force on the electron is equal to the electron's mass times its acceleration (Newton's second law). The result is that the electron can exist stably only at certain average distances from the nucleus, and these distances are specified by giving n , the integer mentioned above. The electron's average distance from the nucleus is equal to the square of this integer times a constant, or $n^2 a_0$, in which a_0 (equal to .525 angstrom) is known as the first Bohr radius (because Niels Bohr first calculated it on the bases outlined here). The number n is usually called the principal quantum number for the orbit. The energy of an electron in a hydrogen-like atom or ion is equal to minus the atomic number (Z) squared times Planck's constant (h) times the speed of light (c) times a constant divided by the principal quantum number squared—*i.e.*, $-Z^2 hcR/n^2$. The constant R is called the Rydberg constant, and its product with Planck's constant and the speed of light (hcR) is approximately 13.6 electron volts. The energy is negative, indicating that the electron is bound to the nucleus. The algebraic value of the energy increases as n increases; hence the principal quantum number n equals one for the ground state of hydrogen. As the integer n takes on larger values toward infinity, the energy approaches zero. As this happens, the electron's average distance from the nucleus increases without limit and the atom becomes more nearly ionized (an ion approaches further ionization). The energy that is added to an atom or ion in its ground state just to cause the removal of an electron is called the ionization potential.

The combination principle suggests that the energies, frequencies (ν), and wavelengths (λ) of photons emitted by hydrogen atoms ($Z = 1$) should be expressed by $E = hf = hcR(1/n_1^2 - 1/n_2^2)$ and $1/\lambda = R(1/n_1^2 - 1/n_2^2)$, in which n_1 and n_2 take on the values of the principal quantum number for the final and initial states, respectively. The latter formula (with $n_1 = 2$) was found empirically by Balmer in 1885 to fit the wavelengths of the visible spectrum in hydrogen if $n_2 = 3, 4, 5, \dots$. This was the first discovery of a spectral series. It was found in 1890 by the Swedish physicist Johannes Robert Rydberg that numerous data for the other spectra of atoms could be fitted by series formulas that are a slight modification of Balmer's formula, $1/\lambda = R[1/(n_1 - a)^2 - 1/(n_2 - b)^2]$, in which n_1 is held fixed for each series, n_2 takes on integer values greater than n_1 , and a and b are nearly constant numbers for a given series and are called quantum defects. In each series, as n_2 becomes much larger than n_1 , the wavelength approaches the series limit given by the wave number, $1/\lambda$, equal to $R/(n_1 - a)^2$.

Orbital quantum number. The second quantum number to be considered is the orbital quantum number. Although classically an electron's orbit may be elliptical with any ratio of major to minor axes, solution of the quantum mechanical equations shows that only certain distributions of the electron cloud exist in space and these depend on the angular momentum of the electron. Angular momentum is a concept applied to a body that is moving in an orbit or rotating on its own axis; it depends on the angular velocity and distribution of mass about an axis; it has the property of direction, being at right angles to the plane of motion. The orbital angular momentum of the atom is equal to the square root of a positive integer times the next successive integer, multiplied by the quantity Planck's constant divided by two pi—*i.e.*, $\sqrt{l(l+1)} (h/2\pi)$, in which l is a positive integer and h is Planck's constant. The number l , called the orbital quantum number, is restricted to be less than the principal quantum number; so if n is equal to one, l can only be zero, and hence the orbital angular momentum is equal to zero. If $n = 2$, l can be 0 or 1, yielding orbital angular momentum = 0 or $\sqrt{2} (h/2\pi)$. If $n = 3$, l can be 0, 1, or 2, etc.

Magnetic quantum number. The third quantum number is the magnetic quantum number. The tilt of an electron's distribution will be restricted to certain values when it is surrounded by a magnetic field. This phenomenon, the restriction of allowed directions for the atomic angular momentum, is known as space quantization and was first demonstrated in 1922 by two German physicists, Otto Stern and Walther Gerlach. The component (value) of the

The first Bohr radius and the Rydberg constant

De Broglie waves

Space quantization

angular momentum of the atom along any given direction is equal to integral units of a quantity, Planck's constant divided by 2π —that is, $m_l(h/2\pi)$, in which m_l is another integer, being positive or negative so long as its magnitude does not exceed l . For instance, if $l = 1$, m_l can have the values $+1$, 0 , or -1 . The number m_l is usually called the magnetic quantum number.

Spin quantum number. The fourth quantum number is concerned with the spin of electrons. Experiments show that an electron has a further characteristic, its spin, which affects its motion and hence its possible energies. The electron behaves as if it were a spinning top, with its own intrinsic angular momentum having magnitude that can be obtained from the expression for orbital angular momentum by substituting $1/2$ for l —i.e., $\sqrt{(1/2)(1/2 + 1)}(h/2\pi) = \sqrt{3/4}(h/2\pi)$ —one says that the electron has spin $s = 1/2$. Whether this angular momentum is directed toward or opposite a particular direction is indicated by giving the component of s along that direction. The allowed values are equal to $m_s(h/2\pi)$, in which m_s is either $+1/2$ or $-1/2$.

Spin-orbit interaction. These four quantum numbers, n , l , m_l , m_s , specify the state of a single electron completely; each number implies a particular wave function (equation) describing that aspect of the electron's motion. The description of an electron's motion can be done entirely mathematically using these numbers and the functions they represent.

The energies of the electron in a hydrogen-like atom or ion are fixed primarily by the mutual electrostatic attraction of the electron and the nucleus; there are, however, significant magnetic effects affecting the energies. An electron has an intrinsic magnetic dipole moment; that is to say, it behaves in some ways as a small bar magnet aligned along its spin axis. Also, because of its orbital motion within the atom, the electron creates a magnetic field in its vicinity. The interaction of the electron's magnetic moment with the magnetic field created by its motion (the spin-orbit interaction) modifies its energy to depend upon n , the principal quantum number, and another quantum number, j , representing a combination of its orbital-angular-momentum quantum number, l , and its spin-angular-momentum quantum number, s . In keeping with the requirement that energy and angular momenta can have only discrete values within an atom, the quantum number, j , can take on positive values only between $l + s$ and $l - s$ in integer steps; because s is $1/2$ for the single electron in a hydrogen-like atom, j is $1/2$ for $l = 0$ states, $j = 1/2$ or $3/2$ for $l = 1$ states, $j = 3/2$ or $5/2$ for $l = 2$ states, etc. The magnitude of the total angular momentum of the atom, then, can be expressed in the same form as for the orbital and spin momenta: $\sqrt{j(j + 1)}(h/2\pi)$, and the component of angular momentum along any direction is a multiple of Planck's constant divided by 2π , namely, $m_j(h/2\pi)$, in which m_j can have any value between $+j$ and $-j$ in integer steps (e.g., $5/2$, $3/2$, $1/2$, $-1/2$, $-3/2$, $-5/2$). The quantum numbers n , l , j , m_j are often used to specify a state in the hydrogen atom. Small differences in energies of levels because of the spin-orbit interaction sometimes cause complexities in spectral lines that are known as the fine structure of spectral lines.

THE PERIODIC TABLE

Although there seems to be no simple justification for the fact, it is found that in any atom no two electrons have the same set of quantum numbers n , l , m_l , m_s (or n , l , j , m_j), defined above. Even when interactions between the electrons occur, and when magnetic interactions between an electron's spin and its orbital motion occur so that a new state of an electron is specified by a different set of four quantum numbers, no two electrons in an atom have the same set. This is the Pauli exclusion principle; its most direct application involves the explanation of the periodic table of the elements first developed by two chemists, Dmitry Ivanovich Mendeleev of Russia and Lothar Meyer of Germany (c. 1869). This table (see Figure 10) lists the elements in rows in order of increasing atomic number Z ; it is found that the elements in the same column have similar chemical properties.

To see how elements fit into the periodic table, it is helpful to start with a hydrogen atom—a singly charged atomic nucleus and one electron—then add exterior electrons and positive charges to the nucleus one by one for successive elements. Each electron will make transitions to its lowest possible energy state. For hydrogen, this is the state with $n = 1$, $l = 0$, $m_l = 0$, $m_s = 1/2$ or $-1/2$; these numbers specify the resulting configuration, or arrangement, of electrons of a hydrogen atom in its ground state. If a positive charge is added to the nucleus and a second external electron is added, it too will go to its lowest state, again $n = 1$, $l = 0$, $m_l = 0$, and with m_s different from that of the first electron (otherwise both electrons would have the same set of quantum numbers n , l , m_l , m_s and this would violate the Pauli exclusion principle). The resulting configuration is that of helium in its ground state. There are only two possible electron states with $n = 1$, and these are now occupied by electrons. It is said that the $n = 1$ shell (or orbital) is filled or closed. This closed shell is relatively stable and difficult to excite; helium is the first of the inert, or noble, gases.

If a third electron is added (to make a lithium-like atom), it cannot occupy the $n = 1$, $l = 0$ shell with the others, because its quantum numbers would then be identical with those of one of the other electrons. This electron has its lowest possible state with $n = 2$. For this value of n , the orbital quantum number l can be either 0 or 1 ; a state for $l = 0$ has slightly lower energy. The quantum numbers of this electron are then $n = 2$, $l = 0$, $m_l = 0$, $m_s = +1/2$ or $-1/2$. The inner $n = 1$ shell is relatively stable and remains inert in chemical processes; the chemical and spectroscopic behaviour of this atom is similar in many ways to that of hydrogen, since lithium and hydrogen both have one external electron free to move (valence electron).

Addition of the next electron to produce a beryllium atom completes the partial shell or subshell $n = 2$, $l = 0$.

Figure 10: Periodic table of the elements.

Left column indicates the subshells that are being filled as atomic number Z increases. The body of the table shows element symbols and Z . Elements with equal numbers of valence electrons—and hence similar spectroscopic and chemical behaviour—lie in columns. In the interior of the table, where different subshells have nearly the same energies and hence compete for electrons, similarities often extend laterally as well as vertically.

A subshell consists of all electrons of the same principal and orbital quantum numbers. The atom is analogous to helium in that both atoms have two outer electrons. The $n = 2$ shell is not filled, however, because an electron with $n = 2$ can have $l = 1$. Outside the inner shell $n = 1$, there are six possible electron states with $l = 1$ because an electron can have any combination of $m = 1$, 0 , or -1 , and $m_s = +1/2$ or $-1/2$. As successive electrons are added to yield boron, carbon, nitrogen, oxygen, fluorine, and neon, the electrons take quantum numbers $n = 2$, $l = 1$, and all possible different combinations of m_l and m_s , until a total of six with $n = 2$, $l = 1$ have been added. This completes the $n = 2$ shell, having a total of eight electrons in two subshells. The resulting atom is neon, the second of the noble gases.

When the next (11th) electron is added, it cannot go into any state with $n = 1$ or $n = 2$ because these are already filled by electrons. The lowest available state is now $n = 3$,

$l=0$, $m_l=0$, $m_s=1/2$ or $-1/2$. This atom is sodium; its outer structure is analogous to those of lithium and hydrogen, and so it has similar spectroscopic and chemical properties. Addition of another electron, which takes quantum numbers $n=3$, $l=0$, $m_l=0$, $m_s=1/2$ or $-1/2$ (m_s opposite to that of the 11th electron) yields magnesium, similar in structure and properties to beryllium, which lies above it in the periodic table. Addition of another electron yields aluminum, similar to boron. As more electrons are added, the elements silicon, phosphorus, sulfur, chlorine, and argon are produced. The spectra, structures, and chemical behaviour of these are similar to those of the elements carbon through neon, respectively, because the numbers of outer (valence) electrons are the same. In a similar fashion, the remainder of the periodic table is constructed, with some irregularities caused by different subshells having nearly the same energies (see Table 4).

As a shorthand method of indicating the electron configurations of atoms and ions, the letters s , p , d , f , g , h , ... are used to denote electrons having, respectively, $l=0$, 1 , 2 , 3 , 4 , 5 , ... (The letters s , p , d , f originate from spectral series that had the designations sharp, principal, diffuse, and fundamental before their origins were fully understood.) A number prefixed to the letters gives the value for n , and a superscript to the right of each letter indicates the number of electrons with those values of n and l . The configuration $2s^1$ represents a single electron with $n=2$, $l=0$ (the superscript 1 is usually omitted). The configuration $1s^2 2s^2 2p^3$ represents two electrons with

$n=1$, $l=0$, two electrons with $n=2$, $l=0$, and three electrons with $n=2$, $l=1$. The ground state configurations for the known atoms are given in Table 4.

For the atoms in the first third of the periodic table, one can often specify both the total orbital angular momentum and the total spin angular momentum in a given state. The total orbital angular momentum is the sum of the orbital angular momenta from all the electrons, taking into account their quantized values and their signs (plus or minus); it has magnitude $\sqrt{L(L+1)}(h/2\pi)$, in which L is an integer. The possible values for L depend upon the individual l values and the orientations of their orbits for all the electrons comprising the atom. The total spin momentum has magnitude $\sqrt{S(S+1)}(h/2\pi)$, in which S is an integer or half an odd integer depending on whether the number of electrons is even or odd. The possible value of the total spin angular momentum can be found from consideration of all the possible orientations of electrons within the atom. (Usually, in taking the L and S values, only the valence, or outer shell, electrons are considered, because in a closed subshell, there are as many electrons quantized in one direction as there are in the opposite direction, with the result that their orbital and spin momenta add up to zero. Thus only the valence electrons contribute angular momenta to the whole atom.) The total of orbital plus spin angular momentum has the magnitude $\sqrt{J(J+1)}(h/2\pi)$, in which J can take any positive value from $L+S$ to $L-S$ in integer steps; i.e., if $L=1$ and $S=3/2$, J can be $5/2$, $3/2$, or $1/2$. The remaining quantum

number, m_j , specifies the orientation of the atom as a whole; m_j can take any value from $+J$ to $-J$ in integer steps. A term is the set of all states with given configuration, L , S , and J . If this specification can be made, it is called LS , or Russell–Saunders coupling (1925), after an astronomer, Henry Norris Russell, and a physicist, Frederick A. Saunders, both of the United States. Energy levels are plotted as bars on a vertical energy scale. Atomic levels are labelled S , P , D , F for $L = 0, 1, 2, 3, \dots$. The designation of such a level is written as ^{2S+1}L ; i.e., the level 3D_1 has $S = 1$, $L = 2$, $J = 1$. Sometimes the term is preceded by the principal quantum number to indicate in which shell the state occurs—e.g., 5^3D_1 . A multiplet is the set of all transitions between two terms.

For heavier atoms, magnetic interactions among the electrons often contrive to make L and S poorly defined, although J and m_j still remain constant quantities for a given state of an atom, a coupling scheme known as j - j coupling.

A simple unifying principle underlies all the internal structures of atoms: atoms or ions having the same number of electrons outside the same, closed electron shell, called an isoelectronic sequence, have quite similar spectra. This similarity is illustrated in Figure 11, which shows drawings to scale of some of the energy levels of one electron near the ground states of a hydrogen nucleus ($Z = 1$), a helium nucleus ($Z = 2$), and a calcium nucleus ($Z = 20$). Similarities in spectra for ions having the same number of electrons are sufficiently close that the spectral lines from a highly ionized (multiple loss of electrons) element can often be identified by extrapolation from known isoelectronic spectra.

TRANSITIONS

An isolated atom or ion in some excited state spontaneously transfers to a lower state with the emission of one or more photons, thus ultimately going into its ground state. The time required for such a transition varies greatly according to the wavelength of the photon to be emitted; for a transition in which a photon of visible light (wavelength typically 500 nanometres or 0.5 micrometre) is emitted, a characteristic average emission time is 1–10 nanoseconds ($1\text{--}10 \times 10^{-9}$ second). The emission time is proportional, approximately, to the cube of the wavelength; i.e., a transition giving rise to a photon having wavelength 5 micrometres will occur in a time characteristically 1–10 microseconds.

Not all conceivable transitions, however, are possible within an atom. Theoretical and empirical selection rules restrict the kinds of transitions that may occur. The first selection rule found (1924, by Otto Laporte, then a physicist of Germany) that all states of an atom can be divided into two sets: odd and even. A transition may take place from an odd to an even state or vice versa, but not between states in the same set.

Another selection rule states that during a transition, only one electron changes values of n and l . Other selection

rules state that J can change only by unity or zero in a transition, and that if L and S are well defined within the atom, L can change by not more than unity ($\Delta = 0, \pm 1$) and S cannot change at all during a transition.

Although these rules are not exact, and violations of them occur, the corresponding transitions for the violations are usually relatively slow and the spectral lines resulting are relatively weak. Such transitions are called forbidden transitions. For atoms in about the first third of the periodic table, the L and S selection rules provide useful criteria for the classification of unknown spectral lines. In heavier atoms, greater magnetic interactions among electrons cause L and S to be poorly defined, and these selection rules are less applicable. Occasionally, excited states are found that have lifetimes much longer than the average, because selection rules prohibit all transitions between levels. Such states are called metastable.

The transition rates from one state to another in all but the hydrogen-like atoms can be calculated only with difficulty. Accurate theoretical values can be obtained only with sophisticated computer routines, paying careful attention to the detailed structure of the atom. Experimental values for state lifetimes are of great importance in checking the accuracy of atomic theory.

Metastable states

PERTURBATIONS OF LEVELS

The energies of atomic levels are affected by external magnetic and electric fields in which atoms may be situated. The effect of a magnetic field (the Zeeman effect, after Pieter Zeeman, a Dutch physicist) is to cause an atomic level to split into its states of different m_j , each with slightly different energy. The result is that each spectral line separates into several closely spaced lines. The number and spacing of such lines depend upon the J values for the levels involved; hence the Zeeman effect is often used to identify the J values of levels in complex spectra. The required magnetic field is usually provided by a massive electromagnet that nearly surrounds the light source.

The corresponding effect of line splitting caused by the application of a strong electric field is known as the Stark effect (after Johannes Stark, a German physicist).

Small modifications to electronic energy levels arise because of the finite mass and nonzero volume of the atomic nucleus and the distribution of charges and currents within the nucleus. The resulting small energy changes, called hyperfine structure, are used to obtain information about the properties of nuclei and the distribution of the electron clouds near nuclei. Systematic changes in level positions are seen as the number of neutrons, N , in a nucleus is increased; these effects are known as isotope shifts. The principal isotope effects are: for light atoms (Z less than about 20), increased binding of electrons to nuclei occurs, and decreased effects are seen caused by correlations in electron motion as the number of neutrons increases. For heavier atoms, a decreased binding of the electrons to the nucleus results as the neutron number increases, because the nuclear volume increases. The isotopic effects are so small that they are of no concern in molecular spectroscopy. The nucleus may behave as a small magnet because of circulating currents within; the magnetic fields produced in this way may affect the levels slightly. If the electric field outside the nucleus differs from that which would exist if the nucleus were concentrated at a point, this difference also can affect the energy levels of the surrounding electrons (see *Radio-frequency spectra* below). (J.O.S.)

Molecular spectra

There are several major divisions of molecular spectroscopy. They include nuclear quadrupole resonance, nuclear magnetic resonance (NMR), electron paramagnetic resonance (EPR), gas phase microwave spectroscopy, electron spectroscopy, Raman spectroscopy, and infrared, visible, and near and far ultraviolet spectroscopy.

EXPERIMENTAL PRINCIPLES

The experimental arrangements for observing absorption spectra will normally involve a source of radiation; a de-

Figure 11: Level diagrams (Grotrian diagrams) for isoelectronic atom and ions, showing similarities in their level structure. The values for the principal quantum number n are for the electron in each case. The numbers at the left of the levels are the binding energies for the outermost electron, in electron volts; the electron is freed from the atom (or ion) at binding energy = zero.

vice for selecting a narrow wavelength range, unless the source itself is monochromatic—*i.e.*, emits a single wavelength that can be changed at will; a cell for containing the sample of matter to be studied; and a radiation detector for measuring and recording the amount of radiation transmitted, both with the matter present and with it removed.

In the different spectral ranges, the sources of radiation for absorption spectroscopy will vary as will the detectors. In the microwave and radio-frequency regions, powerful monochromatic sources of controllable frequency have been available for some time. With the advent of the tunable laser (a monochromatic source of variable frequency in the optical regions), such sources became available in the early 1970s for the production of infrared, visible, and near ultraviolet. Otherwise, sources having a natural broad range of wavelengths combined with some optical device for selecting the desired monochromatic wavelengths, such as a prism or diffraction grating, are needed.

The photographic plate, the eye, photocells and photomultipliers, thermal detectors, and silicon rectifier crystals are among the detectors employed.

The molecular spectra of various substances are observed under a variety of conditions. Depending in part on the type of spectroscopy, the substances may be studied as gases, liquids, or solids, or in liquefied or solid solutions, as single crystals, polycrystals, glasses, or as solid mixtures with other crystals. Similarly, circumstances make it advantageous to work in certain temperature ranges, sometimes at extremely low temperatures. Interesting work has been done with materials in unusual, possibly transient states, for example, molecules that are ionized, parts of molecules that have been broken (*i.e.*, free radicals), highly reactive species trapped and preserved at low temperatures in inert, unreactive media such as frozen argon, special impurity centres in crystals, and molecules passing through a vacuum as a molecular beam. Each of these special circumstances confers advantages in particular cases.

THEORY OF MOLECULAR SPECTRA

Origins of molecular spectra. The spectra emitted by molecules can be much more complicated than those emitted by atoms because there are not only energy contributions from the electrons but also from the relative motions of the atomic nuclei. Molecules are made up of two or more atoms and hence consist of atomic nuclei surrounded by clouds of electrons. The moving electrons are attracted by the nuclei and thereby bind the latter together.

The energy of a molecule can be usefully divided into parts. The electrons have kinetic energy of motion and potential energy because of their attraction to the nuclei and repulsion by each other. Another potential energy originates in the mutual repulsions of the positive nuclei. These parts together constitute the electronic energy of the molecule, energy that is changed under electron or molecular impact, or when X-rays, ultraviolet, or visible light is absorbed, processes called excitation. X-rays primarily affect the inner atomic electrons; visible light or impact energy mainly excites the outer, so-called valence electrons.

The nuclei also can move, particularly in a back and forth vibrational motion with respect to one another. A molecule with several nuclei can display various patterns of vibration. Radiation in the infrared region may excite some of these vibrations.

Molecules also rotate about their centres of mass and thus possess rotational energy, at least when the substance exists in the gas phase. Finally, in a gas they are normally moving about as a whole—*i.e.*, executing translational motion.

The magnitude of these energies can be ordered, with the electronic energy of the inner electrons the greatest, that of the outer electrons next, followed by changes in vibrational energy, and, finally, by those in rotational energy. Changes in translational energy usually are not involved in spectra except for certain effects connected with the breadth of spectral lines.

There are some interactions, or interdependence, between these different kinds of energies, but the separation into kinds of energy, or energy parts, is nevertheless a

concept of great practical importance. It is also true that changes in the smaller energy terms usually accompany changes in the larger ones. Thus, absorption of ultraviolet or visible light will normally change the vibrational and rotational energies as well as the electronic energy of a molecule. Similarly, in gases at least, rotational changes usually accompany vibrational changes brought about by absorption of infrared radiation.

Quantization of molecular energy. One consequence of quantum mechanics is that the energies of a molecule (except the translational energy) are quantized; *i.e.*, a molecule is not allowed by nature to possess an arbitrary amount of electronic, vibrational, or rotational energy; instead, only certain restricted discrete values of the energy are allowed.

Figure 12 shows the allowed values—that is, the energy levels—of the vibrational energy of a molecule composed of two atoms. The lower levels, designated as E_v , are nearly equally spaced as is predicted by quantum mechanics for a hypothetical case in which the force between the atoms of a molecule increases linearly (at a constant rate) with the increase in internuclear distance. For such a vibrating molecular system, called a harmonic oscillator, theory gives an energy for each level equal to a factor of some integer plus $1/2$ (by substituting for v its values 0, 1, 2, etc., one gets $1/2$, $3/2$, $5/2$, etc.) times a constant (v_0), the vibration frequency calculated according to ordinary or classical mechanics and Planck's universal constant (h): $E_v = (v + 1/2) h v_0$, $v = 0, 1, 2, \dots$, in which v , an integer, is called the vibrational quantum number. The actual levels converge upon one another as this quantum number increases, because the chemical bond (the force holding the molecule together) weakens and ultimately breaks when it is stretched sufficiently—*i.e.*, the constituent atoms are separated. Beyond the dissociation energy, when the bond breaks, all values of the relative translational kinetic en-

Allowed energies for a harmonic oscillator

Electronic energy of a molecule

Figure 12: Allowed values of the vibrational energy E_v of a diatomic molecule. Levels are labelled with the quantum $v = 0, 1, 2, \dots$. The zero energy (dashed line) is not an allowed value. The point D_0 is the dissociation limit, above which the molecule breaks into two separate atoms.

ergy of the atoms are allowed without any restriction from quantum mechanics.

When a molecule is exposed to radiation, it is found from both theory and experiment that it will not efficiently absorb radiation and thereby undergo a transition from one energy level to another unless the energy of a quantum of radiation (which has the value $h\nu$, the product of the frequency of radiation ν , and Planck's constant h) matches the energy difference between the energy level initially occupied by the molecule and some higher level. If, on the other hand, the value of $h\nu$ matches the energy difference to a lower energy level, the molecule may be caused to emit the frequency ν . This phenomenon is called induced emission.

Not only must energy be conserved (*i.e.*, $\pm h\nu = E_{\text{final}} - E_{\text{initial}}$) but also there may be additional restrictions, called selection rules, on what changes of energy level may occur. Thus for a polar diatomic molecule (a molecule with an unsymmetric charge distribution), vibrational transitions from one energy level to the adjacent level symbolized as $\Delta v = 1$ are much more probable than changes in the quantum number v by 2, 3, etc. These rules have a sound theoretical foundation, and often it is possible to make firm predictions regarding selection rules and intensities.

APPLICATIONS

The most obvious application of many of the branches of molecular spectroscopy is for characterizing and identifying specific chemical species—*i.e.*, for chemical analysis, either qualitative or quantitative. The infrared spectra of materials in the gaseous, liquid, or solid state at moderate resolution are highly characteristic of individual species—a sort of molecular fingerprint that, once taken, usually permits the same substance to be identified if encountered again. Raman spectra (after Sir Chandrasekhara Venkata Raman, a physicist of India) are similar in their utility. Pure rotational spectra (microwave spectra) are even more characteristic but are obtainable for far fewer species. Visible and ultraviolet spectra are usually considerably less structured than infrared spectra but are easy to observe, quantitatively measurable, often obtainable on tiny samples, and have been of great importance in chemistry. In a similar way, the closely related fluorescence spectra are of wide utility for analysis. X-ray spectra are mostly useful for identifying the atoms that are present. One of the most useful branches for these chemical applications is that of nuclear magnetic-resonance spectroscopy.

Besides these important analytical uses—important in controlling manufacturing processes as well as in the laboratory—spectroscopy has been one of the major sources of scientific information about the geometry of molecular structure, including much of the data on the way electrons are distributed in molecules and how they bring about chemical binding of the atoms. Some of these applications will be discussed below.

FIELDS OF MOLECULAR SPECTROSCOPY

Microwave spectroscopy. (See also *Radio-frequency spectra* below.) Microwave radiation is electromagnetic radiation with wavelengths of a few millimetres to several centimetres (see Table 3). The region is differentiated from its neighbours (the far infrared at shorter wavelengths, ultrahigh frequency radio at longer wavelengths) only by the practical techniques of generation, transmission, and detection used. Microwaves can be generated by special electronic vacuum tubes—*e.g.*, klystrons—or by backward wave oscillators, and more recently by certain solid-state devices such as the Gunn effect diode. These sources can be made highly monochromatic.

Microwaves can be transmitted through hollow metal tubes, often of rectangular cross section (wave guides) and can be detected by a silicon diode rectifier crystal connected to a suitable amplifier and recording or display device.

If a wave guide with mica windows at the ends is arranged to form an absorption cell and then evacuated and filled to a low pressure (perhaps one hundred thousandth of atmospheric pressure) with a suitable gas, such as car-

bonyl sulfide (COS), certain frequencies in the microwave region are weakly but sharply absorbed by the gas. Figure 13 shows the signal strength versus frequency of p -bromotoluene. In practice, some form of modulation of the absorption is generally used in order to increase the sensitivity. In almost all such cases, the molecule absorbs a photon or quantum of microwave energy and converts it to increased molecular-rotational energy; *i.e.*, the molecule undergoes a transition from one specific, quantized discrete rotational level to another.

In order to display a sharp microwave spectrum, a substance normally must have a nonvanishing, permanent electrical dipole moment (an electric dipole moment means that the electric charge is not symmetrically distributed over the molecule); it must be in the vapour state at a low pressure; and its molecules must not be too large and complicated. Many thousands of kinds of molecules have already been found suitable for producing microwave spectra.

Detailed information about individual molecules that can be obtained from microwave spectroscopy includes quantitative molecular structures, electrical dipole moments, magnetic moments, nuclear-electrical quadrupole moments that measure the deviation of the nuclear charge from sphericity, nuclear spins, low vibration frequencies, barriers to internal rotation, molecular quadrupole moments, and information about chemical bonds. The spectra are highly characteristic of each kind of molecule and hence can be used for analysis. Some transient species, such as the free radicals hydroxyl (OH), sulfur monoxide (SO), bromine monoxide (BrO), and others, have been studied.

Astronomers have used special radio telescopes to discover the presence in interstellar space of certain molecules—hydroxyl, water, ammonia, formaldehyde, and others—by means of characteristic, recognizable microwave lines (see below *Radio spectroscopy*).

A simple example of how structures can be obtained is provided by diatomic molecules, consisting of two atomic nuclei and linear molecules, for which an adequate model is provided by the linear-rigid rotor—a rotating rigid body made up of a set of mass points (each representing a nucleus) arranged in a straight line. The orientation is measured with the two polar angles of the axis, and the only parameter, or characteristic quantity, required is the moment of inertia (I) specified as a sum of terms, each of which is equal to the mass of a nucleus (electrons are not considered because of their relatively negligible mass) times the square of its distance along the axis from the centre of mass; *i.e.*, $I = m_1 z_1^2 + m_2 z_2^2$, in which m_1 and m_2 are the masses and z_1 and z_2 are their distances. For this model system, quantum mechanics leads to the result that the energy is inversely proportional to the moment

Figure 13: Microwave spectrum of p -bromotoluene at low resolution. Signal strength in absence of electric field is upward, in presence of field downward. Note pairs of peaks arising from two isotopes of bromine.

of inertia (I) and dependent on a quantum number (J) that takes on integral values; *i.e.*, $E_J = J(J+1)(h^2/8\pi^2 I)$, in which $J = 0, 1, 2, \dots$ for the allowed values of the rotational energy E_J . Here h is Planck's constant.

Although this system provides a good model for the rotational energy levels of diatomic and linear molecules, it is not perfect; for example, molecules are not really rigid but stretch because of the centrifugal force of the rotation.

Rotational levels

selection rules

This characteristic and other interactions of rotation and vibration are observable but not large. In addition, electrons contribute a small amount to the moment of inertia.

Quantum mechanics also provides selection rules (*i.e.*, prescribes the energy levels involved) for transitions in this case. If the molecule has a permanent dipole moment, emission or absorption of radiation can occur between adjacent levels; that is, the selection rule is obeyed by a difference in quantum numbers $\Delta J = 1$ for a pure rotational transition. Consequently, the spectrum should consist of a series of lines, equally spaced in frequency ν_J , which follows from the energy equation and selection rule: $h\nu_J = E_{J+1} - E_J = [(J+1)(J+2) - J(J+1)] \hbar^2/8\pi^2 I = 2(J+1) \hbar^2/8\pi^2 I$, in which the term $(J+1)$ takes on the values 1, 2, 3, etc. This equation means that the transitions have frequency spacings $2\hbar^2/8\pi^2 I$. From a measured frequency of known quantum number J , the moment of inertia, I , for the particular kind of molecule can be obtained. For a diatomic molecule consisting of two nuclei of masses, m_1 and m_2 , with internuclear distance r , the moment of inertia expression reduces to the product of the masses times the separation squared, divided by the sum of the masses, or, $I = m_1 m_2 r^2 / (m_1 + m_2)$; so that a knowledge of the moment of inertia obtained from spectral measurements leads to a value for the internuclear separation. For nonlinear molecules, molecules having their nuclei arrayed other than in a straight line, the expressions for the rotational energy levels and transitions in terms of the moments of inertia are more complicated, but they have been developed and are widely applied.

Nonlinear
molecules

For molecules with more atoms, the structure involves more parameters (internuclear distances) and the information from one microwave spectrum is not sufficient. The internuclear distances of molecules that differ only in that one or more nuclei are replaced by other isotopes are found to change but slightly, however, so that the microwave spectra of a number of such isotopic species can be used in order to provide sufficient information for the complete structure of a simple molecule. Figure 14 shows an example.

Infrared spectroscopy. Infrared radiation has a range of wavelengths from about 8×10^{-4} millimetre (0.8 micrometre) to about 10^{-1} millimetre (100 micrometres)—*i.e.*, from that of visible light down to that of microwaves. It is customary to divide the infrared region into near, medium, and far infrared domains. Photography can still be used out to about .0012 millimetre (1.2 micrometres) wavelength (the near infrared), and various special photoconductive detectors are available for part of the medium region, but at longer wavelengths one must use much less sensitive thermal detectors, such as thermocouples, bolometers, or Golaycell detectors, all of which use the radiation to produce a temperature rise in some temperature-sensitive element.

Heated objects were the primary sources of infrared radiation before the discovery of lasers. The latter be-

came available in the early 1970s for many specific sharp frequencies (narrow lines), whereas the thermal sources used theretofore gave radiation spread continuously over a broad range of wavelengths.

Present-day infrared spectrometers still use thermal sources, a prism of special material or a diffraction grating to select out narrow ranges of wavelength, mirrors instead of lenses for focussing the radiation, and either photoconducting or thermal detectors. Depending on the wavelength range, prisms and windows may be made of rock salt (sodium chloride), potassium bromide, quartz, or other materials chosen because they are transparent to the desired rays. Glass does not transmit except in the visible and adjacent infrared. The difficulty of finding suitable transparent materials for the remainder of the infrared region explains the use of concave mirrors instead of lenses and also favours the use of gratings over prisms. Grating instruments are commonly used in infrared studies (see *Methods for dispersing spectra* above).

A type of spectrometer different from those employing prisms and gratings uses the interferometric principle and has the advantage of large aperture; *i.e.*, it accepts a large cone of light from the source and hence is particularly advantageous in the infrared where sources are weak and detectors are of low sensitivity.

Lasers are useful sources, and some spectroscopy is being done with them, but lasers tunable over an adequate range became feasible only in the early 1970s.

The main impact of infrared spectroscopy is probably in the medium region, say from 0.003 millimetre to perhaps 0.025 millimetre (or 3 to 25 micrometres), because most of the vibration frequencies of not too complicated molecules fall in this range.

The vibrational behaviour of a molecule is quite well simulated by a model consisting of point masses (the atomic nuclei) held together by weightless springs (representing the chemical-valence bonds). These binding forces are really caused by the electrons, which, being many thousands of times lighter than the nuclei, can be treated as approximately massless. If a macroscopic, mechanical model of a molecule made of steel balls (nuclei) and springs (bonds) is vibrated at a slowly increasing frequency, it will display a series of resonances (*i.e.*, certain frequencies at which the model will respond fairly sharply and vibrate in a particular way) with specific ratios of the amplitudes of motion of the different balls. Each resonance involves a different pattern of motion, these patterns being the normal modes of motion, each with its own frequency (see Figure 15).

Resonant
frequencies

Figure 14: Structure of nitric acid molecule, determined by microwave spectroscopy. Principal axes a and b , and direction of dipole moment μ are also shown. Interatomic distances are in units of 10^{-8} centimetre (see text).

Such mechanical models are not actually used, because classical mechanics permits the ready calculation of the frequencies and modes of motion of an idealized model with point masses and weightless springs. A molecule is much closer to this idealization than any achievable mechanical model. Actually, of course, a molecule obeys quantum mechanics and not classical mechanics. Fortunately, the quantum-mechanical results for the molecular model are closely related to the classical ones. Calculations for the infrared spectrum show absorptions only at frequencies equal to certain of the classical resonant frequencies discussed above. The frequencies that can appear are those for which the electrical dipole moment of the molecule changes during the normal mode of motion.

Further refinement of the calculations shows that other frequencies may occur weakly, for example, at twice those of certain classical frequencies. In addition, these infrared absorptions are not extremely sharp and for light gases under high resolution are seen to consist of bands of many sharp lines. This fine structure arises from simultaneous changes in rotational energy.

The infrared spectrum of a molecule is highly charac-

teristic and hence is widely used by chemists to identify substances by comparing the substance to be identified with an authentic sample (see Figure 16). Moreover, it is found that certain groups within the molecule, such as

Figure 16: Vibrational infrared spectrum of styrene. The individual peaks are characteristic of the various structural features of the styrene molecule shown along the bottom edge of the figure. The hexagons represent the benzene ring of six carbon atoms present in the structure; X represents the entire group of carbon and hydrogen atoms attached to the benzene ring.

the hydroxyl (OH), lead to the appearance of frequencies that are rather constant from one molecule to another and hence can be used to indicate the presence of the group in the molecule. Other groups that show their own frequencies include carbon-hydrogen (CH), sulfur-hydrogen (SH), double bonded carbon-oxygen C=O, and carbon-carbon double bond C=C. A great deal of empirical information of this nature has been accumulated.

From a more theoretical viewpoint, infrared vibrational frequencies can be used to determine the forces between the atoms within a molecule, and they can also provide information about molecular symmetry.

The rotational fine structure, when observable, provides much the same kind of structural information as does the pure rotational spectra studied in the microwave region. The frequency resolving power in the infrared region is a great deal lower than in the microwave regions at present; on the other hand, nonpolar (uniform-charge distribution) molecules can be studied.

Raman spectroscopy. Raman spectroscopy makes use of the fact that photons can be scattered by molecules (whether in the gaseous, liquid, or solid state), with or without a change in frequency—i.e., loss or gain in energy. Most scattered photons continue on with the same energy; a small percent lose some of their energy to the scattering molecule as additional vibrational or rotational energy;

the remainder of the photons gain energy at the expense of the vibrational or rotational energy of the scattering molecule. Because the vibrational energy of a molecule is quantized (as is the rotational energy of a gas molecule), the changes in energy or frequency that occur are limited to a few discrete values. When using photons initially of a single frequency, the scattered radiation contains a small number of discrete frequencies corresponding to energies that have been shifted by rotational or vibrational energy intervals.

Experimentally, modern Raman spectrometers use a strong monochromatic, visible laser beam to illuminate the sample, which can be quite small. The light scattered, usually at right angles to the incident beam, is passed into a spectrometer (normally of a grating type) that is scanned over the desired spectral range, and the spectral output is detected with a phototube and recorded as a function of frequency and intensity (see Figure 17).

If a Raman line has frequency ν resulting from incident radiation of frequency ν_0 , the frequency shift $\nu - \nu_0$ (or $\nu_0 - \nu$ if ν is less than ν_0) is the frequency of a transition, usually vibrational, in the sample. The Raman effect therefore provides information about vibration frequencies, as does infrared spectroscopy. If the scattering molecule has any symmetry, however, the selection rules for the Raman and infrared transitions may differ.

Pure rotational Raman spectra have been observed in gases for small molecules and have provided structural information. For the Raman effect, the molecule can be polar or nonpolar.

Visible and ultraviolet spectra. Coloured substances absorb radiation having frequencies in the visible portion of the spectrum. Thus a solution that looks blue when viewed by transmitted white light does so because the material absorbs yellow light from it. Other materials may be transparent in the visible region but may or may not absorb in the near ultraviolet region. More and more substances show absorption bands as the region considered is moved farther into the ultraviolet.

These particular absorptions are almost always due to the excitation of electrons. As in atoms, the electronic energy in a molecule is quantized, so that certain discrete values are allowed. If the quantum of radiation is energetic enough to remove an electron or an atom from the molecule, however, the resulting system can have any relative translational energy (nonquantized) so that part of the spectrum can show regions of continuous absorption.

An approximate way of describing the behaviour of the electrons in a molecule has been found to be useful, though not exact. Whereas each electron is actually influenced in its motion by the instantaneous position of every other electron, an approximation is made by replacing this complicated interaction by an interaction that has been averaged over the motions of the other electrons. In this way, it is possible to treat the complex problem in a cer-

Laser beams for Raman scattering

tain sense as if the electrons acted independently of each other. In quantum mechanics, the location of an electron in a molecule is determined by specifying the probability of its presence at any point. Thus a plot of the probability would have the appearance of a cloud. This probability distribution in space of a particular electron in the present approximation is then governed by a single-electron function called a molecular orbital. For a given molecule there exists a whole set of these molecular orbitals (of various cloudlike shapes); and for the state of lowest energy for the whole molecule (called the ground state), the electrons are assigned to the molecular orbitals of lowest energy, two at a time. Two electrons can occupy a single molecular orbital if the two electrons have opposite electron spin orientations; the Pauli exclusion principle forbids occupancy of an orbital by more than two. In the simplest form of the theory, the electronic energy is then considered to be twice the sum of the energies of these occupied molecular orbitals.

Besides the filled molecular orbitals, there are others that are not filled when the molecule is in its ground state. A molecule, however, may be raised to an excited electronic state by absorption of radiation or by a collision. The excited states can be approximately described by assigning one or more electrons to previously unfilled molecular orbitals (MO's) of higher energy, leaving a corresponding number of holes among the previously fully occupied lower MO's. The transition of lowest frequency would involve transferring one electron from the highest MO occupied in the ground state to the lowest empty MO. See Figure 18.

Correlation energy

This method of labelling and classifying excited states and electronic transitions is of enormous value, but the mathematical approximations related to it do not always give good quantitative results. The missing energy correction, called the correlation energy, arises from the difference between the actual instantaneous repulsions of the electrons and the averaged interaction, and this energy can be large.

Frequently, the additional approximation is made by describing a molecular orbital as a combination of two or more atomic orbitals from different atoms of the same molecule. The electronic orbitals of lowest energy are usually in fact describable as essentially pure inner-shell atomic orbitals. On the other hand, the highest occupied molecular orbitals, in a covalently bound molecule (each atom contributes one electron to the mutual bond) at least, will involve outer-atomic orbitals of more than one atom. Some of the MO's are largely responsible for the chemical binding energy of the molecule because they have lower energy than the atomic orbitals into which they transform when the atoms separate.

Molecules with simple, covalent electron-pair bonds with all inner-electron orbitals fully occupied tend to be transparent to visible radiation. In other words, there is a fairly

Figure 18: Example of an energy occupancy diagram for molecular orbitals (MO's). (A) For ground electronic state; each lower MO is occupied by a pair of electrons with opposite spins (arrows). (B) For lowest excited singlet state, in which an electron has been excited to a previously empty MO. Vertical position of bars indicates energy, E_{MO} , of individual MO's. Second level shows two MO's of same energy (degeneracy).

large energy gap between the completely filled MO's and the lowest unfilled one.

There are two classes of molecules, on the other hand, that tend to be coloured (*i.e.*, to absorb in the visible region). One class consist of compounds of such transition-group metals as iron, nickel, platinum; that is, those with

Figure 19: Two classic Kekule structures for benzene, C_6H_6 , which show two equivalent ways of drawing alternate single and double bonds between neighbouring pairs of carbon atoms. In the actual molecule all six bonds are equivalent, and the bonding is approximately the average of the two Kekule structures.

partially filled atomic orbitals. In many cases, electrons can undergo transitions to low-lying (inner-electron) orbitals of the same shell. (When the probability distributions in space of all the electrons of an atom in the ground state are considered, it is found that the electrons are grouped more or less in shells around the nucleus.) Another class contains molecules for which the simple bonding diagrams are inadequate; but there are several alternate ways of drawing in the lines representing chemical bonds, and the more correct representation (called conjugation or resonance) is a kind of quantum-mechanical superposition of the several bond structures. The two classic Kekule structures of benzene (Figure 19) provide a good example of resonance. The six carbon atoms of the molecule form a closed, six-sided structure that has six-fold symmetry (all sides equal, all angles equal) with all carbon-carbon bonds identical and with properties intermediate between those of double and single bonds. Theory shows that molecules displaying resonance should have low-lying empty MO's and therefore the possibility of visible or near-ultraviolet absorption bands. Organic dyes are in this category. Sometimes the MO's responsible for absorption are quite localized in part of the molecule. Such groups of atoms are called chromophores.

The fact that an electron is endowed with an intrinsic angular momentum (spin) that can display only two orientations, roughly speaking, in space gives rise to a number of spectroscopically interesting effects. The Pauli exclusion principle requires that if two electrons are in the same molecular (or atomic) orbital, they must have opposite spin orientations, cancelling their spin angular momenta, so that a majority of molecules exist in ground states with the electron spins completely paired. If one of these electrons is excited to another orbital that happens to have a vacancy, the atom or molecule will be excited to one of four energy states, grouped as a singlet state or a triplet level. The singlet state arises when the excited electron and its original partner are antiparallel (that is, have spins in the opposite direction); the triplet level, on the other hand, results when the excited electron and its original partner are parallel, having spins in the same direction. The combined two spins can have any one of three overall orientations, or more correctly, three possible values of the component of spin-angular momentum, versus only two for a single electron spin. There are many orbitals to which an excited electron may be raised, and consequently there exists a series each of singlet and triplet levels; an atom or molecule will thus lose energy by radiation by making transitions either from one singlet state to another singlet state or from one triplet set to another triplet set, transitions between singlet and triplet states being forbidden.

Singlet and triplet states

Many organic molecules, mostly so-called aromatic molecules, absorb in the visible or near ultraviolet and return rapidly to the ground state with the emission of nearly the same frequency as was absorbed. This phenomenon is fluorescence. The efficiency may be quite high; *i.e.*, nearly all the radiation absorbed is rapidly (in about 10^{-8} second) reradiated. Much of fluorescent light is of somewhat lower frequency than that absorbed, because the molecule can return not only to the lowest state but also to one or another of the excited vibrational levels of the ground electronic state (see Figure 20). In some cases,

Figure 20: Lower vibrational and electronic energy levels of a complex molecule, showing ground electronic level S_0 , the lowest excited singlet electronic state S_1 , the lowest triplet electronic level T , plus associated vibrational levels for each. Zigzag arrows R show nonradiative loss of vibrational energy by collisions. ISC represents an intersystem crossing.

this phenomenon leads to a fluorescence spectrum with a vibrational pattern that is approximately a mirror image of the pattern of the absorption spectrum.

With some molecules another process competes with fluorescence. Absorption raises the molecule to an excited singlet state, perhaps with some vibrational excitation also. Collisions cause a rapid loss of vibrational energy, but not of electronic energy. The molecule then has a certain probability of intersystem crossing—*i.e.*, of undergoing a transition without radiation—to a highly excited vibrational state of the triplet manifold. Collisions again remove this vibrational energy, leaving the molecule in the triplet electronic state. From there it can return to the ground state either by radiation—*i.e.*, phosphorescence—or by another intersystem crossing to a high vibrational state of the ground, singlet, electronic manifold, with subsequent loss of vibrational energy. In various molecules, one or another of these pathways is used.

Triplet states generally have much longer lifetimes than singlet states, especially in solid glassy media at low temperatures, because the radiative transition to the ground singlet state is a forbidden one. Its occurrence is explained in terms of certain small interactions, in particular that between the magnetic moments of the electron spin and electronic orbital motion.

These phenomena are of chemical interest, for some compounds undergo different reactions in their excited states depending upon whether they are in the excited-singlet or excited-triplet state. Furthermore, these excitation energies can in suitable circumstances be transferred from one molecule to another of the same or of different species.

One important application of visible and ultraviolet spectra is to the accurate determination of the energy required to dissociate a diatomic molecule into its constituent atoms. The energy-level pattern for the ground electronic state consists of a sequence of vibrational states, the lower members of which are approximately equally spaced (see

sequence
of
vibrational
states

Figure 21: Potential energy function $V(R)$ and vibrational energy levels (E_v) for a diatomic molecule, showing dissociation limit at energy D_0 above lowest vibrational level.

equation in section above on quantization of molecular energy). As the vibrational energy is increased, the energy levels are more and more closely spaced and ultimately converge to a limit, which is the maximum vibrational energy possible without actually tearing apart the molecule into two atoms (see Figure 21).

In favourable cases, it is possible to observe an emission spectrum consisting of a series of lines that converge to a limit in the high-frequency direction. These lines are transitions from an excited electronic state to the various vibrational levels of the ground electronic state, as shown in Figure 21. Planck's constant (h) times the difference in frequency between that of the limit and that of the transition to the lowest vibrational level is the energy of dissociation (D_0) and can sometimes be obtained with great accuracy. It is naturally necessary to know the states of the resulting atoms, because they need not be in their lowest states.

Electron spectroscopy. In most forms of spectroscopy, the fractions of the radiation for various wavelengths absorbed by the sample are measured. These data are then often used to determine the energy levels of the matter. There are other ways, however, of obtaining the same or similar information. In one of these, monochromatic radiation of quite high energy—in the X-ray or ultraviolet regions—is passed into the matter. Because of its high energy, it can cause the complete removal of an electron from the irradiated molecule, leaving the latter in the form of a positive ion. The ejected electron will carry away as kinetic energy the excess energy, and this kinetic energy can then be rather accurately measured by recently improved instruments. For example, Planck's constant (h) times the frequency (ν_0) of the incident photon is its energy ($h\nu_0$); if E_{elec} is the kinetic energy of the ejected electron, then the energy of the resulting ion, relative to the initial state of the neutral molecule, is equal to their differences, or $E_{ion} = h\nu_0 - E_{elec}$, by conservation of energy. In a typical experiment to determine an ionization energy, a gas may be irradiated by the 585-angstrom line of a helium discharge and the velocities of the electrons measured to give E_{elec} . Normally there will be several peaks in a curve plotted to show numbers of electrons versus energies. Each peak will represent one quantum state of the ion (provided that all the molecules were initially in their lowest energy level). Consequently, this method provides information about the states of the ion.

The ionic states can be approximately described in terms of the molecular orbital, now empty, from which the electron came. With ultraviolet excitation only outer electrons can be removed.

With X-ray excitation, electrons from the inner atomic shells (K or L electrons) can be ejected. The energies of these electrons are primarily characteristic of the particular atom involved; but there are small shifts from one molecule to another molecule, especially for molecules in which the chemical binding or environment of the particular atom differs markedly. These electron spectra (giving E_{elec} in the above equation) are therefore of use in identifying the atoms present and in obtaining some information about their environment.

Related to electron spectroscopy are various experiments in which energy levels and other types of information are obtained by collisions between the molecule of interest and beams of electrons, neutrons, ions, or other particles. Various quantities can be measured, such as the energy loss of the stream of particles, or the angular and velocity dependence of this loss. One advantage of some of these collisional techniques is that they can sometimes detect transitions forbidden in optical spectroscopy, so that energy levels that are difficult to locate by conventional methods can be found.

Molecular-beam spectroscopy. In the long-wavelength regions, the minimal width of a spectral line, and hence the achievable resolving power, is often limited by collisions between molecules, or between molecules and a wall of the container, or by the effect of the motion of the molecules along the direction of propagation of the radiation (Doppler effect). All of these effects can be largely eliminated by examining the molecules in the form of a

Forbidden
transitions

narrow stream moving through an evacuated chamber in a direction at right angles to the direction of propagation of the radiation. Such a stream is called a molecular beam and can be produced by allowing a gas to flow through a small opening into an evacuated vessel.

In principle, extremely narrow spectral lines are thereby made possible, but the difficulty is that there are so few molecules in the path of the radiation that it is difficult to detect the absorption. A physicist, Isidor Rabi of the United States, solved this problem by reversing the usual procedure; instead of measuring the photons absorbed from the radiation beam by the molecules, he devised a scheme for measuring the number of molecules that have absorbed or emitted a photon. Figure 22 is a schematic diagram of a typical molecular-beam spectrometer, showing

Figure 22: Molecular beam spectrometer.

Beam molecules (dashed line) originate in source s ; S_1 , S_2 , S_3 , S_4 are slits; D_1 and D_2 produce an inhomogeneous magnetic or electric field, which deflects molecules in different states by different amounts; F is the central region where molecules are subjected to oscillating electrical and magnetic fields; d is the molecule detector. Molecules that undergo a transition in F do not reach the detector.

a source, s , from which the beam of molecules (or atoms) issues and a device, D_1 , that deflects molecules in different quantum states by different amounts so that only those in one state (or sometimes one group of states) passes through the slit, S_2 , into the central region. In this region, the molecules are exposed to radiation, the frequency of which can be varied; usually in the same region there is a constant magnetic or electric field as well. The beam then enters a second state selector, D_2 , that passes on to the detector, d , only those molecules still in the quantum state selected by D_1 . In operation, the radiation frequency is varied until its energy, $h\nu$, is equal to the energy transition (up or down) from the selected state of the molecules to some other state. If a transition to this other state is allowed, some of the molecules will then absorb or emit energy and thus be changed from their original state. Such molecules will not pass through the second state selector, D_2 . The detector output will therefore show a minimum at this resonance frequency.

Several varieties of state selectors are available. Small polar molecules, especially diatomic molecules, can often be separated according to their rotation-space orientation quantum numbers by an inhomogeneous (nonuniform) electric field. Molecules having sufficient rotational magnetic moments, even if they have no electrical dipole moment, may sometimes be state-selected by an inhomogeneous magnetic field.

This method has been mostly used to observe transitions between different space-quantized states of the same rotational-vibrational level split apart in energy by an electrical or magnetic field, but transitions between different rotational states are also observed. The main application of the molecular-beam technique is to the study of hyperfine structures of transitions arising from tiny effects, such as interaction of the magnetic moments of nuclei with the magnetic moments generated by molecular rotation.

The molecular-beam method has been used to measure molecular electric dipole moments with great accuracy so that the small changes that occur from one vibrational state to another are easily measurable. These quantities are useful for testing theories of chemical binding. For example, a reasonably satisfactory and quite simple model for highly ionic molecules such as sodium chloride (in the vapour phase at high temperatures) attributes the chemical bond to the attraction of the oppositely charged ions balanced by the repulsion resulting from the interpenetration of the electron clouds of the ions. This picture can be made quantitative in a way that accounts for much molecular-beam data on ionic molecules.

Double and multiple photon effects. The interaction between matter and an electromagnetic field of radiation can usually be treated as a small effect that causes the matter to undergo occasional transitions with the absorption (or emission) of a single photon. With stronger radiations fields, however, transitions from one energy level to another can occur with the involvement of two (or even more) photons. Two photons can be absorbed simultaneously by the same molecule or one may be absorbed and one of a different frequency emitted (as in the Raman effect). Double photon absorption permits two different types of spectroscopy to be combined. For example, there can be simultaneous absorption of an infrared and a microwave photon. The development of lasers has provided sources of infrared and visible radiation strong enough to make these multiple-photon effects readily observable.

These various phenomena have extended the range of techniques available to the spectroscopist and have been most useful, therefore, for assisting in the analysis of complex spectra.

This brief discussion necessarily omits many topics, such as Mössbauer spectroscopy, the effects of electric and magnetic fields, and information obtainable from intensities and line widths. Molecular spectroscopy is a broad and growing field, continually developing new techniques and new capabilities for obtaining valuable information about molecules. (E.B.W.)

X-ray spectroscopy

A penetrating, electrically uncharged radiation was discovered in 1895 by a German physicist, Wilhelm Conrad Röntgen, and named X-radiation because its origin was unknown. This radiation was produced when electrons (cathode rays) struck glass or metal surfaces in high-voltage evacuated tubes, and was detected by the fluorescent glow of coated screens and by the exposure of photographic plates and films. The medical applications of this radiation that penetrated flesh more easily than bone were recognized immediately, and X-rays were in medical use in Vienna within three months of their discovery.

Initially, vain attempts were made to deflect the rays by means of electric and magnetic fields, on the assumption that they were composed of charged particles. Classical mechanics of the day showed that charged particles, such as cathode rays in an X-ray tube, when decelerated quickly from high to low speed in their collision with matter, should give off electromagnetic radiation (bremsstrahlung, or braking radiation), which in turn should show a wave character. Tests made to show the wave character of X-rays by diffraction were inconclusive, however, indicating that the wavelengths must be shorter than about 1×10^{-10} metre if X-rays were indeed waves. The first clear demonstration of the wave nature of X-rays were provided in 1912 when X-rays were diffracted by the closely spaced atomic planes in a crystal of zinc blende (zinc sulfide). Because the details of the diffraction patterns depended upon the wavelength of radiation, these experiments set the stage for the spectroscopy of X-rays. The first spectrographs for this radiation were devised in 1912–13 by two British physicists—father and son—William Henry and Lawrence Bragg, who showed that not only did there exist continuum X-ray spectra, to be expected from processes involving the stopping of charged particles, but also discrete characteristic spectra, indicating that the details of atomic structure determine some X-ray properties (see Figure 4). The systematic increase of characteristic X-ray energies with atomic number was shown by Moseley in 1913 to be explainable on the basis of the Bohr theory of atomic structure.

Wavelengths for X-rays range from about 0.05 angstrom to 100 angstroms, with the range 10–100 Å, known as soft X-rays, overlapping the far ultraviolet. A convenient unit of wavelength is the X-unit or X.U., defined so that approximately 1,000 X.U. = 1 Å (the actual value is 1,000 X.U. = 1.00203 Å). The X-ray wavelength range is then approximately 50–100,000 X-units.

Relation to atomic structure. Short wavelength radiation can be produced by isolated atoms and ions by two

Discovery of X-rays

related processes. If two or more electrons are removed from an atom, the remaining outer electrons are more tightly bound to the nucleus by its unbalanced charge, and transitions of these electrons from one level to another can result in photon wavelengths of 100 angstroms or less. The resulting spectra can be observed in spark sources. An alternate process occurs when in a neutral atom an electron is removed from an inner shell. This removal can be accomplished by bombarding the atom with electrons, protons, or other particles at sufficiently high energy and also by irradiation of the atom by sufficiently energetic X-rays. Almost immediately, the remaining electrons in the atom readjust, making transitions to fill the "hole" left by the removed electron, and X-rays are given off in these transitions. The latter process occurs in an ordinary X-ray tube, and the resultant X-ray lines, the characteristic spectrum, is superimposed on a spectrum of continuous radiation resulting from decelerated electrons.

The shells in an atom, labelled by $n = 1, 2, 3, 4, 5$, by the optical spectroscopist, are labelled K, L, M, N, O, \dots by the X-ray spectroscopist.

In many ways the vacancy, or "hole," remaining when an electron is removed from one of these shells, behaves as a positively charged electron; e.g., if after an electron is removed from the K shell of an atom, an L -shell electron makes a transition to the K shell, the net result is the transfer of a single "hole" from the K to the L shell. The possible energies of such a vacancy thus can be labelled by the hydrogenic quantum numbers, n, l, j, m ; because the production of a vacancy is equivalent to cancelling the negative charge at a region within the atom (i.e., adding positive charge there), however, the energy of a vacancy is highest at the K shell, lowest in the outermost shell, and X-ray energy levels by convention are inverted compared to those of atoms having single outer electrons.

Within a shell, there are some differences in vacancy energy according to whether or not an s, p, d , etc., electron has been removed and according to the total angular momentum of the electrons. The subshells are labelled by Roman numerals according to their energies. Figure 23 shows an X-ray energy-level diagram for uranium (Z , atomic number 92), including the allowed transitions.

If the continuous spectrum from an X-ray tube is passed through a pure absorbing material, it is found that the absorption coefficient changes suddenly at X-ray wavelengths corresponding to the K, L, M , etc., shell energies. The sudden increases of absorption coefficients as the wavelength is reduced past these shell energies are called absorption edges and serve as useful reference wavelengths that can be precisely determined (see Figure 4). Wavelengths of absorption edges range from 247.92 angstroms for the L_{II} edge in magnesium to below 0.1 angstrom for the K edges of elements heavier than plutonium ($Z \geq 94$).

Inverted
energy
levels

Figure 23: X-ray levels in uranium, showing transitions allowed by the selection rules $\Delta l = \pm 1$, and $\Delta j = \pm 1, 0$. The ordinate scale is logarithmic. Since an X-ray level occurs when there is vacancy rather than an electron in a shell, the levels are inverted relative to hydrogenic levels.

The X-ray fluorescence radiation of materials is of considerable practical interest. Atoms irradiated by X-rays having sufficient energies, which may consist of either characteristic or continuous rays or both, lose electrons and as a result emit X-rays characteristic of their own structures. Such sources are weak; they have, however, an advantage over primary sources, such as X-ray tubes, in that there is little or no background caused by bremsstrahlung; the emitted spectrum is then nearly a pure-line spectrum. Such methods are used in the analyses of mixtures of unknown composition.

Production methods. An X-ray tube consists of a source of electrons (usually a heated filament) and a massive anode, mounted within an evacuated chamber or envelope (see Figure 5). A potential difference of 10–100 kilovolts is maintained between cathode (the negative electrode) and anode (the positive electrode), and typical power inputs range from 100 to several thousand watts. At the higher power levels, it is often necessary to cool the anode with circulating fluid. The anode material of an X-ray tube determines the range of wavelength for the discrete spectra, with the shortest discrete wavelengths produced by material having highest atomic number. Bremsstrahlung, the continuous part of an X-ray spectrum, extends to a minimum wavelength (λ_0). It is found that this wavelength diminishes as the accelerating potential (V) is increased across the X-ray tube; in fact, the minimum wavelength and X-ray voltage are related by the Duane-Hunt law stating that electronic charge times voltage is equal to Planck's constant times speed of light divided by minimum wavelength—i.e., $eV = hc/\lambda_0$.

If the X-ray fluorescence spectrum of some element is desired, a sample of the element is placed near the anode, usually outside the window of the tube where it is accessible. The potential voltage, of course, must be sufficiently high to release electrons from an inner shell (e.g., at least 70 kilovolts to produce the characteristic K lines of tungsten). Baffles are placed in and around the tube to reduce the amount of primary radiation escaping from the tube other than through the exit window. Great care must always be taken in the operation of X-ray machines to avoid excessive exposure of any part of the body to the radiation.

Analysis. In the soft (10–100 angstroms) X-ray-wavelength region, it is possible to use grating spectrometers for analyzing spectra. Optical materials do not transmit radiation in this wavelength range, and they reflect this radiation inefficiently. It is necessary to use gratings at grazing incidence; that is, with the incident and reflected radiation moving nearly parallel to the grating.

For shorter wavelengths, crystal spectrometers are used. X-ray radiation falling on a set of geometrically aligned atoms is diffracted only in certain directions set by the requirement of constructive interference. A crystal spectrometer consists typically of an entrance slit, a bent crystal, and a detector, in a geometrical arrangement similar to that of a concave grating spectrometer. In such an instrument, the so-called bent crystal is a crystal of mica, quartz, germanium, or gold a few square centimetres in area and a millimetre or so thick, curved to a radius of a metre or more. The lattice spacing for the crystal is accurately known, and the observed angles of diffraction are used to measure and identify the wavelengths entering the spectrometer.

A source of X-rays of known wavelength can also be used to find the lattice spacing, crystal orientation, and crystal structure of an unknown crystalline material. The crystalline material is placed in a well-collimated beam of X-rays, and the angles of diffraction are recorded as a series of spots on photographic film. This method, known as the Laue method after a German physicist, Max Theodor Felix von Laue, is effective for studying crystals having dimensions of the order of a millimetre (0.04 inch) or larger. If microcrystalline materials (powdered crystals) are placed in the X-ray beam (Debye-Scherrer method, after Peter Debye and Paul Scherrer, chemists in Holland), the pattern observed is a series of concentric rings the diameters and intensities of which depend upon the lattice spacings of the crystal and its structure.

Use of
crystal
spectrom-
eters

X-ray detectors. The most universally used detectors for X-ray spectroscopy are photographic plates and films and semiconductors (crystals that become conductive when irradiated).

For electrical recording of X-ray intensities, scintillators and ionization chambers are often used. A scintillator is a material that emits light when X-rays are absorbed. It is used in conjunction with a photomultiplier to provide an electrical signal, the intensity of which is proportional to the X-ray flux. An ionization chamber contains a positive and a negative electrode; when an X-ray photon enters the chamber through a thin window, it ionizes the gas inside and an ion current flows in the electrical circuit connected to the electrodes. The window is often beryllium, chosen for mechanical strength and relative transparency to X-rays. The gas is chosen to absorb strongly (*i.e.*, it gives a copious supply of ions) in the desired wavelength region. With increased voltage on the electrodes, the ionization chamber becomes a proportional counter, which gives out an amplified electrical pulse when an X-ray photon is absorbed within it. At still higher voltages, absorption of an X-ray photon with consequent ionization of many atoms in the gas initiates a discharge breakdown of the gas and causes a large electrical pulse output. This device is known as a Geiger-Müller tube and forms the basis for radiation detectors known as Geiger counters.

Semi-
conductors

Semiconductor analyzer-detector combinations have replaced many of the other detectors. A semiconductor can serve as a detector because an X-ray photon passing through it creates electron-hole pairs, allowing charge to flow in the circuit attached to the semiconductor junction. The amount of charge can be proportional to the photon energy if the entire energy is absorbed in the junction; thus this device serves both as an energy analyzer and a detector of lines in an X-ray spectrum. Connected to a multichannel analyzer, the combination can record the number of photons per unit of energy and display them as a curve. In more sophisticated equipment, these data are automatically fed into a computer for analysis.

Applications. X-ray fluorescence and location of absorption edges can be used to identify quantitatively the elements present in animal tissues, paint, industrial chemicals, and many other substances. Emission of X-rays from high-temperature laboratory plasmas (a fourth state of matter, consisting of almost equal numbers of fast-moving particles of negative and positive charges) is used to probe the conditions within them. In the temperature range 10^6 K to 10^7 K, plasmas emit X-rays strongly; X-ray spectral measurements show both composition and temperature of a source. Similar measurements have been made on astronomical sources, such as the Sun. Because X-rays are absorbed by the Earth's atmosphere, such measurements are made above the atmosphere by apparatus carried by balloons, rockets, or orbiting satellites (see COSMOS: *X-ray sources*).

Radio-frequency spectra

The energy states of atoms, ions, molecules, and other particles are determined mostly by the mutual attraction of the electrons and the nucleus and by the mutual repulsion of the electrons. Electrons and nuclei have magnetic properties in addition to these electrostatic properties. The spin-orbit interaction has been discussed in the section on hydrogen-atom states. Other (usually weaker) magnetic interactions within the atom exist between the magnetic moments of different electrons and between the magnetic moment of each electron and the orbital motions of others. Separations between levels having different energies because of these magnetic interactions vary from less than 10^8 hertz to greater than 10^{13} hertz, being generally greater for heavy atoms.

Origins. Nuclei of atoms often have intrinsic angular momentum (spin) and magnetic moments because of the motions and intrinsic magnetic moments of their constituents; the interactions of nuclei with the magnetic fields of the circulating electrons change slightly the energies of the states in the atom. As a result, an atomic level that consists of several states having the same energy

when the nucleus is nonmagnetic may be split into several closely spaced levels when the nucleus is one that has a magnetic moment. The levels will have different energies depending on the relative orientation of the nucleus and the magnetic field produced by the surrounding electrons. This additional structure of an atom's levels or of spectral lines caused by the magnetic properties of its nucleus is called magnetic hyperfine structure. The nuclear angular momentum is added to the orbital and electron-spin angular momenta to give the total angular momentum (F), the magnitude of which is $\sqrt{F(F+1)}(h/2\pi)$, in which h is Planck's constant, and the projection of which along the magnetic-field direction is $m_F h/2\pi$ in analogy with the quantum numbers J and m_J . Separations between levels differing only in the relative orientation of the magnetic field of the nucleus and electron range typically from 10^6 hertz to 10^{10} hertz.

Hyperfine
structure

Because of the motions and the intrinsic magnetic moments of its constituent electrons, an atom generally has a total magnetic moment. The atom then has different energies when aligned in different ways in an applied magnetic field (Zeeman effect).

Atoms, ions, and molecules can make transitions from one state to another state that differ in energy because of one or more of these magnetic effects. Molecules also undergo transitions between rotational and vibrational states. Such transitions can be either spontaneous or can be induced by the application of appropriate external electric or magnetic fields at resonant frequencies. Transitions also can occur in atoms, molecules, and ions between high-lying electronic states near the ionization limit. The resulting spectra are known as radio-frequency (rf) spectra, or microwave spectra; they are observed typically in the frequency range from 10^6 to 10^{11} hertz.

The spontaneous-transition rate as an atom goes from an excited level to a lower one varies roughly as the cube of the frequency of the transition. Thus radio-frequency and microwave transitions occur spontaneously much less rapidly than do transitions at visible and ultraviolet frequencies. Because of this, most radio-frequency and microwave spectroscopy is done by forcing a sample of atoms to absorb radiation instead of waiting for it to emit radiation. These methods are facilitated by the availability of powerful electronic oscillators throughout this frequency range. The principal exception occurs in the field of radio astronomy; there emission spectra of astronomical sources, (*e.g.*, stars, galaxies, nebulae) are collected by large antennas and are amplified and detected by cooled, low-noise electronic devices.

Methods. The first measurements of the absorption spectra of molecules for the purpose of finding magnetic moments were made in 1940 by Rabi and his collaborators, using molecular and atomic beams (see above *Molecular-beam spectroscopy*). A beam focussed by magnets when no radio-frequency field was present was defocussed and lost when a frequency corresponding to one of the atomic absorption frequencies was applied to the coil, resulting in the atoms making transitions to other states. A spectrum then comprised a graph of the number of atoms coming through the magnets versus the frequency applied to the coil; the number of dips in this curve and the frequencies at which they occurred could be used to find the magnetic moment and angular momentum of the nucleus of the atom under investigation.

One of the most famous laboratory experiments with radio-frequency spectra was performed by two physicists, Willis E. Lamb, Jr. and Robert Curtis Retherford of the United States, in 1947. Their experiment involved a measurement of the energy difference between two almost-coincident levels in hydrogen, designated as $2^2S_{1/2}$ and $2^2P_{1/2}$. Although optical measurements had indicated that these levels might differ in energy, the measurements were difficult and were open to alternative interpretations. Atomic theory suggested that those levels should have exactly the same energy. Lamb and Retherford showed that hydrogen atoms in the $2^2S_{1/2}$ level would undergo a transition to the $2^2P_{1/2}$ level when subjected to radiation at about 1,058 megahertz; hence the levels did not have the same energy and the theory was incomplete. This energy

separation in hydrogen (corresponding to a frequency of about 1,058 megahertz) is now known as the Lamb shift.

Radio-frequency measurements of intervals in ground levels and excited levels of atoms can be made by placing a sample of atoms (usually a vapour in a glass cell) within the coil of an oscillator and tuning the oscillator until a change is seen in the absorption of energy from the oscillator by the atoms. In the method known as optical double resonance, optical radiation corresponding to a transition in the atom of interest is passed through the cell. If radio-frequency radiation is absorbed by the atoms in either of the levels involved, the intensity, polarization, or direction of reradiation of the absorbed light may be changed. In this way a sensitive optical measurement indicates whether or not a radio-frequency interval in the atom matches the frequency applied by the oscillator.

The operation of a maser (a type of microwave amplifier) depends upon the production of more atoms in the upper of two atomic levels separated by typically several hundred to several thousand megahertz. If such atoms are fed into a cavity that is tuned to the transition frequency, the atoms give off their excess energy to set up an oscillation in the cavity. Thus an oscillator is formed that resonates at the atomic frequency; this frequency can often be measured with extraordinary precision and can serve as a standard for time interval, called an atomic clock. The primary standard of time in the metric system is based on cesium vapour oscillating at 9,192,631,770 hertz.

In those atoms in which the nucleus has a magnetic moment, the energies of the electrons depend slightly upon the orientation of the nucleus relative to the magnetic field produced by the electrons near the centre of the atom. The magnetic field at the nucleus depends somewhat upon the environment in which the atom is found, which in turn depends upon the atoms nearby. Thus the radio-frequency spectrum of a substance indicates both the constituents and the forms of chemical binding in the substance. Spectra resulting when the nucleus changes orientation are known as nuclear magnetic-resonance spectra, or NMR spectra, and are of considerable utility in identification of organic compounds (see above).

Radio-frequency transitions have been observed in astronomy in the frequency range from about 400 megahertz to about 9,000 megahertz (.75- to .033-metre wavelength). The earliest observation was of the 21-centimetre (1,420-megahertz) transition that occurs in the ground level of hydrogen as the proton spontaneously flips its spin direction relative to the electron from parallel ($F = 1$ states) to antiparallel ($F = 0$ states). Observations on this transition have provided much information about the temperature and density of hydrogen in the Earth's galaxy. Observation of the hydroxyl OH emission at 1,665 megahertz and other frequencies and of water emission at 2,220 megahertz indicates chemical composition and temperature for the regions in which they are observed. Transitions have been observed for which hydrogen atoms go from principal quantum numbers as high as n from 253 to 252, down to a transition as low as n from 91 to 90. Such atoms are presumably formed when protons capture electrons in large orbits; the spectra yield details of the local temperature and electric and magnetic fields. Lines caused by helium and possibly carbon have also been observed.

Spectral analyses

The simplest method of analysis involves observation of a spectrum through a spectroscope. The advantages of this method are flexibility and speed; quantitative properties of a spectrum can be followed easily. Such observations, limited to the visible region, are useful for checking light sources for the presence of major constituents, because prominent, easily recognized lines or patterns can be found in the arc spectra of most elements. The transmitted spectrum of a solution can indicate the presence or absence of chemical substances.

ANALYSES OF PHOTOGRAPHIC DATA

Two principal classes of experiments in which photographic recording has found wide use are composition

analysis and studies of the structure of atoms and ions.

In the simplest form of composition analysis, the spectrum of a source, consisting of a direct-current electric arc between two electrodes, is recorded and compared to spectra of pure elements by direct superposition. If the spectrograph possesses sufficiently high resolving power, the presence of an element in the source is indicated by coinciding lines on the two spectrograms. When quantitative determination is important, relative intensities may be compared. To do this, measured quantities of the sample the composition of which is being investigated may be mixed in several ratios with much larger quantities of graphite, copper, or other carrier material (called a matrix), and placed one at a time in the tip of the graphite or copper negative electrode of the arc. Several spectra of the sample material are thus obtained, in each of which one such electrode and a pure positive electrode (not of the element under observation) are used for the source. Comparison-arc spectra, each taken with the negative electrode of graphite or copper containing a small known amount of a pure element, are then compared with the spectra of the unknown material. If the operating characteristics of each of the arcs and of the spectrometer are maintained constant, and care is taken that all of the photographic films or plates are processed in the same way, it is possible to determine approximate amounts of many elements in concentrations ranging from greater than 50 percent down to a few parts per million.

As the admixture of any element in an arc is reduced, the weaker lines in its spectrum disappear first. The last lines to disappear are the most sensitive indicators of the presence of that element and are known as the persistent lines of the element.

If comparison spectra are not readily available for the element the presence of which is being investigated, it may be necessary for the investigator to measure wavelengths in the spectrum of the unknown material and compare these wavelengths with those tabulated for the suspected element. In order to facilitate measurement of wavelengths, a known reference spectrum (e.g., that of iron) is usually exposed onto the same film without changing the spectrometer setting so that the known and unknown spectra are superimposed; wavelengths in the unknown spectrum are then calculated by interpolation between lines in the reference spectrum.

Study of the structure of a given atom or ion by means of its spectrum proceeds in a different manner. In such cases, it is necessary to make accurate measurements of wavelengths over as great a range as can be obtained. Reference wavelengths are again included on the photographic record of the spectrum of interest; if the greatest accuracy is desired, the reference wavelengths must have been measured in terms of the fundamental standard of length, the line of krypton-86 at about 6,057 angstroms, in terms of which the metre is defined. Determination of wavelengths in the spectrum of the atom of interest is again accomplished by interpolation between known reference lines, correcting where necessary for nonlinearity of the spectrograph.

After the wavelengths have been obtained, their wave numbers, proportional to the photon energies emitted by the atom, are calculated with correction for the index of refraction of air. Next, all sums and differences of wave numbers are calculated, and from recurring values of these quantities, relative positions of energy levels within the atom can be obtained. The levels are then classified according to their probable quantum numbers with the help of comparisons with isoelectronic spectra (atoms with the same number of electrons outside the last closed shell have similar spectra), application of selection rules, and study of the Zeeman effect in the spectrum.

For an element such as a rare earth or actinide, which may have a complex spectrum involving many thousands of lines, much of the analysis is automated. The photographic plate with its line spectrum is placed in a microdensitometer, which takes successive readings of the line positions across the plate and feeds these numbers directly into a digital computer. The numerical manipulations required for the analysis are then carried out electronically.

Linear-response photoelectric detectors

ANALYSES WITH SCANNED SPECTRA

The development of scanning spectrometers that use linear-response photoelectric detectors has revolutionized the study of details in the structures of spectral lines from laboratory and astrophysical sources. For example, changes amounting to only a few percent in the intensity of the Fraunhofer *D* lines, caused by the presence of sodium in the Earth's atmosphere, can be detected photoelectrically without difficulty but are difficult to observe photographically because of the nonlinear response of the photographic process. Changes of several percent in the widths (the measure of the spread in wavelength) of spectral lines from plasma sources can be followed if photoelectric detectors are used but not with photographic detectors; such changes may show changes in pressure or free-electron density within the discharge. In cases where two spectral lines overlap or blend, careful numerical analysis of data obtained by a photoelectric detector can often permit identification of positions and relative intensities of both lines; this analysis is far more difficult to do if the lines are recorded photographically and data are obtained by a microdensitometer.

The quantum efficiency, the ratio of the number of incident photons to the number of recorded bits of information, can approach unity for photomultiplier detectors in the ultraviolet and visible regions, but the corresponding efficiency for photographic detectors is only about one part in 1,000; hence measurements with photoelectric detection are possible at lower light levels than with photographic detection. This sensitivity has made possible the recording of spectra from sources that send less than one photon per second into the spectrometer. Examples of studies in which low light levels are the rule include analyses of positions and profiles (*i.e.*, intensity changes across line widths) of spectral lines in weak discharges in a lamp at low temperatures to identify the details of processes leading to excitation, study of the spectra of fast ion beams excited by collisions with gases or thin foils, and high-resolution studies of absorption spectra of planetary atmospheres to identify their constituents.

In the production of a spark or in the initiation of a glow discharge, the effective temperature of the gas, the amount of ionization, and the relative excitations of different atomic levels change significantly within times of the order of microseconds. The details of such variations can be followed by photomultiplier detectors; in fact, photomultiplier detectors can be designed to follow changes occurring in less than a nanosecond (1×10^{-9} second). Time-resolved spectroscopy of sources is accomplished by arranging an electronic switch to operate the source repetitively, perhaps at line frequency of 50–60 times per second. A second switch, triggered by the first, sensitizes the detector photomultiplier for a brief interval at the desired time after the excitation pulses. The signals recorded by this photomultiplier depend on the spectrum only at that particular time after excitation.

(J.O.S.Jr.)

Astronomical spectroscopy

Almost the only means of learning about celestial objects is through the analysis of electromagnetic radiation emitted by or reflected from them. Spectroscopy, as mentioned earlier, can give a remarkable amount of information. Individual atoms and molecules absorb or emit light at characteristic frequencies and can, therefore, be selectively observed.

The spectrum of a star is a series of overlapping images in its constituent colours, arranged in order of frequency (or wavelength). An example is the display of colours produced by sunlight when it is refracted and dispersed by a prism. Because a spectrum covers a much larger area than a single image, the spectrum of a star is much fainter than is the star as it appears in integrated light.

Information on the physical state of an object can be obtained through the spectrographic comparison of different frequencies of its radiation (emission) or lack of it (absorption). Line-of-sight velocities of stars, planets, regions of the Sun, and so on can be obtained from the

Doppler frequency shift (*i.e.*, an alteration in the frequency of the radiation from a moving source in proportion to the change in line-of-sight velocity). The spectral region that has been studied most is that of visible light with small extensions into the infrared and ultraviolet: the range of frequencies may be included, from microwave radio to X-rays, a ratio of 200,000,000 to 1. Although frequency is the more fundamental property of a wave, it is conventional to speak of wavelength, which is easier to visualize and which is related to frequency in that the frequency times the wavelength equals the speed of light. The spectroscopist is concerned with wavelengths from 20 centimetres to 10 angstroms ($100,000,000 \text{ \AA} = \text{one centimetre}$). The wavelength limits of visible light are roughly 4,000 \AA (blue) and 7,000 \AA (red).

THE NATURE OF ASTRONOMICAL SPECTRA

Spectral lines and the continuum. The methods of spectrum analysis vary according to the wavelengths region being studied. A familiar example of a spectroscope is a radio receiver, which can be adjusted to any wavelength between 550 and 1,870 metres, or to 30 metres for a short-wave set. Each broadcast station may be said to produce a "line" in the spectrum; the use of the word "line" arises from the appearance of a single visible frequency when the light is passed through a narrow slit; in a spectroscope, the series of coloured images of the slit are focussed in orderly array. The best known natural line that is produced in interstellar space by hydrogen atoms is in the radio region at 21 centimetres. Radio spectroscopists usually work at a single wavelength region. They must use not only a very sensitive receiver as their spectroscope but also a large antenna or radio telescope, which like other telescopes, selects a small area of the sky and collects from it as much energy as possible. Optical spectroscopy is done with the aid of prisms or, more commonly now, diffraction gratings, which disperse light into its component wavelengths. With suitable optical arrangements, the spectrum can be recorded on a photographic plate or measured by a photoelectric detector.

A common spectral feature is the so-called continuum, in which energy is radiated over a broad band of wavelengths, or colours. A familiar example of continuous radiation is the radiation from the glowing filament in a light bulb, or from hot coals in a fire. Because of the lack of discrete features comparable to the spectral lines, continua tend to contain less information than line spectra, but they are still important. In particular, the change of colour from red through white to blue indicates increasing temperature for a solid body and for most stars. Most astronomical continua contain absorption lines, which are closely related to the emission lines mentioned above. Whether a line from a given element will appear as an absorption or an emission line depends on physical conditions in the vicinity of the source and in the background.

Molecular lines and bands. Dust, gas, and solid bodies near a star will reflect or scatter its light, imposing in the process additional spectral features. The spectra of the planets are quite similar to the solar spectrum because they shine by reflected light from the Sun. Most contain additional absorption lines and molecular bands, however, because of gases in the planetary atmospheres. If solid surfaces can be seen, they modify the reflected continuous spectrum, the colour of which is changed by absorptions in the rock or other material. The Earth's own atmosphere adds its absorption to all astronomical spectra viewed from below it. No X-rays or ultraviolet light beyond 3,000 \AA can reach the surface; oxygen and ozone absorb everything at the longer wavelengths between 1,000 \AA and 3,000 \AA , all gases absorb them below 1,000 \AA . Discrete bands (groups of closely spaced lines) of molecular oxygen, O_2 , are found at red and near-infrared wavelengths, particularly near 7,600 and 12,700 \AA . Starting in the yellow wavelengths and becoming stronger and stronger in the infrared, water vapour produces many complicated bands and is opaque over large regions. Other important infrared absorbers are carbon dioxide and ozone; absorptions by extremely small (trace) amounts of other gases can also be observed. Out to 14 micrometres (140,000 \AA), only about

21-centimetre line

Continuous radiation: the so-called continuum

Absorption
by water
vapour

half the spectrum can be observed through the Earth's atmosphere; from 14 to 1,000 micrometres the atmosphere absorbs everything and the opacity is complete. Because much of the infrared absorption is due to water vapour, a very large improvement can be obtained by observing from a jet aircraft; a balloon, though it can go higher, is little better because it generally floats in a cloud of its own vapour. For the ultraviolet and X-ray regions a rocket or satellite is necessary, and even for the infrared these vehicles give a clearer view.

Formation of spectra. The spectrum of a star is influenced by a number of competing effects, which may be seen most clearly in simple situations. It is useful to consider what happens to light from a strong source with a continuous spectrum as it passes through a cool gas: the case approximated by sunlight passing through the Earth's atmosphere, or by the light from a distant star passing through the interstellar medium. Radiation at certain frequencies (written as f) is absorbed by molecules in the atmosphere as they make a transition from their normal "ground state," or state of lowest energy, to some "excited state" at a higher energy (E) according to the relation $E = hf$ (in which h is Planck's constant). Dark lines (gaps) in the spectrum correspond to the absorbed frequencies. The excited state may be one of increased rotation or vibration of the atoms within the molecules, and the absorbed wavelengths are then in the infrared spectral region. A change in electronic motion influences

frequencies in and near the visible region. Removal of an electron (ionization) or separation of the component atoms (dissociation) of a molecule requires still more energy, and results in the strong continuous absorptions of the ultraviolet spectral region. The frequencies absorbed by a given atom or molecule are unique to it and give an absolute identification. Analysis of the closely spaced lines in a molecular band gives an excellent measurement of the temperature of a gas; this method can be applied to the atmospheres of several of the planets and the coolest stars. The width of individual lines depends mainly on the gas pressure or on the temperature if the pressure is very low.

The second simple case of influences on spectra is that of a low-pressure gas in which some of the atoms or molecules are continually receiving energy; that is, being excited by the impact of fast electrons, as in a neon sign. Relaxation of the excited particles to lower energy states, and eventually to the ground state (lowest of all), is accompanied by the emission of radiation at characteristic frequencies. Transitions that end at the ground state give bright lines at the wavelengths that are absorbed under other conditions. Perhaps the purest natural example of such radiance at discrete wavelengths (bright lines) is the aurora borealis, the northern lights produced in the upper atmosphere by fast electrons associated with the interaction of the solar wind and the Earth's magnetic field. The spectra of many gaseous nebulae in the Galaxy beyond the solar system show similar effects.

Unit optical depth

The concept of optical depth in gases. In the above examples it has been implicitly assumed that the gas is “optically thin”; i.e., it is at least somewhat transparent even at the wavelengths it absorbs most strongly. The opposite extreme is a gas that is “optically thick” at all wavelengths, or at least over a wide range; a prominent example is a stellar atmosphere such as that of the Sun (though it is not equally opaque at all wavelengths). In describing depths within any gas such as an atmosphere of a star or planet, it is convenient to speak in terms of unit optical depth—the depth from which radiation has a probability of about 37 percent of escaping freely. (This percentage is used because it is numerically equal to $1/e$, e being the symbol for the number 2.71818..., the base of natural logarithms; with this definition, calculations are greatly simplified.) As a practical example, unit optical depth (or distance) in a fog—the point at which about one-third of the details can be seen—is quite close; on a clearer day it could be almost at the horizon. The corresponding level in the medium depends strongly on wavelength, especially near an absorption line. It is deepest for wavelengths between lines, but even here the gas is remarkably tenuous. For the Sun, unit optical depth in the continuum occurs at pressure and density one-tenth and a few ten-thousandths respectively of the values at the Earth’s surface. It was long a mystery how such a thin gas, consisting mostly of atomic hydrogen and helium, could be so opaque, even at a temperature greater than 6,000 K (about 10,300° F). The identity of the most important absorber was recognized only in 1938: it is the negative hydrogen ion, a rather loosely bound combination of a hydrogen atom with an extra electron, which can be dissociated (with corresponding absorption of energy) by any photon of wavelength shorter than 16,500 Å.

Stellar spectra. Even when the opacity is known at each wavelength, it is a complicated problem to predict the spectrum of a star. A feeling for the processes at work may be obtained by regarding the radiation at each wavelength as arising from the level of the corresponding unit optical depth. The continuum is produced at the lowest visible level, and the centre of a strong line at a higher level. If the lines are to appear dark, this higher level must be cooler, and indeed the temperature is expected to decrease outward from any star. For the Sun, the temperature at heights somewhat above unit optical depth begins to climb again in the chromosphere, the extremely tenuous layers of the outer solar atmosphere; any lines formed there should therefore appear bright instead of dark, as is indeed observed, particularly in the far ultraviolet. A similar explanation applies to the bright lines at visible wavelengths for certain stars.

The “shape” of the continuum is a graph or plot of its intensity at different wavelengths. Over a considerable wavelength range, this resembles the spectrum of a “black body” (the physicist’s name for a perfect radiator), which has a definite shape for each appropriate temperature. In general, the apparent temperature deduced from one region may differ from that measured from another. The reason for this is that the continuous absorption coefficient; that is, the ratio of absorption to emission at a given temperature is changing. The radiation, consequently, comes from different depths and, therefore, from different temperature regions. Temperature found by measuring the shape of the continuum (apparent temperature) is only approximately equal to the actual temperature at the “surface” (unit optical depth).

Two sources of details in planetary spectra

Planetary spectra. For planets and satellites, problems arise from the presence and amount of atmosphere. Such bodies can have a spectrum that combines contributions from two, almost independent, sources—reflected solar radiation and their own thermal emission at much longer wavelengths. The thermal component is similar to black-body radiation for airless bodies such as Mercury and the Moon; the reflected light, however, does show coloration and some broad absorptions because of surface constituents. For planets with appreciable atmosphere, the physics of the thermal emission resembles that for a star, discussed above. For Mars, the reflected solar radiation can be regarded as coming entirely from the surface,

modified by two passages through the thin atmosphere. This approximation breaks down in the ultraviolet and is similarly poor for the Earth, especially in hazy or cloudy regions. Deep, cloudy atmospheres are present on Venus, Jupiter, Saturn, Uranus, and Neptune; the returned solar radiation must be regarded as having been scattered by the same medium that does the absorbing. Again the situation resembles that of a stellar atmosphere, except that the radiation is imposed from outside instead of flowing up from the interior.

THE DEVELOPMENT OF ASTRONOMICAL SPECTROSCOPY

Early work on the solar spectrum. In 1666, Isaac Newton discovered how to produce a spectrum of the Sun, by means of a glass prism and a hole in a window blind. Much later, 1800–02, several important discoveries were made with similar equipment. The English astronomer William Herschel probed the solar spectrum with a thermometer and found the measurable heat produced to continue beyond the red end of the spectrum; he had discovered the infrared. In 1802, the ultraviolet was observed by its ability to darken silver chloride. And at this time, an English scientist noted a few dark lines in the solar spectrum, which was studied in much more detail by Joseph von Fraunhofer of Germany in 1814. Fraunhofer was able to map 754 lines in the solar spectrum, the most prominent of which are still called “Fraunhofer lines.” He also observed several bright stars and found that their lines differed from those of the Sun. Fraunhofer made the first crude diffraction grating by stretching wires between the threads of two screws; with it he was able to measure actual wavelengths in centimetres.

The work of Fraunhofer

Interpretation of the Fraunhofer lines awaited further developments in physics, which in turn depended on further laboratory work. Similar delays in understanding of discoveries recurred until well into the 20th century; only since then has immediate physical interpretation been available for the majority of astronomical discoveries. Earlier, however, astronomers often found many uses for empirical classifications (particularly of stellar spectra) long before a detailed understanding was reached.

Another point to be noted is the importance of advances in technology, as illustrated by Fraunhofer’s work and that of his successors; in his day, it was difficult to obtain glass in large, homogeneous pieces. Telescope lenses were small, and reflecting telescopes did not become practical until methods were developed, initially in 1856, for the deposition of a reflecting film of silver on the front surface of a glass mirror. Without large reflecting telescopes, spectroscopy would still be limited to the study of the Sun and a few bright stars.

In 1859, Gustav Kirchhoff formulated his laws connecting the absorption and emission of light and explained that the Fraunhofer lines were due to absorption by familiar elements present on the Sun. He pointed out that a perfect absorber (black body) should also be an ideal emitter of light, and suggested its realization in the form of a small hole leading into a large cavity. Two years later, Anders J. Ångström found the lines of hydrogen on the Sun and initiated a program of wavelength measurements in the unit that now bears his name.

In 1868, the relatively faint solar prominences at the edge of the Sun’s disk, the limb, were observed in full daylight. Subsequently, in Sweden the rotation of the Sun was determined from the Doppler effect at its limbs and found to be different in different latitudes of the Sun. A United States physicist, Henry A. Rowland, devised methods of ruling diffraction gratings of very high quality; some Rowland gratings are still in use. In the years 1887–96 he produced a solar spectrum of very high resolution and a catalog of wavelengths and intensities. The spectroheliograph, which enabled observation of the whole Sun or large areas of it simultaneously at a particular wavelength, was invented independently in the United States and France. In 1908 the large magnetic fields in sunspots were discovered from observation of the Zeeman effect; that is, the shift in the positions, shapes, and structure of the sunspots’ spectral lines that results from the interaction of the atoms with the magnetic field. In recent years the solar magnetograph

has been used to extend this work to the production of detailed maps of the solar magnetic field.

Early work on the spectra of stars and nebulae. In 1855, an English astronomer, William Huggins, began the study of the spectra of the Sun, stars, nebulae, comets, and planets. He reaped a harvest of astronomical discoveries, mainly by visual observation of spectra, though he succeeded in applying photography in 1875. He found many different types of stellar spectra. He showed from the nature of its emission spectrum that the Orion Nebula is gaseous but found the Andromeda Nebula (now known to be a galaxy) to have a stellar-type spectrum and therefore concluded that it was composed of stars. He measured some of the first stellar Doppler shifts and obtained the corresponding line-of-sight, or radial, velocities.

Line-of-sight velocities. The German astronomer Hermann Karl Vogel was the first to introduce the photographic method into spectroscopy, in 1873, and succeeded in determining accurate radial velocities of many stars by measuring the positions of the lines on the photographic spectra. Vogel's work, especially his measurements of radial velocities, stimulated astronomers elsewhere to undertake systematic studies in this field. At Victoria, British Columbia, for example, many spectroscopic double stars were discovered and many of their orbits have since been determined from measurements of the spectral lines. At Mount Wilson Observatory, California, the velocities of hundreds of faint stars were determined. Soviet scientists working at Pulkovo, near Leningrad, and at Simeiz, in the Crimea, also made contributions in this field. Numerous measures of stellar motions in the southern sky have been published.

Chemical composition. A striking result of astronomical spectroscopy is the discovery of the uniformity of chemical composition throughout the universe. Belief in the universal occurrence of the same chemical elements was greatly strengthened when the lines of helium, originally found in the spectrum of the chromosphere of the Sun in 1868, were first produced in terrestrial laboratories about 25 years later. In 1941 the last great enigma of line identification was solved when previously unidentified lines of the solar corona were found to originate in the atoms of the common elements iron, calcium, nickel, and argon excited to a degree of ionization not even dreamed of previously. Earlier, when the so-called nebular lines in certain nebulae were disposed of in a similar manner, it was remarked that the mysterious substances of the astrophysicists one after another disappeared into "thin air"; the nebulae had, in fact, been found to consist of oxygen, nitrogen, hydrogen, and a few other gases—not very different in composition from air.

The principle of the uniformity of chemical elements has now been extended to include even the distant galaxies, whose light travels for hundreds of millions of years at the rate of about 299,300 kilometres (186,000 miles) per second before it reaches the eye of the observer. This uniformity means that the atomic building blocks of the universe are the same throughout space. It does not mean that the proportions of these elements are the same in all astronomical objects. Certain stars differ strikingly from others in their composition, and among the most interesting spectroscopic problems of today is the measurement of these differences in the abundance of the elements. Such measurements permit the nuclear processes responsible for the formation of the elements to be inferred. The occasional observation of the unstable element technetium shows that it must have been produced within the last few million years, indicating that element building is still proceeding in stars.

PRINCIPLES OF DESIGN FOR SPECTROSCOPIC INSTRUMENTS

The formation of spectra. Astronomical spectroscopes operate on the same principles as their laboratory counterparts, though they have special features of their own. Spectroscopy is used here as a general term for any kind of spectroscopic instrument, such as a spectrograph, which uses photographic detection, or a spectrometer (also called a scanner by astronomers), which uses photoelectric detection.

Spectrographs are used with ground-based reflecting or refracting telescopes. They operate at wavelengths from 3,000 Å in the ultraviolet (limited by atmospheric ozone absorption) to about 10,000 Å in the infrared (limited by the sensitivity of available photographic emulsions); most work is done at wavelengths in the range 3,500–7,000 Å. Further limitations are encountered if refractors are used because glass refracts different colours by different amounts (the refractive index across the spectrum varies) and only a narrow range of wavelengths can be brought to a good focus. The same effect in cheap or defective field or opera glasses can cause coloured halos around objects in view.

High photographic speed, which is necessary when faint objects are to be recorded, requires a camera lens, or mirror system, of short focal (f) length and large diameter; that is, a small f -number just as in an ordinary camera. Schmidt cameras (named after their inventor, Bernard Schmidt, a German optical worker) can be made at $f/1$ or slightly less, in sizes large enough to accept the light beam from any available grating. In small sizes, semisolid cameras, in which the photographic film is pressed against the glass of the mirror system, can be as fast as $f/0.35$. The limits of faintness that can be recorded have been greatly extended as a result of such increases in speed.

The collimator, a lens introduced to make the light beam parallel, and grating must be matched to the telescope, as illustrated in Figure 25. The telescope admits parallel light that is refracted or reflected into a cone that should just fill the grating. A small grating is used with a short-focus collimator; and the longest useful focal length is limited by the size of available gratings. The advantage of a long focal length is that a wider slit can be used for a given resolution (*i.e.*, the degree of spectral purity). The choice of resolution depends on the nature of the investigation and on the brightness of the source; higher resolution always requires longer exposure. For extremely faint stars, or galaxies, the spectrum must be kept short—that is, the dispersion must be kept low, if there is to be any blackening at all in the image; a small grating and a wide slit can be used to prevent any cutoff of light at the slit edges (called jaws). Overlapping images of nebulae of galaxies are produced by instruments, called nebular spectrographs, which have such arrangements. On large telescopes, such instruments are placed at the focus of the primary mirror (the prime focus) to minimize the loss of light by extra reflections. Medium-dispersion spectra can be obtained with instruments of moderate size that can conveniently be used as shown in Figure 25. High disper-

Optical limitations

Figure 25: Astronomical spectrograph mounted at the focus of a Cassegrain reflecting telescope. The cones of light converging from the telescope and diverging to the collimating mirror must be matched (see text).

sion spectra are produced by instruments of large size that must be fixed and are therefore mounted at the *coudé* ("elbowed") focus, to which the light is brought by means of two or three additional plane mirrors. In the *coudé* spectrograph many combinations of grating size and camera focal length are possible. The longest cameras are rather slow photographically; moreover, it is not unusual to lose 90 percent of the light from the telescope behind the slit edges, because even a star has a finite size and when its apparent diameter is increased, or blown up, by atmospheric turbulence, it can be wider than the slit and only part of the light can pass through. Under such conditions, much of the light gathered by a large telescope is wasted. Only the development of much larger gratings, or a different approach to spectroscopy, can change this situation.

The first measurements from photographic

Comparison spectrum

For accurate wavelength identification and measurement, it is essential to include a comparison spectrum from a laboratory source on the same plate. The usual practice is to illuminate both ends of the slit with a spectrum produced by an electric arc, so that the astronomical spectrum is flanked by two comparison spectra. Neon and iron arcs are most commonly used. Use may also be made of natural lines from the Earth's airglow, frequently accompanied by mercury lines from the lights of nearby or distant cities.

Since about 1965, there has been increasing use of image-tube spectrographs for recording very faint objects. In this method, the spectrum is focussed on a photoelectric screen, the cathode, which emits a pattern of electrons. These electrons are focussed by electric and magnetic fields on a fluorescent screen, or sometimes directly on a photographic plate in the vacuum of the tube. If a fluorescent screen is used, the light from it is then transferred to a photographic plate.

Spectral dispersion. *Low-dispersion spectra.* Because the light from a star reaches the Earth in a parallel beam, it is possible in some arrangements to dispense entirely with the preliminary telescope, optical system, slit, and collimator. The essential parts of a spectrograph then remain the grating (or prism) and the camera (usually a wide-field telescope). When photographed, the star field becomes a field of spectra; these spectra are usually widened for more convenient viewing by a slow motion of the camera at right angles to the dispersion. The ability to take many spectra at once is the chief virtue of the method of "slitless," or "objective prism," spectroscopy. The enormous *Henry Draper Catalogue*, published 1918–24, in which 225,300 bright stars were classified, was produced from objective-prism photographs with small telescopes; more recently, very good quality spectra, over a large angular area of sky, have been obtained with prisms or gratings with angles of a few degrees placed in front of Schmidt-type (wide-field) objectives (see below *Spectroscopy at short wavelengths*). The slitless method is also used in space spectroscopy, in which compactness and a small number of reflections are advantages. Objective-grating spectrometers and spectrographs have been used in rockets in various experiments and also on board several Earth-orbiting astronomical observatories.

Radial velocities (velocities in the line of sight from object to observer) can be measured by the Fehrenbach method developed in the 1940s and named after the French astronomer Charles Fehrenbach. A special prism is used, containing two elements of different glasses, somewhat as in an achromatic lens. The angles are chosen so that a central known wavelength is not deviated; red goes one way and blue the other. Two exposures are made on one plate, with the prism rotated 180 degrees between them. The stellar spectrum can thus be made to serve as its own reference. With suitable precautions, a precision of three to five kilometres per second is achieved.

High-resolution spectra. Spectroscopy of solar, planetary, and interplanetary lines usually requires high spectral resolution. Modern solar work is concentrated on obtaining accurate line profiles; that is, measures of the distribution of absorption or emission with wavelength, which can be obtained only at high resolution. Planetary and interstellar lines are very narrow, because temperatures and pressures are low; such lines may not even be detectable at low and medium resolution because the overlap from neighbouring wavelengths may completely mask them. A further difficulty with planetary atmospheres is that nearly all their absorption lines are in the infrared, for which sensitive detectors do not exist.

The diffraction grating, described above, though valued for its versatility, is only one of several means for selecting wavelengths.

The Fabry-Pérot interferometer consists of a pair of closely and accurately spaced plane-parallel glass plates, with special reflecting coatings on the inner surfaces. Used with photoelectric detection, it has become popular since the introduction of efficient evaporated coatings for the two reflecting surfaces. The plates are located in a chamber in which the pressure can be changed, which makes

it possible to measure radiation over a very narrow range of the spectrum. Its greatest virtue is the large angular acceptance; high resolution can be obtained, with no loss of light at a slit, when it is used with the largest telescopes. It is inconvenient when used to scan more than a small range of wavelengths; the Fabry-Perot interferometer is most useful for detailed exploration of a single line for profiles or Doppler shifts.

For the infrared above 10,000-angstroms wavelength, an old device, the Michelson interferometer has been perfected into a valuable spectroscopic tool. The principle of Fourier spectroscopy, in its modern form, was suggested by the English astrophysicist Peter Fellgett in 1950, and was subsequently applied successfully to astronomical spectroscopy. The angular acceptance of this instrument is large, like that of the Fabry-Perot interferometer, and, in addition, there is the multiplex advantage, or Fellgett advantage: all wavelengths of the spectrum are measured simultaneously and recorded in a coded form, called an interferogram. The spectrum is obtained from the interferogram by the mathematical process of Fourier transformation in an electronic computer. This method has been used to produce spectral atlases of the one to three micrometre region for the Sun, the four brightest planets, and several bright stars. The spectral atlases of the inner planets are of better quality than solar atlases of the early 1950s in spite of the enormous differences in light level. The improvement in resolution, by a factor of 10 to 100 over the best previous work, has resulted in the identification of several new gases in the atmospheres of Mars and Venus. At shorter wavelengths, for which photomultipliers are available, the Fellgett advantage is cancelled by the corresponding increase of the noise in the detector, and the method is little better than older conventional methods.

Still further in the infrared, medium-resolution spectroscopy is possible with a small Fourier spectrometer, or with a filter disk. An interference filter (a version of the Fabry-Perot interferometer: see above) is deposited around the rim of a transparent disk so that the transmitted wavelength varies smoothly with angle. The spectrum is scanned by the slow rotation of the disk past an aperture, through which the radiation passes to a detector.

At radio wavelengths, an enormous increase of sensitivity is possible because the electromagnetic waves can be treated as electrical signals rather than crude energy fluxes. The difference may be compared to that of using a radio receiver rather than a sensitive thermometer in trying to detect the presence of broadcast radio signals. As mentioned in the introduction, a standard radio receiver is a spectrometer, and the methods used for radio astronomy differ only in technical detail from those of astronomical spectroscopy. Nevertheless, some of the details are important. It is common to obtain a multiplex advantage by the use of multiple channels—essentially, many receivers tuned to adjacent frequencies. Or, a correlation technique may be used that in principle resembles an electrical form of the Fourier spectrometer and, like it, uses an electronic computer.

Spectrometry. In a spectrometer, a selected wavelength or band of wavelengths from the spectrum passes through an exit slit to a detector. At wavelengths in the ultraviolet, visible, and near infrared ranges, the most sensitive detector is a photomultiplier. At longer wavelengths the preferred detectors are photoconductive cells of lead sulfide, or bolometers (heat detectors) of germanium. From the visible onward, the detectors must be refrigerated at lower and lower temperatures by means of ordinary refrigeration systems, solidified carbon dioxide, liquid nitrogen, and finally liquid helium.

A spectrum can be produced by rotation of the grating, which progressively changes the wavelength that falls on the slit; the successive readings of the detector are recorded. The advantages over photography are the possibility of more accurate measurement, a strictly linear intensity scale, and greater sensitivity at longer wavelengths. The spectrum must, however, be recorded one wavelength at a time while the light of all the rest of the spectrum is wasted. Even so, photoelectric recording may be superior, especially if only a short region of the spectrum is required

High resolution spectra in the infrared region

Radio spectroscopy

and if the external conditions do not change during the exposure. Also, various schemes of multiplex spectroscopy are possible by which many wavelengths can be observed simultaneously. Most of them show their advantage best in the infrared; with photomultipliers, the most practical scheme is through the use of many detectors, each with its own amplifying system.

Spectroscopy at short wavelengths. Spectroscopes designed for the shortwave end of the spectrum, the ultraviolet, do not differ in principle from those used for visible wavelengths. An important change of detail occurs at 1,200 Å: shorter wavelengths are absorbed by all known materials, and, therefore, prisms, lenses, and windows cannot be used. In addition, unnecessary reflections must be avoided because efficient reflecting surfaces do not exist. Concave gratings and windowless photomultipliers are therefore used. All instruments must be carried above the atmosphere by rockets or satellites; consequently, sizes are limited and photoelectric detection is favoured, so that the data can be transmitted to the ground by radio. Below 100 Å, X-ray techniques become applicable, and windows can again be used. To improve their efficiency, concave gratings may be used at very small angles of incidence ("grazing" incidence), at which the reflection is almost total, or they may be replaced by Bragg crystals, which operate on the same principles as gratings but use layers of atoms instead of ruled lines. At the shortest wavelengths, below 10 Å, low-resolution spectroscopy can be done by measurement of the photon energy; one suitable device for this measurement is the proportional counter.

Developments in instrumentation have continued to be important in extending the range of spectroscopy. In 1931 reflecting surfaces with evaporated coatings of aluminum were found to be superior to those of silver for resisting tarnish and for achieving higher reflectivity in the ultraviolet. At about the same time, Schmidt developed his wide-field, short-focus camera, which after a few years came to be widely applied in astronomical spectrographs. In 1936, improvements in ruled gratings made possible the concentration of light to an efficiency of 60 percent or better (such a concentration is called a "blaze"). The use of large plane gratings and Schmidt cameras (instead of one or more prisms with lens cameras, which absorbed a significant proportion of the incoming light) totally altered the appearance and the efficiency of astronomical spectrographs. Although photoelectric cells had been used for stellar photometry for several decades, their application to spectroscopy was not practical until the development of the photomultiplier between 1935 and 1939. Later, a great interest developed in image tubes and television techniques.

PROGRAMS IN SPECTROSCOPY

Solar spectroscopy. The Sun is a typical star, near the middle of the known range in both temperature and luminosity. It offers a unique opportunity for detailed study because of the enormous amount of available light and because light from different regions of it can be studied separately. More distant stars are probably at least as complicated as the Sun, and present models of them may omit essential features.

The solar spectrum can be observed in great detail; the available light can be spread out into a spectrum many metres long. The dispersion can be made so great that many centimetres may be needed to record the lines in a single angstrom. It is clear, therefore, that with high resolution, a spectrum of very great purity can be recorded and many details of solar behaviour can be accurately studied.

By using a very long focus telescope, a large image of the Sun can be produced, even when the light-gathering power (determined by the mirror or lens diameter) of the telescope is quite small. Quite small areas such as sunspots, the chromosphere, a flare, or granules (see SOLAR SYSTEM: *The Sun*) can be studied in detail. A major difficulty in most solar observations is the heating of the instrument and its environment by the Sun, although many sophisticated methods have been tried to overcome it.

Because of the problem of heating, solar telescopes are usually of small to moderate aperture but of long fo-

cal length, so that a relatively small amount of light is collected even when a large image is produced. A solar telescope usually has a fixed combination of mirrors, and the light is reflected into it by an arrangement of one (heliostat) or two (coelostat) auxiliary moving plane mirrors. To minimize the effect of the heating of the ground, these mirrors may be mounted on a high tower; or the telescope may be placed in the middle of a small lake. The associated spectroscopes usually feature very high dispersion and spectral resolution, and, therefore, also normally have a long focal length.

A special feature of solar spectroscopy is the study of limited areas that may be much fainter than the disk, or photosphere, such as sunspots on the disk, and the chromosphere and corona near and above the limb. Detailed study of such features requires extreme precautions to avoid inclusion of stray light from the photosphere; telescopes designed for observation of the chromosphere and corona are often called coronagraphs. The chromosphere and corona are optically thin, and the temperature increases with height—that is, distance outward from the Sun; for both reasons, their line spectra appear in emission, not absorption. The classical way of studying them is during a total eclipse, when the Moon just hides the photosphere; the great disadvantage of this method is the infrequency of solar eclipses that occur in convenient locations. The name "flash spectrum" refers to the spectrum of the chromosphere at eclipse. It can also be observed, with care, outside eclipse by setting a solar image tangent to a spectroscopy slit. Chromospheric features on the disk are best studied in the far ultraviolet because relatively little such light is produced from the underlying photosphere. As the Earth's atmosphere absorbs ultraviolet light, it is necessary to make such observations from outside it. The series of space probes called Orbiting Solar Observatories has been particularly successful, and good results have also come from many rocket flights. Another method is that of surveying the Sun at a single wavelength by a spectroheliograph in which a spectrograph functions as a very narrow-band filter. An image either of the whole disk or of part of the Sun can be built up by a scanning process. Some of the same results can be obtained by a Lyot filter, which is built up of elements of quartz crystals and polarizers. The two commonest wavelengths studied belong to hydrogen (6,563 Å) and ionized calcium (3,933 Å); here, the light from the photosphere is reduced by the presence of deep Fraunhofer lines, and the chromospheric emission can be observed.

Spectroscopy can be expected to give information of several kinds on the chemical and physical state of the solar atmosphere: the composition, the temperature, the density, and the state of motion. The best results are obtained from detailed descriptions of the atmosphere (called models) that include all these factors at once. In such a model there is no single temperature for the atmosphere, but a profile relating the temperature to some quantity such as height, density, or optical depth. The only unique "temperature of the Sun" that can be assigned is the effective temperature, about 5,800 K (10,000° F). This is the temperature at which a black body, or perfect radiator, would emit the same total radiant energy. The temperature of the deepest "visible" region (unit optical depth) is a few hundred degrees greater; about 300 kilometres (200 miles) higher, the temperature of the Sun's disk has its smallest value, about 4,600 K (7,800° F). (This cool region is still occasionally called the "reversing layer," from the obsolete picture of a "photosphere" in which the continuum is produced and a cooler layer above it in which dark—or reversed—lines are formed. The hotter and cooler regions are realities, but the separation of the roles is not.) At still greater heights the temperature rises rapidly. First, in the chromosphere, the temperature rises to 30,000 K (about 54,000° F); farther out, the very extended corona is at about 2,000,000 K (3,600,000° F). The effective temperature of a large sunspot is only about 4,400 K (7,500° F).

The main results of the chemical analysis are as follows: molecules are rare, because of the high temperature; atoms and some positive ions are dominant; nearly all the atoms are hydrogen and helium, in a ratio 14:1; and the remain-

Solar characteristics

X-ray spectroscopy

length of solar spectrum at high dispersion

ing 1 percent of the atoms have relative abundances much like those of the Earth and meteorites, except that the three lightest elements after helium (lithium, beryllium, and boron) are much rarer. Some elements are easier to detect and measure in sunspots (low temperature) or in the chromosphere (high temperature). In addition, simple molecules are rather prominent in sunspots.

The rotation of the Sun is most readily determined by following spots at the latitudes at which they occur. The Doppler method works at latitudes far enough from the poles: at the solar equator, one limb (or edge) of the Sun's disk is found to be receding and one approaching, at nearly two kilometres (1.2 miles) per second, giving a period of 26.9 days for a complete rotation as seen from the Earth; the period with respect to the stars is shorter by about a day, because the Earth has moved in its orbit around the Sun by 26 degrees in 27 days. At higher solar latitudes the period increases steadily, and at 45° a complete rotation takes 29.5 days.

Close inspection of an image of the Sun reveals that it is covered by bright "granules", separated by a network of slightly darker material. The supposition that the granules represent rising convection cells is supported by the observed radial velocity, about 900 metres (2,953 feet) per second upward.

The bright lines of the corona were a mystery for many years and were at one time suspected to be caused by an unknown element "coronium." In 1941, a nearly complete explanation was found in terms of iron lacking nine to 14 electrons, nickel lacking 11 to 15 electrons, and similar ions of calcium and argon. Several other elements have since been included, to account for weaker lines. The energy required to remove as many as 15 electrons from an atom corresponds to a temperature of over 1,000,000 K. The breadth of the lines also implies a high temperature, which produces large line-of-sight random velocities. Many details concerning the properties and behaviour of the outer layers of the Sun that can be obtained from a study of the spectrum at high or low dispersion are described in the article SOLAR SYSTEM: *The Sun*.

Telluric and interstellar absorption lines. Absorptions in the Earth's atmosphere, called telluric absorption lines and bands, are prevalent at nearly all wavelengths except in the blue and near-ultraviolet parts of the spectrum. The features in the solar spectrum called A and B by Fraunhofer are due to atmospheric molecular oxygen, O₂. As described above the atmosphere is opaque below 3,000 Å and through much of the infrared. In the photographic spectral range the principal absorbers, which produce dark bands in the spectrum, are molecular oxygen, O₂, and water, H₂O. In addition there are a number of diffuse bands due to the double molecule, (O₂)₂; some are near the O₂ bands, but others are also found at other wavelengths.

It is not always easy to distinguish a telluric line from one coming from the light source, particularly since water has a very complicated spectrum, which is not fully tabulated, and since it is variable in amount. There are two principal tests: telluric lines, unless they are very strong, are narrower than solar and stellar lines; and they vary in strength according to the zenith angle of the source, being much stronger when the source is near the horizon. A third test can be applied if the radial velocity of the source varies with time; the telluric lines are of course "stationary"; that is, they do not share the velocity of the source.

There is another class of stationary line, formed in the interstellar medium. In the spectra of bright distant stars such lines are particularly prominent because their strength depends on the number of the interstellar particles that produce them between the observer and the source, especially those that are reddened by intervening clouds of interstellar dust: these clouds contain gas as well. Sometimes several lines are seen that correspond to different radial velocities, implying that two or more clouds are moving with distinct speeds along the path. Such patterns are found in the two sodium D lines (5,890, 5,896 Å) and the H and K lines of the calcium ion (3,933, 3,968 Å) as would be expected in clouds containing both sodium and calcium. (Here D, H, and K are the Fraunhofer designations, still in use.) Any other explanation of the cor-

respondence is difficult to imagine. Lines are also known that are produced by simple molecules—CH, CH⁺, and CN. The molecular bands are much simpler than those produced at normal temperatures, showing only two or three lines instead of the normal 20 or 30. The temperature of the molecules seems to be in equilibrium with the universal 3 K (−454° F) background radiation that has recently been discovered; and the line intensities for the interstellar compound cyanogen have been used to verify this temperature.

Other absorptions in the ultraviolet that are attributed to interstellar gas have been detected by rocket-borne spectrographs and by the spectrometers aboard orbiting astronomical observatories. Hydrogen, the most abundant atom in nature, is prominent and produces an enormously strong line (called Lyman alpha) at 1,216 Å. Molecular hydrogen has been detected in the difficult-to-observe region 1,000–1,120 Å.

Spectroscopy at radio wavelengths has been used with regard to a number of molecules, in addition to the famous 21-centimetre emission line of atomic hydrogen. This subject is discussed below in a separate section.

Stellar spectroscopy. Spectroscopy of faint objects, such as even the brightest stars, poses problems of a quite different nature from those associated with the Sun.

Stellar spectroscopy necessarily must be concerned with the problem of the concentration of radiation, particularly of light. The light from the brightest stars falls on the Earth with an intensity 10¹⁰ times less than that of sunlight. Since any possible increase in light-gathering power is limited to a few powers of 10, improvements in stellar spectroscopy can be obtained mainly by an increase in exposure time, by a decrease in the dispersion, and by efficiency of design in the spectrograph. The exposure time must be increased to minutes or hours, the length of the spectrum cut down to a few centimetres (at high dispersion) or less (at medium or low), and the sensitivity of the receiver, usually a photocell or photographic plate, made as great as possible. The three examples of classes of spectral dispersion—high, about two angstroms per millimetre; medium, about 40–100 angstroms per millimetre; low, from about 200 angstroms per millimetre—can be compared with the dispersion possible in solar spectroscopy, in which, because of the enormous amount of light available, as has been noted above, several centimetres may be used to record the lines in a single angstrom.

Classification of stellar spectra. Spectral classification of stars was initiated in the middle of the 19th century by the astronomer Angelo Secchi in Italy.

At the beginning of the 20th century, a group at Harvard undertook the classification of several hundred thousand stars over the entire sky, an effort that culminated in the *Henry Draper Catalogue* (1918–24). It provides the basis for all modern astrophysical work.

The system used in the catalog has been refined many times, by means of physical theory and empirical methods. Some terminology has survived from the days of pure empiricism, in particular, "early" and "late" spectral class for "hot" and "cool" stars. Most stars can be placed in the sequence O-B-A-F-G-K-M, which is controlled by the temperature of the surface. The sequence is further subdivided by adding the figures 0 to 9 to the letters; e.g., the type B9 precedes type A0. The range is from about 40,000 K (O type, 71,500° F) to 2,000 K (3,100° F) or even 1,500 K (M type); the Sun is intermediate—type G1 at 5,800 K (10,000° F). Parallel sequences exist at the low-temperature, or late, end; stars of class C (formerly class R-N) are rich in carbon, and class S stars are rich in metals like zirconium.

The effect on the spectrum of differences in composition is less marked for hotter stars, but such differences are readily resolvable on medium and high-dispersion spectrograms. Much effort has also been expended in luminosity (or brightness) classification, because the distance of a star can immediately be found if its absolute brightness is known. For two stars of equal temperature, the luminosity is proportional to the surface area, or to the square of the radius. Thus, luminous stars are called giants and less luminous ones are called dwarfs. The pressure at the

So-called
stationary
lines

Figure 26: Principal types of stellar spectra, flanked by comparison lines from a laboratory source. Hot stars, at the top, are brightest in the blue; and cool ones, at the bottom, are red. The spectrum at the bottom contains emission lines, denoted by the e attached to the spectral class.

By courtesy of Mount Wilson and Palomar Observatories

visible surface of a giant is relatively small, and spectral information about pressure, therefore, indicates the size of the star. Surface pressure may be indicated by the width of hydrogen lines (broad for dwarfs, narrow for giants), or by a comparison between the line strengths or intensities from neutral atoms and those from ions (neutrals favoured for dwarfs, ions for giants). Such work was at first done with high-dispersion spectra and extended to medium dispersion in the 1940s.

The effect of temperature on a stellar spectrum was first quantitatively explained by the Indian physicist M.N. Saha in 1920. At the low temperatures of M-stars, many simple molecules are present, and their bands dominate the spectrum. Increasing thermal agitation at higher and higher temperatures has several effects: molecules dissociate into atoms; many atoms are maintained in excited states in which they can absorb new lines; and atoms are ionized by the loss of an electron. The solar spectrum (class G) illustrates an intermediate temperature stage in which neutral atoms and ions (such as those of calcium and iron) both are seen. Hydrogen lines are moderately strong: they originate from the first excited state of the atom. At Class A, these hydrogen lines are very strong, but most other atoms are ionized and show only a few weak lines. In Class B, even hydrogen begins to be ionized, and helium lines are found; the hotter O-stars show ionized helium.

Many stars of Class F and hotter have broad, dish-shaped lines, though the areas (that is, the total amounts of absorption) are normal. The spread of the line across the spectrum has been shown to be due to rapid rotation of the star; the resulting line shape is characteristic of the rotation speed and from the shape it is found that speeds of rotation at the equator may be as much as 400 kilometres per second (250 miles per second) or more. Such speed is almost enough to throw material out from the equator. Rapid rotation is much less common in cooler stars. It is surmised that most stars are created with high angular momentum from the motions of the collapsing nebula that forms them. For the cooler stars, some braking mechanism must operate to slow them to velocities as modest as that of the Sun.

Velocities in the line of sight have been determined for many stars from the Doppler effect, which shifts all lines by an amount proportional to wavelength. To make such a determination, a spectrum of medium to high dispersion is taken, with a comparison spectrum from a laboratory source on each side. Many precautions are necessary for accurate results; with high dispersion and sharp lines the probable error can be as small as 0.1 km/sec (0.06 mi/sec), but more often, it is 1–2 km/sec (0.6–1.2 mi/sec). A photoelectric method has been developed in which a mask resembling a negative of the stellar spectrum is placed over it. Wherever the transparent lines of the mask are in register with the dark lines of the star, the transmitted

light is weakest. This minimum light can be detected by a photomultiplier; the corresponding position of the mask gives the radial velocity in terms of the measured shift from its expected position. This method is much faster than photography, but a given mask can be used only for a narrow range of spectral class. All radial velocities must be corrected for the motion of the observer that results from the rotation and orbital motion of the Earth.

Among the results obtained with the aid of radial velocities are the following: (1) the determination of the velocity (about 20 km/sec or 12 mi/sec) and the direction in space of the motion of the solar system with respect to the nearer stars; (2) the estimation of the random motions of the stars, which for the massive B-stars averages as little as 15 km/sec (9 mi/sec), increasing to nearly 60 km/sec (37 mi/sec) for typical M-dwarfs; (3) the recognition that the entire Galaxy rotates around a distant centre located in the direction of the constellation Sagittarius, with a velocity of between 200 and 300 km/sec (125 and 200 mi/sec) in the region of the Sun; (4) the comparison of radial velocities and proper motions (the rate of movement across the sky is called proper motion) to determine mean distances of groups of stars of any one kind; (5) the discovery of a group of high-velocity stars that are moving with respect to the Sun with speeds of the order of 100 km/sec (62 mi/sec) and in a direction opposite to the normal direction of galactic rotation; (6) the measurement of red shifts in very dense stars (white dwarfs), which are probably the gravitational red shifts predicted by Einstein (see GRAVITATION); (7) the law of linear increase with distance in the velocity of recession of external galaxies; (8) the discovery of numerous stars showing periodic variations in radial velocity—resulting from orbital motions of close double stars or from pulsations in the radii of individual stars (such as Cepheid variables); (9) the study of eruptions in novae and in other expanding shells of gas which surround such stars as P Cygni; (10) the discovery of stationary lines, which do not show the Doppler shifts characteristic of the stars but are interpreted as absorption by clouds of interstellar gas.

Stellar temperatures. The temperature of a stellar “surface,” like that of the Sun, is not a well-defined quantity, because the atmosphere is not isothermal (at the same temperature everywhere) and different wavelengths originate at different levels. In a spectral region for which the continuous opacity changes slowly with wavelength, however, the spectrum resembles that of a perfect radiator (black body) at the temperature of the layer at unit optical depth. This condition obtains both for stars that are cooler and for those that are hotter than the Sun, in which the negative hydrogen ion is the dominant cause of the opacity. Measurement of the continuous spectrum, the continuum, of such stars thus yields realistic temperatures, and the colours of the stars obey the usual rule of going from red to yellow, white, and blue as the temperature increases. In the coolest stars (Class M, also C and S), however, so many lines and molecular bands are present that they dominate the spectrum. As a result, the colours, though very red, do not give a good measure of the temperature. Similar reservations apply in the ultraviolet range for almost all stars.

Another measure, called “excitation temperature,” can be obtained from the relative intensities of suitable lines of an atom, of an atom and its ion, or even of lines of different atoms such as hydrogen and helium. In essence, such intensities form the basis of spectral classification.

Line broadening. The lines of spectra are not perfectly sharp; indeed, a perfectly sharp absorption line would be nearly unobservable. Several broadening mechanisms exist, and observations of the actual shapes of lines (density plotted against wavelength—the line profiles) can be used to infer something about physical conditions in the star. (1) Natural broadening is intrinsic to the atom (or molecule); it is intimately related to the Heisenberg uncertainty principle of quantum mechanics and is usually a very small quantity. (2) Pressure, collisional, or Lorentz broadening is caused by collisions or near-misses with other atoms while the atom in question is radiating or absorbing and becomes more important at high pressures.

Colour-temperature relationships

Measurement of radial velocities

The shape or profile is similar in the two cases: the opacity falls off as the square of the wavelength difference from the line centre, but at a rate that depends on pressure. (3) Doppler broadening is due to random motions in the line of sight; such motions can be produced in any of several ways. First is thermal agitation; the characteristic speeds are proportional to the square root of the ratio of absolute temperature to atomic or molecular weight and are, therefore, largest for light atoms at high temperature. Mass motions (turbulence) can also be important and are classified according to the optical thickness of the individual moving elements, measured at the centre of the line. Turbulence on a small scale, called microturbulence, for which the elements are thin, affects the spectral lines in the same way as thermal agitation: generally speaking, the lines become strong as well as broad. Turbulent motion on a large scale, called macroturbulence, like stellar rotation, spreads the lines out but does not strengthen them: they become shallow and broad.

Electric
and mag-
netic fields

The shapes and intensities of spectral lines are also affected by the presence of electric and magnetic fields (Stark and Zeeman effects). If a line is produced in the presence of a magnetic field and if the magnetic field is uniform, the line is split into several components; this phenomenon is observed in the spectra of so-called magnetic stars and in sunspots (Zeeman effect). The Zeeman effect produces a broadened line if the spectral purity is not good enough to show the separate components. Strong, uniform electric fields are not present in most astronomical objects, for they are short-circuited by the flow of electrons and ions. Stark broadening, caused by local electric fields around abundant ions, is important, however, especially for hydrogen; collisions with ions are particularly effective in perturbing this atom.

Unusual stellar spectra. A variety of stellar objects show emission lines along with, or instead of, the usual absorptions. According to the general principles discussed above, the regions of the star's atmosphere where these lines are formed are optically thin or, if opaque, must be hottest near the surface. In the most commonly observed case, a star is surrounded by an extended envelope or shell of gas. If this envelope can be observed directly, it is called a nebula.

Spectra of
novae

Not all the processes operating in the formation of stellar spectra, especially the unusual or peculiar ones, are understood, but several can be mentioned here. (1) Rapidly rotating stars, most of which are hot, can throw off gas from their equatorial regions. (2) Processes resembling the emission of the solar wind seem to operate in cool stars, especially giants; here the driving force is probably energy from the violent convection in the outer part of the star. (3) Extremely hot stars may be able to evaporate gas at a substantial rate. (4) Finally, a rather common configuration is that of a close pair of stars. Particularly if one of them has evolved into a giant, a star with an extremely large radius, gas can spill out towards the other star or go into orbit about both of them. Novae, or exploding stars, seem to be of this sort: the gas accumulates on the small, hot star, and is periodically blown off to form an expanding shell. This expansion may be measured by the Doppler effect. At first the shell is optically thick, and its spectrum resembles that of a star, but it is abnormally bright because of its large area. In time bright lines appear, as the gas becomes optically thin; finally, "forbidden lines" characteristic of very low densities are seen (the term "forbidden" should be interpreted as meaning "highly improbable"). All these details are noted by careful observations and measurement of details of the spectrum and, in some cases, of their charges.

The rather small class of stars with unusual spectral characteristics called Wolf-Rayet stars are extremely hot; they show emission lines of several-times ionized elements and clear evidence of expanding shells. Many are known to be close binaries. Even normal O- and B-stars, when observed in the far ultraviolet from space, are seen to have expanding shells; the behaviour of the spectral lines resembles that of the P Cygni stars, another class of peculiar stars with expanding shells of gas. Another interesting class contains the cooler T Tauri stars, which are probably

accreting material from an associated nebula, and may be in the last stages of formation. (The P Cygni and T Tauri classes are named after the prototype stars).

White dwarfs are stars that are believed to have used up all their nuclear fuel. They concentrate a mass comparable to that of the Sun into a volume comparable to that of the Earth; hence the name dwarf. The colour of their radiation is white. As would be expected, the surface pressure is high and the few spectral lines observed are greatly smeared. White dwarfs cannot have a much greater mass than the Sun; more massive stars must presumably shed the excess. It is thought that planetary nebulae, discussed below, represent the mass ejected in this way. Other stars, perhaps more massive originally, are believed to eject their outer layers more violently, while the core implodes into a neutron star, releasing a vast amount of gravitational energy. This train of events is identified with the rare and unpredictable phenomenon of a supernova. The spectrum of the early stages of a supernova is almost impossible to record. Spectroscopic study of supernovae in nearby galaxies does suggest that very violent events take place, but the spectra are difficult to decipher. There is little doubt that the Crab Nebula, discussed below, is the product of a supernova explosion observed by Chinese and Japanese astronomers in 1054.

Planetary spectroscopy. The solar radiation reflected from a planet contains information of two kinds about the planet. (1) In addition to the normal solar spectrum, this radiation produces atomic lines (which are rare) and molecular bands characteristic of the constituents of the atmosphere during the passage of the light through it. (2) Colorations and broad absorptions are characteristic of solid surfaces or cloud material from which the light is reflected; the interpretation of such data is seldom unique, but with care, useful conclusions can be obtained.

Spectral
features
added by
planetary
material

Atmospheric absorption lines are usually narrow and can be observed best with high spectral resolution. With the development of *coudé* spectrographs of long focus, with which high-dispersion spectra could be obtained, and infrared-sensitive emulsions in 1933, astronomers succeeded in observing carbon dioxide on Venus and complex absorptions on Jupiter that were later shown to be due to ammonia and methane. Methane is also found on Saturn, Uranus, and Neptune. The lack of ammonia absorption (though there are some reports of it for Saturn) is reasonable at the low temperatures of the outer planets; and the upper clouds of Jupiter and Saturn contain significant amounts of ammonia ice.

Observations in the infrared and ultraviolet wavelength regions. Other substances were sought in planetary atmospheres without success, and progress had to await extension of the observable wavelength band further into the infrared region. In 1947 use of a lead-sulfide detector extended the observable infrared out to 2.5 micrometres, enough to detect carbon dioxide on Mars. The spectral resolution was not high, but the carbon dioxide bands in this region are extremely strong. By 1963, improvements in infrared photography and in *coudé* spectrographs produced a single plate showing a weak band of carbon dioxide at 8,689 Å. The actual purpose of the exposure was to search for evidence of water vapour on Mars at a time of large planetary motion in the line of sight and, therefore, large Doppler shift, which would separate the contributions to the water vapour bands from the Earth's atmosphere and that of the planet; weak absorptions were indeed found. It soon became clear, however, that the atmosphere of Mars is nearly pure carbon dioxide; the only other gases likely to be present in substantial amounts are nitrogen and argon, which are invisible to this type of spectroscopy.

Still another advance, the perfection of high-resolution Fourier spectroscopy, permitted the detection of a trace of carbon monoxide in spectra of Mars obtained by Pierre and Janine Connes, two French astronomers. The resolution and consequent purity of this method is such that many new identifications of features, hitherto hopelessly blended with neighbouring ones, are now possible.

Space observations suggest a trace of ozone absorption around 2,500 Å. The emission spectrum of the atmosphere of Mars was observed by spectrometers aboard U.

S. flyby spacecraft in 1969 and by the Viking landers in 1976. The latter confirmed the presence of carbon dioxide and detected traces of nitrogen, argon, oxygen, water, krypton, and xenon.

Venus

Observations of small planetary areas. Quantitative analysis of the Venus atmosphere is hampered by the ubiquitous haze. The path taken by the radiation as it is scattered from point to point in the atmosphere is unknown but is presumably similar at nearby wavelengths; thus, the relative abundances of various gases can be obtained. The most abundant gas is known to be carbon dioxide again, from direct chemical analysis by U.S. and Soviet probes. With this knowledge, the amounts of the remaining gases can be obtained. One hundred and ninety bands of carbon dioxide have been identified in the Connes spectra. Rare isotopes of carbon and oxygen also have been identified from peaks in the spectra that are shifted from the positions of the main carbon dioxide lines because of the mass differences between the isotopes. This technique has been possible for the first time because of the very large improvement in the resolution provided by the Connes spectra. The isotopic abundances are found to be the same as on Earth. Nitrogen is also present, as are much smaller amounts of water vapour, argon, neon, and sulfur dioxide.

The outer planets

It has long been realized that the low density of Jupiter (and also of the other three giant planets, Saturn, Uranus, and Neptune) implies the presence of large amounts of hydrogen, and the detection of methane (CH_4) and ammonia (NH_3) offered support for this reasoning. But direct detection of H_2 became possible only in 1949, when laboratory work showed the existence of two classes of infrared absorption that could be sought by direct observation. Broad pressure-induced lines were soon found in the spectra of Uranus and Neptune. A decade later, the narrow quadruple lines of hydrogen produced in relatively rare transitions were observed on Jupiter, and they have been studied in detail since; the expected dominance of hydrogen was confirmed by the Pioneer 10 probe. Data transmitted by the spacecraft also corroborated the presence of substantial amounts of helium.

Spectroscopy of comets. Special difficulties in comet observation include the sporadic nature of cometary appearances; also, as all cometary radiations are either reflected or induced by the effect of sunlight, changes occur constantly in the spectrum as the comet approaches and recedes from the Sun. In the past, most comet spectra have been made at low dispersion, partly because a short exposure or the use of a slow or small telescope was necessary. Such spectra show the gross features well, but fine details can best be studied only on the rare occasions when a really bright comet can be observed at high dispersion.

The nature of comets has been revealed in some detail by spectroscopy. A nucleus, heated by the Sun, gives off a cloud of gases, many of which are unstable free radicals. Ions are also produced and are blown radially away from the Sun by the solar wind. Spectra of the head, the brightest and densest part of the comet, show the presence of C_2 , C_3 , CH , CN , NH , NH_2 , OH , H , and O ; sometimes, near the Sun, sodium and iron lines also appear. The tail ions are CO_2^+ , CO^+ , and N_2^+ ; the presence of dust is revealed by the solar spectrum it scatters. The nucleus is composed of compounds like H_2O , NH_3 , and CH_4 along with heavier hydrocarbons and dust. These molecules are released by the heat of the Sun and dissociated and ionized mainly by solar ultraviolet radiation. The detection of hydrogen atoms was accomplished only in 1970 by two spacecraft, the first "Orbiting Astronomical Observatory" and an "Orbiting Geophysical Observatory." The hydrogen cloud is enormous, even on the scale of the visible comet, the tail of which can be millions of kilometres long.

Detailed study of high-dispersion spectra reveals additional information. Motions are found from Doppler shifts, and intensities of molecular bands give "temperatures," which relate to the equilibrium of the molecules of the tenuous gas with solar radiation.

Spectroscopy of meteors. Though meteorites can be recovered and analyzed in the laboratory, there is no assurance of a similar composition for the much smaller

objects, the meteors, that vaporize high in the atmosphere. Meteor spectroscopy is worthwhile not only for chemical analysis, but also for clues to the physical conditions in the meteor trail. Meteors form short-lived bright tails, lasting for a few seconds; they appear unpredictably in any part of the sky, but more frequently during meteor showers. The only practical method is to use an objective prism or, more often, a grating with a widefield camera. Long exposures at random or during meteor showers have yielded a total of some 1,500 spectra, most at very low dispersion, enough for a detailed study. The chemical elements found do indeed suggest a composition similar to the larger meteorites; they include iron, magnesium, sodium, calcium, manganese, chromium, aluminium, nickel, hydrogen, and silicon, some of them ionized. A curious fact is the appearance of the auroral green line of atomic oxygen in some meteor spectra. Its presence is not fully understood, but presumably it is due to the excitation of atmospheric oxygen. Bands and lines of nitrogen are also seen. One existing spectrum shows, in addition to the usual metallic lines, many molecular bands suggesting cometary material. Apparently present are the oxides of iron, magnesium, calcium, and carbon, as well as CN and C_2 . For the other lines, the degree of excitation depends on the velocity and consequent heating of the meteoric particle: slow ones show temperatures around 1,700 K (2,600° F), and faster ones may reach 3,200 K (5,300° F).

Spectroscopy of nebulae. The word nebula in Latin means a cloud, and has been applied in the past to many kinds of cloudy objects. Current usage favours restriction of the term to literal clouds of gas, dust, or both; aggregations of stars are called clusters or galaxies, depending on their size and structure. Usually a distinction can readily be made with the spectroscope: clusters and galaxies show a stellar spectrum, whereas gaseous nebulae show a bright-line spectrum. Borderline cases exist; some galaxies have emission lines, and dust clouds near a suitable star (effective temperature 20,000 K or cooler) can behave as reflection nebulae showing essentially the same spectrum as the exciting star. A well-known example is found in the Pleiades star cluster.

Spectra of gaseous irregular nebulae. Gaseous nebulae are usually excited by intense ultraviolet light from one or more hot stars in the neighbourhood. A very hot star emits huge amounts of far-ultraviolet radiation—the maximum of the black-body spectrum is at 1,000 Å for a temperature of 29,000 K (about 52,000° F). All the gas near it is, therefore, ionized and constitutes an "HII region." The term HII, or H^+ , refers to ionized hydrogen. The outer boundary of an HII region is rather sharp; here the ionizing radiation is quickly used up, and the hydrogen in the surrounding HI region is mostly neutral. If the gas is uniform around the star, the HII region is called a Strömgren sphere after the Danish astronomer Bengt Strömgren, who first studied their structure in detail. The observed nebula may appear irregular because of patchy absorption by dust clouds, or because the density of hydrogen varies in different directions.

The emission lines of an HII region, or emission nebula, are produced by two main processes. Electrons and positive ions are continually recombining; in particular, electrons and protons recombine into hydrogen atoms. The result is a continual production of excited atoms and of ions in lower stages of ionization; a rich recombination spectrum results. Because hydrogen is very abundant, its lines are particularly prominent. In addition to the familiar lines in the visible and near ultraviolet ranges, there are many more in the radio region. Recombination also produces continuous spectra extending over several hundred angstroms in various spectral regions, and through much of the radio region. These spectra are produced by electrons approaching ions with considerable energy and combining with them into a specific bound energy level. Thus, the width of each continuum gives, in principle, a direct measure of the energy distribution of the electrons. In practice this information is difficult to obtain because of uncertainties in photometry over the required wavelength range.

Analyzing meteor spectra

Emission processes in nebulae

Figure 27: The emission spectrum of the Orion Nebula from 3,700 to 5,100 Å, showing the Balmer lines of hydrogen, due to recombination, and the forbidden lines of ionized oxygen, sulfur, and neon, due to electron impact.

By courtesy of Mount Wilson Observatory; from C. Payne-Gaposchkin and K. L. Haramundanis, *Introduction to Astronomy* (© 1970), Prentice-Hall

Subsequently, the electrons are ejected again, having absorbed energy from the radiation of the central star, and most of them have considerable kinetic energy. This energy is quickly shared with the other electrons and ions, which typically attain a temperature of 10,000 K (17,500° F). The more energetic electrons can collisionally bring the atoms and ions of the medium to their lowest excited states. Many of the lines in such an electron-impact spectrum are unobservable in the laboratory; they were for many years half-seriously ascribed to an unknown element nebium. But in 1927 the U.S. physicist and astronomer Ira S. Bowen found that they were due to forbidden transitions in the ions of common elements, especially oxygen and nitrogen. In the laboratory the excited states are unable to radiate before they are quenched by a collision with another atom or the wall of the vessel. But in the tenuous environment of a nebula such collisions are so rare as to be unimportant. The excited states in question are of low energy and are very efficiently populated by the electrons in the nebula; indeed, the production of forbidden lines is the process that limits the temperature of the electrons. In 1925 the green auroral line had been similarly identified as a forbidden transition in neutral oxygen, and several other forbidden transitions are now known in the spectrum of the Earth's upper atmosphere.

Bowen
fluores-
cence

A third excitation process was worked out by Bowen in 1934: it is known as Bowen fluorescence. The strongest line of the helium ion, at 304 Å, is emitted by the nebula, and this wavelength happens to coincide with a line of doubly ionized oxygen (OIII). Ions raised to this state may cascade down, through several intermediate energy levels, emitting the observed lines. The last photon radiated can initiate a similar process in nitrogen ions (NIII).

The best known nebula, visible to the naked eye as the middle "star" in the sword, is the Orion Nebula. Well over 200 lines are identified in its spectrum, representing a dozen of the common elements in several stages of ionization. Several lines are known in the radio region. The composition is similar to that of the Sun. A complicated field of radial velocities is found. The general expansion is about 12 km/sec (7 mi/sec) relative to the central stars. Expanding bubbles are shown in many places by doubled lines—both the front and the back are seen, one approaching and the other receding. It seems that the whole region is in rapid turbulent motion, with discontinuities suggesting shock fronts. Similar data are available for one or two other diffuse nebulae, but in most cases only a general velocity of approach or recession can be obtained.

HII regions can readily be observed in nearby galaxies; in more distant ones, the brightest lines sometimes show above the stellar continuum. The forbidden doublet (a spectral line with two close components) of O^+ at 3,727 Å is found this way in about half the galaxies observed, and even more frequently in spiral and irregular galaxies that tend to be rich in gas.

Spectra of planetary nebulae. Somewhat over a thousand planetary nebulae are known. The term planetary has nothing to do with the nature of the objects: it refers to the telescopic appearance of the brighter ones—a greenish disk resembling Uranus or Neptune. Photographs usually reveal considerable structure in addition to the basic cir-

cular shape. Usually a central star can be seen. Spectral lines near the centre are double and indicate expansion velocities of 10–30 km/sec (6–18 mi/sec). Comparison of this velocity with a typical diameter suggests a lifetime of only 30,000 years. It is generally believed that such nebulae represent the outer envelope of a very old star, whose inner parts are in the process of collapsing into a star of very small diameter called a white dwarf. It is not surprising that this stellar core has an exceedingly high temperature, typically 50,000 K (90,000° F) and sometimes as much as 100,000 K (180,000° F). Though such an object would be expected to be deficient in hydrogen (which is consumed by the processes that cause a star to shine), the abundances of it and of the other chemical elements in both nebulae and central stars seem to be normal. Perhaps the hydrogen is not used up in the outer parts of the star; or perhaps the picture of the central star as a white dwarf is in error.

It is uncertain whether the outer boundary of a planetary nebulae represents the boundary of the ejected gas or a Strömgren sphere embedded in this gas. It is difficult to tell directly from the spectra, because any surrounding HI region would be very faint. Indirect evidence suggests that the smaller nebulae, which are also the youngest and densest, may have HI regions around them. Stratification may be seen directly for ions like He^+ and Ne^{++} , which tend to be found closer to the centre than the less-ionized species.

Supernova remnants. The third principal species of nebula is the supernova remnant. The most famous and best understood example is the Crab Nebula; the supernova associated with it was observed by Chinese and Japanese astronomers in 1054. This remarkable nebula still presents major new insights; in 1968 the supernova remnant was found to be a pulsar.

It is thought that a supernova represents the explosion of a massive star, during which a core, about the mass of the Sun, is imploded into a neutron star less than 20 kilometres (12 miles) in radius. Such a collapse releases an enormous amount of gravitational energy, comparable to the nuclear energy radiated during the lifetime of the normal star; and a large fraction is stored in the rapid rotation of the neutron star. At the same time, the stellar magnetic field is enormously compressed and strengthened. As the star rotates, its magnetic field acts as a powerful dynamo, accelerating ions, and especially electrons, to high velocities: 900 years after the explosion, the rotation rate of the whole star is still 30 revolutions per second, very close to that of a standard electric motor.

Spectroscopically, the star appears blue but shows no absorptions. Photometry and time-resolved photography show that the light is emitted in flashes, twice per revolution, as in a rotating beacon. The source of the light is not understood; no other pulsar is detectable optically, but they are all older than the one in the Crab. The surrounding nebula consists of two parts: an amorphous mass with a continuous spectrum and a high degree of polarization; and a complicated network of ropy filaments with a normal nebular spectrum. In 1953 it was suggested that the continuum is due to synchrotron emission: light given off by electrons moving at almost the speed of light when deflected by a magnetic field. The subsequent observation

Explana-
tion of
supernova

of polarization confirmed this idea, but the energy source for the electrons was a mystery until the discovery of the pulsar. The synchrotron continuum extends all the way from the radio, through the optical, into the X-ray region. The ultraviolet part of this spectrum seems adequate to explain the excitation of the gas in the filaments. The gas is distinctly deficient in hydrogen and rich in helium.

The radial velocities of the filaments have been explored in some detail. There are large irregularities, but the general speed of expansion is about 1,150 km/sec (710 mi/sec). The corresponding transverse expansion can be measured by comparing photographs taken many years apart; the results strongly suggest that the motion has accelerated somewhat since the explosion, presumably under the influence of the energy emitted by the pulsar.

The Crab, though it has received most study, is not a typical supernova remnant. Several others are known; they show much greater expansion velocities, up to 20,000 km/sec (12,000 mi/sec); naturally, they dissipate much faster and are usually observed as rings or hollow spheres. Much of the optical excitation may be from interaction with the interstellar gas at the advancing front.

Spectroscopy of galaxies. One of the most striking of all spectroscopic results was the discovery of the apparent expansion of the universe, by the U.S. astronomer Edwin P. Hubble. He found the remarkably regular rule that distant galaxies appear to recede faster than those that are near our own system: their spectral lines are shifted towards the red. Hubble's Law states that the velocity of recession is proportional to the distance; it has continued to be confirmed by later work. On such faint objects as galaxies, for most of which only low- or medium-dispersion spectra can be obtained even with very long exposure and large telescopes, Doppler shifts can be measured only because they are so large; a typical spectrum on a blue-sensitive plate is only three millimetres long. The nebular spectrograph is used at the prime focus of the telescope to conserve light.

For the brighter galaxies, it is possible to classify the spectra in much the same way as the spectra of individual, relatively close stars and also to obtain some idea of which kinds of star contribute most to the light. Galactic spectra resemble the spectra of the median type of their component stars and can be simulated by combining the spectra of a number of stellar types. The results depend on the wavelength region used: hot stars have a more important effect on the combined spectrum in the blue,

and cool ones in the red. A correlation of the spectrum with the appearance of the galaxy exists. For blue wavelengths, elliptical galaxies tend to have predominantly G- or K-type spectra, indicating that most stars in them are somewhat cooler than the Sun. Irregular galaxies have A-type spectra, considerably hotter than the Sun. Spirals are intermediate, the tightly wound ones having cooler spectra than the loosely wound ones.

The presence of gas is indicated by emission lines, especially the nebular doublet (explained above) of ionized oxygen at 3,727 Å, and lines of hydrogen and ionized nitrogen in the red. The correlation with the type of galaxy resembles that for spectral class: prominent in irregulars and improbable in ellipticals. Gas is associated with young, hot stars because copious amounts of gas are necessary for star formation, and because hot stars make the gas more visible. The situation in the nuclei of galaxies appears to be more complicated, but gas is quite common there.

About two dozen of the type called Seyfert galaxies are known, named for the U.S. astronomer, Carl Seyfert, who first studied them in detail; they exhibit starlike, very bright nuclei, with a high-excitation spectrum of broad emission lines. Turbulent motions of several thousand kilometres per second are implied. Somewhat similar are the N galaxies (nuclear galaxies), usually strong radio sources, and some of which have considerable redshifts. The relationship of the two groups to each other is obscure, as is the relation of N galaxies to quasars.

Spectroscopy of quasars. Quasi-stellar objects (qso's), or quasars, are objects that appear to be point sources of light, like stars, but have large redshifts appropriate to distant galaxies. In their spectra, emission lines are prominent, as is a continuum with absorption lines. Spectra of these objects can only be obtained with very large telescopes because of their extreme faintness.

The nature of the line spectrum was a mystery for several years, in 1963 when a redshift of 0.158 (the increase of wavelength divided by the original wavelength) was found. Within two years a redshift of 2 had been found, and subsequently even larger ones were detected. If interpreted as Doppler shifts, redshifts of 2 or larger correspond to velocities of 80 percent or more of the speed of light. Altogether, lines of 10 common elements have been identified, and as far as can be determined the composition is like that of the Sun. Relative intensities differ from quasar to quasar, but these differences could be due to different conditions of excitation. Also, since forbidden lines are seen, densities must sometimes be very low in the regions where the spectrum, or part of it, is formed.

Absorption lines are common only in those objects with redshifts approaching or exceeding 2. Most often, the absorption redshift is less than that for the emissions, and in some cases there are two or more redshifts. Unidentified absorptions short of the Lyman-alpha emission are common and may be due to hydrogen at still other shifts, which cannot be verified by correlation with other lines.

The cause of the redshifts is still undetermined. Its interpretation remains one of the fundamental problems of spectroscopy. Among other possibilities, it has been suggested that they are caused by gravitational redshifts, but it is difficult to imagine any so large; also, the narrowness of the spectral lines presents a serious problem because it indicates that they must originate in a uniform region of the gravitational field.

Radio spectroscopy. The most famous spectral line of the radio region is the 21-centimetre emission of the hydrogen atom. There are two reasons for its importance: hydrogen is the most abundant constituent of the interstellar gas; and the Galaxy is transparent in this wavelength region. Moreover, Doppler shifts and the corresponding radial velocities can be found by a procedure as simple as tuning a radio receiver. The existence of the 21-centimetre line was predicted during World War II and was detected almost simultaneously by three different groups a few years later.

The states involved in the 21-centimetre transition are the so-called hyperfine levels of the ground state. In a hydrogen atom, the magnetic moments of the electron and proton can point either parallel or antiparallel; the

The presence of gas in galaxies

Alternative interpretations of redshift

latter situation has the lower energy, just as it would for a pair of bar magnets. But the number of electrons with higher energy—that is, at the upper level—is kept up by thermal collisions; even in the extremely tenuous gases of the interstellar medium such collisions occur once every 400 years. On the average, a radio-frequency photon is emitted by an undisturbed, excited atom every 11,000,000 years: the transition is very infrequent; that is, it is highly “forbidden.” Nevertheless, in practice, the line is readily detected in any direction, because there is so much hydrogen and because radio techniques with large antennas are so sensitive.

Mapping the Galaxy

In surveying the Galaxy, the different Doppler shifts of various spiral arms are significant. With the aid of a model of galactic rotation, a detailed map was built up by 1958. Because the Doppler shifts are zero in the directions toward and away from the centre, there are two gaps in the map. The spiral arms can be seen rather well and traced for long distances. In the confused region towards the centre, rapid motions can be discerned; it appears that a ring of gas is moving outwards at about 50 km/sec (30 mi/sec). It was found that about 2 percent of the mass of the Galaxy is in the form of gas. The velocity distribution that was once assumed has been shown to be too simple to fit the real Galaxy. Despite progress in refining the map, a truly satisfactory result has yet to be achieved.

Other galaxies can also be observed, and their general Doppler shifts measured. For the nearest objects, fairly detailed maps have been produced.

Atomic hydrogen also has a rich recombination spectrum in the radio region, as first predicted in 1959. These lines are unobservable in the disturbing environment of the laboratory because they are highly susceptible to atomic collisions. The electronic states of hydrogen are described by a quantum number n , which is 1 for the ground state. Lyman alpha, a well-known ultraviolet hydrogen, line, is emitted in a transition from $n = 2$ to $n = 1$; Balmer alpha, or hydrogen alpha ($H\alpha$), in the red, is the 3–2 transition. These lines belong to well-known hydrogen series of lines named after prominent physicists. Radio lines have been observed from 8.2 millimetres (56 α , 57–56) to 75 centimetres (253 α , 254–253). Jumps of two, three, and four are also found, as are lines of helium and (probably) carbon. The best sources are HII regions, as would be expected for a recombination spectrum. The physical information that can be obtained is similar to that found from optical recombination lines. But the radio lines have the important advantage of needing no corrections for interstellar absorption. A radio continuum is also produced, as in the optical region, by the electrons as they are captured into the high orbits.

Molecular lines are known in the range of wavelengths 2.6 millimetres to 36 centimetres. By the early 1980s approximately 50 varieties of molecules and radicals had been identified. These include water vapour, ammonia, formaldehyde, methyl alcohol (CH_3OH), carbon monoxide, hydrogen, cyanide, and some sulfur compounds. It is common to find emission lines, as well as absorptions against strong sources. The emission lines of OH are notable for their high intensity, small size, and unexpected intensity ratios. The only likely explanation is that stimulated emission is amplifying the radio waves; in other words, an interstellar maser is operating. (D.M.H.)

Mass spectroscopy

Mass spectroscopy denotes that field of physics in which the motion of ions in electric and magnetic fields is used to sort ions according to their mass-to-charge ratios. The instruments used in these studies are called mass spectrometers and mass spectrographs, and they operate on the principle that moving ions may be deflected by electric and magnetic fields. The two instruments differ only in the way in which the sorted charged particles are detected. In the mass spectrometer they are detected electrically, in the mass spectrography by photographic or other nonelectrical means; the term mass spectroscopy is used to include both kinds of devices; a person who specializes in their use is called either a mass spectrometrists or a mass spectroscopist.

Mass spectroscopes consist of five basic parts: a high vacuum system; a sample handling system, through which the sample to be investigated can be introduced; an ionization chamber (ion source), in which a beam of charged particles characteristic of the sample can be produced; an analyzer, in which the beam can be separated into its components; and a detector or receiver by means of which the separated ion beams can be observed or collected.

Many investigations have been conducted with the help of mass spectroscopy. These include the identification of the isotopes of the chemical elements and determination of their precise masses and relative abundances, the dating of geological samples, the analysis of inorganic and organic chemicals especially for small amounts of impurities, structural formula determination of complex organic substances, the strengths of chemical bonds and energies necessary to produce particular ions, the identification of products of ion decomposition, and the analysis of unknown materials, such as Moon samples, for their chemical and isotopic constituents. Mass spectroscopes are employed also to separate isotopes and to measure the abundance of concentrated isotopes when used as tracers in chemistry, biology, and medicine.

HISTORY OF MASS SPECTROSCOPY

The foundation of mass spectroscopy was laid in 1898, when Wilhelm Wien, a German physicist, discovered that beams of charged particles could be deflected by a magnetic field. In more refined experiments carried out between 1907 and 1913 by J.J. Thomson, who had already discovered the electron and its deflection by an electric field, a beam of positively charged ions was passed through a combined electrostatic and magnetic field. The two fields in Thomson's tube were situated so that the ions were deflected through small angles in two perpendicular directions. The net result was that the ions produced a series of parabolic curves on a photographic plate placed in their paths. Each parabola corresponded to ions of a particular mass-to-charge ratio, and the lengths of the parabolic curves provided a measure of the range of ion energies contained in the beam. Later, in an attempt to estimate the relative abundances of the various ion species present, Thomson replaced the photographic plate by a metal sheet in which was cut a parabolic slit. By varying the magnetic field, he was able to scan through a mass spectrum and measure a current corresponding to each separated ion species. Thus he may be credited with the construction of the first mass spectrograph and the first mass spectrometer.

The most noteworthy observation made with the parabola spectrography was the spectrum of rare gases present in the atmosphere. In addition to lines due to helium (mass 4), neon (mass 20), and argon (mass 40), there was a line corresponding to an ion of mass 22 that could not be attributed to any known gas. The existence of different mass forms of the same element had been suspected since it had been found that many pairs of radioactive materials could not be separated by chemical means. The name isotopes was suggested by Frederick Soddy in 1913 for these different radioactive forms of the same chemical species since they could be classified in the same place in the periodic table of the elements. The ion of mass 22 was, in fact, a stable heavy isotope of neon.

Focussing spectroscopes. The spectroscopes discussed so far are analogous to the pinhole camera in optics because no focussing of the ion beams is involved. The introduction of focussing types of mass spectroscopes came in the years 1918–19 and was due to F.W. Aston and to A.J. Dempster.

In Aston's version, successive electric and magnetic fields were arranged in such a way that all perfectly collimated ions of one mass were brought to a focus independent of their velocity, thus giving rise to what is known as velocity focussing. Aston's design was the basis of his later instruments with which he systematically and accurately measured the masses of the isotopes of many of the elements. He chose ^{16}O (the isotope of oxygen of mass 16) as his standard of mass.

Dempster's spectrometer utilized only a magnetic field,

Applica-
tions

Contribu-
tions of J.J.
Thomson

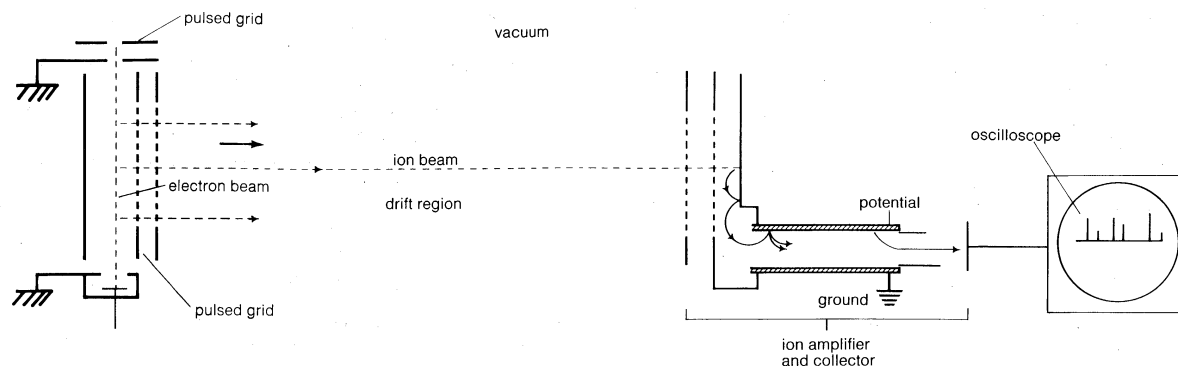

Figure 29: Linear time-of-flight mass spectrometer.

A pulse of electrons ionizes the sample and a pulsed grid draws ions out of ionizing region and accelerates them along a drift region. Since all ions acquire the same energy of acceleration, the lighter ions arrive at the collector first. The separated ion beams can be displayed on an oscilloscope.

which deflected the ion beam through an arc of 180° . In Dempster's machine, an ion beam homogeneous in mass and energy, but diverging from a slit, could be brought to a direction focus. This spectrometer was employed by Dempster to make accurate determinations of the abundances of the isotopes of magnesium, lithium, potassium, calcium, and zinc, laying the foundation for similar measurements of the isotopes of all the elements.

The resolving power of a mass spectroscope is a measure of its ability to separate adjacent masses that are displayed as peaks on the detector. If two peaks due to mass m and $(m + \Delta m)$ can just be separated, the resolving power is $m/\Delta m$. The early machines had resolving powers of only a few hundred. In 1935 and 1936, Dempster, K.T. Bainbridge, and Josef Mattauch working independently, developed instruments with electric and magnetic fields arranged in tandem in such a way that ion beams that emerged from the source slits in divergent directions and with different velocities were refocussed. Such focussing is termed double focussing. It was thus possible to achieve a resolving power of about 60,000.

Alternating field spectrometers. The spectrometers described so far employ steady electric and magnetic fields. In 1932 the use of alternating electric fields to separate ions of different mass was introduced by Henry D. Smyth. Instruments employing this technique are known as radio-frequency mass spectrometers, and by 1950, developments had improved them so that a resolving power of 100,000 was possible. Nonfocussed spectrometers were introduced that did not require deflecting fields but operated on the principle of the pulsed beam. Typical of these is the "time-of-flight" spectrometer, shown in Figure 29, which depends upon the fact that an accelerated bunch of ions will separate during its flight through the drift tube and arrive at the collector as a series of ion pulses, the lighter ions arriving first.

In 1953, Wolfgang Pauli and Helmut Steinwedel described the development of a quadrupole mass spectrometer. The application of superimposed radio-frequency and constant potentials between four parallel rods can be shown to act as a mass separator in which only ions within a particular mass range will perform oscillations of constant amplitude and be collected at the far end of the analyzer. This device, like the others, has the advantage of high transmission.

ION PRODUCTION AND DETECTION

Ion sources. The electron bombardment ion source was first used by Dempster. Its operation depends on the fact that an electron, when colliding with a molecule, may transfer a sufficient amount of its energy to eject one of the electrons in the molecule, thus forming a positively charged ion. A bombarding electron can transfer much more than the minimum amount of energy necessary to produce an ion, and the excess energy can cause the ion to decompose in various ways with the loss of neutral fragments, thus giving rise to a mass spectrum. A simplified electron bombardment ion source consists of a heated

filament, generally of tungsten or rhenium, that emits electrons in copious numbers. The electrons are attracted by slits having a high positive charge and pass through the ionization chamber containing the gaseous sample to be analyzed; here they are constrained to move in a narrow beam by a magnetic field in a direction along their lines of motion. Positive ions are formed in the ionization chamber along the length of the electron beam and are ejected from the chamber by positively charged, or repeller, electrodes. The ions leaving the source have a spread in energy of only a fraction of an electron volt. A sample is required in gaseous form at extremely low pressure, and a sample consumption of less than a thousandth of a microgram each second is typical. The source is frequently used for examination of organic compounds that can be vaporized without decomposition, as well as for gas analysis.

Instead of electrons, photons in the far ultraviolet region may be used, as they have sufficient energy to produce positive ions in a sample gas or vapour to be analyzed. A discharge in a capillary tube through which is passed a suitable gas, such as helium, is a good source for such radiation. Photo-ionization sources usually produce fewer ions than electron bombardment sources but have advantages when the ionization chamber must be held at low temperature.

In the vacuum spark source a pulsed, high-frequency potential of about 50 kilovolts is built up between two electrodes until electrical breakdown occurs. Hot spots appear on the electrodes, and electrode material is evaporated and partially ionized by bombardment from electrons present between the electrodes. The principal merit of the vacuum spark source is its ability to produce copious quantities of ions of all elements present in the electrodes.

To obtain large ion currents a low voltage arc source can be used. The sample vapour, contained in a capillary, starts a low-current discharge in the filament chamber, the walls of which act as the anode. Electrons from this discharge ionize the vapour within the capillary and strike an arc to the anode, the ion density within the capillary being particularly high. When a magnetic field is used parallel to the direction of the primary electrons, the discharge is constrained without the use of a capillary. A weak electrostatic accelerating field extracts ions from the arc plasma, and these can be collimated and focussed. Ion beams of one milliamper (a million times greater than those from the sources described above) can be obtained and collected to give usable amounts of separated isotopes. The surface ionization source depends upon the fact that when an atom of low ionization potential is heated on a surface of high work function, it is likely to evaporate as a positive ion. Neutral atoms striking the hot filament may also be re-emitted as ions. The ionization efficiency is so high in favourable cases that samples weighing less than a picogram (10^{-12} gram) may be analyzed with a precision of a few percent. This type of source has been widely used in the age determination of rocks. Substances that are adsorbed on a surface can be desorbed as positive ions under the action of a sufficiently strong electric field.

Intense fields, of the order of 10^8 volt per centimetre, can be generated in the neighbourhood of sharp points and edges, and these have been used as field emission sources. This source is becoming popular in the study of organic compounds, which can be introduced as vapours and ionized in the intense fields. The ions are formed with very little excitation energy so that there is little fragmentation of the molecular ions, making molecular formulas easier to determine.

Fragmentation of ions

Types of ions. In any of the ion sources described, a polyatomic molecule ordinarily is transformed into a mixture of so-called parent and fragment ions. Parent ions or molecular ions are ions that have been formed from complete molecules by removal of one or more electrons without fragmentation. One can represent, in equation form, the action of an electron e upon a neutral molecule M to produce an ion and two electrons (electron bombardment), or the action of a photon $h\nu$ to produce an ion and one electron (photo-ionization). Most organic compounds are held together by bonds that each contain two electrons, so the neutral molecule contains an even number of electrons. When an electron is removed, the ion formed will contain an unpaired electron; which can be symbolized by a dot. The equation for electron bombardment is thus $M + e = M^+ + 2e$, and for photo-ionization, $M + h\nu \rightarrow M^+ + e$. These ions may contain an energy considerably in excess of the minimum required for fragmentation and may break into a variety of fragment ions and neutral species. Thus the molecular ions are the "parent" ions of the mass spectrum. Molecular ions may carry one or more charges because transfer of a large amount of energy by a bombarding electron (or photon) may expel two or more electrons from the molecule; thus, for example, processes such as are represented by the equation $M + e \rightarrow M^{2+} + 3e$, or $M + e \rightarrow M^{3+} + 4e$ can occur. These are examples of the formation of multiply charged ions.

Most of the research carried out in mass spectroscopy is concerned with positive ions; that is to say, ions formed by removing an electron from a neutral molecule. Electrons having a low kinetic energy can attach to molecules, forming *negative ions*, and these can also be studied by mass spectroscopy.

The fragmentation of a molecular ion $ABCD^+$ can occur in several ways. For example, the expression $ABCD^+ \rightarrow AB^+ + CD^+$ represents simple cleavage, and $ABCD^+ \rightarrow AC^+ + BD^+$ a rearrangement reaction when (the ion AC^+ is called a rearrangement ion). The fraction or moiety B has transferred during fragmentation to combine with moiety D. Such rearrangements are commonly found in the mass spectra of organic compounds and involve transfer of hydrogen atoms, or occasionally, small groups of atoms.

Ions that make up a mass spectrum also can be classified according to their stability. Ions that undergo fragmentation within the ionization chamber are classified as unstable, ions (both molecular and fragment ions) that leave the ionization chamber and undergo fragmentation between the ionization chamber and the detector are said to be metastable. Metastable ions that decompose in field-free regions of the flight tube can give rise to diffuse peaks in the mass spectrum. The positions and shapes of these "metastable peaks" can be used to give information about the individual steps in the fragmentation processes.

The detection and identification of ions. The two most widely used detection systems for energetic ions are the photographic plate and the secondary electron multiplier.

Especially sensitive photographic plates are employed to compensate for the low penetrating power of the ions. It has proved possible with these to detect an element over a sensitivity range of 1 part in 1,000,000,000. In addition to the sensitivity, a major advantage of the photographic plate arises when it is used in a double-focussing mass spectroscopy in which the whole, or a major part, of the mass spectrum is focussed in a plane (see the design of Mattauch and Richard Herzog shown in Figure 32 and described below). In this case, one can make use of the integrating action of the plate and compare the densities of lines due to different elements.

The basic electrical detector is the so-called Faraday cage. The current due to ions striking the cage is usually measured with an electrometer amplifier. The stability of electrometer amplifiers is such that the ion current issuing from the ionization chamber, minute as it is, permits intensity measurements of 10 parts per million. An ion-collector system can be built with two or more slits and a corresponding number of Faraday cages that allows the simultaneous collection of two or more ion beams. Such a system allows the ratio of two ion beams to be measured continuously; it is particularly valuable in measuring the abundance ratios of the isotopes of an element and in detecting small changes in these ratios.

Secondary electron multipliers of the conventional kind are used to detect the smallest currents and to reduce the time constant, thus increasing the plotting rate of spectra. They can give a measurable current for the arrival of a single ion and be used for single ion counting. A scanning time of one second for several hundred mass peaks can be achieved if one sacrifices the accuracy of measurement of relative peak heights for the smallest peaks.

Single ion counting

Another method of detecting the positive ions in a beam is to allow them to strike a phosphor, thus producing scintillations that can be detected by a photomultiplier. A more sensitive method is to allow the ion beam to impinge upon a secondary emitting electrode, maintained at a high negative potential. The secondary electrons produced are accelerated to a phosphor that is optically coupled to a photomultiplier. In this way, high sensitivity is attained and the photomultiplier is never exposed to the atmosphere yet is conveniently located outside the vacuum system.

THE ANALYSIS OF IONS

Magnetic field analysis. Ions of mass m and charge e moving *in vacuo* with a velocity v in a direction perpendicular to a magnetic field H will follow a circular path with radius R given by

$$R = mv/He.$$

Therefore, all ions with the same charge and momentum entering the magnetic field from a common point will move in the same radius R and will come to a first order focus after 180° as shown in Figure 30, no matter what their masses. Hence, the mass spectrometer used by Dempster can be referred to as a "momentum spectrometer." If all ions of charge e enter the magnetic field with an identical kinetic energy eV , due to their acceleration through a voltage drop V , a definite velocity v will be associated with each mass and the radius will depend upon the mass. Since $eV = \frac{1}{2}mv^2$, substitution in the previous equation will give $m/e = H^2 R^2 / 2V$. This formula shows that the radius of curvature R for ions in this spectrometer depends only on the ratio of the ions' mass to charge, as long as their kinetic energy is the same. Thus, a magnetic field can be used to separate a monoenergetic ion beam into its various mass components. A magnetic field will also exert a focussing action on a monoenergetic beam of

Figure 30: Paths of monoenergetic ions moving in a plane perpendicular to a magnetic field, passing through focal point B after originating at point A (see text).

ions of mass m as is shown in Figure 30. In this figure an ion beam emerges from a point A with a spread in direction 2α and comes to an approximate focus at B after traversing 180° . When a molecular ion of mass m_1 , carries a single positive charge, it may decompose in front of the magnetic sector to form a fragment ion of mass m_2 and a neutral fragment. If there is no kinetic energy of separation of the fragments, the ion m_2 , and also the neutral fragment, will continue along the direction of motion of m_1 with unchanged velocity. The equation of motion for the ion m_2 entering the magnetic sector can now be written from a previous relationship, $R = m_2 v / He$. In this equation v is the initial velocity appropriate to m_1 and given by $\sqrt{2eV/m_1}$. Multiplying both sides of the equation $v = \sqrt{2eV/m_1}$ by m_2 , one obtains $m_2 v = \sqrt{2eV} (m_2 / m_1)$. Since the general momentum equation for any mass m can be written $mv = \sqrt{2eV} m$, it is apparent from the former equation that the momentum $m_2 v$ is appropriate to an ion of mass m_2^2 / m_1 . Thus, the decomposition of the metastable ion will give rise to a peak at an apparent mass $m^* = m_2^2 / m_1$, not necessarily an integral number. This peak is known as a metastable peak. Generally, metastable peaks occur at nonintegral mass numbers, and because there usually is a kinetic energy of separation during fragmentation of the polyatomic ion, they tend to be more diffuse than the normal mass peaks and thus are recognized easily. For any value of m^* a pair of integers m_1 and m_2 can be found such that $m^* = m_2^2 / m_1$. Thus, the action of the magnetic field on the charged metastable-ion decomposition product can be used to give information on the individual fragmentation processes taking place in a mass spectrometer.

Electrostatic field analysis. An electrostatic field that attracts ions toward a common centre—that is, a radial field—will also exert a focussing action on a divergent beam of ions as shown in Figure 31. The radial force on

Figure 31: Focussing action of a radial electrostatic field produced by two semicylindrical charged electrodes on a monoenergetic beam of ions. The ions diverging from point A are brought to a focus at point B.

the ions due to the electrostatic field will be Ee , the product of the field E and the ionic charge e , and is equal to the centripetal force mv^2/R , of mass m moving with velocity v about a radius R . Thus, one may write the equation

$$Ee = mv^2/R \text{ or } R = \frac{1}{2}mv^2 / \frac{1}{2}Ee.$$

The radius of the arc traversed by the ions will be proportional to their kinetic energy, and an electric sector, will thus produce an energy spectrum of the ions passing through it. Alternatively, if narrow collimating slits are placed at either end of the sector a monoenergetic beam of ions can be selected.

The possibility of using an electric wedge or sector to obtain a monoenergetic beam of ions, which is then separated for mass analysis by a magnetic sector, is an obvious possibility. General equations for combined electric and magnetic sectors have been developed; they show that a suitable combination of fields will give direction focussing for an ion beam of given mass-to-charge ratio, even though the beam may be heterogeneous in energy. The term double focussing is used for those combinations in which the angular and velocity aberrations effectively cancel.

Two of the best examples of double-focussing mass spectrometers, both of which have been used in a variety

of commercial instruments, were built by Mattauch and Herzog and by Alfred O. Nier and his collaborators. The Mattauch-Herzog geometry is shown in Figure 32 and has

Figure 32: Arrangement of the electrostatic and magnetic sectors in the Mattauch-Herzog double-focussing mass spectrometer. The ions are deflected in opposite directions in the electrostatic and magnetic fields. The divergent monoenergetic beam contains two ion species of different mass to charge ratio. All ions are brought to a focus along the plane AB.

the remarkable property of being double focussing for all masses. Ions of all masses focus along a line that coincides with the second magnetic field boundary. Many versions of this design have been used when high resolution (up to 10^5) is desired for accurate mass and abundance measurements and general analytical work. It can give good spectra, even for a spread of 5 percent in energy of the ion beam, and can be used with virtually any ion source. The resolved ion beams can be recorded electrically or with a photographic plate.

The design due to Nier is illustrated in Figure 33.

Figure 33: Arrangement of the electrostatic and magnetic sectors in the Nier double-focussing mass spectrometer. The angle of the electrostatic sector is 90° and that of the magnetic sector 60° . The direction of deflection of the ion beam is the same in both sectors.

In a second instrument, Nier was able to achieve high sensitivity as well as high resolution. Using an electron-bombardment ion source, a resolving power of 2×10^5 has been attained in a commercial instrument. The design has yielded mass measurements of the highest precision for a very large number of the isotopes and it has also been the most popular design for high resolution work in organic chemistry.

A few methods of attaining perfect double focussing are known. The simplest is to allow ions to move in a plane perpendicular to a homogeneous magnetic field. If the ions originate at a point, each ion will travel in a circular path appropriate to its momentum and will pass exactly through its point of origin after each revolution. In any practical system it is necessary to modify the arrangement so as to produce mass dispersion. This was first done by injecting a beam of positive ions into crossed homogeneous magnetic and electric fields. An ion moving in the

Figure 34: Ion path in the cycloidal mass spectrometer. The magnetic field H is in a direction perpendicular to the plane of the diagram.

Nier's efforts

plane of the electric field E and normal to the magnetic field H will describe a trochoid (the locus of a point on a wheel rolling along a straight line) as shown in Figure 34, and all ions originating at the source or point A will be brought to a focus at the collector slits at point B. The separation distance AB of the source and collector can be written $AB = (2\pi E/H^2)(m/e)$. Neither the initial velocity nor direction of motion of the ions appears in this expression; so these factors do not affect the focus.

All the designs described so far use electric and magnetic fields that are invariant with time. Several other designs, however, have been constructed in which alternating or pulsed fields are used. A method of obtaining mass separation by the use of crossed magnetic and radio-frequency fields makes use of the principle of cyclotron resonance. The "omegatron" spectrometer is illustrated in Figure 35.

Figure 35: Path of the ions in the omegatron radio-frequency mass spectrometer. A magnetic field is in a direction perpendicular to the plane of the diagram.

Cyclotron
resonance

Positive ions are produced by a stream of electrons moving along the direction of the magnetic field. If the time of revolution of an ion is equal to the period of the radio-frequency field (in phase), the ion can gain energy from the field and, as its energy increases, it will travel outward in an Archimedean spiral towards a collector. An ion of slightly different mass will be out of phase with the radio-frequency field and pass successively through maximum and minimum radii as it attains its maximum and minimum velocities. Ions of mass m , which are in phase, will be collected, and those ions of mass $(m + \Delta m)$ will be prevented from reaching the collector. The resolving power $m/\Delta m$ can be shown to be $\pi n/2$, in which n is the number of revolutions made by the ion before arriving at the collector. The resolving power attainable in practice is limited by ion scattering over the very long path length, which dictates a small instrument. The absence of limiting slits makes the instrument very sensitive and therefore useful in such studies as residual gas analysis.

Two other types of mass spectrometer, neither of which makes use of a magnetic field, have been developed into successful commercial instruments. The first of these is the linear time-of-flight spectrometer illustrated in Figure 29. Ions are formed in the source region and pulses of ions are injected into a region where there is no accelerating force, the so-called drift region. Since all ions enter the drift region with essentially the same kinetic energy $K.E.$, it can be seen from the equation $K.E. = \frac{1}{2}mv^2$, or $v = \sqrt{2K.E./m}$, that their velocities v will be inversely proportional to the square root of their masses m and they will take different times to traverse the drift region. A detector at the end of the drift region detects the arrival of the separated ion beams. Each pulse of ions thus gives rise to a complete mass spectrum, and spectra can be produced at rates as high as 10^5 per second, making the instrument particularly suitable for the study of fast reactions and transient species.

Quadru-
pole field

The basic concept of the quadrupole mass spectrometer is to provide a potential field distribution, periodic in time, which will allow ions of a selected mass to pass along an axis. The field is produced, ideally, between four hyperbolic electrodes, a cross section of the ideal arrangement being shown in Figure 36. In practice, four cylindrical electrodes are used, and combinations of dc and radio-frequency potentials are fed to opposite pairs of electrodes. Modern versions of the quadrupole mass spectrometer are compact and versatile instruments, offering a resolving power of the order of 500, plus a high ion transmission

Figure 36: Quadrupole mass spectrometer, showing the four hyperbolic electrodes. Radio-frequency and direct-current potentials are applied to opposite electrodes.

and sensitivity. It has been used to detect microscopic traces of gases, and complete spectra can be obtained about once every second. The ion mass transmitted by a quadrupole mass spectrometer can be selected with high precision merely by adjusting the radio frequency, thus making the instrument suitable for computer control and automatic data presentation.

PRINCIPAL APPLICATIONS

Studies with stable isotopes. The mass spectrometer is widely used to measure the masses of isotopes and to record the relative abundances with which they occur in nature or in artificially enriched samples. Mass spectrometers giving separated ion currents of several milliamperes are known as calutrons, and these have been employed to produce relatively large and pure samples of particular isotopes. Separated isotopes are useful as targets in accelerators and reactors, and as labels in tracer studies.

A variety of compounds is commercially available in which the molecules are chemically labelled with a specific isotope. Labelling with the heavy isotopes ^2H , ^{13}C , ^{15}N , ^{17}O , and ^{18}O is of particular importance in organic chemistry and in biology and medicine. The stable isotopes of nitrogen and oxygen are used for labelling, as no suitable radioactive isotopes of these elements exist. In the so-called isotopic dilution method a known amount of a labelled compound is added to a complex mixture containing some of the same (but unlabelled) compound. Measurement with a mass spectrometer of the percentage labelling in a small sample of the compound extracted from the mixture establishes the original amount of the compound present. Important advances have been made in such fields as metabolism studies, plant respiration, photosynthesis, the direct utilization of oxygen in biological oxidations, enzymic hydrolyses, phosphate transfer reactions. Stable isotopes of elements beyond oxygen are also commonly employed. For example, ^{59}Fe has been used to follow hemoglobin cycles in the body.

Exact measurement of atomic masses. Over two-thirds of all exact atomic masses are now based on mass spectroscopic determinations. Large double-focussing mass spectrometers are employed for the highest accuracy. The standard used is the mass of the ^{12}C isotope taken as 12 units exactly, and relative to the standard, many isotopic masses have been measured to better than one part in 10^7 . It is possible to deduce the composition of a polyatomic ion solely on the basis of an accurate measurement of its mass. This information is of particular importance in organic chemistry and is discussed below.

Organic chemists nowadays use mass spectrometers routinely to determine the structural formulas of organic compounds. Any compound that can be vaporized without decomposing can be examined by this technique. Both high-resolution (20,000 to 100,000) and low-resolution (500 to 5,000) mass spectrometers are used. With a high-resolution mass spectrometer it is possible to carry out mass measurements on the molecular ion (or any other ion in the spectrum) to an accuracy of 1 part in 1,000,000, or so. This mass provides the best index for determining ionic formulas. The accurate masses of the ions $\text{C}_6\text{H}_{12}^+$

Isotopic
labelling

structural
formulas

and $C_4H_4O_2^+$ are, for example, 84.0939 and 84.0211, respectively, and these ions can easily be distinguished solely on the basis of their masses. Once the molecular formula is known it is possible to deduce the total of rings and double bonds making up the molecular structure and to begin to speculate on possible structural formulas. In order to deduce structural formulas from molecular formulas it is essential to study the fragment ions in the mass spectrum. It is still not possible to predict fragmentation patterns for organic molecules, but many semi-empirical rules of fragmentation are known, and it is usually possible to pick out peaks in the spectrum that are characteristic of particular chemical groups. The technique is valuable in that it is generally not necessary to know any details of the composition of the unknown compound in order to deduce a complete or partial structure. Only a small quantity of compound, a hundred micrograms or less, is necessary for an analysis.

Using a computer coupled to a high-resolution mass spectrometer, about 1,000 mass peaks per minute can be plotted at a resolving power of up to 20,000, accurate measurements can be made on each peak, and peak heights and ion compositions printed out in the form of an "element map" to aid in the interpretation of the spectrum. It is also possible for the computer to carry out many of the logical steps in reducing the data that lead to structural elucidation.

Continuous sampling of the materials contained in a reaction vessel, followed by analysis with a mass spectrometer, has been used to identify and measure the quantity of intermediate species formed during a reaction as a function of time. This kind of analysis is important, both in suggesting the mechanism by which the overall reaction takes place, and enabling the detailed kinetics of reactions to be resolved.

Isotopic labelling is widely used in such studies. It can indicate which particular atoms are involved in the reaction; in rearrangement reactions it can show whether an intramolecular or intermolecular process is involved; in exchange reactions it can show that particular atoms of, say, hydrogen, are exchanging between the reacting species. Labelling is also widely used in mass-spectrometric research to give information about the fragmentation reactions occurring in the mass spectrometer.

paleolithic
temper-
atures

There are appreciable "isotope effects" by which isotopes may be distinguished apart from their difference in mass. It has been found, for example, that differences can be measured in the oxygen-18 content of the shells of marine animals that depend upon the temperature of the water in which the shells were formed. Such differences are preserved for millions of years, and they have been used to obtain information concerning oceanic temperatures in paleolithic times.

Analysis of other chemical substances. Using the high-frequency spark source already described, many less volatile substances can be examined by mass spectrometry. The usual method of sample preparation is to construct the electrodes for the high-frequency spark source out of the pure substance to be examined, or if the sample is a powder, to mix it with, say, pure nickel powder and to compress the mixture into the form of the electrodes. The combination of high temperature and high electric field within the spark produces ions characteristic of the sample. The method has found particular application in the analysis of inorganic substances, alloys, minerals, and the highly purified materials used in atomic-energy research, and semiconductor technology. It is possible to detect impurities of the order of one part in 100,000,000, or lower by this technique.

If a monoenergetic beam of electrons or photons is used as the ionizing radiation and if the energy in the beam is slowly increased from a low value, the bombarding energy at which ions begin to appear gives the ionization potential. As the energy is increased further, fragmentation of molecular ions will occur. The energy at which a particular ion appears gives the appearance potential for that ion. Appearance potentials of fragment ions can be used in conjunction with ionization potentials and calorimetric data to estimate various thermodynamic quantities such as latent heats and bond strengths.

Appear-
ance
potentials

The absolute time scale of geologic history can be constructed by the use of various isotopic clocks based on the radioactive decay of relatively long-lived isotopes (see *GEOCHRONOLOGY: Relative and absolute dating*). For example, uranium occasionally is found in fairly high local concentrations in radioactive rocks, along with the stable isotopes of lead-206 and lead-207, which are decay products of uranium-238 and uranium-235. Hence, knowing the decay rates of uranium-238 and uranium-235, the relative abundances of the uranium and radiogenic lead isotopes can be measured to give an estimate of age. Other natural radioactive processes that have been used in age determinations include the decay of potassium-40 to argon-40 and the decay of rubidium-87 to strontium-87.

Vacuum techniques. A type of small spectrometer adjusted for helium detection is commonly associated with vacuum systems in laboratories and industry. Connected to an evacuated system, it is an efficient and reliable aid for locating air leaks. In searching for a leak, a small jet of helium is played over the exterior of the system at the suspected joint or leakage area. When the exact point is reached, helium is sucked in along with the air, and the spectrometer sounds an alarm. The sensitivity of the technique is so great that an air leak can be detected, even if hundreds of thousands of other leaks of the same magnitude are present. (J.H.Be.)

RADIATION MEASUREMENT

Radiation detection is concerned with a great variety of atomic and subatomic particles moving at different speeds and with electromagnetic waves of different wavelengths moving always at the speed of light. Both waves and particles emanate from the Sun, other stars, naturally occurring radioactive elements, radioactive isotopes produced synthetically, nuclear reactors, nuclear fission, and in general from interactions between colliding particles, between waves and particles, and between bulk matter and particles or waves.

The particles considered in this context are long-lived electrons, protons, alpha particles (*i.e.*, helium nuclei), neutrons, several hundred short-lived subatomic particles, and all antiparticles. The whole spectrum of electromagnetic waves is also considered in this context, from long radio waves through light waves, X-rays, to the shortest of gamma rays.

For details of the phenomena treated here in general terms relevant to radiation detection, see *RADIATION; MATTER; ATOMS: Radioactivity*.

The fundamental mechanism underlying the operation

of all radiation detectors is the dissipation of energy by a charged particle in a suitable medium and the distribution of this energy among atoms and molecules of the detecting material. Electromagnetic waves and neutral particles that react only weakly with many detection mediums must first interact with some suitable material in a way that will produce a charged particle, which can then in turn dissipate its energy in the detection media. The essential concept of detection lies in the fact that energy is provided by the radiation, and in this discussion it is therefore appropriate first of all to consider general aspects of matter and energy in relation to the charged particles that have already been mentioned and to electromagnetic waves and neutrons; following this, the characteristics of the various types of radiation are described and, finally, the detectors themselves are reviewed briefly.

THE STRUCTURE OF MATTER AND ITS INTERACTIONS WITH RADIATION

A normal atom consists of a central nucleus, composed of electrically neutral neutrons and positively charged

protons, around which orbit several negatively charged electrons. The number of electrons equals the number of protons in the nucleus, the negative charge on each electron just balancing the positive charge on each proton, so that the atom is electrically neutral; this number is called the atomic number of the atom, Z , and determines its chemical identity. Electrons around the nucleus exist in stable groups of orbits, the innermost, called the K shell, containing two electrons, the next, the L shell, containing eight electrons when it is complete, and each larger shell, M , N , O , P , etc., being complete with larger numbers of electrons. Each orbit corresponds to a definite state of energy, and movement of an electron from one orbit to another can take place only by the emission or absorption of a fixed amount of energy, an amount that depends on the initial and final orbits. It takes energy to move an electron away from the nucleus. When an electron is removed entirely from the atom, excess energy can be absorbed by it in such a way that this excess is manifested as kinetic energy (motion) of the free electron. A convenient unit of energy for describing atomic phenomena is the electron volt (eV), which is equal to 1.6×10^{-12} erg. The minimum energy needed to remove an outer electron from its orbit is called the ionization potential (E_i) and is about 15 electron volts for atoms in the gaseous state. To eject one of the innermost electrons from the innermost or K shell, a minimum energy, E_K , of much greater value is needed, and E_K is approximately equal to 10 times the square of the quantity, atomic number minus one ($E_K = 10[Z - 1]^2 \text{ eV}$). An atom from which an electron has been removed is left with a positive charge and is called a positive ion.

Energy of
ionization

The energy required to ionize an atom can be provided either by collision with a charged particle, such as an electron or a proton, or by absorption of electromagnetic radiation in the form of light, X-rays, or gamma rays. In the latter type of interaction, electromagnetic energy behaves as though it existed in packets, or quanta, of energy proportional to the frequency of the radiation. Such quanta are called photons. Blue light, for instance, has a quantum energy of about three electron volts, whereas photons of deep-red light of twice the wavelength and half the frequency interact as quanta of 1.5 electron volts. An X-ray photon capable of providing just enough energy to remove one of the K electrons from an atom of argon, ($Z = 18$), has an energy of 3,000 electron volts. A photon of higher energy than E_K removes one of the K electrons and provides an excess kinetic energy to the electron, but it is rather less likely to cause ionization by photoelectric absorption than radiation having a quantum energy just equalling E_K ; the probability of interaction by this process decreases as the photon energy increases. Usually, radiations of the highest frequencies and photon energies are the gamma (γ) rays. The probability of photo-ionization as a function of photon energy is expressed as the effective cross-section area presented to the radiation by each atom. As noted earlier, the unit of cross section is the barn, which is equal to 10^{-24} square centimetre.

When a photon of high energy strikes an atom, it can remove an electron by a scattering process called Compton scattering, the energy of the primary photon being shared between the released electron and a scattered photon. The cross section for Compton scattering is proportional to the number of electrons in the atom and inversely proportional to the square root of the photon energy.

A fundamental mode of interaction for high-energy photons is by pair production, in which a photon of energy slightly greater than 1,000,000 electron volts (one million electron volts, abbreviated MeV) materializes into an electron and its antiparticle, a positive electron, or positron, in the proximity of an atomic nucleus. This interaction is possible because of the equivalence of matter and energy first enunciated by Albert Einstein in his theory of relativity (*i.e.*, energy equals mass times speed of light squared: $E = mc^2$). An electron (or a positron) of mass m_0 has a self-energy $m_0 c^2$ equal to just over 500,000 electron volts (in fact, 0.51 MeV), and a photon of energy 1.02 MeV can thus provide the energy for two electron masses, one negative and one positive, because the net charge must

remain zero. The cross section—*i.e.*, the probability—for pair production increases as the square of the atomic number of the target atom and roughly as the square of the excess energy (photon energy less 1.02 MeV).

Ionization caused by a charged particle colliding with an atom is a much less well-defined process than those described above, and electrons may be ejected with a range of energies depending on the mass and energy of the incident-charged particle. The average energy abstracted from the particle is about twice the ionization potential of the atom ionized, and the symbol w is used for this parameter (a constant that is characteristic for different conditions); w , the average energy per ionizing event, depends to a slight extent on the mass and energy of the incident particle. The probability of ionization at collision is much larger for slow-moving particles; therefore, as an energetic charged particle traverses a given thickness of material, it is slowed down more and more rapidly as energy is dissipated in the ionizing process, until all the energy is lost and the particle is absorbed. Massive particles, such as protons, which have a mass about 1,800 times that of an electron, are not greatly deflected by the electron structure of the atoms through which they pass and a fairly definite range for them can be assigned, depending on their initial energy. Electrons, on the other hand, are easily deflected; a beam of electrons initially having the same energy (*i.e.*, being monoenergetic) undergoes exponential absorption as it passes through matter, owing to electrons' being scattered out of the beam. A maximum range, however, can still be measured.

Neutrons, having no electric charge, cannot interact with the electron structure of atoms but can penetrate the nucleus and cause a reaction. In some cases, the disturbed nucleus splits apart, as in the case of the uranium isotope of mass 235 (^{235}U), which breaks up into two fission fragments carrying kinetic energy of 150 MeV. In other cases, a charged particle, either a proton or an alpha particle (α ; a helium nucleus) is ejected; for example, a boron-10 (^{10}B) nucleus ejects an alpha particle, and a lithium-7 nucleus is left, after reaction with a neutron. The reaction is written: $^{10}\text{B} + n \rightarrow ^7\text{Li} + \alpha$ (2.5 MeV); or $^{10}\text{B}(n, \alpha)^7\text{Li}$. Sometimes a neutron is absorbed by a nucleus. When a stable nucleus is formed by absorption of a neutron, the excess energy is released as a gamma ray. Some nuclei that result, however, are unstable and decay by what is called radioactive emission of electrons (usually referred to as beta [β] particles) and gamma rays. The radiation resulting from such neutron capture and reaction appears many seconds, days, or years later. In the other examples mentioned, the radiation is prompt; *i.e.*, it is emitted in a time less than a nanosecond (10^{-9} second) after the reaction.

In one class of interaction, an elastic collision takes place, and the energy of the neutron is shared between a scattered neutron and a projected nucleus.

Neutron
reactions

DETECTION PROCESSES AND DETECTION MEDIUMS

The distribution of energy among the atoms and molecules of a suitable detection medium is the fundamental process in a radiation detector.

A charged particle (electron, proton, alpha particle, or fission fragment) of energy E that dissipates all its energy in a gas, by knocking electrons out of atoms, leaves a column of positive ions and free electrons along its track. The number of such electron-ion pairs produced is equal to the energy E , divided by the value of w , the energy per ion pair appropriate to the gas and the particle. If electrodes are set up on either side of the track, to produce an electric field, free electrons are attracted to the positive electrode, or anode, and positive ions are attracted to the negative electrode, or cathode. If all of the separated ions and electrons are collected, the electric charge available for measurement is equal to E/w multiplied by e , the electron charge, of value 1.6×10^{-19} coulomb (unit of charge). For an energy of 1,000,000 electron volts and energy per ion pair of 30 electron volts, the charge collected would be 5×10^{-15} coulomb. Because the minimum value of a pulse of electric charge that can be measured by available electronic apparatus is about 1,000 electron charges (1.6×10^{-16} coulomb), an ionization chamber can be used

for detecting the passage of a charged particle that dissipates a minimum energy of about 30,000 electron volts in the detection medium; *i.e.*, the gas in the chamber.

One source
of charged
particles

The charged particle providing energy to ionize the gas may be produced by decay of a radioactive material emitting an alpha or beta particle; and the radioactive source may be placed outside the detector, so that the radiation must pass through a suitably thin portion of the chamber wall (a window) to reach the gas. If the absorption of particle energy in a window would be inconveniently large, the source is mounted inside the detector, directly in contact with the gaseous detection medium. In some circumstances, the radioactive material is available in the form of a gas—*e.g.*, carbon dioxide with carbon-14 ($^{14}\text{CO}_2$)—which can be mixed with the ionization-chamber gas or can itself be used as the detection medium.

When the charged particles are produced as a result of gamma ray or neutron interactions, similar considerations apply; the interacting material may be in the form of a radiator outside the detector, inside the detector but separate from the detection medium, or distributed throughout the detection medium. For example, a neutron detector might consist of an ionization chamber containing a layer of boron-10, or it might be made by filling an ion chamber with boron trifluoride containing boron-10 ($^{10}\text{BF}_3$), a gas at room temperature. In either case, neutron interactions would be detected by ionization produced in the gas by the $^{10}\text{B}(n, \alpha)$ reaction.

Ionization detection. A detection system meant to produce electrical signals when a particular type of radiation is present thus consists of a source of radiation, an interacting medium (for neutrons and gamma rays), and a detecting medium together with some means of converting the energy dissipated in this material into the required signal. Such an active detector may make use of ionization and charge collection in the detection process; the ionization medium may be a gas or may be a suitable semiconducting solid. The class of detectors comprises ionization chambers and conduction counters.

Geiger-Müller counter tubes. In some gas-filled devices, a sufficiently high electric field is applied to cause the free electrons produced by the primary particle to move sufficiently fast to ionize more atoms, thereby increasing the original charge by the process of gas multiplication. Proportional counters use this process to give internal amplification factors of up to 1,000,000 times while still giving an output proportional to the initial signal. At higher values of gas multiplication, complex processes come into play that give a large output signal from the smallest levels of initial ionization, and the output is then independent of the primary signal. Such tubes are called Geiger-Müller counter tubes.

Spark chamber. A gas detector using high values of gas multiplication is the spark counter, in which a spark jumps between two electrodes along the track of an ionizing particle. Because the spark indicates the position of the particle, assemblies of spark counters are arranged inside spark chambers to indicate the paths of penetrating particles by observation of the sparks produced.

Cloud and bubble chambers. Rather less active track delineating devices depending directly on the production of ions along the path of the particle are cloud chambers and bubble chambers. In the former, vapour from a supersaturated atmosphere of water or alcohol condenses on ions to form visible droplets, which can be photographed. In the bubble chamber, a superheated liquid is used, and ions form nuclei for local boiling, again giving a visible track.

The detailed physics of the various types of ionization detector summarized above depends to a large degree on the behaviour of electrons and ions under the applied electric field.

Fluorescent detectors. A second main class of radiation detectors depends on the conversion of the distributed energy of the primary ionizing particle into light, which is then used to generate photoelectrons (electrons emitted from a surface as a result of light falling on that surface) from the cathode of a photomultiplier tube. The photoelectron current is multiplied in the tube to give

an adequately large output signal. Detection mediums that convert the energy of moving electrons into light are known as phosphors. The light of a television picture tube is produced by the impact of energetic electrons on a phosphor deposited on the inner surface of the faceplate of the picture tube. The process of light production is known as fluorescence. Early examples of its use in radiation detection, albeit with visual rather than instrumental observation of the light, are the detection of X-rays by the German physicist Wilhelm Conrad Röntgen in 1895 using barium-platinocyanide, and the detection of alpha particles by observation of the scintillations produced in zinc sulfide by the British physicist Ernest Rutherford during the early 1900s.

Fluorescence

As well as the rather transient effects so far considered, the passage of an ionizing particle through certain types of material can give rise to more or less permanent changes along the track. A familiar example is the photographic film. Perhaps less well known is the blackening of glass under intense irradiation from beta particles or gamma rays. The degree of darkening either of film or glass can be used to determine the total exposure of the sample to radiation, and badges containing sensitive substances are sometimes worn to indicate the amount of invisible radiation to which their wearers are exposed.

The properties of ionization mediums. *Gases.* Once a gas has been ionized, the free electrons must be separated from the positive ions by an electric field if a useful charge signal is to be produced. In the absence of a field, the attraction between positive and negative charges, combined with the random motion of the gas molecules, causes the oppositely charged particles to recombine. At room temperature, molecules of a gas are in constant random motion with an average kinetic energy of 0.04 electron volt. This energy is proportional to the absolute temperature of the gas. For a given mass of gas in a fixed volume (*i.e.*, a given gas density), the pressure exerted by the gas on the walls of the vessel is proportional to the absolute temperature and to the density. The average distance travelled by a gas molecule before it collides with another molecule is called the mean free path and is inversely proportional to the number of molecules per unit volume.

In a gas at the standard temperature of 0°C and the standard pressure of one atmosphere, one cubic centimetre contains 2.7×10^{19} molecules, and the mean free path (symbolized by the Greek letter lambda, λ) is about 2×10^{-5} centimetre.

Between collisions with gas molecules, a positive ion obtains energy from an electric field produced between electrodes in an ion chamber and thus is accelerated toward the negative electrode, or cathode. This energy is small compared with the average kinetic energy that the ion possesses in common with the surrounding gas molecules, and because the ion and the molecules are similar in mass, velocity (the downfield velocity component) is lost at each collision. The positive ion thus drifts toward the cathode in a series of steps that have an average value proportional to the field strength multiplied by the square of the free time between collisions. The drift velocity is proportional to this average step distance divided by the free time. Since the free time is inversely proportional to the mean free path, the drift velocity, W^+ , is proportional to field strength, E , multiplied by the mean free path, λ . At a constant temperature, mean free path is inversely proportional to the gas pressure, p , and the ion drift velocity can be written $W^+ = \mu E/p$, in which the constant symbolized by the Greek letter mu, μ , is called the mobility of the ion for the particular gas. With the electric field, E , expressed in volts per centimetre and the velocity, W^+ , in centimetres per second, the mobility, μ , is given in cmsec per V/cm, otherwise written as centimetres squared per volt-second.

Drift
velocity

The electric field between plane parallel electrodes is equal to their potential difference (P.D.) divided by their spacing. With a spacing of x cm and a P.D. of v volt, $E = v/x$ volts per centimetre, and for a gas pressure of p atmospheres, the ion drift velocity (see above) is $W^+ = \mu(E/p)$, which, substituting for E , gives $W^+ = \mu v/p x$ centimetres per second; the time t for the ion to travel a distance s centimetres is $t = s/W^+ = s p x / \mu v$ second (*i.e.*,

the distance multiplied by spacing and pressure, divided by field, multiplied by mobility). For an ion formed close to the anode, so that $s = x$, the transit time is proportional to the square of the electrode spacing. With argon at one atmosphere, an applied voltage of 500 volts and a spacing of five centimetres, E is 100 V/cm; W^+ , for the argon ion Ar_2^+ , is 190 cm/sec; and the transit time is 26 milliseconds. With a gas filling pressure of one-tenth atmosphere, the velocity would be 10 times higher and the transit time 10 times smaller.

A free electron, having a mass only $1/70,000$ of that of an argon molecule, cannot transfer much kinetic energy to a gas molecule in an elastic collision, being somewhat analogous to a table tennis ball bouncing off a cannon ball. The energy acquired by the electron from the electric field thus accumulates, and the agitation energy becomes much larger than that of the thermal energy (heat) of the gas. The electron changes direction at each collision with a molecule, so that the motion remains random; with a superimposed drift velocity, as with the ion, and, by a similar argument, the drift velocity, W^- , is found to be proportional to field multiplied by mean free path. The mean free path of an electron in a gas, λ , is affected by the value of E , because this determines the agitation energy, and a simple value of mobility is not applicable. In fact, it can be shown that the drift velocity is proportional to the field E multiplied by electron mean free path λ divided by the square root of the parameter symbolized by the Greek letter eta, η , which is the ratio of average agitation energy of electron and gas molecule: $E\lambda/\eta^{1/2}$. A free electron thus has an agitation energy of 0.04η electron volt in a gas at room temperature, and, under sufficiently high values of electric field, this energy can increase to a value at which inelastic collisions with molecules occur, when the electron transfers energy to the structure of the molecule. In a monatomic gas such as argon, the lowest level at which energy can be transferred from an electron is 11.57 electron volts, so η can rise to about 300. In a more complex gas, such as carbon dioxide, energy can be exchanged at low values with the vibrational and rotational energy systems of the polyatomic molecule, keeping the electron agitation energy down to a low value for fields below 2,000 volts per centimetre.

Mean free
path in
argon

The mean free path of free electrons in argon decreases markedly as the agitation energy increases. As a result, the drift velocity of electrons in pure argon at a pressure of one atmosphere does not exceed 10^6 centimetres per second. The admixture of a small proportion of a complex gas to argon reduces the agitation energy of electrons, however, and allows much higher values of drift velocity to be obtained. In an ion chamber containing argon plus 1 percent nitrogen, at one atmosphere, an electron has a drift velocity of 0.5×10^6 centimetres per second in a field of 100 volts per second and crosses a distance of five centimetres in 10 microseconds (10^{-5} second). A knowledge of the value of drift velocity and the way it depends on electric field strength is necessary to understand the mechanism of ionization detectors.

The effect of small admixtures of other gases to a noble gas such as argon has been described in relation to electron drift velocity. A similar profound effect is produced on the ionizing efficiency of fast charged particles.

The value of w , the energy per ion pair abstracted from, say, an alpha particle in pure neon, is 36.3 electron volts. (The ionization potential of neon is 21.5 electron volts.) If, however, about 0.1 percent of argon is added to the neon, w is reduced to 26.3 electron volts, which is the energy per ion pair for pure argon. The improvement in energy transfer is caused by the fact that much of the energy abstracted from the primary particle in pure neon is used in exciting a level in the neon electron system that requires 16.6 electron volts but that does not result in ejection of an electron. This excited state in neon lasts for a long time (on the time scale of atomic phenomena) and has an average lifetime of about a millisecond, after which it decays by emission of an ultraviolet quantum. Such long-lived excited conditions are called metastable states. The mean free time between collisions is about 10^{-7} second, so that a neon atom excited into its metastable

state will undergo many collisions in its life, and in the gas mixture containing argon it will certainly collide with an argon atom, having an ionization potential of 15.7 electron volts. Because the excitation energy, E_e , of the neon atom is 16.6 electron volts, there is a high probability that the energy can be transferred to the argon atom, causing ionization. Such collisions of the second kind, as this type of energy transfer is called, greatly increase the efficiency of production of ionization in a mixture of a noble gas with another gas having an ionization potential less than E_e , the energy of excitation of the metastable state of the noble gas.

The same principle that allows energy transfer from a metastable state of one molecule to ionize a second molecule allows a charge transfer from a positive ion to a molecule of lower ionization potential. Thus, in an argon-alcohol mixture, collision between an argon ion and a molecule of ethyl alcohol results in neutralization of the argon ion by extraction of an electron from the alcohol molecule. This process is of particular importance in understanding the operation of a Geiger counter tube.

At high values of electric field, electrons obtain high average energy, the instantaneous value being distributed statistically about the average. Occasionally an electron attains an energy larger than the ionization potential of the gas molecule with which it collides, and ionization occurs. The actual number of ions produced by an electron in moving one centimetre through a gas under the influence of a field E (in units of volts per centimetre per atmosphere [V/cm/atm]) is given by a coefficient, called the first Townsend coefficient and symbolized by the Greek letter alpha, α . Values are given in Table 5, as is the effect of adding argon to neon.

Table 5: Townsend Coefficient for Various Gases

E (V/cm/atm)	α , ion pairs per centimetre			
	argon	neon	neon + 0.1% argon	air
3,800	0.2	6	120	—
7,600	3.8	38	230	—
19,000	40	200	380	—
38,000	530	530	830	38

In such high electric fields, electrons produced by an ionizing collision are themselves accelerated and cause further ionization, and the tertiary electrons thus produced go on to produce further ionizing collisions, an electron avalanche rapidly building up. The process can be visualized by considering two parallel electrodes in a chamber filled with argon at a pressure of one atmosphere and supporting a voltage difference of just over 10,000 volts. At this field, the first Townsend coefficient in argon produces about 10 electron-ion pairs per centimetre. An electron produced at the cathode—for instance, by an incident ultraviolet photon—is accelerated toward the anode; after passing through one millimetre of gas, it is probable that one ionizing collision has occurred, and so there are now two electrons; after two millimetres each electron has ionized again, and there are four electrons. This process continues, and, at the n th millimetre, there are 2^n electrons; when the avalanche reaches the anode it contains 2^{10} electrons ($2^{10} = 1,024$). This analysis is only illustrative. An accurate analysis shows that an electron formed at the cathode under the given conditions produces 150 times more ion pairs on its way to the anode than does an electron formed halfway between the plates. Some possible arrangements, therefore, are not all suitable for use in a gas multiplication detector, because the amount of multiplication varies markedly with the position of the initial ionization in the chamber. A cylindrical geometry, consisting of an anode wire stretched along the axis of a cylindrical cathode, provides an electric field that has a high value close to the anode surface and falls away rapidly as distance from the anode increases; this arrangement allows of controllable gas multiplication in the proportional counter.

At higher values of electric field than the 10,000 volts per

Electron
avalanche

centimetre per atmosphere applied across a parallel plate system in an argon filled chamber that gives a coefficient α equal to 10, the initial part of the electron avalanche is so intense that ultraviolet photons of high enough energy to ionize the gas are produced, generating electrons at a little distance from the primary region. A second bead of intense ionization is produced, generating photons in its turn, and the discharge is propagated across the gap between the electrodes to form a spark, in a time of about 10^{-8} second, short compared with the transit time of an electron, which is about one microsecond (10^{-6} second). Providing the high voltage supply to the electrodes is capable of supplying the required current without reduction in voltage, the spark becomes a sustained discharge, fed by electrons generated from the cathode by photoemission (from the ultraviolet photons produced in the spark) and by electrons produced at the cathode by the arrival of positive ions. An ion of argon having a potential energy of 15.7 electron volts, extracts an electron from the metal of the cathode against the surface force (symbolized by the Greek letter phi, ϕ) of phi electron volts and becomes a neutral atom with an excitation energy of $(15.7 - \phi)$ electron volts. All this happens at a distance of about 5×10^{-8} centimetre from the surface, and in a time of 10^{-12} second the excited atom strikes the metal. If the excitation energy is greater than the surface force, ϕ , which is called the work function, then there is some probability that a further electron will be extracted and move into the discharge. Typical values of the work function lie around four electron volts, and, because $\frac{1}{2}E_i$ (E_i is the ionization potential) for many gases is greater than five electron volts, this process is quite effective in generating electrons.

Certain complex gas molecules, such as ethyl alcohol, dissipate the excitation energy left after neutralization among the vibrational states; in this case, no electron is extracted.

If the high voltage supply to the electrodes is not capable of supplying a continuous current to the discharge, the spark persists until the charge drawn from the capacitance (*i.e.*, the property of nonconduction that allows storage of charges; here, the capacitance is formed by the electrodes and the connections to the system) causes the field to drop below the level at which ionization by collision can occur: the spark is then extinguished.

The processes described above are of importance in Geiger counters and spark chambers.

Solids. In an ionization chamber using gas as the detection medium, no current passes between the electrodes in the absence of ionization in the gas; the neutral gas is an insulator. It is equally difficult, however, to make a gas detector with adequate stopping power to absorb the energy from a penetrating particle, such as a high-energy electron, or with a high enough atomic number and atomic density to provide a high detection efficiency for gamma rays, and it would be desirable to use a solid detection medium. In such solid material, atoms are relatively immobile, and their electronic structures interact with each other to such an extent that it is not possible to assign specific outer orbital electrons to a particular atom. The concept of ionization is thus not as clear-cut as it is with a gas, in which the atoms or molecules are essentially independent; furthermore, in metals and semiconductors at room temperature, some electrons are always free to move under the influence of an electric field, and so these materials show electrical conductivity. An insulating solid has the outer electrons sufficiently firmly bound to the array of atoms so that they are not free to move. Absorption of energy from a photon or a charged particle may break the bonds holding an electron in place, and it is then free to move in a field. The vacancy thus created in the electron structure of the atomic array leaves a net positive charge in the locality, which charge is referred to as a positive hole. The imbalance in forces produced by an electric field causes a neighbouring valence electron to move toward the anode, filling up the original vacancy; the hole has now migrated one step toward the cathode. Conduction in an insulator can thus take place by migration of holes and electrons. In some materials, however, the holes have low or zero mobility.

The minimum energy needed to free an electron from

the valence band of energy to the conduction band of energy, so that it can move in an electric field, is called the band gap, which is about five electron volts in diamond and in silver chloride. In semiconductors, the band gap is lower; in silicon, it is 1.1 electron volts, and in germanium it is 0.72 electron volt. In these materials, which are used for making transistors, the conductivity is lower as the material is purer (pure silicon has a resistivity in excess of 100 megohms at room temperature, between opposite faces of a cube with sides of one centimetre). This conductivity results from the presence of electrons raised into the conduction band by the statistical fluctuation of thermal energy and corresponds to an electron density of 10^{10} per cubic centimetre and a lifetime of 100 microseconds before the electron is trapped. Each electron produced under these circumstances generates a hole, so that the hole density in silicon of a high purity is also 10^{10} per cubic centimetre at room temperature. High-purity material in which all charge carriers (both electrons and holes) are thermally generated is said to have intrinsic conductivity. The rate of generation is 10^{14} per second per cubic centimetre at room temperature.

The movement of a free electron in a solid under the influence of an electric field is similar to the description given for the movement of an ion in a gas; energy is obtained from the field and is lost when the electron is scattered by the pattern of forces formed by the interlocking electron bonds that hold the solid together. The drift velocity thus turns out to be proportional to the product of field and mean free path, as in the case of the gas ion, and a mobility, μ , can be assigned. For silicon at room temperature μ_- is 1,350 centimetre squared per volt-second, whereas μ_+ , hole mobility, is 500 centimetres squared per volt-second.

The range of an electron of initial energy of two million electron volts in solid silicon is 0.5 centimetre, compared with 500 centimetres in argon gas at atmospheric pressure, and the energy per electron-hole pair, w , is 3.5 electron volts. A conduction counter made from a one-centimetre cube of intrinsic conductivity silicon could thus be used to absorb the energy from high-energy particles. An energy of 250,000 electron volts absorbed generates about 75,000 electron-hole pairs, giving a collected charge of 1.2×10^{-14} coulomb, which is well above the limit of detection set by amplifier noise. With a potential difference of 100 volts between opposite faces of the cube, this charge is collected in a time of about 10 microseconds.

During this time, however, 10^9 charge carriers generated by thermal energy have been collected, and this number is not constant for each 10-microsecond period but is subject to statistical variation about this average value. For 5 percent of the time the value will deviate from the mean by more than twice the square root of the average number; in this case by more than 6×10^4 . If the conduction detector is imagined as a device sampling the charge collected in successive periods of time, each of which is equal to the time taken for charge carriers to cross the block from anode to cathode (10 microseconds in the example considered), then the statistical fluctuation described would make it difficult to identify with any certainty the extra signal caused by the absorption of 0.25 million electron volts from a charged particle in the sensitive volume of the silicon block. In order to reduce this conductivity noise, it is necessary to cool the material because the density of thermally generated carriers is proportional to the thermal agitation energy of the electron in the solid. At the temperature of liquid nitrogen, the density of free carriers is reduced from 10^{10} per cubic centimetre of silicon to effectively zero, and the cooled silicon should then be suitable for detecting electrons.

Unfortunately, it is difficult to make silicon of intrinsic purity, and the impurities that are commonly present decrease the resistivity. Silicon is tetravalent, which means that the outer shell of the atom contains four electrons. In the lattice of the crystalline form in which silicon is normally prepared, each atom shares its valence electrons with four neighbouring atoms, so that each electron pairs with an electron from the adjacent atom. An atom of phosphorus is pentavalent (*i.e.*, has five outer shell elec-

medium

trons); when it is incorporated in the silicon lattice as an impurity, it forms electron pair (or covalent) bonds with the four adjacent silicon atoms. This bonding leaves a spare electron that has a binding energy of only 0.054 electron volt and so is readily freed from its parent atom by thermal energy at room temperature and is free to take part in conduction. Trivalent impurities, such as boron, bind three adjacent atoms with covalent bonds, leaving a positive hole that can drift away under thermal excitation and having an effective binding energy of 0.08 electron volt.

Silicon of the highest purity contains about 10^{13} atoms per cubic centimetre of excess impurity of either type, giving rise to resistivity of about 10^4 ohms per centimetre cube at room temperature, which increases to about 10^6 ohms per centimetre cube if the temperature is lowered to 77 K. Material with excess of pentavalent (donor) impurity conducts by electrons and is called an *n*-type semiconductor. With trivalent (acceptor) impurity and conduction by hole migration, the material is called a *p*-type semiconductor.

Various methods have been developed to manufacture materials with low electronic conductivity, with *p*- and *n*-type layers, and with *p-n* junctions. Although silicon and germanium are by far the most commonly used materials for solid-state ion chambers, the classical work in this area was carried out on single crystals of silver chloride cooled to 77 K.

Scintillation counter. The distributed energy of a charged particle may be used to cause the emission of light from a suitable medium, the absorption of this light by a cathode, called a photocathode, produces electrons (photoelectrons) that escape from the surface of the cathode into the evacuated interior of an electron tube called a photomultiplier. The photoelectrons are accelerated by an electric field and strike an electrode coated with secondary emitting material. Each electron striking this surface with an energy of 1–500 electron volts knocks out secondary electrons that can be accelerated in turn onto a second electrode, or dynode, as the coated electrodes are called, and so on through a series of dynodes that are at successively more positive potential.

With a secondary emission coefficient of four electrons per primary electron of energy 100 electron volts, a 10-dynode multiplier gives a gain of four raised to the 10th power, (4^{10}), which is slightly more than 1,000,000. Each primary photoelectron produced by the absorption of a light photon then produces at the anode of the tube a pulse of charge containing 1,000,000 electrons and of magnitude 1.6×10^{-13} coulomb. Two primary electrons striking the first dynode simultaneously produce a pulse of 2,000,000 electron charges at the output, and so on. The photomultiplier is a linear amplifier—*i.e.*, giving an output proportional to the primary photoelectron signal. A light-emitting detection medium (a phosphor), coupled to the photocathode of a photomultiplier operated to give a suitable value of gain, forms a scintillation counter; and in this type of detector the useful primary signal, comparable to the electrons and ions formed along the track of a particle in a gas, is the emission of photoelectrons. A high yield of photoelectrons for a given energy dissipated in the phosphor requires a photocathode of high quantum efficiency (efficiency measured by photoelectrons per incident photon), coupled with minimum light loss to a transparent phosphor that converts ion excitation energy into photons, with high efficiency. The wavelength of the fluorescent light must match the photocathode efficiency curve. In practice it is found that the most useful photocathodes give high quantum efficiency in the blue region of the spectrum and that the most useful phosphors emit blue fluorescence.

Photocathodes. Cathodes useful for scintillation counters are formed by semiconducting compounds of antimony and the alkali metals cesium, sodium, and potassium. Most commonly used are cesium-antimony (Cs_3Sb) and cesium-potassium antimony (K_2CsSb).

Secondary emitters. The two cathodes described above are good secondary emitters and are conveniently formed in photomultiplier tubes by reacting the alkali metals (cesium and potassium) with antimony-coated dynodes at

the same time as the cathode is formed. Another useful material is beryllium oxide.

In a photomultiplier tube, dynodes are arranged so that an electric field accelerates secondary electrons from the surface and directs them to the next dynode in line. One method of doing this is to make a dynode in the form of parallel inclined slats with the upper plane covered by a fine, transparent mesh. Electrons pass through the mesh of the first dynode to strike the inclined slats. The field from the mesh of the second dynode, spaced two millimetres below, extracts the secondaries from the space between the slats of the dynode of origin and accelerates them through the mesh to strike the second dynode slats, and so on. The efficiency of extraction of secondary electrons in this "venetian-blind" geometry lies between 90 and 95 percent.

Other types of dynode in common use are the box-and-grid and the linear-focussed structure. The latter consists of carefully shaped electrodes arranged in facing but offset pairs and designed to direct the secondaries from their point of origin to the next dynode without producing low-field regions, which are inherent in the venetian-blind and box-and-grid systems.

Photomultiplier tubes. The great majority of scintillation counters use end-window photomultiplier tubes having semitransparent photocathodes of diameter ranging from two to 30 centimetres. All of these employ a dynode system fitting into a neck of five centimetres diameter, the cathode being spaced away from the first dynode by a distance of about half the end-window diameter. An electron optical system provides shaped electric fields to direct photoelectrons into the first dynode, and larger tubes in general require higher voltages between cathode and first dynode. With the gain of an individual dynode varying as the seven-tenths power of the interdynode voltage, a 10-dynode tube has a gain varying as the seventh power of the overall tube voltage, so that it is necessary to provide stable high voltage supplies to operate photomultiplier tubes at constant gain.

The secondary emission coefficient of dynode surfaces is slightly dependent on temperature, and most photomultiplier tubes decrease in gain by about 0.5 percent as the temperature (around 20° C, or 68° F) increases by one degree Celsius (1.8 degrees Fahrenheit). For accurate measurement, it is therefore necessary to hold the system at constant temperature or to provide a circuit that makes slight adjustments to the tube operating voltage to keep the gain constant. The transit time of an electron from the cathode to its arrival at the anode as a pulse of charge depends on the tube design and the operating voltage.

Because scintillation counters are often used to measure the strength of small sources of radioactive isotopes, it is necessary to construct the photomultiplier tube with the minimum amount of radioactive contamination. In practice this condition requires the use of glass containing the minimum amount of potassium-40, which is a beta- and gamma-emitting isotope, and sometimes calls for the tube envelope to be made, as far as possible, of fused silica.

Phosphors. In a scintillation counter, a large, transparent block of phosphor is coupled to the end window of a photomultiplier tube and surrounded by an efficient diffuser to ensure efficient transfer to the photocathode of the fluorescent light provided by particle excitation. With such an arrangement the energy, absorbed from a charged particle that results in the emission of a single photoelectron from the cathode of 24 percent quantum efficiency for three-electron-volt photons, can be measured. This figure is analogous to w , the energy per ion pair, for a conduction medium, and the most efficient phosphors in use require about 200 electron volts to give a single photoelectron.

One useful class of phosphors is provided by fluorescent organic materials, such as anthracene and naphthalene, that can be made as transparent crystals of useful size. As molecules excited by absorption of energy from a primary particle return to their ground state, light is emitted, and the decay time of this fluorescence is a few nanoseconds (10^{-9} second). If a small amount of anthracene is dissolved in naphthalene, however, the composite crystal emits light characteristic of anthracene fluorescence—but

Types of
dynodes

Photo-
multiplier

with the longer decay time of naphthalene. It appears that energy is transferred from molecule to molecule without radiation until radiation occurs, and this will take place from molecules having the highest emission probability.

This effect is exploited in liquid and plastic phosphors, which consist of efficient organic fluors, such as p-terphenyl dissolved in toluene or in polyvinyl-toluene.

Quenching

All of these materials show a marked loss of efficiency as the rate of energy loss from the primary particle increases, a loss that has been explained in terms of nonradiative dissipation of energy by damaged molecules. The reduction of fluorescent efficiency by competing routes for energy dissipation is called quenching; oxygen dissolved in the solvent of a liquid phosphor must be carefully removed to prevent quenching.

Inorganic phosphors are transparent insulating crystals containing a small proportion of a suitable impurity. Production of an electron-hole pair by an energetic ionizing particle occurs as described above. The hole is neutralized by extracting an electron from a nearby impurity centre, and this ionized centre in turn attracts the free electron from the conduction band to form a neutralized but excited impurity centre. The excess energy is emitted as a photon of energy that is less than the band-gap of the crystal and dependent on the properties of the impurity.

The phosphor in greatest use in scintillation counters is thallium-activated sodium iodide; this can be grown into single crystals up to 75 centimetres (30 inches) in diameter and 25 centimetres (10 inches) thick. The material is extremely hygroscopic (moisture absorbing) and must be protected from the water vapour in the atmosphere by mounting it in a hermetically sealed can, with a window for coupling to a photomultiplier tube. In order to maximize the collection of fluorescent light, all the surface of the crystal except that facing the window is covered with a tightly packed thin layer of white diffusing titanium dioxide. This method of mounting is applied to many types of phosphor, whether hygroscopic or not.

Non-scintillating phosphors. Some phosphors are used for radiation detection because of their ability to store up energy in the crystal lattice over a period of exposure to nuclear radiation. Such materials are inefficient scintillators because the metastable state of the excited impurity centre is long-lived at room temperature and requires thermal excitation to temperatures perhaps 200°–300° C (392°–572° F) above room temperature to cause de-excitation. Calcium fluoride activated with manganese is one such phosphor. Energy stored in the lattice is estimated at some later time by rapidly heating the material, which starts to emit light at a temperature of about 200° C. The light rapidly rises in intensity to a peak at about 260° (500° F) then falls off as the temperature rises further and all the excited states are returned to ground level. The light output from the thermoluminescent phosphor is observed by a photomultiplier tube and plotted against the temperature of the sample. The total amount of light emitted is proportional to the energy absorbed.

The energy dissipated in a solid can be stored, after a fashion, by disrupting the bonds holding atoms to their neighbours, thus changing their potential energy. A special glass made from equal proportions of aluminum and lithium phosphate incorporating a few percent silver phosphate is nonfluorescent under ultraviolet light. Exposure to ionizing radiation breaks the silver atom bonds and produces silver impurity centres that turn the glass into a phosphor that fluoresces under ultraviolet light with an intensity depending on the energy dose absorbed. The weak fluorescence is orange in colour, and the intensity is measured in a photoelectric instrument.

Photographic emulsion

A mechanism similar to the above operates in photographic emulsion, in which the bonds of silver atoms to bromine atoms are disrupted by energy absorption. In this material, however, the evaluation technique involves development of the emulsion that causes each grain or small crystal of silver bromine (AgBr) to contain two or three free silver atoms reduced to atomic silver, thus becoming visible. Photographic films are widely used for measuring exposure to radiation, as are thermoluminescent and radiation-activated phosphors.

Ionization counters. The basic detection process, the collection of separated charge carriers produced by energy from a fast ionizing particle, and the properties of conduction mediums, have been described. In the case of a gas, it has been shown that the value of w , the energy per ion pair, is about 30 electron volts but depends on the gas and is modified by small admixtures of other gases. The movement of electrons in the collecting field also depends on the gas composition and pressure.

Detectors using variations of the same principles are pulse ion chambers, silicon and germanium detectors, Geiger counters, spark chambers, and cloud chambers.

Spark chambers, cloud chambers, and bubble chambers. The production of a spark, initiated by the presence of one or more primary electrons, has been described. In a spark chamber, an assembly of accurately parallel plates spaced perhaps one centimetre apart has plates 1, 3, 5, etc. connected together and to electrical ground. Plates 2, 4, 6, etc. are connected via a resistor to a relatively low voltage supply of 100 volts or so and also to a pulsed high-voltage unit, which applies a field of about 20,000 volts per centimetre across the plates in the opposite sense to the low-voltage field when triggered from a coincidence detector. Such chambers are made with dimensions up to three metres on a side and contain up to 80 plates. They are mounted between the poles of large magnets to measure particle momentum by forcing a particle to move in a circular path the radius of which depends on the magnetic field and the particle's mass, velocity, and charge. The gas used in a spark chamber is commonly air.

Spark location is usually obtained by photographing the chamber, but electronic methods of locating the spark within the chamber have also been developed.

A venerable precursor to the spark chamber for track delineation was the cloud chamber, developed by the Scottish physicist C.T.R. Wilson between 1896 and 1912. A chamber with a glass window opposite a movable floor is filled with a gas saturated with ethyl alcohol vapour. Expansion of the chamber volume by rapidly lowering the floor of the chamber, thus increasing its volume and thereby reducing the pressure suddenly, causes supersaturation of the alcohol vapour, which then condenses as droplets on any ions (or dust particles) that are present. With a dust-free filling and a clearing field between electrodes in the chamber, which is switched off when an observation is to be made, droplet-delineated particle tracks show up clearly against the black floor of the chamber and can be photographed. The reset time after expansion is five to 10 seconds, a time that compares unfavourably with the few milliseconds of the spark chamber.

The bubble chamber, developed by a U.S. nuclear physicist, Donald A. Glaser, in 1952, uses a superheated liquid in place of a vapour to obtain better stopping power in the track medium. Diethyl ether, compressed to a pressure of several atmospheres and heated well above the boiling point, remains superheated when the pressure is released, long enough for tiny bubbles to form around the ions in a particle track. Liquid hydrogen is used in neutron detection chambers. Being built up to two metres (6.6 feet) in diameter, bubble chambers, with their large magnet systems, are impressive engineering achievements. Their recycle time is about one second.

The Wilson cloud chamber

APPLICATIONS IN SCIENCE, INDUSTRY, AND TECHNOLOGY

The dissipation of energy by ionizing radiation in matter causes damage, either temporary, as in the ionization of a gas, or more permanent, as when chemical bonds are broken or atoms are displaced from their position in the lattice structure. The unit used for the measurement of radiation dosage is called the rad. This unit corresponds to the dissipation of an energy of 100 ergs per gram of material at the point of interest. Devices for measuring dosage are ion chamber dosimeters, photographic dosimeters; thermoluminescent phosphor dosimeters; and radiophotoluminescent glass dosimeters. The use of a Geiger counter for uranium prospecting is part of general public knowledge. It is one example of an instrument used to detect gamma rays emitted by a radioactive material; it gives an electrical pulse each time a gamma ray interacts

Dosage measurement

in the sensitive volume of the counter tube. Radioactive elements may also emit beta particles, which are high-velocity electrons, and alpha particles, which are positively charged nuclei of helium atoms, and specialized detectors are necessary for these radiations. The distinction between alpha and beta particles, which are components of ordinary matter, and gamma rays is that the latter consist of electromagnetic waves, essentially similar to X-rays and light waves but extending to higher energies and shorter wavelengths.

In nuclear reactors, uranium undergoes fission when bombarded with neutrons, and the two (or sometimes three) fragments of the uranium nucleus fly apart with great velocity, generating heat as they lose energy to the surrounding material. Neutrons are uncharged particles, about 1,840 times more massive than an electron, and are produced in fission and in a number of nuclear reactions. Detectors are needed for the detection and measurement of neutrons and sometimes for fission reactions.

Extraterrestrial radiation

The surface of the Earth is bombarded day and night with cosmic rays, possessing extremely high energy, even after passing through the full depth of the atmosphere. Outside this protective mantle there is a continuous bombardment of ultraviolet rays and X-rays, protons from the Sun and, passing through space and through the Earth as though it were transparent, a cosmic flux of neutrinos, which are almost undetectable uncharged particles produced during radioactive decay.

Scientists seek to detect these different radiations, to measure their energies and to determine the instant at which they interact with instruments, and to measure the total amount of particles or radiation that has passed through a particular position over a period of time. The absorption of radiation may also be used to provide information on the thickness of the absorbing material.

The widespread use of X-rays and radioisotopes in medicine and industry, the lethal concentrations of radioactive material in nuclear reactors, the possibilities of widespread contamination following nuclear warfare, all combine to generate a need for detectors and instruments that measure the degree of hazard existing in any given environment—the so-called health-physics instruments. The possibility of tagging individual molecules with radioactive atoms, and so extending the sensitivity of analytical methods, has produced a huge demand for detectors used in analytical instruments that find application in medicine, biology, and chemical analysis. Improvements in spectrographic techniques both on the surface of the Earth and in satellite environments give rise to a need for detectors of hard (high-energy) ultraviolet radiation, which merges into the soft (low-energy) X-ray region; these in general have to be specially developed for the experiments in hand.

Nuclear physics experiments demand increasingly complex arrays of detectors that are connected together in elaborate computer-controlled systems and that may involve the precise measurement of position of interaction of a particle of known energy and its time of interaction to an accuracy of a fraction of a nanosecond. In the industrial field, the control of nuclear reactors demands specialized detectors, and the application of radioisotopes (radioactive atoms) in thickness gauges and in analytical instruments generates a need for a wide range of equipment. In the search for raw materials for nuclear power, a range of portable instruments involving rugged detectors has become necessary, and, of course, similar instruments merge into the health-physics aspects of civil-defense instrumentation. More complex instruments and detectors are used in geological evaluation of rock strata for the petroleum industry and in the search for other raw materials. (Ed.)

ASTRONOMICAL PHOTOMETRY

Astronomical photometry is a branch of astronomy dealing with the measurement and study of the brightness of celestial objects. In astronomy, the term photometry is most commonly applied to measurements of brightness that extend, in any one observation, over a limited band of wavelengths only, rather than over all wavelengths of light. The relationship of the dominant, or effective, wavelength (represented by λ_0) to the bandwidth being observed (rep-

resented by $\Delta\lambda$) is a ratio ($\Delta\lambda/\lambda_0$) that is typically between one-third and $1/300$. In contrast, the terms radiometry and bolometry, in astronomical usage, are applied to brightness measurements comprising all wavelengths, while the term spectrophotometry is generally used when only a very narrow band of wavelengths is measured at one time; i.e., when the ratio $\Delta\lambda/\lambda_0$ is chosen close to zero. (For the related study of the electromagnetic spectra produced by celestial objects, see the section *Spectroscopy: Astronomical spectroscopy*).

Originally, the role of photometry was to help identify stars in the compilation of star catalogs and charts. As photometric methods became more sophisticated, photometry became a developed branch of astronomy aimed toward the determination of the physical properties of stars; it is also used extensively in studies of most other classes of celestial objects, each of which requires special consideration and treatment or, in some instances, a special technique.

Historical survey. Photometry is one of the earliest branches of astronomy, the variety of brightnesses of the stars and planets having been obvious from time immemorial. Originally, it sufficed to arrange these celestial objects subjectively in sequence from the brightest to the faintest, as was done by Hipparchus around 130 bc. His work was expanded by Ptolemy about 300 years later to include about 1,000 stars. Both men used a system of "magnitudes," in which the brightest stars were ranked first magnitude and the faintest perceptible to the naked eye sixth. Further classification of the naked-eye stars by magnitudes was done in the late 16th and early 17th centuries by Tycho Brahe and Johann Bayer. After the telescope was invented, classification was rapidly extended to fainter stars by Galileo and others. All these early observers employed subjective estimates of stellar magnitude (sometimes using their own terminology and units, such as grades). As a result, there was little homogeneity to their systems.

The need for a comprehensive and consistent set of visually estimated stellar magnitudes was first met by Friedrich W.A. Argelander in several works, culminating with his great *Bonner Durchmusterung* ("Bonn Survey," publisher between 1859 and 1862), a catalog that gave magnitudes for about a third of a million stars in the northern half of the sky, down to about the tenth magnitude. The magnitude intervals were subdivided into 10 subclasses, corresponding closely to the least perceptible differences in brightness as judged by eye; thus, Argelander's magnitude estimates appear in decimal form. For example, 4.3 designates a stellar brightness three subclasses fainter than fourth magnitude. Argelander fitted his magnitude scale to the traditional one of six magnitude classes for the naked-eye stars. This system of magnitudes, while convenient and useful, was entirely subjective in nature and lacked a physical or quantitative definition.

Early in the 19th century, astronomers began to intercompare quantitatively the brightness of stellar images with visual photometers, devices with which the observer matches two star images, one of which may be that of an artificial star, in the field of view of a telescope. Gustav Fechner, a German scientist, observed that the response of the eye was characterized by approximately equal sensation for equal ratios of brightness, while others found that the old magnitude intervals corresponded to brightness ratios of between 2.2 and 2.8—or, in other words, stars of the second magnitude, for example, were from 2.2 to 2.8 times brighter than stars of the third magnitude. The English astronomer Norman Robert Pogson proposed in 1856 the adoption of 2.512 (the fifth root of 100) as the formal basis of a physically defined magnitude scale. This, the Pogson scale, is now universally adopted by astronomers and may be stated conveniently: the difference in magnitude between two stars is given by 2.5 times the logarithm (to base 10) of the brightness ratio. If the ratio is obtained from measurements at a specific wavelength, the result is a monochromatic (one-colour) magnitude; if the ratio is obtained in terms of the response of a particular light receiver to a specific band of wavelengths, the result is a heterochromatic (more than one colour) magnitude

Major applications

Pogson scale of magnitude

in what is called a natural system characteristic of that photometric instrument and technique.

Adopting the Pogson scale, astronomers made use of visual photometers toward the end of the 19th century to re-establish the magnitude system on a physical basis, while they fixed the magnitudes in the range from fourth to sixth to agree with the ancient and the *Durchmusterung* values. Several new catalogs achieved improved accuracy because of the physically defined scale. The most important of these were the *Potsdamer Photometrische Durchmusterung*, which included 14,199 stars brighter than 7.5 magnitude in the Northern Hemisphere, and the *Revised Harvard Photometry*, which included 9,110 stars brighter than 6.5 magnitude over the entire sky as well as 36,682 fainter stars to about ninth magnitude.

In the last decade of the 19th century, bright stars were found to produce photographic images larger and denser than those of faint stars, so that measures of these image properties could be used to establish magnitudes. It is notable, however, that the dimensions of the optical images of stars in the focal plane of a telescope are substantially identical for all stars, bright and faint. The form and dimensions of the image are determined chiefly by the disturbing influences of atmospheric turbulence upon the diffraction pattern formed by the objective. The optical images from bright and faint stars differ only in energy flux. On the other hand, photographic images of bright stars are larger because of the turbidity and halation (a blurring caused by reflection) characteristics of the photographic emulsion; in particular, the size of a stellar photographic image is not a manifestation of the star's diameter.

Photographic photometry, despite calibration difficulties, soon largely displaced visual photometry. The photographic method not only determined photographic magnitudes in the blue spectral region, to which it was primarily sensitive, but, with suitable colour filters and orthochromatic emulsions, established photovisual magnitudes that closely matched the colour characteristics of the visual system of magnitudes. The photographic and photovisual magnitudes were adopted as the International System and served until about the middle of the 20th century, when photoelectric techniques were adopted because of their greater accuracy.

The earliest efforts to measure stellar brightness by means of the photoelectric effect, the conversion of light to electric current, were made in 1913. The technique was restricted to the brightest stars, however, because of inadequate sensitivity, although its inherent accuracy surpassed that of all other photometric methods. One of the chief difficulties was the accurate measurement of the feeble current produced by photocells. Until electronic amplifiers displaced the more primitive electrometers, photoelectric photometry remained severely handicapped. In 1932 in the United States Albert Edward Whitford made use of an electronic amplifier for the first time in astronomy. A second major advance took place when practical photomultipliers (see below *Principles of photometric methods: General techniques*) became available after World War II. Photoelectric methods now surpass all others in reliability, accuracy, and sensitivity.

The UVV system. What is called the UVV system of stellar magnitudes has been widely adopted as a successor to the International System. It is based on photoelectric photometry in three broad bands: the ultraviolet (U), blue (B), and visual (V) spectral regions; the latter two are similar to those of the old photographic and visual magnitudes. The additional U band includes the important spectral region that includes the Balmer discontinuity, in which light intensity drops suddenly owing to absorption by ionized hydrogen.

Apart from the Balmer discontinuity and the spectral lines, the distribution of stellar radiation with wavelength is known to approximate roughly the distribution of radiation from what the physicist calls blackbodies (*i.e.*, bodies emitting radiation freely at all wavelengths) with temperatures ranging from about 2,000 to 50,000 K. The relative strengths of the B and V magnitudes vary with stellar temperature and consequently with spectral type. For a given star, the quantity B-V, termed a colour index, expresses in

magnitude form the ratio of brightnesses in two different wavelength bands. It might be expected, therefore, that a star's spectral type could be inferred from its B-V colour index; but this inference is valid only when the starlight has not passed through regions of interstellar dust. The dust scatters light more strongly at short wavelengths; and for every three magnitudes lost in the V band there are about four lost in B, resulting in an apparent reddening of the B-V colour index by about one magnitude. The apparent B-V of a star must therefore be corrected for this reddening, called colour excess, before any inference of the star's spectral type can be made. It is here that a third band in the ultraviolet plays a role, as it makes possible the determination of colour excess, total absorption, and spectral type for many stars. This kind of information about stars can be obtained more certainly when the UVV photometric data are supplemented by spectroscopic data, but UVV photometry can be carried out on stars far too faint for spectroscopic studies.

Many more stars have been measured in the UVV than in any other photoelectric system. Such measurements are available to observers as standards of reference over the entire sky. Included are stars of most spectral types, luminosities, and degrees of reddening. The magnitudes have been made to coincide closely with the historical magnitudes for the bright stars; that is, the zero point for the V magnitudes has been fitted to selected stars in the North Polar Sequence, which in turn had been fitted to the old *Durchmusterung* values. The B-V and U-B colour indices are defined as zero for A0 stars of normal luminosity, thus conforming to the earlier zero-point convention. On the whole, the UVV bands are readily duplicated to a sufficient accuracy by appropriate combinations of photomultipliers and standard filters as well as standard photographic emulsions whenever photographic photometry is desired.

Principles of photometric methods. General techniques. In astronomical photometry, the process starts at the focal plane of a telescope, and from the start the principal methods differ greatly.

In photoelectric photometry, the image of a single star is passed through a small diaphragm in the focal plane and falls upon a photoelectric detector; all other images in the focal plane are blocked off and wasted. Photographic photometry, on the other hand, has the advantage of recording simultaneously all the images to which the plate is exposed. An additional advantage of the photographic method is that the plate becomes a permanent record, useful also for purposes other than photometry. Unfortunately, these advantages can be gained only at the cost of considerably reduced accuracy, for the complex relationships between the size and density of photographic images of stars and the brightness of the optical images are not subject to full control or accurate calibration. Nonuniform sensitivity or development over the surface of the emulsion, other photographic effects, the atmospheric dispersion and turbulence as they affect the chromatic form of the images, and field errors caused in the telescope optics all act to introduce large accidental and systematic errors.

Photoelectric photometry owes its accuracy primarily to two factors: the highly linear relation between the amount of incoming radiation and the electric current it produces and the use of precise electrical measurement techniques. In contrast, the photochemical processes and densitometric techniques (measuring the degree of darkening of photographic film) used in photographic calibration are relatively crude. For this reason, virtually all modern magnitude scales are established with photoelectric photometers, whereas the photographic methods are used only where their advantages may be exploited and deficiencies minimized. For example, after photoelectric measurements have been made, in a small area of the sky, of a select few individual stars that embrace an adequate range of magnitude and colour index, a photograph of the same area offers a means of determining the magnitudes of many more stars by interpolation. This simultaneously eliminates some of the chief shortcomings of the photographic method and provides much data with little telescope observing time.

The two chief stellar photometric instruments in current

The International System of photometry

Advantages and disadvantages of photography

The colour index

Two principal photo-metric instruments

use are the photoelectric photometer, which attaches directly to the telescope, and the iris photometer, a device used to measure the degree of darkening of images on a photographic plate. As noted above, a diaphragm in the photoelectric photometer's focal plane serves to isolate the single image to be measured. Large diaphragms admit images of extended objects such as nebulae or planets; small ones isolate a star from a close companion or reduce the amount of background light from the sky when the star to be measured is very faint.

The light comprising the stellar image passes through the diaphragm, an appropriate filter, a field lens, and into a photomultiplier, a device that produces a relatively strong electric current from a weak light input. The purpose of the field lens is to focus a small image of the telescope's entrance pupil onto the input of the photomultiplier. Typical output currents for stellar measurement lie in the range from 10^{-5} to 10^{-11} ampere, despite the large amplification factor achieved within the photomultiplier, typically around 10^6 . The output current may be measured in a variety of ways.

A photoelectric photometer has some viewing eyepieces to allow selection of and alignment on the object to be measured or to permit guiding on a separate stellar image. There may also be provisions for simultaneous observing of several colours or multiple images or for scanning across an image.

Limitation on accuracy

In order to retain the highest accuracy in photoelectric photometry, all of the instrumentation must be stable, accurately calibrated, and free from effects that are dependent on such extraneous influences as temperature or orientation in the Earth's magnetic and gravitational fields. But even when these effects are minimized, there remain limitations to accuracy imposed by the atmosphere.

Because the transparency of the Earth's atmosphere is neither perfect nor constant and may not be uniform around the sky, it is usually necessary to compare photoelectric measurements of stars quickly and repeatedly, using nights of the greatest clarity. (Exceptions to this rule are sometimes permissible; for example, when the instrument is equipped to compare two nearby images simultaneously.) Reference stars of known magnitude as near the program stars as possible are customarily chosen to facilitate rapid manipulation of the telescope and to minimize the influence of differences in atmospheric conditions. The atmosphere's extinction of starlight is dependent on both the path length traversed by the light and the transparency of the air; it also depends on colour, being more pronounced at shorter wavelengths. Accordingly, all photoelectric measurements require slight corrections, since seldom will the stars be observed through identical lengths of air path. It is customary to apply these corrections to convert the magnitudes into what they would be in the absence of an atmosphere.

Use of the iris photometer

In the iris photometer, a beam of light is made to pass through the photographic plate, and the diameter of the beam is adjusted by means of an iris diaphragm to always pass a constant amount of light around and through a stellar image. The iris diameter thus adjusted will usually be found to be approximately proportional to the magnitudes of the imaged stars, over a range of several magnitudes. The stars of the calibrated sequence provide the link between arbitrary iris diameters and the magnitudes and permit the magnitudes of the program stars to be determined by interpolation. Another method of calibrating the image properties with magnitudes, believed by some to be superior in accuracy and range, consists of studying the image profiles with a microdensitometer; *i.e.*, by passing through them a very fine pencil beam of light.

Visual photometry continues in use in a few special areas of research. For extremely close visual binary stars, no other method has proved successful in measuring the magnitude of each component separately or in obtaining a difference in magnitude, Δm . Experienced observers of double stars attempt to estimate Δm directly, but the reliability varies with the seeing quality and proximity and Δm of the pair. Some observers of double stars make use of a double-image polarizing eyepiece that provides for equalizing the brightnesses in calibrated fashion; accu-

cies of about 0.05 magnitude can be obtained, although the measures are difficult.

Visual estimates of stellar brightness are also made by dedicated hobbyists, a particularly valuable pastime for those who observe the long-period variable stars whose slow variation few major observatories can follow thoroughly or economically. Although such visual estimates of magnitude seldom are more accurate than 0.1 magnitude, the amplitudes of variation of the long-period variables are so large that this accuracy is sufficient for most purposes.

From photographs of wider double stars, estimates of the difference in magnitude can also be made profitably by visual inspection, particularly when an objective grating has been used to limit the apparent difference in magnitude to 0.5 magnitude or less.

Selected areas; transfer photometry. At one time, the magnitudes of stars in one region of the sky were determined by making a photograph of the desired region and superimposing on it a second exposure of a region containing stars of known magnitude. In this process, termed transfer photometry, both the magnitude scale and the zero point of one region were effectively transferred to another. The reference regions were set up in several places in the sky, known as selected areas. Because one of the regions was centred about the north celestial pole and was therefore observable at all seasons in the Northern Hemisphere, it became the standard reference region. The photometrically calibrated stars in it make up the North Polar Sequence. The accuracy of the photographically determined magnitudes in this and other selected areas is insufficient to warrant their continued use; indeed, systematic errors of scale amount to as much as 30 percent at the 18th magnitude. All modern transfer work is therefore done with photoelectric photometers.

North Polar Sequence of stars

Broad-band photometry. If all stars were of identical colour—that is, of identical spectral energy distribution—their apparent magnitudes would be independent of the wavelength chosen for measurement and of the bandwidth used. In this idealized situation, any detector could be employed without spectral restrictions; and consequently, an observer would exploit the full spectral response of his most sensitive detectors in order to measure the magnitudes of the faintest objects in the most efficient way. In fact, however, the stars do have a wide variety of spectral energy distributions, and this imposes the necessity of determining magnitudes in restricted bands of colour.

From the definition given earlier of the Pogson magnitude scale, it would appear that monochromatic magnitudes pertaining to a specific wavelength are best suited to physical interpretation, because comparing the brightnesses of stars at wavelengths that might differ among stars of different energy distribution would have little physical meaning. But in order to study the most distant stars, whose apparent intensity is inherently so feeble, moderately broad bands are needed to provide sufficient energy to be detectable by even the most sensitive light receivers. Thus, the astronomer is compelled to make a compromise between a clear physical definition and the need to use sufficiently broad bands to examine stars in a consistent fashion, from the brightest to the faintest. In this discussion of the way in which broad-band magnitudes may be used and interpreted, it will simplify matters to exclude from consideration peculiar stars, novae, emission nebulae, and other sources of nonthermal radiation whose spectral energy distribution may be entirely dissimilar to that of most stars.

With any broad spectral band there can be associated a representative wavelength, λ_r , at which a monochromatic band of arbitrary narrowness would produce the same system of magnitudes for stars of a given spectral energy distribution when measured with the same telescope and detector system. Accordingly, the representative wavelength, λ_r , can be defined by an equation that includes variables for photometer response and for stars of differing spectral energy distribution. In comparing the values that the representative wavelength takes for the hottest and coolest stars, it is found that its range of variation depends on both the width and symmetry of the band in question. As a typical example, the V and B bands of

the UBV system have values of representative wavelength that vary by about 2 or 3 percent over the normal range of stellar energy distributions. Experience has shown that this departure from monochromaticity is quite tolerable in the context of many applications, some of which will be mentioned presently, but that it is unacceptable for certain more critical applications, which will be taken up in the following section.

In practice, a broad-band-magnitude system is readily defined by (1) a set of magnitudes for specified stars as measured with a particular photometric apparatus and (2) a specification of the instrument's response function. Although exact duplication of the apparatus response function cannot be expected in other photometers, sufficiently close approximation can usually be achieved, and small corrective transformations can be applied to produce results virtually consistent with those of the original equipment. It can be shown that broad-band magnitudes are in many instances adequate approximations of monochromatic magnitudes when the wavelength of the latter is defined by an equation that is somewhat different, though analogous, to that for λ_e . This is designated as the effective wavelength, λ_0 , and it lies within the range through which λ_e varies over the range of stellar energy distribution encountered among stars and can be thought of simply as a kind of mean value of λ_e .

Some examples of applications to which broad bands are suited have been mentioned earlier: estimating the spectral types of stars as well as measuring the amount of reddening and absorption influencing their apparent colour indices and magnitudes. (In instances of extreme reddening, small corrections may be required if λ_e differs significantly from λ_0 .) Other examples are stellar distances derived photometrically and absolute magnitudes.

Distances of remote stars can be deduced from their apparent brightnesses. In principle, it suffices to compare the apparent brightness of a star of unknown distance with that of one of the same spectral type and luminosity class at a known distance, since the ratio of apparent brightnesses (due allowance being made for any absorption) is simply the ratio of the square of their distances. A more customary way of treating this problem involves the concept of absolute magnitude, which is taken to be the apparent magnitude that a star would have if it were to be viewed from a standard distance of 10 parsecs (about 32.6 light-years). The relation between the absolute and apparent magnitudes, M , m , and the distance, d , expressed in parsecs can be derived from the inverse-square law of diminishing brightness in magnitude form; it states that the absolute magnitude is equal to the apparent magnitude minus a logarithmic value of the distance:

$$M = m - 5 \log \frac{d}{10}.$$

If there is any interstellar absorption, A , then it is also subtracted from the apparent magnitude:

$$M = m - A - 5 \log \frac{d}{10}.$$

These relationships serve to define a set of absolute magnitudes for stars of known distance, so that the relative intrinsic brightnesses and total energy outputs of different types of stars can be determined. A profoundly important relationship between the absolute magnitudes and spectral types of stars was established in this way by Ejnar Hertzsprung and Henry Norris Russell early in the 20th century and elaborated upon by numerous subsequent investigators. The relationship, commonly referred to as the Hertzsprung-Russell diagram from the form in which it is usually displayed, has played a fundamental role in studies of the constitution and evolution of the stars.

Conversely, the absolute magnitude of a star can be inferred from its spectral type and luminosity class, and this inference together with its apparent magnitude permits a determination of its distance.

Broad-band systems, such as the UBV system and its predecessors, have been of immense value in providing

information about the stars in the Galaxy, extragalactic distances, and other important basic and statistical data. For this kind of application, monochromatic magnitudes would not have been significantly better.

Narrow-band photometry. Several types of investigation require narrow bands even at the cost of limiting sensitivity and thereby excluding application to the faintest stars. In general, the narrower and more numerous the bands are within a spectral range, the more may the photometric methods approach the spectroscopic in terms of the number of independent parameters that can be determined. In addition, the narrowing of a band toward monochromaticity aids in physical interpretation, particularly in relating the photometric data to theoretical stellar models and to spectrophotometry.

Two general types of narrow-band photometry have been profitably applied to stellar problems: one in which the strength of a stellar absorption line is measured, the other in which selected regions of the continuum are measured. In the former, the bandwidth is typically very narrow, 10 to 30 Å wide, while in the second the bands are of intermediate width, typically 150 to 300 Å.

As an example of the former, the H β (hydrogen-beta) system introduced by Bengt Strömberg is based on measures of the strength of the Balmer H β line, a hydrogen absorption line at 4861 Å, which, for the stars of spectral type O9 to B9, is well correlated with luminosity. When UBV photometry is supplemented by H β photometry, the colour indices B-V and U-B (corrected for reddening) show spectral type, while the H β strength shows the luminosity. Despite the narrow band required for the H β measure, the efficiency of the photometric method, in terms of the time needed to reach a given faint star, is higher than that of the traditional spectroscopic method. Stars of other spectral types may be studied in an analogous way, making use of other appropriate spectral-absorption features.

In a different approach to obtaining two-dimensional classification of stars through photometry, several investigators have used four or more bands of intermediate width that, being less wasteful of light, allow the study of fainter stars. A number of general characteristics of stellar spectral energy distribution may be selected as criteria: a colour index based on the region at shorter wavelengths than the Balmer discontinuity (see above *The UBV system*), the depth of the Balmer discontinuity, a colour index in the region between 3,800 and 4,600 Å that is generally characterized by a different colour temperature than that at longer wavelengths than 4,600 Å, or various combinations of these. In some instances it is possible to form compound colour indices that are insensitive to interstellar reddening but that remain sensitive to some inherent property of the star. In general, it has not been possible to accomplish two-dimensional classification over the entire range of spectral types; instead, particular systems are devised for use within restricted spectral ranges.

Spectrophotometry. In spectrophotometry, photometric methods are employed to study in great detail the spectral energy distribution of stars, generally with emphasis on the continuum rather than the spectral lines. Spectrophotometry has been done both photographically, by the scanning of a spectrogram and its calibration images with a microphotometer, and photoelectrically, by the direct scanning of a spectrum at the telescope. The scanning can be continuous or may consist of discrete measures made at selected places along a spectrum. If at selected places, the spectral regions may be isolated by filters; it is more customary, however, to use a spectrograph as a dispersing instrument with one or more slits located in the focal plane that admit restricted and well-defined bands of wavelengths into the light receivers. The bandwidth is generally so restricted that the measures are essentially monochromatic.

As in broad-band photometry, the photographic method is less wasteful of light, since the entire spectrum is photographed; photoelectric direct scanning wastes most of the light but is capable of very high precision. Spectrophotometry, at least with high resolution, is applicable only to the brightest stars and requires large telescopes for maximum light collection. Fortunately, among the bright stars

The concept of absolute magnitude

The hydrogen-beta system

there are examples of most types of normal stars, so that a large body of fundamental knowledge on stellar radiation can be obtained.

An important application of spectrophotometry is the study of interstellar absorption, particularly how the absorption varies with wavelength. For this purpose, two stars of the same spectral type, one reddened, the other unreddened, are compared spectrophotometrically. Another important result of spectrophotometry is the absolute calibration of stellar energy output through direct comparison with artificial standards of radiation. From such measurements, it is known, for example, that the radiation received at the Earth from an A0 star of 0 magnitude at 5,560 Å (close to the effective wavelength of the V magnitude) is 3.8×10^{-9} erg per second per square centimetre per angstrom.

Surface photometry. Many celestial objects extend over an appreciable angle and present an apparent surface in the field of view. Examples are galaxies, nebulae, the Sun, the Moon, and most planets. Photometric studies of such objects can be made in two ways: in detail over the surface, as a function of position, or in whole, whereby the integrated light of the entire surface is taken.

The results of detailed surface photometry of an object are conveniently displayed in an isophotal map, a map in which contours of constant brightness are drawn much in the same fashion as altitudes in a terrestrial contour map. Customarily, isophotometric mapping is done by an instrument that follows contours of constant density on a photograph. This technique of isophotometry can be applied in the study of galaxies. If photographs have been made at different effective wavelengths, it is possible to distinguish regions containing the older and redder objects from those regions containing young stars and stellar associations.

A more recent technique consists of the superposition of a positive photograph taken in one colour onto a negative taken in another colour. By appropriate control of the balance of photographic densities, the images of selected types of stars will cancel, leaving the regions containing extreme blue and red objects showing up boldly as dark or light areas. This is an example of the use of photometric techniques in a qualitative rather than quantitative fashion.

While furnishing less information than detailed surface photometry, integrated magnitudes based on the entire surface of an extended object provide a convenient measure of the total radiation emitted. The ratio of the total luminosity to the total mass of a galaxy is an important parameter in the study of these objects. Moreover, for the most remote galaxies, integrated magnitudes provide a means of estimating their approximate distances.

In the study of emission nebulae, measures of the strength of various emission lines provide information about the constitution, density, and temperature of the nebulae. Recently developed techniques employing pressure-modulated Fabry-Pérot interferometers provide, in addition, details about the mass motions of the nebular gases.

Variation of light from astronomical objects. A considerable number of celestial objects vary in brightness, some being highly regular and repetitive in behaviour, others quite irregular. Many of these objects have provided important clues to astronomical problems.

Among the variable stars are some, such as the RR Lyrae variables and the Cepheids, whose light variation is caused by physical pulsation. Since early in the 20th century the Cepheids have played a vital role as astronomical distance indicators. Because those stars possess easily recognized light-variation characteristics in terms of the shapes, amplitudes, and periods of their light curves, they have been studied intensively. In particular, those Cepheid variables located in the neighbouring galaxies called the Magellanic Clouds show that their average brightnesses are highly correlated with their periods. Since all stars in the Magellanic Clouds are roughly at the same distance, the correlation must apply to their average absolute magnitudes also. Once their mean absolute magnitudes are known, it is sufficient to observe the period of any other Cepheid variable to infer its mean absolute magnitude and from this (and its mean apparent magnitude) its distance. This process,

stated here in an oversimplified form, is used to determine the distances of the nearest galaxies. Although the RR Lyrae variables are not as intrinsically luminous and cannot be seen as individual stars at such distances, they serve a similar purpose in aiding the astronomer to deduce the distances of some star clusters within the Galaxy.

Pulsating stars, in some instances, also provide knowledge of stellar diameters. Their brightnesses are known to vary as a consequence of a pulsation process in which both diameter and surface temperature vary cyclically. If at two times during the cycle the colour indices and, thus, surface temperatures are the same, then the ratio of brightnesses must be proportional to the square of the radii at these times. If radial velocities are also known, the varying rate at which the stellar surface moves throughout the cycle is known; and, when the rate is integrated, the distance traversed between any two instants can be deduced. Thus, the difference between, as well as the ratio of, the two radii is available, and thus the radii can be determined. By carrying out such a process for many pairs of instants of common colour index, detailed knowledge of the star's pulsation in diameter can be obtained.

An important group of stars is the eclipsing binaries, double stars too remote and too close together to be resolved, and whose orbital plane is oriented in space to pass through or very near the Earth. The combined light of an eclipsing binary, viewed of necessity in a single image, diminishes whenever one star eclipses the other; thus, there are two times per period when the apparent brightness reaches a minimum. From an analysis of the geometrical shape of the light curve, it is possible to infer important properties of the stars and their orbits. If radial-velocity curves are also available for the two components, it is possible to determine the stars' masses and diameters.

In the solar system, the rotational characteristics of many minor planets have become known from cyclic variation in their brightnesses, as has the rotational period of the planet Pluto. Observations of the occultation of stars by the Moon have provided important new information on the diameters of stars. Very fast photometry is required to follow the rapid extinction of light as the Moon's edge cuts the star from view; the shape of the extinction curve requires resolution in time on the order of milliseconds.

Two types of cosmic objects discovered in recent years show characteristic variations in energy output, sometimes including the optical spectral region. They are pulsars and quasi-stellar sources. In one pulsar, near the centre of the Crab Nebula, the optical brightness varies with the same periodicity (33 milliseconds) as its radio emission. Irregular brightness variations occurring in quasi-stellar sources over times of only months imply that their sizes must be no larger than the distance traversed by light in such times, and thus they must be many times smaller than galaxies.

Limits of observations. There are practical limitations to both the accuracy and dynamic range of astronomical photometry. The factors determining the limits are to be found in the statistical character of the detection of small numbers of photons, the irreducible units of light; in the nature of the photometric instrumentation; and in the behaviour of the terrestrial atmosphere.

The spectral transmission of the atmosphere is characterized by numerous wavelength regions called windows (regions of relative clarity) separated by regions of high opacity. Even within the windows, the atmosphere not only absorbs light and disturbs the images formed by telescopes; it also emits light, so that even a moonless sky is not totally dark. In addition, there is a background of scattered light from interplanetary dust and distant unresolved stars, nebulae, and galaxies. On a dark, clear night, the surface brightness of the sky is equivalent to about one star of 22nd visual magnitude in every square second of arc. Ultimately, this background light limits the extent to which faint stars can be detected on a fully exposed photograph.

The faintest stars that have been photographed thus far by traditional methods are at about the 23rd magnitude, approximately one-third as bright as the sky background. This limit, 23rd magnitude, also represents the extent to which photoelectric photometry has been carried, because,

Eclipsing
binary stars

Iso-
photome-
try of
galaxies

23rd-
magnitude
stars

in the absence of photographic star charts, the positions of any fainter stars remain unknown. If photoelectric photometry of a 23rd-magnitude star is carried out with a 5"-of-arc diaphragm, the light from the star would represent only about 2 percent of all the sky light admitted. At this faint level, only about two photons of visual light arrive per hour per square centimetre at the Earth from the star. Thus, quite apart from the brighter sky background, a very large telescope aperture and a very long observing time are necessary to collect a statistically significant quantity of light. Similar statistical considerations may limit the speed with which even bright objects may be observed, as in the case of rapid-scanning devices or observations of occultations of stars.

At the faintest levels, it appears that electronographic techniques, as developed by André Lallemand and Gerald E. Kron, will make possible the measurement of fainter stars beyond the reach of either conventional photoelectric or photographic methods. Kron has extended photometry in this fashion almost to the 24th magnitude. The essential principle employed is the replacement of the photographic plate by a photoelectric imaging device. In the latter, an image is produced on a photographic plate by highly accelerated electrons emitted by a photocathode placed at the optical focal plane of the telescope. The advantage over conventional photography lies in the much higher efficiency and sensitivity, while the advantage over conventional photoelectric photometry lies in the fact that a feeble star does not have to compete for detection with all the light from the surrounding sky background as admitted by a diaphragm, but only with that sky light arising from the small area occupied by the image itself.

There are also limitations on the working range of photometric processes. A photoelectric photometer, for example, typically is restricted to a range of less than 15 magnitudes because of factors such as saturation and fatigue of instrumental components at the brightest levels and electrical or statistical limitations at the faintest levels. Much wider ranges are possible by means of calibrated optical attenuation and overlapping intervals of measurement. The full range of photoelectrically measured astronomical objects is now about 50 magnitudes, extending from the Sun at an apparent magnitude of -26.8 to the faintest star at about 23rd magnitude.

In terms of accuracy, photometric measures in principle can be carried out over sufficiently long time intervals or can be repeated indefinitely to reduce the residual uncertainty inherent in the averaged results. Even this procedure, however, reaches practical limits imposed by systematic errors caused by imperfect calibration or observational procedures, the approximate character of transformations to standard systems, residual errors in the known magnitudes of standard stars, and unrecognized sources of error. In practice, the best photoelectric magnitudes of bright stars are typically accurate within about 1 percent, while, for certain forms of differential photometry, accuracies about 50 times greater can be achieved. On the other hand, photographically interpolated magnitudes are seldom more accurate than about 4 percent.

(R.H.H.)

MATERIALS TESTING

Materials testing involves measuring the characteristics and behaviour of such substances as steel or wood under various conditions. The data thus obtained can be used in specifying materials and their properties for various applications. A full- or small-scale model of a proposed machine or structure may be tested. Alternatively, investigators may construct mathematical models that utilize known material characteristics and behaviour to predict capabilities of the structure.

Materials testing breaks down into five major categories: mechanical testing; testing for thermal properties; testing for electrical properties; testing for resistance to corrosion, radiation, and biological deterioration; and nondestructive testing. Standard test methods have been established by such national and international bodies as the International Organization for Standardization (iso), with headquarters in Geneva, and the American Society for Testing and Materials (ASTM), Philadelphia.

MECHANICAL TESTING

Structures and machines, or their components, fail because of fracture or excessive deformation. In attempting to prevent such failure, the designer estimates how much stress (load per unit area) can be anticipated, and specifies materials that can withstand expected stresses. A stress analysis, accomplished either experimentally or by means of a mathematical model, indicates expected areas of high stress in a machine or structure. Mechanical property tests, carried out experimentally, indicate which materials may safely be employed.

Static tension and compression tests. When subjected to tension (pulling apart), a material elongates and eventually breaks. A simple static tension test determines the breaking point of the material and its elongation, designated as strain (change in length per unit length). If a 100-millimetre steel bar elongates 1 millimetre under a given load, for example, strain is $(101-100)/100 = 1/100 = 1$ percent.

A static tension test requires (1) a test piece, usually cylindrical, or with a middle section of smaller diameter than the ends; (2) a test machine that applies, measures, and records various loads; and (3) an appropriate set of grips to grasp the test piece. In the static tension test, the test machine uniformly stretches a small part (the test

section) of the test piece. The length of the test section (called the gauge length) is measured at different loads with a device called an extensometer; these measurements are used to compute strain.

Conventional testing machines are of the constant load, constant load-rate, and constant displacement-rate types (see Figure 37). Constant load types employ weights directly both to apply load and to measure it. Constant load-rate test machines employ separate load and measurement

Use of mathematical models

Elements of a static tension test

Figure 37: Testing machines: (A) constant displacement-rate type; (B) constant load type; (C) constant load-rate type.

units; loads are generally applied by means of a hydraulic ram into which oil is pumped at a constant rate. Constant displacement-rate testing machines are generally driven by gear-screws.

Test machine grips are designed to transfer load smoothly into the test piece without producing local stress concentrations. The ends of the test piece are often slightly enlarged so that if slight concentrations of stress are present these will be directed to the gauge section, and failures will occur only where measurements are being taken. Clamps, pins, threading, or bonding are employed to hold the test piece. Eccentric (nonuniform) loading causes bending of the sample in addition to tension, which means that stress in the sample will not be uniform. To avoid this, most gripping devices incorporate one or two swivel joints in the linkage that carries the load to the test piece. Air bearings help to correct horizontal misalignment, which can be troublesome with such brittle materials as ceramics.

Static compression tests determine a material's response to crushing, or support-type loading (such as in the beams of a house). Testing machines and extensometers for compression tests resemble those used for tension tests. Specimens are generally simpler, however, because gripping is not usually a problem. Furthermore, specimens may have a constant cross-sectional area throughout their full length. The gauge length of a sample in a compression test is its full length. A serious problem in compression testing is the possibility that the sample or load chain may buckle prior to material failure. To prevent this, specimens are kept short and stubby.

Static shear and bending tests. Inplane shear tests indicate the deformation response of a material to forces applied tangentially. These tests are applied primarily to thin sheet materials, either metals or composites, such as fibre glass reinforced plastic.

A homogeneous material such as untreated steel casting reacts in a different way under stress than does a grained material such as wood or an adhesively bonded joint. These anisotropic materials are said to have preferential planes of weakness; they resist stress better in some planes than in others, and consequently must undergo a different type of shear test.

Shear strength of rivets and other fasteners also can be measured. Though the state of stress of such items is generally quite complicated, a simple shear test, providing only limited information, is adequate for most purposes.

Tensile testing is difficult to perform directly upon certain brittle materials such as glass and ceramics. In such cases, a measure of the tensile strength of the material may be obtained by performing a bend test, in which tensile (stretching) stresses develop on one side of the bent member and corresponding compressive stresses develop on the opposite side. If the material is substantially stronger in compression than tension, failure initiates on the tensile side of the member and, hence, provides the required information on the material tensile strength. Because it is necessary to know the exact magnitude of the tensile stress at failure to establish the strength of the material, however, the bending test method is applicable only to a very restricted class of materials and conditions.

Measures of ductility. Ductility is the capacity of a material to deform permanently in response to stress. Most common steels, for example, are quite ductile and hence can accommodate local stress concentrations. Brittle materials, such as glass, cannot accommodate concentrations of stress because they lack ductility; they, therefore, fracture rather easily.

When a material specimen is stressed, it deforms elastically (*i.e.*, recoverably) at first; thereafter, deformation becomes permanent. A cylinder of steel, for example, may "neck" (assume an hourglass shape) in response to stress. If the material is ductile, this local deformation is permanent, and the test piece does not assume its former shape if the stress is removed. Finally, fracture occurs.

Ductility can be expressed as strain, reduction in area, or toughness. Strain, or change in length per unit length, was explained earlier. Reduction in area (change in area per unit area) may be measured, for example, in the test section of a steel bar that necks when stressed. Toughness

measures the amount of energy required to deform a piece of material permanently. Toughness is a desirable material property in that it permits a component to deform plastically, rather than crack and perhaps fracture.

Hardness testing. Based on the idea that a material's response to a load placed at one small point is related to its ability to deform permanently (yield), the hardness test is performed by pressing a hardened steel ball (Brinell test) or a steel or diamond cone (Rockwell test) into the surface of the test piece. Most hardness tests are performed on commercial machines that register arbitrary values in inverse relation to the depth of penetration of the ball or cone. Similar indentation tests are performed on wood. Hardness tests of materials such as rubber or plastic do not have the same connotation as those performed on metals. Penetration is measured, of course, but deformation caused by testing such materials may be entirely temporary.

Some hardness tests, particularly those designed to provide a measure of wear or abrasion, are performed dynamically with a weight of given magnitude that falls from a prescribed height. Sometimes a hammer is used, falling vertically on the test piece or in a pendulum motion.

Impact test. Many materials, sensitive to the presence of flaws, cracks, and notches, fail suddenly under impact. The most common impact tests (Charpy and Izod) employ a swinging pendulum to strike a notched bar; heights before and after impact are used to compute the energy required to fracture the bar, and, consequently, the bar's impact strength. In the Charpy test, the test piece is held horizontally between two vertical bars, much like the lintel over a door. In the Izod test, the specimen stands erect, like a fence post. Shape and size of the specimen, mode of support, notch shape and geometry, and velocities at impact are all varied to produce specific test conditions. Nonmetals such as wood may be tested as supported beams, similar to the Charpy test. In nonmetal tests, however, the striking hammer falls vertically in a guide column, and the test is repeated from increasing heights until failure occurs.

Some materials vary in impact strength at different temperatures, becoming very brittle when cold. Tests have shown that the decrease in material strength and elasticity is often quite abrupt at a certain temperature, which is called the transition temperature for that material. Designers always specify a material that possesses a transition temperature well below the range of heat and cold to which the structure or machine is exposed. Thus, even a building in the tropics, which will doubtless never be exposed to freezing weather, employs materials with transition temperatures slightly below freezing.

Fracture toughness tests. The stringent materials-reliability requirements of the space programs undertaken since the early 1960s brought about substantial changes in design philosophy. Designers asked materials engineers to devise quantitative tests capable of measuring the propensity of a material to propagate a crack. Conventional methods of stress analysis and materials-property tests were retained, but interpretation of results changed. The criterion for failure became sudden propagation of a crack rather than fracture (see Figure 38). Tests have shown that cracks occur by opening, when two pieces of material part in vertical plane, one piece going up, the other down; by edge sliding, where the material splits in horizontal plane, one piece moving left, the other right; and by tearing, where the material splits with one piece moving diagonally upward to the left, the other moving diagonally downward to the right.

Creep test. Creep is the slow change in the dimensions of a material due to prolonged stress; most common metals exhibit creep behaviour. In the creep test, loads below those necessary to cause instantaneous fracture are applied to the material, and the deformation over a period of time (creep strain) under constant load is measured, usually with an extensometer or strain gauge. In the same test, time to failure is also measured against level of stress; the resulting curve is called stress rupture or creep rupture. Once creep strain versus time is plotted, a variety of mathematical techniques is available for extrapolating

The Charpy and Izod tests

Tensile testing of brittle materials

Figure 38: Typical fracture toughness test. The clip-on extensometer output signal is monitored to recognize the stress level at which the crack suddenly propagates because the extensometer will sense a sudden increase in strain without a corresponding increase in load.

creep behaviour of materials beyond the test times so that designers can utilize thousand-hour test data, for example, to predict ten-thousand-hour behaviour.

A material that yields continually under stress and then returns to its original shape when the stress is released is said to be viscoelastic; this type of response is measured by the stress-relaxation test. A prescribed displacement or strain is induced in the specimen and the load drop-off as a function of time is measured. Various viscoelastic theories are available that permit the translation of stress-relaxation test data into predictions about the creep behaviour of the material.

Fatigue. Materials that survive a single application of stress frequently fail when stressed repeatedly. This phenomenon, known as fatigue, is measured by mechanical tests that involve repeated application of different stresses varying in a regular cycle from maximum to minimum value. Most fatigue-testing machines employ a rotating eccentric weight to produce this cyclically varying load. A material is generally considered to suffer from low-cycle fatigue if it fails in 10,000 cycles or less.

The stresses acting upon a material in the real world are usually random in nature rather than cyclic. Consequently, several cumulative fatigue-damage theories have been developed to enable investigators to extrapolate from cyclic test data a prediction of material behaviour under random stresses. Because these theories are not applicable to most materials, a relatively new technique, which involves mechanical application of random fatigue stresses, statistically matched to real-life conditions, is now employed in most materials test laboratories.

Factors in material fatigue

Material fatigue involves a number of phenomena, among which are atomic slip (in which the upper plane of a metal crystal moves or slips in relation to the lower plane, in response to a shearing stress), crack initiation, and crack propagation. Thus, a fatigue test may measure the number of cycles required to initiate a crack, as well as the number of cycles to failure.

A cautious designer always bears the statistical nature of fatigue in mind, for the lives of material specimens tested at a common stress level always range above and below some average value. Statistical theory tells the designer how many samples of a material must be tested in order to provide adequate data; it is not uncommon to test several hundred specimens before drawing firm conclusions.

MEASUREMENT OF THERMAL PROPERTIES

Thermal conductivity. Heat, which passes through a solid body by physical transfer of free electrons and by vibration of atoms and molecules, stops flowing when the

temperature is equal at all points in the solid body and equals the temperature in the surrounding environment. In the process of attaining equilibrium, there is a gross heat flow through the body, which depends upon the temperature difference between different points in the body and upon the magnitudes of the temperatures involved. Thermal conductivity is experimentally measured by determining temperatures as a function of time along the length of a bar or across the surface of flat plates while simultaneously controlling the external input and output of heat from the surfaces of the bar or the edges of the plate.

Specific heat. Specific heat of solid materials (defined as heat absorbed per unit mass per degree change in temperature) is generally measured by the drop method, which involves adding a known mass of the material at a known elevated temperature to a known mass of water at a known low temperature and determining the equilibrium temperature of the mixture that results. Specific heat is then computed by measuring the heat absorbed by the water and container, which is equivalent to the heat given up by the hot material.

Thermal expansion. Expansion due to heat is usually measured in linear fashion as the change in a unit length of a material caused by a one-degree change in temperature. Because many materials expand less than a micrometre with a one-degree increase in temperature, measurements are made by means of microscopes.

MEASUREMENT OF ELECTRICAL PROPERTIES

Understanding of electrical properties and testing methods requires a brief explanation of the free electron gas theory of electrical conduction. This simple theory is convenient for purposes of exposition, even though solid-state physics has advanced beyond it.

Electrical conductivity involves a flow or current of free electrons through a solid body. Some materials, such as metals, are good conductors of electricity; these possess free or valence electrons that do not remain permanently associated with the atoms of a solid but instead form an electron "cloud" or gas around the peripheries of the atoms and are free to move through the solid at a rapid rate. In other materials, such as plastics, the valence electrons are far more restricted in their movements and do not form a free electron gas. Such materials act as insulators against the flow of electricity.

The effect of heat upon the electrical conductivity of a material varies for good and poor conductors. In good conductors, thermal agitation interferes with the flow of electrons, decreasing conductivity, while as insulators increase in temperature, the number of free electrons grows, and conductivity increases. Normally, good and poor conductors are enormously far apart in basic conductivity, and relatively small changes in temperature do not change these properties significantly.

Variation among conductors

In certain materials, however, such as silicon, germanium, and carbon, heat produces a large increase in the number of free electrons; such materials are called semiconductors. Acting as insulators at absolute zero, semiconductors possess significant conductivity at room and elevated temperatures. Impurities also can change the conductivity of a semiconductor dramatically by providing more free electrons. Heat-caused conductivity is called intrinsic, while that attributable to extra electrons from impurity atoms is called extrinsic.

Conductivity of a material is generally measured by passing a known current at constant voltage through a known volume of the material and determining resistance in ohms. Total conductivity is simply the reciprocal of total resistivity.

TESTING FOR CORROSION, RADIATION, AND BIOLOGICAL DETERIORATION

Testing for breakdown or deterioration of materials under exposure to a particular type of environment has greatly increased in recent years. Mechanical, thermal, or electrical property tests often are performed on a material before, during, and after its exposure to some controlled environment. Property changes are then recorded as a function of exposure time. Environments may include heat, moisture,

chemicals, radiation, electricity, biological substances, or some combination thereof. Thus, the tensile strength of a material may fall after exposure to heat, moisture, or salt spray, or may be increased by radiation or electrical current. Strength of organic materials may be lessened by certain classes of fungus and mold.

Corrosion. Corrosion testing is generally performed to evaluate materials for a specific environment or to evaluate means for protecting a material from environmental attack. A chemical reaction, corrosion involves removal of metallic electrons from metals and formation of more stable compounds such as iron oxide (rust) in which the free electrons are usually less numerous. In nature, only rather chemically inactive metals such as gold and platinum are found in pure form; most others are mined as ores that must be refined to metal. Corrosion simply reverses the refining process, returning the metal to its natural state. Corrosion compounds form on the surface of a solid material. If the compounds are hard and impenetrable, and if they adhere well to the parent material, the progress of corrosion is arrested. If the compound is loose and porous, however, corrosion may proceed swiftly and continuously.

Analogy
of the
galvanic
cell battery

If two different metals are placed together in a solution (electrolyte), one metal will give up ions to the solution more readily than the other; this difference in behaviour will bring about a difference in electrical voltage between the two metals. If the metals are in electrical contact with each other, electricity will flow between them and they will corrode; this is the principle of the galvanic cell or battery. Though useful in a battery, this reaction causes problems in a structure; for example, steel bolts in an aluminum framework may, in the presence of rain or fog, form multiple galvanic cells at the point of contact between the two metals, corroding the aluminum.

Corrosion testing is performed to ascertain the performance of metals and other materials in the presence of various electrolytes. Testing may involve total immersion, as would be encountered in seawater; or salt fog, as is encountered in chemical-industry processing operations or near the oceans where seawater may occur in fogs. Materials are generally immersed in a 5 percent or 20 percent solution of sodium chloride or calcium chloride in water, or the solution may be sprayed into a chamber where the specimens are freely suspended. In suspension testing, care is taken to prevent condensate from dripping from one specimen onto another. The specimens are exposed to the hostile environment for some time, then removed and examined for visible evidences of corrosion. In many cases, mechanical tests after corrosion exposure are performed quantitatively to ascertain mechanical degradation of the material. In other tests, materials are stressed while in the corrosive environment. Still other test procedures have been developed to measure corrosion of metals by flue or stack gases.

Radiation. Materials may be tested for their reactions to such electromagnetic radiation as X-rays, gamma rays, and radio-frequency waves, or atomic radiation, which might include the neutrons given off by uranium or some other radioactive substance. Most affected by these forms of radiation are polymers, such organic compounds as plastic or synthetic rubber, with long, repeated chains of similar chemical units.

Radiation tests are performed by exposing the materials to a known source of radiation for a specific period of time. Test materials may be exposed by robot control to nuclear fuels in a remote chamber, then tested by conventional methods to ascertain changes in their properties as a function of exposure time. In the field, paint samples may be exposed to electromagnetic radiation (such as sunlight) for prolonged periods then checked for fading or cracking.

Exposure to radiation is usually, but not always, detrimental to strength; for example, exposure of polyethylene plastic for short periods of time increases its tensile strength. Longer exposures, however, decrease tensile strength. Tensile and yield strength of a type of carbon-silicon steel increase with exposure to neutron radiation, although elongation, reduction in area, and probably fracture toughness apparently decrease with exposure. Certain new wood/polymeric composite materials are even pre-

pared by a process that employs radiation. The wood is first impregnated with liquid organic resin by high pressure. Next, the wood and resin combination is exposed to radiation, causing a chemical change in the form of the resin, producing a strengthened material.

Biological deterioration. In recent years there has been considerable activity in the new field of formulating tests to ascertain the resistance of organic materials to fungi, bacteria, and algae. Paints, wrappers, and coatings of buried pipelines, structures, and storage tanks are typical materials exposed to biological deterioration.

When biological composition of the soil in a given area is unknown, colonies or cultures of its various fungi, bacteria, or algae are isolated and incubated by standard laboratory techniques. These are then used to test materials for biological degradation, or to test the effectiveness of a fungicide or bactericide. In testing for algae resistance, for example, treated and untreated strips of vinyl film, such as might be used to line a swimming pool, are immersed in growing tanks along with seed cultures of algae plants. Within three days, luxuriant algae growths appear on untreated samples.

NONDESTRUCTIVE TESTING

The tensile-strength test is inherently destructive; in the process of gathering data, the sample is destroyed. Though this is acceptable when a plentiful supply of the material exists, nondestructive tests are desirable for materials that are costly or difficult to fabricate, or that have been formed into finished or semifinished products.

Liquids. One common nondestructive technique, used to locate surface cracks and flaws in metals, employs a penetrating liquid, either brightly dyed or fluorescent. After being smeared on the surface of the material and allowed to soak into any tiny cracks, the liquid is wiped off, leaving readily visible cracks and flaws. An analogous technique, applicable to nonmetals, employs an electrically charged liquid smeared on the material surface. After excess liquid is removed, a dry powder of opposite charge is sprayed on the material and attracted to the cracks. Neither of these methods, however, can detect internal flaws.

Radiation. Internal as well as external flaws can be detected by X-ray or gamma-ray techniques in which the radiation passes through the material and impinges on a suitable photographic film. Under some circumstances, it is possible to focus the X-rays to a particular plane within the material, permitting a three-dimensional description of the flaw geometry as well as its location.

Sound. Ultrasonic inspection of parts involves transmission of sound waves above human hearing range through the material. In the reflection technique, a sound wave is transmitted from one side of the sample, reflected off the far side, and returned to a receiver located at the starting point. Upon impinging on a flaw or crack in the material, the signal is reflected and its travelling time altered. The actual delay becomes a measure of the flaw's location; a map of the material can be generated to illustrate the location and geometry of the flaws. In the through-transmission method, the transmitter and receiver are located on opposite sides of the material; interruptions in the passage of sound waves are used to locate and measure flaws. Usually a water medium is employed in which transmitter, sample, and receiver are immersed.

Ultrasonic
method

Magnetism. As the magnetic characteristics of a material are strongly influenced by its overall structure, magnetic techniques can be used to characterize the location and relative size of voids and cracks. For magnetic testing, an apparatus is used that contains a large coil of wire through which flows a steady alternating current (primary coil). Nested inside this primary coil is a shorter coil (the secondary coil) to which is attached an electrical measuring device. The steady current in the primary coil causes current to flow in the secondary coil through the process of induction. If an iron bar is inserted into the secondary coil, sharp changes in the secondary current can indicate defects in the bar. This method only detects differences between zones along the length of a bar and cannot detect long or continuous defects very readily. An analogous technique, employing eddy currents induced by a primary

coil, also can be used to detect flaws and cracks. A steady current is induced in the test material. Flaws that lie across the path of the current alter resistance of the test material; this change may be measured by suitable equipment.

Infrared. Infrared techniques also have been employed to detect material continuity in complex structural situations. In testing the quality of adhesive bonds between the sandwich core and facing sheets in a typical sandwich construction material such as plywood, for example, heat is applied to the surface of the sandwich skin material. Where bond lines are continuous, the core materials provide a heat sink for the surface material, and the local temperatures of the skin will fall evenly along these bond lines. Where the bond line is inadequate, missing, or faulty, however, temperature will not fall. Infrared photography of the surface will then indicate the location and shape of the defective adhesive. A variation of this method employs thermal coatings that change colour upon reaching a specific temperature.

Finally, nondestructive test methods also are being sought to permit a total determination of the mechanical properties of a test material. Ultrasonics and thermal methods appear most promising in this regard. (K.E.H.)

BIBLIOGRAPHY

Chemical analysis. I.M. KOLTHOFF and P.J. ELVING (eds.), *Treatise on Analytical Chemistry*, in several parts and volumes (1959–), is an authoritative series that treats the broad field comprehensively. H.A. LAITINEN, *Chemical Analysis* (1960), is an excellent text for topics such as equilibria, titrimetry, precipitation processes, electrochemistry, statistical evaluation of data, errors, and sampling. LOUIS MEITES and H.C. THOMAS, *Advanced Analytical Chemistry* (1958), is especially valuable for its coverage of electrochemistry, spectrometric methods, radiochemistry, ion-exchange, and chromatographic methods. RONALD BELCHER, *Submicro Methods of Organic Analysis* (1966), gives the essential details of methods for working with samples weighing less than one milligram. D.R. BROWNING (ed.), *Electrometric Methods* (1969), contains a brief but fairly rigorous treatment of the fundamental principles of these techniques. MAX DONBROW, *Instrumental Methods in Analytical Chemistry*, 2 vol. (1966–67), surveys electrochemical and optical methods. Specialized topics are covered by ERICH HEFTMANN, *Chromatography*, 2nd ed. (1967); WILLIAM RIEMAN and H.F. WALTON, *Ion Exchange in Analytical Chemistry* (1970); SIDNEY SIGGIA, *Quantitative Organic Analysis Via Functional Groups*, 3rd ed. (1963); E.S. STERN and C.J. TIMMONS, *Gillam and Stern's Introduction to Electronic Absorption Spectroscopy in Organic Chemistry*, 3rd ed. (1970); GARY H. HIEFTJE, JOHN C. TRAVIS, and FRED E. LYTLE (eds.), *Lasers in Chemical Analysis* (1981); JAMES A. PLAMBECK, *Electroanalytical Chemistry* (1982); HERMENEGILDO A. FLASCHKA, ALFRED J. BARNARD, and P.E. STURROCK, *Quantitative Analytical Chemistry*, 2nd ed. (1980). See also ROBERT D. BRAUN, *Introduction to Chemical Analysis* (1982); and DOUGLAS A. SKOOG and DONALD M. WEST, *Fundamentals of Analytical Chemistry*, 4th ed. (1982).

(D.M.W.A.)

Chemical separations and purifications. B.L. KARGER, L.R. SNYDER, and G. HORVATH, *An Introduction to Separation Science* (1973), a modern treatment of theory and practice, with emphasis on small-scale operation; J.A. DEAN, *Chemical Separation Methods* (1969), deals with separation methods in analysis; C.T. KENNER and R.E. O'BRIEN, *Analytical Separations and Determinations: A Textbook in Quantitative Analysis* (1971), up-to-date treatment of classical methods; ERICH HEFTMANN (ed.), *Chromatography*, 2nd ed. (1967), especially useful for applications of chromatography to organic and biochemical mixtures; E.S. PERRY and C.J. VAN OSS (eds.), *Progress in Separation and Purification* (annual since 1968), a continuing series of chapters by experts in specialized fields; J.J. KIRKLAND (ed.), *Modern Practice of Liquid Chromatography* (1971), an up-to-date appraisal of a rapidly changing field; WILLIAM RIEMAN III and H.F. WALTON, *Ion Exchange in Analytical Chemistry* (1970), broad coverage of applications of ion exchangers in analysis; ROBERT LEMMICH (ed.), *Adsorptive Bubble Separation Techniques* (1972), the only book on this technique; HELMUT DETERMANN, *Gelchromatographie* (1967; Eng. trans., *Gel Chromatography, Gel Filtration, Gel Permeation, Molecular Sieves: A Laboratory Handbook*, 2nd ed., 1969), the best available presentation of ion-exclusion methods; E.W. BERG, *Physical and Chemical Methods of Separation* (1963), a good overview of separation science, but somewhat out of date; ROLAND S. YOUNG, *Separation Procedures in Inorganic Analysis* (1980), a practical handbook.

Periodicals: *Separation Science* (bimonthly) deals with all as-

pects of separation techniques; *Analytical Chemistry* (monthly) treats separations as part of analytical procedures for chemical compounds; *Journal of Chromatographic Science*, *Journal of Chromatography*, and *Chromatographia* (all monthly) deal specifically with chromatography; *Industrial and Engineering Chemistry* (monthly) often treats separations from the industrial viewpoint.

(B.L.K.)

Chromatography. E. HEFTMANN (ed.), *Chromatography*, 2nd ed. (1967); H.G. CASSIDY, *Fundamentals of Chromatography* (1957). Some specific aspects are discussed in ALBERTO FRIGERIO and MALCOLM MCCAMISH (eds.), *Recent Developments in Chromatography and Electrophoresis: Proceedings of the 10th International Symposium . . . June 1979* (1980); and T.C.J. GRIBNAU, J. VISSER, and R.J.F. NIVARD (eds.), *Affinity Chromatography and Related Techniques: Proceedings of the 4th International Symposium, June 1981* (1982).

Theory: J.C. GIDDINGS, *Dynamics of Chromatography* (1965).

Thin-layer chromatography: J.G. KIRCHNER, *Thin-Layer Chromatography* (1967); E. STAHL (ed.), *Thin-Layer Chromatography: A Laboratory Handbook* (1965).

Paper chromatography: R.J. BLOCK, E.L. DURRUM, and G. ZWIG, *A Manual of Paper Chromatography and Paper Electrophoresis*, 2nd ed. rev. (1958); I.M. HAIS and K. MACEK, *Paper Chromatography: A Comprehensive Treatise*, 3rd ed. (1963).

Gas chromatography: A.B. LITTLEWOOD, *Gas Chromatography: Principles, Techniques, and Applications*, 2nd ed. (1970); O.E. SCHUPP, *Gas Chromatography* (1968).

(J.C.Gi/Ro.A.K.)

Spectroscopy. *Atomic and X-ray spectroscopy:* R.A. SAWYER, *Experimental Spectroscopy*, 3rd ed. (1963), treats in detail instruments and practical methods especially for photographic spectroscopy and gives a survey of the historical development of spectroscopy, with many references. G. HERZBERG, *Atompektren und Atomstruktur* (1936; Eng. trans., *Atomic Spectra and Atomic Structure*, 2nd ed., 1944), develops the elementary theory needed for the understanding of spectra; HARVEY ELLIOT WHITE, *Introduction to Atomic Spectra* (1934), is an older, but thorough treatment. Brief tabulations including the wavelengths of the brightest spectral lines emitted by most atoms may be found in R.C. WEAST (ed.), *Handbook of Chemistry and Physics*, 48th ed. (1967, revised periodically). Extensive tabulations of wavelengths may be found in G.R. HARRISON, *Wavelength Tables* (1939); A. ZAIDEL et al., *Tables of Spectral Lines* (1970); and A.R. STRIGANOV and N.S. SVENITSKII, *Tables of Spectral Lines of Neutral and Ionized Atoms* (1968). X-ray data, samples of optical spectra of some materials, tabulation of wavelengths, and details of methods of detection of radiation may be found in D.E. GRAY (ed.), *American Institute of Physics Handbook*, 2nd ed. (1963). A.E. SANDSTROM, "Experimental Methods of X-ray Spectroscopy," *Handbuch der Physik*, vol. 30 (1957), is a survey of X-ray spectroscopy, written in English.

Molecular spectroscopy: Elementary general books include: C.N. BANWELL, *Fundamentals of Molecular Spectroscopy* (1966); GORDON M. BARROW, *Introduction to Molecular Spectroscopy* (1962); and GERALD W. KING, *Spectroscopy and Molecular Structure* (1964). Classic, authoritative works include: G. HERZBERG, *Molekülspektren und Molekülstruktur* (Eng. trans., *Molecular Spectra and Molecular Structure*, vol. 1, *Spectra of Diatomic Molecules*, 2nd ed., 1950; vol. 2, *Infrared and Raman Spectra of Polyatomic Molecules*, 1946; vol. 3, *Electronic Spectra and Electronic Structure of Polyatomic Molecules*, 1966); C.H. TOWNES and A.L. SCHAWLOW, *Microwave Spectroscopy* (1955); and N.F. RAMSEY, *Molecular Beams* (1963); ALEXIS T. BELL and MICHAEL L. HAIR (eds.), *Vibrational Spectroscopies for Absorbed Species* (1981), a collection based on a 1979 symposium of the American Chemical Society.

(J.O.S.Jr./E.B.W.)

Astronomical spectroscopy. Stellar, nebular, and galactic spectroscopy are covered in the compendium *Stars and Stellar Systems*, ed. by G.P. KUIPER and B.M. MIDDLEHURST; most relevant volumes are 1, *Telescopes*; 2, *Astronomical Techniques*; 5, *Galactic Structure*; 6, *Stellar Atmospheres*; and 7, *Nebulae and Interstellar Matter*. Articles in the *Annual Review of Astronomy and Astrophysics* are: C. ARPIGNY, "Spectra of Comets and Their Interpretation," 3:351–376 (1965); E.M. BURBIDGE and M. SCHMIDT respectively, "Quasi-Stellar Objects," 5:399–452 (1967) and 7:527–552 (1969); F.J. KERR, "The Large-scale Distribution of Hydrogen in the Galaxy," 7:39–66 (1969); and A.K. DUPREE and L. GOLDBERG, "Radiofrequency Recombination Lines," 8:231–264 (1970); WILLIAM BUSCOMBE (comp.), *MK Spectral Classifications* (1981), is a general catalog.

(D.M.H.)

Mass spectroscopy. F.W. ASTON, *Mass Spectra and Isotopes* (1933), a comprehensive account of the early work that laid the foundations of accurate mass and isotopic abundance measurements; M.G. INGRAM and R.J. HAYDEN, *A Handbook on Mass Spectroscopy* (1954), a survey of instrument types including detailed descriptions of the physics of ion sources and detectors together with the theory of ion sources and detectors together with the theory of ion focussing and mass analysis; F.H. FIELD and J.L. FRANKLIN, *Electron Impact Phenomena and the Properties of Gaseous Ions* (1957), a study of the properties of gaseous ions with particular emphasis on the chemical physics of the systems; H.E. DUCKWORTH, *Mass Spectroscopy* (1958), a monograph giving good general coverage, including applications in physics, geophysics, and related sciences; J.H. BEYNON, *Mass Spectrometry and its Use in Organic Chemistry* (1960), practical information and many references to all aspects of mass spectrometry; H. BUDZIKIEWICZ, C. DJERASSI, and D.H. WILLIAMS, *Mass Spectrometry of Organic Compounds* (1967), a comprehensive account of the methods used to determine structural formulas of organic compounds. See also H.E. ROSE and R.A.W. JOHNSTONE, *Mass Spectrometry for Chemists and Biochemists* (1981); URS P. SCHLUNEGGER, *Advanced Mass Spectrometry: Applications in Organic and Analytical Chemistry* (1980); and FRED W. MCLAFFERTY, *Interpretation of Mass Spectra* (1980).

(J.H.Be.)

Radiation measurement. JACK SHARPE, *Nuclear Radiation Detectors*, 2nd ed. rev. (1964), is a compact survey of the basic physics of detectors; W.H. TAIT, *Radiation Detection* (1980), is an introductory text; GLENN F. KNOLL, *Radiation Detection and Measurement* (1979), is a more extensive work covering techniques. Specific detectors are dealt with in the following: GEOFFREY DEARNALEY and D.C. NORTHROP, *Semiconductor Counters for Nuclear Radiations*, 2nd ed. rev. (1966); C.H. WANG, DAVID L. WILLIS, and WALTER D. LOVELAND, *Radiotracer Methodology in the Biological, Environment and Physical Sciences* (1975), which includes a detailed explanation of liquid scintillation counting; D.H. WILKINSON, *Ionization Chambers and Counters* (1950, reissued 1970); BRUNO B. ROSSI and HANS H. STAUB, *Ionization Chambers and Counters* (1949, reprinted 1977). Of the last two books, Wilkinson's is predominantly theoretical in nature, whereas Rossi and Staub's deals with experimental techniques developed in the Manhattan Project. The International Atomic Energy Agency (IAEA), Vienna, publishes a number of books and reports that are readily available. In the field of health physics, reports no. 109 and 120 in the IAEA "Technical Reports Series" deal with personnel dosimetry systems and the monitoring of radioactive contamination on surfaces, respectively, whereas *Nuclear Accident Dosimetry Systems* is one of the IAEA "Proceedings Series" (all 1970). Papers on detectors are regularly published in many journals, including the *Review of Scientific Instruments* (monthly), of which the May 1961 issue was devoted entirely to spark chambers; *Nuclear Instruments and Methods* (bimonthly); and *IEEE Transactions: Nuclear Science* (bimonthly), which include the proceedings of the Scintillation and Semiconductor Counter Symposium held every other year since 1948. Specific questions are discussed in PARRY H. MOON and DOMINA EBERLE SPENCER, *The Photic Field* (1981).

(Ed.)

Astronomical photometry. *Historical:* H.F. WEAVER, "The Development of Astronomical Photometry," *Pop. Astr.*, vol. 54 (1946); G. EBERHARD, H. KOHLSCHUETTER, and H. LUDENDORFF (eds.), *Handbuch der Astrophysik*, vol. 2 (1929-31); W. WIEN

and F. HARMS (eds.), *Handbuch der Experimentalphysik*, vol. 26 (1937); JOEL STEBBINS, "The Electrical Photometry of Stars and Nebulae," *Mon. Not. R. Astr. Soc.*, 110:416-428 (1950); *Publ. Washburn Obs.*, vol. 15, ch. 1 (1928).

Photographic photometry: H.F. WEAVER, "Photographic Photometry," in S. FLUGGE (ed.), *Handbuch der Physik*, vol. 54 (1962), in English; J. STOCK and A.D. WILLIAMS, "Photographic Photometry," with a section by B.M. MIDDLEHURST, in W.A. HILTNER (ed.), *Astronomical Techniques*, ch. 17 (1962); C.E.K. MEES, *The Theory of the Photographic Process*, 3rd ed. (1966).

Photoelectric photometry: A.E. WHITFORD, "Photoelectric Techniques," in S. FLUGGE (ed.), *Handbuch der Physik*, vol. 54 (1962), in English; F.B. WOOD, *Photoelectric Photometry for Amateurs* (1963).

Spectrophotometry: A.D. CODE, "Stellar Energy Distribution," in J.L. GREENSTEIN (ed.), *Stellar Atmospheres*, ch. 2 (1960); J.B. OKE, "Absolute Spectral Energy Distributions in Stars," *A. Rev. Astr. Astrophys.*, 3:23-46 (1965).

General: G.P. KUIPER and B.M. MIDDLEHURST (eds.), *Stars and Stellar Systems*, vol. 2 and 3 (1962-63), contain many articles dealing directly or indirectly with astronomical photometry. The UVB system was first described by H.L. JOHNSON and W.W. MORGAN in "Fundamental Stellar Photometry for Standards of Spectral Type on the Revised System of the Yerkes Atlas," *Astrophys. J.*, 117:313-352 (1953). See also ARNE A. HENDEN and RONALD H. KAITCHUCK, *Astronomical Photometry* (1982).

Materials testing. J. MARIN, *Engineering Materials: Their Mechanical Properties and Applications* (1952), a classic work describing the qualitative mechanical behaviour of materials, and *Mechanical Behaviour of Engineering Materials* (1962), a comprehensive treatment of the determination and utilization of mechanical properties of materials in design; Z.D. JASTRZEBSKI, *Nature and Properties of Engineering Materials* (1959), similar to Marin's earlier work, but updated to the end of the decade; H.R. CLAUSEN *et al.* (eds.), *Encyclopedia of Engineering Materials and Processes* (1963); and J.M. ALEXANDER and R.C. BREWER, *Manufacturing Properties of Materials* (1963); two comprehensive and easily read texts on material properties.

Other general works include: C.W. RICHARDS, *Engineering Materials Science* (1961), a highly readable and up-to-date book; F.A. MCCLINTOCK and A.S. ARGON (eds.), *Mechanical Behavior of Materials* (1966), an excellent description of both sophisticated and conventional techniques for acquiring and utilizing modern material property data; and O.J. HORGEV (ed.), *ASME Handbook*, vol. 1, *Metal Engineering: Design*, 2nd ed. (1965), the official Mechanical Engineering Society position on the utilization of advanced material properties in design; I.E. CAMPBELL, *High-Temperature Technology* (1956); and W.D. KINGERY, *Introduction to Ceramics* (1960); books illustrating the utilization of ceramic materials and emphasizing high-temperature applications; J.E. DORN (ed.), *Mechanical Behavior of Materials at Elevated Temperatures* (1961), a thorough treatment of advanced material properties, particularly of metals, as influenced by high temperature; and H.E. DAVIS, G.E. TROXELL, and C.T. WISKOCIL, *The Testing and Inspection of Engineering Materials*, 3rd ed. (1964), a highly comprehensive and easily understood work offering sufficiently detailed information on the various testing methods for use in the training of materials testing personnel. JOHN J. BURKE and VOLKER WEISS (eds.), *Non-destructive Evaluation of Materials* (1978), is a compendium of conference papers.

(K.E.H.)

Angiosperms: The Flowering Plants

The angiosperms, more generally known as the flowering plants, constitute the largest and most conspicuous group of modern plants. They predominate in number of species—perhaps up to 250,000—and in number of individuals and constitute the dominant vegetation of the Earth's surface today. Even in coniferous forests, in moss and lichen tundra, and in fern and cycad thickets, angiosperms often play a conspicuous role.

The taxonomic disposition of the flowering plants is

somewhat unsettled; some earlier classifications list them as a class, Angiospermae (of the division Spermatophyta), but more recent systems raise the group to the level of a division (roughly comparable to the “phylum” rank among animals), called Anthophyta, or more recently, Magnoliophyta.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 313, and the *Index*.

THE ANGIOSPERMS: DIVISION MAGNOLIOPHYTA

Angiosperms inhabit the most diversified environments and may be found wherever higher plants can survive. They have evolved a remarkable variety of life forms, a much greater variety than is to be found in the other divisions of the plant kingdom. They range in life span from a few weeks to several thousand years. Angiosperms provide man with food, shelter, clothing, drugs, and ornamental plants. The most important of all sources of food are such angiosperms as the cereal grasses (especially rice; wheat; and maize, or corn), sugarcane, potatoes, tuberous vegetables (yams, taro, etc.), and fruits.

Vegetable fats, oils, and masticatories are also of great value. Besides providing nourishment, fats and oils are used in technology, medicine, and the perfume industry. Spices are supplied by such angiosperms as pepper, laurel, clove, cinnamon, and vanilla. Plants containing stimulants, especially tea, coffee, and cacao, are of great importance, as are those that produce narcotics that are widely used in medicine (e.g., morphine). Vegetable fibres (e.g., cotton and flax) are important for the manufacture of clothing. Many trees yield useful woods, a number of which are of high commercial value. Chemicals of various kinds are also derived from wood. More than 10,000 species of flowering plants are used in medicine. The number of species used in industry is considerably less, but

some of them, especially the tropical rubber trees, are exceptionally important. Finally, angiosperms ornament the land and provide the most natural human environment.

Flowering plants present an immense diversity in habit, form, and size, ranging from the minute, almost microscopic watermeal (the smallest known angiosperm) to gigantic trees like eucalyptuses. Most angiosperms grow erect upon the ground, but many of them are trailing, climbing, or physically supported on other plants. The majority are terrestrial. Most of them contain chlorophyll and can manufacture their own food from raw materials, but some (as saprophytes) absorb their food from decaying plants or (as parasites) obtain their food from other living plants. Members of several families are carnivorous, like the sundew (*Drosera*), obtaining a part of their food from insects and other small animals.

Although many angiosperms are woody (trees and shrubs), the majority are herbaceous. It is now widely accepted that the arborescent habit is in general primitive in angiosperms and that all herbaceous plants originated from woody ancestors; the exceptions include woody representatives of the goosefoot family (*Chenopodiaceae*) and all of the arborescent monocots (palms, screw pines, bamboos, and others). Herbaceous angiosperms have more advanced characters than woody angiosperms and are more

Diversity
of the
flowering
plants

Diversity among flowering plants.

(Top left) Australian eucalyptus tree (*Eucalyptus regnans*, family Myrtaceae), largest of the flowering plants. Top row: (left) Dodder (*Cuscuta*, family Convolvulaceae), a climbing parasite; (centre) Old World pitcher plant (*Nepenthes*), a photosynthetic plant that captures insects; (right) duckweed (*Lemna*, family Lemnaceae), one of the smallest of the flowering plants. Centre: (above) Blossom of saucer magnolia (*Magnolia soulangeana*, family Magnoliaceae), a primitive flowering plant; (below) Sumatran rafflesia flower, world's largest known flower. The flower of this parasitic plant, which has no green parts, is bright red and fleshy. (Centre right) A bromeliad, an epiphytic air plant that grows upon (but is not parasitic on) trees and shrubs. (Bottom left) Golden barrel cactus (*Echinocactus grusonii*, family Cactaceae), a xerophyte. (Bottom right) Victoria water lily (*Victoria amazonica*), a hydrophyte.

(Top left) Douglass Baglin; top row: (left) Ray Kriner—Grant Heilman, (centre) W.H. Hodge, (right) Dennis Brokaw; centre: (above) A.W. Ambler—National Audubon Society, (below) W.H. Hodge; (centre right) Russ Kinne—Photo Researchers; (bottom left) W.H. Hodge; (bottom right) John H. Gerard

plastic in terms of evolution. In herbs, the reproductive phase comes much earlier and with a minimum expenditure of material for construction of vegetative organs, while production of seeds is at a maximum in comparison to the vegetative mass. Furthermore, herbaceous species

commonly expand their geographic range more rapidly than trees and play an important role in global vegetation. The development of herbaceous angiosperms has had special significance for the evolution of herbivorous mammals and ground-feeding birds.

Life cycle

The typical angiosperm plant body—with its leaves, stems, and roots—is the conspicuous phase of the angiosperm life cycle and is called the spore-bearing (sporophyte) generation; each of its living cells has at least two complete sets of chromosomes, twice as many as the cells of the gamete-bearing (gametophyte) generation that follows. During flowering this plant produces microspores, which develop into male gametophytes, and megaspores, which develop into female gametophytes.

As in gymnosperms, both male and female gametophytes are reduced to microscopic proportions. The male gametophyte is ultimately shed as the pollen grain; the female gametophyte, the embryo sac, is retained on the sporophyte in the ovule. If suitable pollen grains are trapped on the receptive stigmatic surface of a flower, they may germinate and one may fertilize the egg nucleus in the embryo sac. A zygote is formed, and the ovule develops into the seed. The seed ripens and awaits germination to become the conspicuous sporophyte plant body. Thus the cycle is complete.

Pollination and fertilization. The vast majority of angiosperms are normally characterized by cross-pollination, or the transfer of pollen from one flower or plant to another, but self-pollination, or the transfer of pollen from anther to stigma of the same flower, is not uncommon. Cross-pollination has the advantage of producing new combinations of existing genes, and the offspring that arise from a

cross are often superior in vigour to those in which both gametes came from the same plant. A great variety of adaptations, in both flower behaviour and structure, prevent or restrict self-pollination. One of the commonest and most effective of these mechanisms is self-sterility (see REPRODUCTION AND REPRODUCTIVE SYSTEMS: *Pollination*).

Shortly after the pollen-grain reaches the stigma, it germinates and the emerging pollen tube grows down the inside of the style and into the cavity of the ovary. The tube nucleus is carried near the tip of the pollen tube, followed by the generative cell. While the tube is developing (or earlier, even before the pollen grain is shed), the generative cell divides into two male gametes. In most cases the pollen tube enters the ovule through a tiny opening, the micropyle. Less commonly the pollen tube penetrates the basal (chalazal) region of the ovule.

After its entrance into the female gametophyte, the tip of the pollen tube ruptures, discharging the two male gametes into the cytoplasm of the female gametophyte. One of the male gametes penetrates the egg and unites with the female nucleus, thus effecting fertilization. The resulting zygote normally develops into the embryo. The other male gamete unites with two other nuclei (the polar nuclei) of the female gametophyte (or with a nucleus formed by prior fusion of the polar nuclei), thus forming the endosperm nucleus. The endosperm nucleus gives rise to a food storage tissue called endosperm. The participation of each of the two male gametes in a fusion process is unique to the angiosperms and is called double fertilization.

Double fertilization

Life cycle of a representative angiosperm.

Embryo and seed development. The development of the embryo from the zygote begins with rapid nuclear divisions accompanied by the formation of cell walls. The early stages of embryo development within the seed are similar in both classes of the angiosperms. But further development proceeds in different ways: in dicotyledons a lateral seed leaf (cotyledon) arises on each side of the stem primordium, while in the monocotyledons only one of two primordial cotyledons develops and is displaced toward the apex. The developmental process clearly indicates that the monocotyledonous embryo arose from the dicotyledonous type by way of a distinct alteration in early stages of development. In dicotyledons the embryo is typically differentiated into four main parts: the radicle, or the embryonic root; the hypocotyl, or the transition region from root structure to stem structure; the cotyledons, attached to the upper end of the hypocotyl; and the plumule, or the bud of the embryo, inserted between the cotyledons (see REPRODUCTION AND REPRODUCTIVE SYSTEMS: *Seed and fruit*).

The primary endosperm nucleus divides to form the endosperm, or food storage tissue of the seed, which serves to nourish the developing embryo and often, later, the germinating seed. From the evolutionary point of view the endosperm is a "new" structure characteristic of the angiosperms only. Often, however, the endosperm degenerates before the seed is mature, and the food is stored in the thickened cotyledons (as in beans, peas, and other legumes) or in other parts of the embryo, especially the hypocotyl.

The seed of a primitive angiosperm is characterized by abundant endosperm and a minute, undifferentiated embryo. The seeds of more advanced groups usually have scanty endosperm or none at all and a large, differentiated embryo.

The nucellus is generally resorbed during development of the seed, but in some groups it persists and gives rise to a food storage tissue called perisperm. The integument develops into the seed coat (testa), a protective covering for the embryo.

The ripened seeds are enclosed in a fruit, which is exclusively an angiosperm organ specialized for protection and dispersal of the seeds. The other major group of seed-producing plants, the gymnosperms, do not bear fruit. A fruit is a modified gynoecium (mainly ovary), often with adherent parts of the flower.

Fruits may be divided into two major types: dry and fleshy. Dry fruits may be further subdivided into two groups depending upon the number of seeds and whether the fruit opens at maturity (dehiscent) or remains closed (indehiscent). Fleshy fruits are indehiscent. When a group of fruits develops from a cluster of distinct but closely packed flowers, as in the mulberry and pineapple, it is called a multiple fruit. This conventional classification of fruits, though empirical, is useful for the classification and identification of angiosperms. But for phylogenetic studies it would be more useful to have an evolutionary classification of fruits based on fundamental features of the flowers from which the fruits are derived.

Form and function

Vegetative organs. Like other vascular plants, angiosperms have specialized conducting tissues. The xylem serves in the conduction of water and minerals and also provides strength. The phloem serves to conduct dissolved food and minerals. In a tree the wood is the xylem and the bark is the phloem. Only the inner (live) bark serves in conduction, and in a large tree only the outer part of the wood serves in conduction. The xylem of most angiosperms has specialized conducting tubes called vessels, but in certain types (aquatics, parasites, saprophytes, and succulents) the vessels have been secondarily lost during evolution. A few primitive angiosperms, however, never had vessels; those include members of the families Winteraceae, Trochodendraceae, and Tetracentraceae, among others. The essential cell type in phloem is the sieve element. The sieve elements are joined end to end to form sieve tubes, with the sieve areas concentrated onto the

sieve plate at the end. Furthermore, each sieve tube is in longitudinal contact with another kind of specialized cell, the companion cell. Gymnosperms, in contrast, have a simpler type of phloem, lacking companion cells, and with the sieve areas not concentrated onto terminal sieve plates. In some of the more primitive angiosperms, such as *Austrobaileya*, the phloem is not very different from that of gymnosperms.

The leaves of angiosperms are endlessly varied in size, shape, and structure. Their arrangement on the stem may be alternate, opposite, or whorled. The alternate arrangement is primitive, opposite- and whorled-leaf arrangements having been derived in the course of evolution. The leaves of primitive angiosperms are mostly simple, entire, pinnately veined, leathery, and smooth. Leaves shed in the winter or in the dry season are secondary and have originated from "evergreen" leaves. The deciduous habit may have evolved primarily in the tropics as an adaptation for survival during the dry season and permitted such forms to spread from the tropical zone to more seasonal belts. But most deciduous woody forms have originated in the course of angiosperm dispersal from the lower to the higher latitudes.

Leaves and other aerial green parts have specialized pores called stomata (singular stoma) in the epidermis. These openings are spaces between two specialized crescent-shaped epidermal cells known as guard cells. In many angiosperms the stomata are associated with two or more cells that differ in shape from the other epidermal cells. These distinct cells are called subsidiary, or accessory, cells of the stoma. A few main types of stomatal complexes based on number and arrangement of subsidiary cells have been recognized among the angiosperms. The stomatal complexes are an increasingly important source of taxonomic characters.

Two types of root structure are apparent among angiosperms, corresponding in general to the division into monocotyledons and dicotyledons (see Table 1 below).

Reproductive organs. The outstanding structure in the life history of angiosperms is the flower, a highly modified and specialized reproductive shoot in which the spore-bearing organs or sporophylls (stamens and carpels) are borne on a more or less shortened axis (receptacle) and are usually surrounded by a perianth (sepals and petals). A flower that has both stamens and carpels is termed bisexual (or, according to more accurate terminology, amphisporangiate). If either the stamens or the carpels are absent, the flower is unisexual (or, more accurately, monosporangiate) and is either male (staminate or microsporangiate) or female (carpellate or megasporangiate). When a plant bears either staminate or carpellate flowers, it is called dioecious; when it bears both staminate and carpellate flowers, it is called monoecious. There are no essential differences between the flower of angiosperms and the strobilus of gymnosperms. It is usually said that angiosperms differ from gymnosperms in having the ovules (potential seeds) borne within a closed cavity, the ovary, formed by the carpel (or carpels). But this difference is not clear-cut; the carpel is open at the time of pollination in some primitive angiosperms, and in some gymnosperms (*Araucaria*) the seed is enclosed in the seed scale. (For details of floral structure, see REPRODUCTION AND REPRODUCTIVE SYSTEMS.)

The receptacle is a stem with internodes much shortened or suppressed. The most primitive flowers have an elongated receptacle with an indefinite and variable large number of floral parts arranged spirally upon it. In the course of flower evolution the receptacle has become shorter, and the parts fewer, fixed in number, and arranged in whorls. These flowers are characteristic of the advanced angiosperms.

The sepals (collectively called the calyx) are usually green and more or less leaflike or bractlike, but they may be reduced. Morphologically, they are specialized leaves. The main function of the calyx is the protection of the inner and more delicate floral parts as these develop in the bud. In some genera (*Trollius*, *Lilium*, *Tulipa*, *Allium*, and others) sepals are much like the petals and scarcely distinguishable except by position and by vascular anatomy.

Leaves

Sepals and petals

The petals (collectively called the corolla) usually alternate with the sepals and differ from them in being usually more delicate in texture, larger in size, and of some colour other than green. In some primitive angiosperms (Magnoliales, Illiciales, etc.), all the perianth parts are morphologically equivalent and of leaf origin. But in most families the petals have originated as an evolutionary petaloid elaboration of stamens. Thus the corolla has arisen in two ways, and the petals of roses, for example, are not morphologically equivalent to those of magnolias. In several advanced orders the petals are united to form a gamopetalous or sympetalous (as opposed to a polypetalous) corolla. The main function of the petals is to attract pollinators. In many angiosperms the perianth consists of sepals only, which may be scalelike, as in the oaks, or large and showy, as in the anemones, taking the place of the corolla. Such flowers, with the perianth consisting of sepals only, are called apetalous. The absence of a corolla is secondary rather than primitive, at least in the great majority of angiosperm species.

Stamens The stamens (microsporophylls) are collectively called the androecium. Each stamen is usually differentiated into a stalk (filament) and a distal, spore-bearing portion (anther). The more advanced types of stamens are characterized by a distinct slender filament, whereas in many primitive angiosperms (*Degeneria*, *Himantandra*, some Magnoliaceae, and others) the stamens are broad, flat structures with no differentiation of a filament. The anther typically consists of four pollen sacs (microsporangia), two in each lobe or anther half, the tissue separating them disintegrating prior to flowering, and the resulting anther seemingly two-celled (bilobulate). The strip of tissue between the pairs of microsporangia is called the connective. In primitive stamens the connective is produced beyond the microsporangia, forming a more or less distal appendage. In primitive groups, the microsporangia are long and narrow.

Floral structures characteristic of angiosperms.

The primary spore-forming cells in a microsporangium give rise to a large number of diploid ($2n$) spore mother cells, each of which produces by two cell divisions a group of four haploid (n) microspores. The microspore, after germination, when the cells of the male gametophyte appear within the wall, becomes the pollen grain. Each pollen grain contains a greatly reduced male gametophyte, which consists of two cells only—a small generative cell and a larger tube cell or “vegetative” cell. The microspore (and pollen grain) has a cell wall of two layers: an outer (exine) and an inner (intine). The exine is more or less sculptured in patterns that characterize particular species. The cell wall usually has one or more thin places (apertures) where the exine is not fully formed and through which the pollen tube later may emerge. There are two major types of germinal apertures: furrows (colpi; singular colpa) and pores. The most primitive angiosperm pollen grain is the

monocolpate type, with one polar germinal furrow. Such monocolpate pollen grains have a continuous aperture membrane devoid of special openings (ora; singular os) in the exine for the emergence of the pollen tube. Monocolpate pollen is characteristic of the Magnoliales and some other primitive dicotyledons, of the majority of monocotyledons, and of many gymnosperms. In the course of evolution, several other types of pollen grains have been derived, differing in number of furrows or pores.

The carpels (megasporephylls) are collectively called the gynoecium. The carpel consists of the ovary with enclosed ovules, and the stigma, a receptive surface for pollen grains, typically borne at the apex of a stalk, called the style (or stylodium, as some authors prefer to name the simple style of an individual carpel). The most primitive carpel is reminiscent of a young leaf folded along the midrib; such a carpel is called conduplicate and is characteristic of certain primitive angiosperms—e.g., the genera *Degeneria* and *Tasmannia*, and to a lesser degree the family Magnoliaceae. A very important taxonomic characteristic of primitive carpels is the absence of styles, the stigmatic surface being along the margins (sutures) of the carpels. Of the two basic types of ovule arrangement (placentation) within the carpel, laminar (superficial) and sutural (submarginal), the former is probably more primitive.

The gynoecium may consist of one to many carpels. The carpels may be arranged in either a spiral or a whorl on the receptacle. The most primitive types of gynoecia are characterized by a large number of carpels arranged spirally upon a long receptacle, as in *Magnolia*. In the course of gynoecium evolution the number of carpels typically decreases, and the whorled arrangement evolves. Gynoecia with individually distinct (free) carpels are called apocarpous; such gynoecia are characteristic for the more primitive orders of angiosperms, as Magnoliales, Ranunculales, Dilleniales, Alismales, and others. During their evolution carpels have gradually united with each other in various forms, generally termed coenocarpous gynoecia. There are technically three types of coenocarpous gynoecia: syncarpous (two—or more—locular, with axile placentation, as in *Lilium*); paracarpous (unilocular, with parietal placentation, as in *Viola*); and lysicarpous (unilocular, with free central placentation, as in *Primula*). In descriptive morphology of plants, however, all gynoecia with united carpels are termed syncarpous. The term pistil has been a source of confusion as it is used both for a single carpel and for coenocarpous gynoecia; some authors suggest abandoning it.

In the less advanced types of coenocarpous gynoecia, the individual styles of carpels are more or less free, and only the ovaries are fused, as in *Hypericum*. In more advanced gynoecia, the styles and their stigmas are united (compound), as in *Rhododendron*. In more primitive groups, the flower is hypogynous, the gynoecium being situated above the place of attachment of the perianth and stamens, and the ovary is termed superior. In more advanced groups, the flower is frequently epigynous, the ovarian part of the gynoecium being fused with the basal part of the perianth, or in a few cases embedded in the receptacle, and the ovary is termed inferior (the perianth and stamens seem to arise from its summit).

The ovule, destined to become a seed, consists of the nucellus (megasporeangium), completely surrounded by one or two integuments, except for a narrow opening (micropyle) at the top of the ovule. Each ovule is borne on a stalk (funiculus) and may be erect (orthotropous) or, more commonly, recurved (anatropous). The basal part of the ovule, where all its parts merge, is called the chalaza. In more primitive angiosperms the ovules are massive and vested with two integuments. In more advanced groups the ovules are small and have only one integument. In some representatives of the order Santalales, especially in the families Loranthaceae and Balanophoraceae, the ovule is reduced, has no integuments, and the sporangium is naked.

The female gametophyte (embryo sac) develops within the megasporeangium and most commonly forms by the division of the innermost megaspore of the tetrad of potential megaspores, the other three degenerating. The func-

Carpels

tional megaspore greatly enlarges, absorbing the abortive megaspores and some of the surrounding nucellar tissue. The nucleus of the functional megaspore divides into two daughter nuclei, which move to opposite ends of the greatly elongated megaspore. Each daughter nucleus then divides, and ordinarily two in turn soon give rise to two groups of four cells (eight in all). One nucleus from each polar group moves to the centre of the young gametophyte. These two nuclei, called polar nuclei, come in contact with each other and may fuse immediately or remain distinct for a time. In the gametophyte there are soon formed three cells at the micropylar end (one is the female gamete, or egg, and the other two are called synergids) and three cells at the chalazal end (called antipodals). Thus, the female gametophyte of angiosperms is extremely simplified and completely devoid of all traces of gametangia.

Evolution and paleontology

Origin of angiosperms. The angiosperms appear to have arisen from some gymnosperm ancestors in a single lineage (monophyly). It is quite possible that the angiosperms were connected with the Bennettitales (a group related to living cycads) through a common ancestor as yet unknown but possibly some primitive seed fern.

The first
angio-
sperms

The first angiosperms (and their immediate gymnosperm precursors) may have been inhabitants of the mountains, where they probably formed small, semi-isolated local populations. Such populations are common in mountain plants and provide the combination of genetic drift and selection that is most effective in promoting rapid evolution. If this supposition is correct, then evolution in the immediate ancestors of angiosperms and in the earliest angiosperms themselves must have been very rapid and must have facilitated the production of large adaptive modifications. Under such conditions, one of the ancient branches of gymnosperms might well have initiated a more progressive group of seed plants characterized by high adaptability.

The basic morphological peculiarities of angiosperms find their most likely explanation in the hypothesis of their neotenic origin (retention of early developmental stages). Thus, the flower may be regarded as a neotenic form of the strobilus of an ancestral gymnosperm. The carpels of the most primitive angiosperms, especially those reminiscent of young folded leaves in *Degeneria* and *Tasmannia*, give the impression of being "infantile" organs corresponding to the juvenile stages of sporophylls of an ancestral gymnosperm. The evolutionary transformation of the open sporophyll into the carpel by folding and gradual closure along its middle vein could easily have occurred in a juvenile stage. The transformation of open megasporophylls into more or less closed carpels may have occurred at a stage in development when they were still in a folded condition. The stamens of angiosperms arose most likely from the juvenile stage of the microsporophylls of an ancestral gymnosperm. Traces of neotenic origin are also visible, though less obvious, in the morphology of angiosperm leaves. The simple and entire leaves of primitive angiosperms, like those of *Magnolia*, could have occurred by arrested development of an ancestral gymnosperm at an early juvenile stage. The primitive structure of the wood of early vesselless angiosperms is also understandable as a neotenic adaptation: it corresponds to the juvenile wood of gymnosperms.

The flower arose most probably from a bisexual strobilus, a supposition bolstered by the discovery of bisexuality associated with insect pollination among certain fossil gymnosperms. Insects must have played a decisive role in the transformation of a gymnosperm strobilus into the angiosperm flower. Insects visiting the strobili of the ancestors of the angiosperms found shelter therein, attracted by the abundance of pollen grains on which they fed. At the same time, they facilitated cross-pollination. But they also ate the ovules. So this primitive type of pollination may have led to protection of the ovules. In the immediate ancestors of angiosperms this may have resulted in a partial closure of the folded juvenile megasporophyll. Even in the primitive carpels of the early angiosperms the

young succulent ovules were protected not only from the primitive unspecialized pollinators but also from the sucking insects of later epochs. Though they probably arose in the first place only as a defensive adaptation against certain types of insects, the carpels also gave protection from other harmful external influences, particularly atmospheric dryness. Inside the carpels, new environmental conditions were created for the development of the ovule and for the process of fertilization.

The origin of carpels made it possible for angiosperms to simplify the structure of their ovules, and this in turn led to smaller ovules, with a reduced gametophyte, capable of much faster development. This was a very important advance, as it enabled the angiosperms to observe the greatest possible economy of material in the construction of the ovules and female gametophyte. The development of carpels also led to the formation of the stigmatic surface, the further evolution of which made possible the perfection of the process of pollination. The acquisition of the stigma was undoubtedly another great event in the evolutionary history of flowering plants. It improved the possibility of pollination, served as a new barrier to "undesirable" pollen and thereby assisted cross-pollination, and still further facilitated the simplification of the ovule. Finally, the evolution of carpels made possible both coenocarpy (union of carpels) and angiocarpy (the enclosure of the carpels by other parts of the flower), which undoubtedly had great adaptive significance, as improving chances of reproductive success.

Fossil evidence. The oldest fully authentic fossil angiosperms are known from the Early Cretaceous Period (130,000,000 years ago), toward the end of which period the frequency and abundance of angiosperms noticeably increased. Fossil angiosperms appear in the company of various gymnosperms (including the Bennettitales) and ferns and predominate only in a few cases. They evidently formed only small populations and were represented by a comparatively small number of individuals. Toward the middle of the Cretaceous Period (100,000,000 years ago), however, one of the most sudden and fundamental transformations of terrestrial plant life occurred, and in the course of a few million years (a very short interval in geological time) the angiosperms came to be widely distributed throughout the world, quickly reaching the Arctic and Antarctic regions. They appeared in great diversity and quickly became dominant, decisively influencing the future of the terrestrial animal world, especially the insects, birds, and mammals, and in the final reckoning made possible the appearance of man.

While the most diverse opinions can be found in the literature concerning the centre of origin and distribution of the angiosperms, an analysis of the present distribution of the more primitive living angiosperms suggests that they arose somewhere in the Old World tropics, in what is now Southeast Asia, where the relatively greatest concentration of primitive angiosperms is found.

origin

Classification of the flowering plants

Distinguishing taxonomic features. The classification of angiosperms is based on the synthesis of all of the available data from many fields: comparative morphology, palynology, embryology, cytology, genetics, biochemistry, serology, and biogeography. Although computers and the scanning electron microscope are being increasingly employed in the development of modern methods in systematics, in practice plant taxonomists still rely to a large extent on morphological features to subdivide the angiosperms into orders and families and to determine relationships among them. These features include principally: numbers and arrangement of flower parts; disposition of the flowers on the plant; the type of gynoecium and placentation; the structure of the carpels; the type and structure of the ovules and the number of integuments; the presence or absence of endosperm and perisperm; the structure and development of the androecium, pollen grains, and perianth; leaf structure and arrangement; stomatal patterns; and structure of the wood.

The division Magnoliophyta is divided into two classes,

the Magnoliopsida (dicotyledons) and Liliopsida (monocotyledons). Some of the differences between these classes are shown in Table 1. Dicots and monocots are distinguished from each other by combinations of characters rather than by any single character. In fact there is no single character that can serve reliably to separate the monocotyledons from the dicotyledons. Even the number of cotyledons, which formed the basis for the original subdivision of the angiosperms into two groups, may fluctuate: in *Agapanthus*, a typical monocotyledonous plant of the order Liliales, some embryos have two cotyledons; whereas *Ranunculus ficaria*, some species of *Corydalis*, some Gesneriaceae, and several other dicotyledonous plants have embryos with a single cotyledon.

Evidence indicates that the monocotyledons originated from some long extinct vesselless herbaceous dicotyledon with apocarpous gynoecia and monocolpate pollen grains (characters much in common with the modern Nymphaeales). The order Nymphaeales is most likely a hydrophilous derivative of some ancient Magnoliales, the vegetative organs of which have more or less degenerated in an aquatic environment. Such ancient herbaceous dicotyledons of nymphaealean type, but more primitive (less reduced) than their present-day representatives, quite probably initiated the monocotyledonous line.

Table 1: Comparison of Dicotyledons and Monocotyledons

Magnoliopsida (dicotyledons)	Liliopsida (monocotyledons)
embryo usually with 2 cotyledons	embryo with 1 cotyledon
leaves usually with (1) reticulate (netted) venation (pinnate or palmate), (2) seldom sheathed at the base, (3) petiole usually well developed	leaves usually with (1) parallel venation, (2) often sheathed at the base, (3) petiole seldom developed
bracteoles (when present) usually 2, lateral	bracteole (when present) usually 1, adaxial
vascular bundles usually borne in a ring, with a persisting cambium; cortex and pith are usually well differentiated	vascular bundles generally scattered or seldom in 2 or more rings, usually without a cambium; usually there are no definable cortex and pith
primary root generally persistent and becoming a taproot; the rootcap and piliferous layer have common origin (with the exception of Nymphaeales)	primary root of short duration, soon replaced by adventitious roots; the rootcap and piliferous layer of different origin
woody and herbaceous (primarily woody)	herbaceous and arborescent (primarily herbaceous)
floral parts usually borne in sets of 5 or 4 (seldom 3 or fewer)	floral parts typically borne in sets of 3 (seldom 4 and never 5)
nectaries of various types, frequently transformed stamens, and rarely of the sepal type	nectaries chiefly of the sepal type (occur in the septa between carpels)
pollen grains usually tricolpate or tricolpate-derived (monocolpate only in a few primitive families)	pollen grains monocolpate or monocolpate-derived type (never tricolpate)

In comparison with the majority of dicotyledons, the monocotyledons are characterized by some degree of "infantism" of their vegetative organs. They usually have no vascular cambium, their primary root is usually ephemeral, the leaves are not differentiated into petiole and blade (or the differentiation is not clear-cut as in the dicotyledons), the leaf venation resembles the venation of the underdeveloped leaf organs of the dicotyledons (like bud scales or bracts), and one of the two cotyledons is suppressed. The earliest monocotyledons were most probably marsh plants with stout rhizomes. Indeed, the majority of Alismales, as well as almost all the Nymphaeales (except *Ceratophyllum*), are typically aquatic geophytes (herbaceous plants with underground storage organs). Apparently the common ancestors of both the Nymphaeales and the monocotyledons were amphibious geophytes that adapted to terrestrial conditions under the forest canopy or in the forest margin.

Annotated classification. The classification employed in this article is based upon that of Armen Takhtajan (1969, 1970), with later modifications. A complete listing of all angiosperm orders is given below. Additional information about the most important orders is presented in the sections that follow; these sections contain detailed information on the natural history, economic importance, morphology, and evolution of each major order. Groups

indicated by a dagger (†) are covered separately in the *Micropedia*. (A.T.)

DIVISION MAGNOLIOPHYTA (Angiospermae)

The entire range of flowering plants, or angiosperms. Perhaps 250,000 species of worldwide distribution.

Class Magnoliopsida (Dicotyledones)

Plants typically with two cotyledons, or seed leaves. The magnolia is the typical form (type genus) for which the class is named.

Subclass Magnoliidae

Mostly woody plants, some of them vesselless and many of them with oil cells. Stomata mostly with 2 subsidiary cells. Flowers mostly bisexual, frequently spiral or spirocyclic. Gynoecium mostly apocarpous. Pollen grains 2-celled or 3-celled, monocolpate or of monocolpate-derived type. Ovules with 2 integuments. Seeds with copious or scanty endosperm or none at all. Six orders.

ORDER MAGNOLIALES

Entirely woody group; flowers hypogynous; bisexual, rarely unisexual accompanied by reduction (*i.e.*, the "other" sex parts are "reduced"; they do not develop); acyclic to cyclic; perianth obvious, tepals may not be differentiated into sepals and petals; endosperm abundant; ethereal oil cells in all organs; pollen mostly uniaperturate. Leaves alternate, simple. Eight families, 166 genera, and about 1,794 species, of which some 1,100 belong to the family Annonaceae (custard apples); other families include Winteraceae (winterases), Magnoliaceae (magnolias), and Myristicaceae (nutmegs). Mainly distributed throughout wet, tropical regions of the Old and New World, but with some temperate outliers.

ORDER LAURALES

Plants woody; ethereal oil cells present; pollen monocolpate, derived polyporate, or acolpate; nodal anatomy unilacunar; staminal appendages often present. Eleven families, 69 genera, and about 2,800 species, of which some 2,500 belong to the family Lauraceae (laurels) and 150 to Monimiaceae (monimias). Distribution is worldwide, with greatest concentration in the tropics.

ORDER PIPERALES

Mostly herbs and shrubs; usually with broad, alternate, entire, petiolate (stalked) leaves with stipules attached to the petiole or lacking; flowers bisexual or, rarely, unisexual, perianth lacking, subtended by bracts, borne in dense spikes or, rarely, racemes, hypogynous to epigynous, stamens 1–10; carpels 1–4 or, rarely, 5, free or united, usually with a single ovule; fruit a drupe, follicle, or capsule; seeds with copious endosperm, a mealy perisperm, and minute embryo with 1 or 2 cotyledons. Two families, 13 to 15 genera, and perhaps 3,000 species, the vast majority belonging to the family Piperaceae (peppers); the remaining Saururaceae (lizard's-tails) comprise fewer than 10 species. Members mostly tropical.

ORDER ARISTOLOCHIALES

Herbs, climbers, scramblers, or lianas, often woody, sometimes with anomalous secondary thickening. Leaves alternate, simple, with petioles (stalks), without stipules, often heart-shaped. Flowers solitary, racemose, or in clusters, bisexual, epigynous ("inferior" ovary) or rarely perigynous ("half-inferior" ovary). Perianth usually uniseriate (petals lacking) but biseriate with 3 sepals and 3 petals in *Saruma*, tubular below, with expanded actinomorphic or more usually zygomorphic (bilaterally symmetric) often strangely shaped limb above. Stamens 6 to many, usually in 1–2 series, or united to the top of the ovary or the stylar column (gynostemium). Anthers opening by slits. Ovary of (4–6) carpels, more or less free or weakly united, usually inferior. Ovules numerous in each carpel. Styles free or more frequently united. Fruit a capsule. Seeds numerous with fleshy endosperm and small embryo. One family, Aristolochiaceae (birthworts), with 10 genera and approximately 600 species, pantropical in distribution and with a few species in north and south temperate regions.

†*Order Rafflesiales.* Probably derived from the ancestors of the Aristolochiales. Two families, Rafflesiaceae (rafflesia) and Hydnoraceae.

ORDER NYMPHAEALES

Aquatic herbs, usually perennial, from stout rhizomes or lacking roots and free-floating, juice sometimes milky, leaves simple, peltate (shieldlike, the stalk attaching near the centre of the disk), or in whorls, floating or emergent or submersed and then with dissected margins. Flowers bisexual, or unisexual, solitary, parts trimerous or numerous and arranged spirally; sepals, petals, and stamens in some intergrading in structure. Sepals 3, 4, 5, or numerous; petals 3 to many, or none. Stamens 3 to many in cyclic or spiral arrangement, anthers splitting lengthwise. Carpels 3 to many or 1, usually free but sometimes

coalescent; ovules 1 to 5 or many; ovary superior or inferior. Fruit a follicle, nutlet, or leathery berry. Four families, 8 genera, and about 70 species, some 53 of which belong to the family Nymphaeaceae (water lilies). Distributed in temperate and tropical regions worldwide.

Subclass Ranunculidae

Near to the Magnoliidae, but more advanced. Mostly herbaceous plants, with vessels and usually without oil cells. Stomata of various types, most frequently without subsidiary cells. Flowers bisexual or unisexual, frequently spiral or spirocyclic. Pollen grains mostly 2-celled, tricolpate or of tricolpate-derived type. Ovules usually with 2 integuments. Seeds usually with copious endosperm. Five orders.

†*Order Illiciales*. Evidently derived from the Magnoliales, most probably from the ancestors of the Winteraceae. Two families, Illiciaceae (illicium) and Schisandraceae (schisandra).

†*Order Nelumbonales*. Usually placed in or next to the Nymphaeaceae but differs in many important features. A link with the Illiciales–Ranunculales stock is much more probable. One family, Nelumbonaceae (lotus).

ORDER RANUNCULALES

Herbs, woody climbers, or shrubs. Shoots dimorphic (of 2 kinds) in *Berberis*, the leaves on the long shoots being replaced by spines. Leaves usually alternate, rarely opposite; exstipulate (without stipules) except in a few genera; variously shaped and divided; deciduous or evergreen; spiny-margined in some genera. Flowers solitary or in inflorescences of varying degrees of complexity, usually with bracts, usually containing both sexes with flower parts arising at the base of the ovary (hypogynous). Perianth of 1, 2, or 3 (rarely more) series, usually spirally arranged. When the perianth is more than 1-seriate it is usually differentiated into an outer series of sepals and 1 or more inner series of petals (honey leaves). The series of the perianth may be in patterns of 3, 4, 5, or larger indefinite numbers. Perianth usually regular (radially symmetrical or actinomorphic) but is irregular (zygomorphic) in some genera of the family Ranunculaceae. Nectar absent, or secreted by nectaries of various shapes, often petaloid, or rarely by the ovary (e.g., in the genus *Caltha*). Stamens usually numerous, spirally arranged, and maturing from the margin inward. They are fewer than or equal in number to the petals and opposite them in many Berberidaceae. Stamens are usually free (anthers united in some Menispermaceae). Anthers open by lengthwise slits or by flaplike valves in some. Pollen granular, variable in appearance. Ovary of several to many usually free (united in some Ranunculaceae) carpels, rarely reduced to a solitary carpel. Ovules several with marginal or sub-basal placentation, or reduced to 1. Fruit a berry or a group of follicles or achenes. Seeds usually with endosperm. Alkaloids usually present. Ten families, about 142 genera, and about 3,100 species, of which some 2,000 belong to the family Ranunculaceae (buttercups); Berberidaceae (barberries) and Menispermaceae (moonseeds) are the next largest families. Distribution is worldwide.

ORDER PAPAVERALES

Mostly fleshy herbs, some shrubs or small trees; sap milky (white to yellow or reddish-orange) or colourless and watery; leaves without stipules, basal or alternate, rarely opposite, flowers regular or bilaterally symmetrical; calyx falling off very early; petals 4–12, often falling early; ovary superior, of fused carpels; fruit a capsule or of 1-seeded indehiscent joints; seeds with small embryos and a fleshy, usually oily endosperm. Three families: Papaveraceae (poppies), Hypecoaceae, and Fumariaceae (fumitories); 45 genera and some 640 species in all, distributed mainly in temperate regions.

ORDER SARRACENIALES

Perennial, rhizomatous, acaulescent (stemless) or caulescent-branched, insectivorous herbs, with usually basal rosettes of tubular or pitcherlike, often winged, leaves specialized for luring and trapping insects and other tiny animals. Flowers solitary, on a leafless stalk or in loose, stalked, axillary racemes (clusters arising from the angle between stem and leaf), radially symmetrical, bisexual. Perianth (sepals and petals) with 1 or 2 series; the sepals commonly 5, overlapping, often coloured and showy, persistent; the petals commonly 5 or absent, free, yellow to purple. Stamens (pollen-bearing organs) many, free; the anthers (male reproductive organs) 2-celled, opening before stigmas are receptive. Pistil (female parts—ovary, style, and stigma) 1, with 3 or 5 fused carpels, the ovary superior (positioned above the attachment point of sepals, petals, and stamens), 3- or 5-loculed (chambered). Ovules numerous. Style simple, cylindrical, with simple, slightly lobed stigma or apex expanded into large umbrella-like structure with as many lobes as carpels, each with a minute stigma beneath. Fruit a capsule, with as many locules as carpels. Seeds minute, numerous. One family, Sarraceniaceae (pitcher plants), consisting of 3 genera and 13 to 16 species, distributed in New World wetlands.

Subclass Hamamelididae

Mostly woody plants, usually with vessels (except in the order Trochodendrales). Stomata with 2 or more subsidiary cells, or subsidiary cells are absent. Flowers more or less reduced, mostly unisexual and apetalous, seldom naked. Gynoecium usually coenocarpous. Pollen-grains usually 2-celled, tricolpate or of tricolpate-derived type. Ovules usually with two integuments. Seeds with copious or scanty endosperm or none at all. Orders number 15.

†*Order Trochodendrales*. In many respects occupies position between the Magnoliales and Hamamelidales, nearer to the latter. Two families, Trochodendraceae (yama-kurumas) and Tetracentraceae (tetracentrons).

†*Order Cercidiphyllales*. Near Trochodendrales. One family, Cercidiphyllaceae.

†*Order Eupteleales*. Somewhat isolated systematically. One family, Eupteleaceae.

†*Order Didymelales*. One family, Didymelaceae.

ORDER HAMAMELIDALES

Woody plants. Leaves simple or palmately lobed, with stipules. Vessel elements in the wood narrow, with oblique end walls, perforation plates scalariform ("ladderlike") with numerous bars. Condensed inflorescences. Flowers mostly small, often unisexual, with reductions in floral structure. Calyx (sepals) lacking in few genera. Corolla (petals) often small or lacking. Wind pollination in some genera. Stamens with connective protrusion. Carpels (structural units of pistil) free or mostly fused in the region of the ovary but with free styles. Distribution centres: Central and East Asia, the Malaysian region, Central and North America, Australia, Madagascar, and tropical and southern Africa. Three families, 30 genera, and 80–150 species, of which 75 to 140 belong to the family Hamamelidaceae (witch hazels); Platanaceae (plane trees), with 2 to 9 species, is the next largest family.

†*Order Eucommiales*. One family, Eucommiaceae.

ORDER URTICALES

Trees, shrubs, vines, or herbs. Leaves usually simple, alternate, with stipules (basal appendages). Flowers male, female, or bisexual; regular, small, greenish; usually with 4 or 5 more or less united sepals (constituting the calyx) but lacking petals. Ovary positioned above other flower parts (superior), of 1 or 2 carpels (ovule-bearing units) but with only 1 interior chamber (locule) and 1 ovule (rarely 2), erect or pendulous. Stamens variable in number but usually few, mostly equal in number to sepals and opposite them; often inflexed in the bud. Fruit with 1 seed; at maturity a nutlet, drupe, achene, samara, or multiple. Seed with or without fleshy or oily endosperm (nutrient tissue for developing embryo). Four families, 125 genera, and about 3,100 species, nearly half of which belong to the family Moraceae (mulberries); the other families are the Urticaceae (nettles), Ulmaceae (elms), and Cannabaceae (hemp). Worldwide distribution.

†*Order Barbeyales*. One family, Barbeyaceae.

†*Order Casuarinales*. Evidently derived from the Hamamelidales. One family, Casuarinaceae (casuarina).

ORDER FAGALES

Deciduous or evergreen monoecious trees or shrubs. Leaves alternate, rarely verticillate (whorled), simple, entire (smooth margins) or with shallow incisions, with deciduous stipules. Flowers unisexual, though often with rudiments of the other sex, with simple, inconspicuous perianth, arranged in catkin-like spikes, composed of dichasia or simple, or in dichasia in the leaf axils. Stamens 4 to about 40. Pistil 1, ovary inferior, usually with 3 or 6 loculi, and 3–12 styles; placentation axile, ovules 2 in each locule. Fruit a 1-seeded nut, the nuts or the female dichasium surrounded by a cupule of axial nature. Seed with a large embryo and no endosperm. Single family, Fagaceae (beeches, including oaks and chestnuts), containing 10 genera and more than 1,000 species with worldwide distribution.

ORDER BETULALES

Woody trees or shrubs, with simple, stipulate, tooth-margined, ultimately deciduous leaves, spirally arranged. Flowers cyclic unisexual, both sexes occurring on the same plant but in different inflorescences. The male flowers with 6 or fewer stamens, completely lacking vestigial pistils, and with or without 6 or fewer tepals. The male flowers in cymose groups of 3 (or fewer) and fused with varying numbers of primary, secondary, and tertiary bracts. The anthers 2-celled, opening longitudinally. The female flowers without vestigial stamens, with or without tepals inserted at the base of the 2 styles, the inferior ovary composed of 2 carpels with axile placentation, but the 2 compartments confluent above the insertion of ovules. Ovules 1–4, anatropous, and with a single integument. The female flowers in cymose groups of 3 or fewer and fused with adjacent bracts

of varying numbers. The aggregations of male flowers attached to a flexible axis, collectively constituting the characteristic cylindrical catkin or ament. The similar female inflorescence with a stiff axis, which is often erect. Pollination by wind in spring, fertilization long delayed; following production of the ovule, the pollen tube (sometimes branching) invades the ovule by way of the chalaza (chalazogamy). Multicellular archesporium. Maturation of the fruit in late summer or fall. The fruit a 1-seeded nutlet (often winged) or nut with a large straight embryo, no endosperm. One family, Betulaceae (birches), with about 6 genera and 120 species. Distributed in cool regions of the Northern Hemisphere.

†*Order Balanopales*. One family, Balanopaceae.

†*Order Myricales*. Probably derived from the Hamamelidales. One family, Myricaceae (sweet gale).

†*Order Leitneriales*. One family, Leitneriaceae.

ORDER JUGLANDALES

Trees; leaves mostly deciduous, alternate or rarely opposite or whorled, equally or unequally pinnately compound; leaflets as few as 3 but usually 5 to 31, serrate (toothed) or entire (smooth margined), dotted beneath with yellow or pale several-celled resinous scales; inflorescences consisting of elongate spikes or catkins, the pistillate (female) spikes sometimes few-flowered and short; bracts (leaflike appendages) associated with the flowers usually as conspicuous as or more conspicuous than the floral parts; individual flowers bisexual or unisexual, inconspicuous, wind-pollinated, lacking petals, with 4 sepals or these lacking; filaments of stamens very short; pistil with 2 carpels, and 2 styles or style branches; ovary completely or incompletely 2-celled but with only one ovule in the middle of the fertile locule; fruit 1-seeded, a small winged nutlet or a large nut, the seed lacking endosperm. Two families, 9 genera, and about 58 species, all but 1 of which belong to the family Juglandaceae (walnuts). Distributed in temperate and subtropical regions of eastern and southwestern United States, Mexico, West Indies, western South America to Argentina, Japan and Philippines to New Guinea and Java, Manchuria and China to Malay Peninsula to Himalayan mountains of India, and Iran and from the Caucasus mountains to Greece. They are absent from Australia, New Zealand, Africa, most of Europe, and western Asia.

Subclass Caryophyllidae

Usually herbaceous plants, undershrubs or low shrubs, rarely trees. Vessels always present. Stomata with 2 or 3 (rarely 4) subsidiary cells, or subsidiary cells absent. Flowers bisexual or rarely unisexual, mostly apetalous. Gynoecium apocarpous or coenocarpous. Pollen grains mostly 3-celled, tricolpate or of tricolpate-derived type. Ovules usually with 2 integuments. Seeds frequently with perisperm. Three orders.

ORDER CARYOPHYLLALES

Dicotyledonous plants; herbs, less frequently shrubs, rarely vines or trees. Flowers typically perfect (with male and female parts) but usually lacking true petals (except in the Caryophyllaceae and in some Aizoaceae). Betalain pigments occurring in most families. There are 10 to 16 families (depending on the authority), including the Aizoaceae (fig marigolds), the Chenopodiaceae (goosefoot family), and the Caryophyllaceae (pinks); with more than 300 genera and between 6,500 and 8,500 species (an accurate figure is not possible because of the differences in interpretation of taxa by different authorities). Distribution is worldwide, with a concentration of species in the tropics and subtropics.

ORDER CACTALES

Stem-succulents, ranging from minute to as tall as 50 feet and up to 2.5 feet in diameter, smooth or covered with ribs and tubercles (knobby projections). Leaves usually absent in adult plants; when present, they are large, flat, and persistent (*Pereskia* and *Peresklopsis*) or conical to cylindroidal and short-lived. Areoles are present in the leaf axils or their structural equivalents and are arranged spirally on the surface of a smooth stem or on the apices of the tubercles, when present, and bear spines (spines rarely absent on the adult stem but present in juvenile stages). Flowers and fruits develop within or associated with a spine-bearing areole. The flower, except in some species of *Pereskia*, is epigynous, but of different origin than the epigyny of other flowering plants; the floral tube is developed from the receptacle, usually bears scale leaves and areoles; the superior floral tube or cup (the part above and free from the ovary) sometimes tubular; scale leaves of the floral tube show a gradation into the sepaloid outer perianth parts and these grade into the petaloid inner perianth parts. Stamens are numerous, spirally arranged. Carpels (structures constituting the innermost whorl of the flower), from 3 to 20, are arranged in a circle; 1 style; stigmas as many as the carpels; the ovary at maturity with 1 chamber; numerous ovules and seeds; ovules usually

campylotropous (curving between the hilum and the micropyle) or sometimes amphitropous or orthotropous. Fruit variable; seeds of various colours (usually brown, black, reddish, gray, or white) and shapes. One family, Cactaceae (cacti), comprising some 30 to more than 200 genera, depending on the author, and from 800 to 1,500 valid species. Distributional centres—Mexico and the South American deserts. The better known genera include *Melocactus* (melon-thistle, or Turk's-cap, cactus), *Ferocactus* and *Echinocactus* (barrel cacti), *Echinocereus* (hedgehog cactus), *Cereus* (torch cactus), *Mammillaria* and *Coryphantha* (fishhook, or pincushion, cacti), *Epiphyllum* (leaf cactus), *Opuntia* (prickly pears and chollas), and *Pereskia*.

†*Order Polygonales*. Probably derived from the same stock as the Caryophyllales. One family, Polygonaceae (buckwheat).

†*Order Plumbaginales*. Probably derived from the same stock as the Caryophyllales. One family, Plumbaginaceae (leadwort).

†*Order Theligonales*. One family, Theligonaceae (sometimes called Cynocrambaceae).

Subclass Dilleniidae

Woody or herbaceous plants. Vessels always present. Stomata of various types, mostly without subsidiary cells. Flowers bisexual or unisexual, usually with both calyx and corolla; in the more primitive families, perianth is frequently spiral or spirocyclic. Gynoecium apocarpous or more frequently coenocarpous. Pollen grains mostly 2-celled, tricolpate or of tricolpate-derived type. Ovules usually with 2 integuments. Seeds mostly with endosperm. Orders number 17.

†*Order Dilleniales*. A connecting link between the Magnoliales and the Theales-Violales group. Two families, Dilleniaceae and Crossosomataceae.

†*Order Paeoniales*. Near to the Dilleniales. One family, Paeoniaceae (peony).

ORDER THEALES

Trees, shrubs, or woody climbers, rarely herbs. Leaves alternate or opposite, usually simple and evergreen, with or without stipules. Flowers solitary or in inflorescences (clusters) of varying degrees of complexity and usually radially symmetrical and bisexual. Sepals sometimes 4 but usually 5 to many, usually free and overlapping, sometimes not distinguishable from the bracts and bracteoles. Petals usually 5, free or rarely united at the base (sometimes to the tube formed by the stamens) or the apex. Stamens usually numerous, maturing from the centre of the flower outward, often united in bundles or in a ring. Carpels usually 5, rarely fewer or more numerous, usually united; when free they are still joined by means of the united styles. Placentation (ovule attachment) usually axile—to the central axis of the ovary. Seeds with or without endosperm. Twenty-one families with approximately 155 genera and 2,550 species; the families Ochnaceae (ochnas), Dipterocarpaceae (merantis), Theaceae (teas), Clusiaceae (mangosteens), and Hypericaceae (Saint-John's-worts) each contain 400 or more species. Distribution throughout the tropics, with extensions into subtropical and temperate regions of both hemispheres.

ORDER VIOLALES

Flowering plants characterized by a woody perennial habit, paired stipules, simple leaves, flowers with parts in 5s, and true parietal placentation. Nine families, about 117 genera, and nearly 2,000 species, of which all but 225 belong to either of 2 families, Flacourtiaceae (flacourtias) and Violaceae (violets). Distribution worldwide.

†*Order Passiflorales*. Derived from primitive representatives of the Violales, and very close to them. Families number 5, including Passifloraceae (passionflower), Caricaceae (carica).

ORDER CUCURBITALES

Annual or perennial herbaceous vines, usually with tendrils, rarely erect or suffrutescent. Leaves alternate, simple, usually with petioles and palmately or pinnately 5-lobed. Tendrils lateral, stipular in position, 1 at each node, simple or variously forked. Roots fibrous or fleshy, some enlarged into storage organs. Flowers mostly unisexual, monoecious or dioecious, occasionally perfect. Staminate or male flower with calyx and corolla united to form a tubular receptacle, corolla lobes usually yellow, white, or cream-coloured; stamens often 3, occasionally 4, with 1 sterile stamen, filaments free or united, anthers free or coherent in a head, stamens basically 5, alternate with the petals, inserted on the receptacle tube or on the basal disk, but always modified in one or more ways. Pistillate or female flowers with calyx and corolla similar to the male flowers; ovary inferior, connate with receptacle to form a globose to fusiform tubular structure, often separated from the remainder of the flower by a constriction; usually with 1 locule and 3 or 4 carpels (primitively 5); style terminal with 2- or 3-lobed stigma (many lobes in some *Cucurbita*). Fruit a dry or fleshy berry or hard-shelled pepo, usually indehiscent, or occasionally

dehiscent (explosive). Seeds large, numerous, rarely 1; with no endosperm, embryo with large cotyledons. One family, Cucurbitaceae (cucumbers or cucurbits), with 90 to 100 genera (depending on the authority consulted) and about 700 species distributed mainly in the tropics and subtropics.

ORDER BEGONIALES

Mostly succulent herbs, but perennial shrublike herbs and large woody trees also occur. Leaves simple, pinnate (with a midrib) or palmate (with radiating leaflets or veins); alternate. Stipules (small leaflike appendages at the base of leafstalks) present, early deciduous, or absent. Flowers usually unisexual (but some bisexual flowers in *Datisca*). Sepals (green or coloured outer whorl of flower parts) often petallike, 2 to 9. Petals 2 to 8 or more, or none in a few. Stamens (male reproductive structures) 4 to 25 or more. Carpels (simple ovaries or segments of a compound ovary) 3, rarely 5 or 2. Styles (the narrow upper part of the pistil) 2 to 5, ovules numerous. Seeds small, numerous, and with a dotted or net-patterned (reticulate) seed coat. Fruit a capsule, rarely a berry. Two families of 3 genera each, very dissimilar in character and number of species, about 1,000 in Begoniaceae (begonias) and only 4 in Datisceae (datiscas). Distributed mainly in the tropics worldwide.

ORDER CAPPARALES

Herbs, shrubs, small trees, and lianas; leaves alternate or opposite, simple, pinnately or palmately compound, with stipules; flowers with petals, bisexual, hypogynous or perigynous, regular or irregular; stamens numerous to few; ovary of 2 or more fused carpels with parietal placentation; fruits fleshy berries or drupes or dry dehiscent siliques, silicles, or capsules; seeds reniform (kidney-shaped) or not, or winged or nonwinged; embryo conduplicate (folded) or curved; endosperm scanty. Eight families, 427 genera, and about 4,200 species, of which some 3,200 belong to the family Brassicaceae (Cruciferae; mustards) and 925 belong to Capparaceae (Capers). Distribution mainly tropics.

†*Order Tamaricales*. Derived from the Violales. Three families—Tamaricaceae, Fouquieriaceae, and Frankeniaceae.

ORDER SALICALES

Woody trees or shrubs with simple, spirally arranged, tooth-margined, usually deciduous (falling) leaves that have stipules, small leaflike appendages at the base of the leafstalk. Flowers unisexual, male and female usually on separate plants. Male flowers with 1 to many stamens, vestigial pistils absent. Female flowers with a single pistil unaccompanied by vestigial stamens. Pistil composed of 4, 3, or, most often, of 2 carpels (ovule-bearing segments). Ovary superior (positioned above the other flower parts), with a single chamber and several to many ovules. Style present or absent, the number of stigmas equal to or double the number of carpels. Inflorescence (flower cluster) a characteristic cylindrical spike (a catkin or ament) that is erect (in *Salix*) or pendulous (in *Populus*). Pollination in the spring by wind (*Populus*) or insects (*Salix*). Maturation of the fruit and shedding of seed occurs in the spring. Fruit a somewhat leathery-walled capsule, splitting into as many segments as there are carpels to release the minute seed, each with a tuft of cottony hair attached at the base. Seeds with a small, straight embryo, lacking endosperm, and with a thin seed coat. Single family, Salicaceae (willows); two genera—*Salix* (willows), with about 320 species, and *Populus* (poplars, aspen, cottonwoods), with about 30 species. Distributed mostly in cooler regions of the Northern Hemisphere.

ORDER ERICALES

Herbs, shrubs, trees, herbaceous saprophytes, or root parasites. Leaves alternate (also opposite or whorled in Ericaceae; opposite in Grubbiaceae), simple, commonly leathery, without stipules (basal appendages). Flowers mostly bisexual, regular or slightly irregular. Calyx of 4 to 10 (rarely fewer) separate or partly united sepals. Corolla of 4 to 10 (rarely fewer) separate or partly united petals or, in a few instances, lacking. Stamens usually as many or twice as many as petals or sepals, very rarely more numerous, and sometimes partly reduced to staminodia (sterile stamens). Ovary of several, usually 2 to 7, fused carpels (ovule-bearing segments) and 2 to 7 (rarely more) chambers, infrequently with incomplete partitions; rarely with 1 chamber. Ovary superior, partly inferior, or inferior (positioned above, partly enclosed, or enclosed by the other flower parts). Styles united except in rare cases. Ovules usually, but not always, numerous. Ovule attachment usually axile (central in Grubbiaceae). Fruit a berry, drupaceous, or a capsule. Seed with copious fleshy endosperm (nutritive tissue). Ten families, about 135 genera, and some 2,700 species, of which 1,500 to 1,900 belong to the family Ericaceae (heaths) and about 340 to Epacridaceae (epacris family). Distributed worldwide.

†*Order Diapensiales*. Evidently closest to the Ericales, especially to the Epacridaceae. One family, Diapensiaceae.

ORDER EBENALES

Trees or shrubs. Leaves simple, entire (smooth-margined), alternate. Flowers radially symmetrical; sepals and petals of 4 or 5 fused segments each. Stamens variable in number, arranged in 1 or more whorls. Ovary superior (sepals, petals, and stamens arise at its base), composed of many carpels (ovule-bearing segments), and with axile placentation (ovules attached along the central axis). Five families, including Sapotaceae (sapodillas), Symplocaceae, and Ebenaceae (ebonies); number of genera in the order varies from 82 to 145, depending on the authority consulted; about 1,700 species in all. Distribution is mainly tropical.

ORDER PRIMULALES

Trees, shrubs, or herbs with leaves usually alternate, simple, and lacking stipules. Flowers usually radially symmetrical; with the basic parts (sepals, petals, stamens, and carpels) 5 in number (rarely 4 to 8). The 5 petals united into a radially symmetrical corolla, the 5 stamens arising from the inner surface of the corolla tube and opposite the corolla lobes. Ovary superior, of 5 fused carpels, but only 1 interior chamber, with few to numerous ovules attached to a centre axis rising from the base of the ovary. Three families: Myrsinaceae (myrsines), Primulaceae (primroses), and Theophrastaceae (theophrastas); about 64 genera and more than 2,000 species in all, with tropical and temperate distribution.

ORDER MALVALES

Trees, shrubs, or herbs, often with mucilaginous juice and fibrous stems. Leaves alternate, rarely opposite, usually with stipules. Flowers cyclical (rarely having the carpels more or less spirally arranged); hermaphroditic, sometimes unisexual. Calyx and corolla members usually 5-merous (present in groups of 5), usually distinct, rarely lacking petals, regular, rarely somewhat bilaterally symmetrical, epicalyx often present; sepals usually valvate; petals mostly convoluted in bud, sometimes imbricate or valvate. Stamens usually numerous, free, or shortly connate at the base into 5–10 bundles, or united into a staminal column surrounding the style. Carpels 2 to many, united, superior, rarely inferior, with 1 to many axile, rarely parietal (attached to ovary wall) ovules. Fruit various, seeds usually with some endosperm. Nine families, about 240 genera, and 3,000 species, of which the families Malvaceae (mallows) and Sterculiaceae (cacaos) each contain 1,000; Tiliaceae (lindens) contains 450 species. Distribution is cosmopolitan, with best representation in the tropics.

ORDER EUPHORBIALES

Trees, shrubs, or rarely annual herbs; with simple, stellate, or scaly hairs; leaves simple or rarely compound; stipules mostly present; flowers hypogynous (superior ovary) or very rarely tending to be epigynous (inferior ovary), unisexual or very rarely bisexual, radially symmetric or very rarely tending to be bilaterally symmetric; tepals overlapping or not overlapping in the bud; petals rarely present; stamens numerous to solitary, free or monadelphous (joined by their filaments); ovary with axile placentation; ovules mostly anatropous; seeds with copious endosperm or rarely without it. Seven families, about 315 genera, and 8,000 species, of which all but 350 belong to the family Euphorbiaceae (spurge); the Buxaceae (boxwoods) contain about 60 species. Distribution is cosmopolitan.

†*Order Thymelaeales*. Shares a common origin with the Euphorbiales and Malvales; i.e., arose from ancestors of the Flacourtiaceae-type. One family, Thymelaeaceae (mezeium).

Subclass Rosidae

Woody or herbaceous plants. Vessels always present. Stomata of various types, most frequently without subsidiary cells or with 2 subsidiary cells. Flowers mostly bisexual, with both calyx and corolla, or apetalous. Gynoecium apocarpous or coenocarpous. Pollen grains mostly 2-celled, tricolpate or of tricolpate-derived type. Ovules usually with 2 integuments. Seeds with or without endosperm. Orders number 19.

ORDER SAXIFRAGALES

Trees, shrubs, lianas (vines), and perennial and annual herbs bearing alternate or opposite, entire or lobed, simple or compound leaves, with or without stipules (basal appendages). Flowers mainly bisexual, sometimes unisexual, radially symmetrical (actinomorphic) or rarely weakly bilaterally symmetrical (zygomorphic), usually both sepals and petals present. Petals free or rarely more or less joined (connate). Stamens (male reproductive organs) few, the same in number as the sepals, twice as many, or numerous. Gynoecium (female flower parts) of separate free carpels (ovule-bearing structures) or more often of fused carpels. Ovary is positioned above the insertion point of the sepals, petals, and stamens (superior), half-inferior, or inferior (i.e., below the attachment point of the other flower parts). Ovules with 2 outer tissue layers (integuments or seed coats) or more rarely with only 1 integument. Seeds usually with

abundant endosperm (nutrient tissue for developing embryo) and a small embryo. Twenty-eight families, including Brunelliaceae (brunellias), Grossulariaceae (currants), Hydrangeaceae (hydrangeas), Crassulaceae (stonecrops), and Saxifragaceae (saxifrages); 165 genera and about 3,340 species with worldwide distribution. Major centres of distribution include New Guinea and Australasia; Australia; Japan, Taiwan, and the Philippines; southern Africa; and tropical and temperate America.

ORDER ROSALES

Usually stipulate, often woody plants with pentamerous (parts in 5s) flowers, many free stamens, and hypogynous to epigynous arrangement of the floral organs. Seeds usually lacking endosperm. Wood vessels with simple perforations. Three families with 115 genera and 3,200 species, of which some 3,000 belong to Rosaceae (roses); distributed in Africa, Northern Hemisphere, and Neotropics.

ORDER FABALES

Herbs, shrubs, trees, or vines; leaves mostly alternate, compound, or simple by suppression of leaflets, stipulate, or infrequently without stipules; flowers bisexual, actinomorphic (radially symmetrical) or zygomorphic (bilaterally symmetrical), perianth (sepals and petals) in two series, the calyx gamosepalous (with fused sepals) and 5-lobed, the corolla typically of 5 petals (rarely absent or reduced to a single petal), distinct or the 2 anterior ones basally fused; stamens mostly 10 (sometimes numerous in Mimosaceae), distinct, monadelphous (stamen-filaments fused), or diadelphous (stamens in 2 bundles of 9 plus 1); the anthers 2-celled, dehiscent (splitting open) by longitudinal slits or infrequently by pores; pistil 1; the ovary superior, 1-loculed, 1-carpelled, the placentation parietal (ovule attachment is to the ovary walls) or seemingly marginal along ventral suture; the ovules 2 to many in 2 alternating rows on a single placenta, amphitropous (half inverted and straight), anatropous (inverted and straight), or infrequently campylotropous (curved, bringing the apex and base nearly together), pendulous or ascending; fruit usually a legume, samara, or loment, sometimes a follicle, or indehiscent or tardily so, seed with a usually leathery testa (covering), funiculus (stalk) sometimes produced into a more or less fleshy aril (appendage) or callosity, the endosperm (starchy nutrient tissue in the seed for the developing embryo) none or very scant. Three families, about 800 genera, and perhaps 20,000 species. The order is cosmopolitan in distribution, with the family Fabaceae (peas or beans) being relatively more abundant in the temperate regions and the Mimosaceae (mimosas) and Caesalpiniaceae (caesalpinias) being more tropical.

†*Order Connarales.* One family, Connaraceae.

ORDER NEPENTHALES

Plants stemmed or stemless, annual or perennial, herbaceous or somewhat shrubby, with alternate leaves specialized in various ways for trapping insects and other tiny animals. Flowers unisexual or bisexual, radially symmetrical, with sepals only or sepals and petals. Stamens few to many, free or more or less fused. Pistil 1, positioned above the other flower parts (superior), with 3 to 5 fused carpels (ovule-bearing segments), the ovules few to numerous. Fruit usually a capsule. Seeds small, few to numerous. Two families—Droseraceae (sundews) and Nepenthaceae (pitcher plants); 5 genera and about 180 species. Distribution is worldwide, with concentrations of species in Borneo (*Nepenthes*) and Australia (*Drosera*).

†*Order Podostemales.* One family, Podostemaceae.

ORDER MYRTALES

Flowers usually regular, bisexual, and 4- or 5-merous (lobed or parted), with a floral tube and showing various degrees of perigyny leading to epigyny (fusion of the floral tube around and above the ovary). Stamens are usually free, but the ovary is syncarpous (of fused sections), and the style (the slender upper part of the ovary) is simple. Fruits are either dry or succulent, with nonendospermic seeds. The order consists of mostly woody shrubs or trees with usually opposite, simple, entire leaves. Internal phloem is present in the stems of all except the Rhizophoraceae and Lecythidaceae families, but this information is not available for the Punicaceae, Anisophylleaceae, or Oliniaceae families. Thirteen families, more than 400 genera, and more than 9,000 species, of which some 7,000 belong to either of 2 families, Myrtaceae (myrtles) and Melastomataceae (melastomes). Other families include Trapaceae (water chestnuts), Punicaceae (pomegranates), and Onagraceae (evening primroses). Distributed in tropical and temperate zones.

†*Order Hippuridales (Haloragales).* Near Myrtales. Three families—Haloragaceae, Gunneraceae, and Hippuridaceae.

ORDER RUTALES

Mainly trees or shrubs, herbs extremely rare; bark resinous or not; leaves mostly alternate or opposite, mostly compound, sometimes simple, often gland-dotted; stipules very rare; flow-

ers hypogynous (*i.e.*, sepals, petals, and stamens arise at the base of the ovary) to slightly perigynous (sepals, petals, and stamens partly enclose the ovary), mostly bisexual, sometimes unisexual; sepals mostly imbricate (overlapping), rarely valvate (meeting at the edges without overlapping); petals mostly present, contorted, imbricate or valvate, usually free; stamens mostly equal to or twice the number of petals, often in 2 whorls; disk mostly conspicuous; ovary superior (hypogynous), syncarpous (of fused carpels), or subapocarpous (of partly free carpels), 1- to 20-carpelled; styles free or united; ovules 1 or 2, rarely more; fruit various; seeds with thin (or without) endosperm, straight, curved, or rolled embryo, and usually fleshy cotyledons. Twelve families, including Anacardiaceae (mangoes), Rutaceae (oranges), Meliaceae (mahoganies), and Burseraceae (myrrhs); 329 genera and some 3,600 species distributed throughout tropical and temperate regions.

ORDER SAPINDALES

Trees, shrubs, or lianas, rarely herbs. Leaves mostly alternate, pinnately compound, and without stipules. Inflorescences mostly thyrses (compact panicles like clusters of grapes), panicles (many-branched loose clusters), racemes (clusters with flowers on short stalks arising from a central axis, the lower flowers maturing first), or corymbs (flat-topped flower clusters maturing from edge to centre). Species mostly polygamous (bisexual and unisexual flowers both present) but functionally monoecious (male and female flowers on the same plant) or dioecious (separately sexed flowers on different plants). Flowers mostly small, with sepals, petals, and stamens attached at the base of the ovary (hypogynous), radially or bilaterally symmetrical, usually unisexual but with rudimentary organs of the opposite sex retained. Sepals 3 to 5, overlapping in the bud (imbricate), separate or basally joined (connate). Petals 3 to 5, imbricate, usually clawed, separate, rarely absent. Nectar-producing disk present. Stamens mostly 8 but sometimes 10, in 2 whorls, distinct or connate at the base; anthers 2-chambered, opening longitudinally. Pollen mostly with 3 germination furrows, subspheroidal in shape with a reticulate (net-patterned) or striate surface. Ovary of 2 to 5 but mostly 3 fused carpels (simple ovaries or segments of compound ovaries) with a similar number of locules (chambers). One or 2 ovules in each locule, attached along central axis of ovary (axile placentation), variously oriented, with 2 integuments (outer tissue layers). Fruits various but basically capsules; seeds mostly with no or scanty endosperm and a well-developed, curved, plicate (pleated, fanlike) or contorted embryo, less commonly with abundant endosperm and a straight embryo. Nine families, including Sapindaceae (soapberries), Aceraceae (maples), and Hippocastanaceae (horse chestnuts); 168 genera and about 2,300 species, primarily of tropical to warm-temperate forests of the world.

ORDER GERANIALES

Leaves commonly alternate. Flowers hypogynous (*i.e.*, sepals, petals, and stamens arise at the base of the ovary), usually bisexual and radially symmetrical (actinomorphic). Sepals overlapped (imbricate) or rarely merely touching at the edges (valvate), free or more or less fused. Petals generally free, contorted (twisted), or imbricate, rarely valvate or convolute (rolled up lengthwise). Anthers (pollen sacs) open by longitudinal slits. Nectar-producing disk or disk glands frequently present. Ovary of fused carpels with ovule attachment along central axis near base or apex of ovary chambers, ovules mostly solitary to few in each locule (chamber). Seeds mostly without endosperm (starch nutrient tissue for developing embryo). Twenty families, including Linaceae (flaxes), Balsaminaceae (balsams), Malpighiaceae (Barbados cherries), Oxalidaceae (wood sorrels), and Geraniaceae (geraniums); more than 140 genera and more than 4,000 species, predominantly tropical in distribution.

†*Order Polygalales.* Very close to family Malpighiaceae of the Geraniales. Five families—Trigoniaceae, Vochysiaceae, Polygalaceae, Krameriaceae, and Tremandraceae.

ORDER CORNALES

Trees or shrubs, rarely herbs (except in the family Umbelliferae, then frequently herbs), rarely lianas. Leaves alternate or opposite, simple with entire (uncut, not toothed) margins or lobed in palmate or pinnate patterns (*i.e.*, the lobes radiate from a common point or from both sides of a central axis, respectively) with toothed segments. Stipules commonly absent or sometimes present and free (in the families Helwingiaceae and part of Umbelliferae). Inflorescences consist of cymes (flower clusters in which the central or topmost flower opens first and further flowers occur on lateral growing points), panicles (many-branched clusters), racemes (flower clusters with the flowers stalked and the lowest flowers opening first), or umbels (clusters radiating from a common point), more rarely spikes or heads or flowers solitary in the leaf axils (upper angles between leaf and stem) or on the leaf surface. Flowers usually small, radially symmetrical except sometimes bilaterally symmetrical in

the enlarged marginal flowers in inflorescences of some species in the Umbelliferae; bisexual, polygamous (male, female, and bisexual flowers on one plant) or dioecious (male and female flowers on separate plants), commonly 4- or 5-merous (basic parts in 4s or 5s) but occasionally with up to 10 petals and sepals. Petals free, touching at the margins or overlapped, rarely absent. Sepals commonly much reduced, sometimes absent, the bases forming a tube fused around the ovary. Stamens in 1 or sometimes 2 or more series or whorls (very numerous in *Davidia*), equal in number to or up to 4 times as many as the petals. Nectar-producing disk present, attached to upper part of ovary. Styles 1 to several, free or fused together. Ovary inferior (enclosed within the basal parts of the sepals, petals, and stamens), of fused carpels. Ovules pendulous, usually solitary, and attached to the inner walls of the ovary. Fruit a berry, drupe (stone-seeded fruit), or a dry schizocarp (splitting fruit), generally formed of 2 segments (mericarps), which do not always separate at maturity. Embryo small to medium in size, endosperm copious to scanty. Ten families, including Cornaceae (dogwoods), Nyssaceae (sour gums), Araliaceae (ginsengs), and Umbelliferae (Apiaceae; parsleys); about 350 genera, and more than 3,700 species with worldwide distribution, but chiefly found in north temperate regions.

ORDER CELASTRALES

Woody plants: shrubs, trees, or vines; occasionally herbs. Leaves simple, alternate or opposite. Flowers usually bisexual, occasionally unisexual; hypogynous to perigynous (attachment of other floral parts either beneath the ovary or around it but not above it). Petals separate from each other. Stamens in a single cycle alternating with the petals; often a nectar-secreting disk of tissue inside or outside the whorl of stamens. Ovules typically 1 or 2 in a locule (compartment of an ovary or fruit). Twelve families, including Aquifoliaceae (hollies), Celastraceae (bittersweets), and Icacinaceae (icacinas); 147 genera, 2,000 species. Distribution pantropical and subtropical, with centres of distribution in Southeast Asia and South America.

ORDER RHAMNALES

Giant trees, large woody vines or lianas to subshrubs or weak vines, rarely herbs (annual herbs in only 1 species, the Guatemalan *Crumenaria steyermarkii* of the Rhamnaceae family); tendrils often present. Leaves simple or palmately compound or rarely twice or thrice pinnately compound; stipules usually present. Inflorescence (the arrangement of the flowers) basically cymose, but the cymes commonly aggregated into 2nd-order inflorescences of various shapes, and these usually leafless or nearly so, occasionally the cymes so reduced that the flowers are merely fasciculate (clustered) or even solitary. Flowers small, rarely more than 5 mm in diameter, rarely brightly coloured (exceptions in *Ceanothus* and *Leea*), radially symmetrical, 4- or 5-merous (parted, lobed), hypogynous, perigynous, or epigynous (*i.e.*, the floral parts arise at the base of, from a cuplike organ around, or from the top of the ovary, respectively), perfect, polygamous, or dioecious (*i.e.*, flowers have both sexes in 1 flower, or on 1 plant there are separate flowers of either sex, or there are separate plants containing flowers all of 1 sex or the other). Sepals free or less commonly joined in the lower part and never overlapping even in bud. Petals rarely any other colour than white, pale yellow, or cream colour, as numerous as sepals and alternate with them, free or uncommonly joined to each other along the margins in the distal moiety (in which case the corolla falls as a unit just before anthesis) or (in *Leea*) forming a short tubular corolla, or petals rarely absent. Stamens as numerous as sepals and alternate with them; anthers minute, usually opening toward the central axis of the flower (introrse), filaments thin, usually inbowed in bud and rarely exceeding the petals in length; pollen production not copious, the pollen binucleate (rarely trinucleate) when shed, usually tricolpate (having 3 equidistant germinal grooves) and angulaperturate, the outer wall being usually, perhaps always, reticulate. Intrastaminal disk present, usually producing nectar, either lining or filling the cup in perigynous flowers or usually lobed and closely associated with the ovary or along with the filaments forming a tube. Gynoecium (female flower parts) of a single pistil (ovary, style, and stigma, the female structure) of 2 or 3, less commonly 4, rarely up to 8 carpels; locules (chambers) as numerous as carpels or fewer by abortion; each locule with 1 or 2 basal, erect, anatropous, bitegmic ovules; the dicotyledonous embryo straight, flat or nearly so, embedded in abundant, firm to corneous endosperm; fruit various, never very large, averaging from a few millimetres to a few centimetres in maximum dimensions. Two suborders—Rhamnaceae and Vitaceae; 3 families—Rhamnaceae (buckthorns), Vitaceae (grapes), and Leeaceae (leas); about 59 genera and 1,550 species in tropical and temperate regions.

ORDER OLEALES

Woody plants, trees, shrubs, or climbers. Leaves opposite, rarely alternate, simple or pinnately compound, and lacking

stipules (small, leaflike appendages at the base of the leafstalk). Inflorescence basically cymose (determinate; *i.e.*, the flowers mature in sequence from the tip, or central flower, downward) but paniculate, decussate, fasciculate (various modes of branching), or single-flowered. Flowers regular (radially symmetrical); bisexual, or rarely unisexual, sometimes by abortion. Calyx (sepals) of 4 lobes (rarely more, or lacking). Corolla (petals) of 4 (rarely to 12) united lobes, rarely almost free or lacking, aestivation (condition of the petals in the bud) imbricate or valvate (rarely contorted). Disk absent. Stamens 2 (rarely 3, 4, or 6), borne on the corolla and alternate with the lobes; anthers usually with a slight extension to the connective, dehiscing (opening) longitudinally. Ovary superior, of 2 fused carpels, each locule with 2 (rarely 1 to 4) axile, pendulous or ascending, ovules, style 1 or lacking, usually with a 2-lobed stigma. Fruit usually one-seeded, a drupe, berry, capsule, or samara, seed with cellular endosperm (nutrient tissue for the developing embryo) or none. Single family, Oleaceae (olives); about 28 genera and between 500 and 600 species in temperate and tropical regions throughout the world, but especially the Old World, eastern Asia, and the tropics.

ORDER SANTALES

Woody plants ranging from a few millimetres to 15 m (49 ft) or more in height, mostly parasitic on the branches of trees or on the roots of perennial plants. Leaves simple, entire, and without stipules (small leaflike appendages at the base of the leaf stalk) alternate or opposite. Corolla (petals) and calyx (sepals) usually 5- or 4-parted (*i.e.*, the number of petals and/or sepals is either 5 or 4) but the calyx greatly reduced in some families and completely absent in others. Stamens as many as the perianth (sepals and petals) members or petals, in the latter case mostly opposite the petals. Ovary superior or (more commonly) inferior, ovules or embryo sacs few and basal, ovules frequently greatly reduced. The number of families in the order is broadly disputed. Among those generally recognized are Olacaceae (olaxes), Loranthaceae (showy mistletoes), Viscaceae (Christmas mistletoes), and Santalaceae (sandalwoods). Mostly tropical in distribution.

†*Order Elaeagnales*. Probably had a common origin with the Celastrales and Santales from the Saxifragales. One family, Elaeagnaceae (oleaster).

†*Order Proteales*. Probably shares common origin with the Elaeagnales and the Santales. One family, Proteaceae (protea).

Subclass Asteridae

Mostly herbaceous plants. Vessels always present. Stomata of various types, most frequently without subsidiary cells. Flowers usually bisexual. Gynoecium coenocarpous (probably morphologically always paracarpous). Pollen grains 3- or 2-celled, tricolpate or of tricolpate-derived type. Small ovules with a single integument. Seeds with or without endosperm. Eight orders.

ORDER DIPSACALES

Herbs or shrubs, seldom small trees. Leaves in basal rosettes or opposite, very rarely alternate, usually lacking stipules. Flowers regular or irregular, bisexual or unisexual, rarely some sterile. Calyx (sepals) absent or poorly developed. An epicalyx sometimes well developed in fruit. Corolla sympetalous, 3- to 5-lobed. Stamens 1 to 5, usually 3 to 5, alternate with the corolla lobes; filaments attached to the corolla tube. Pollen trinucleate. Ovary syncarpous, inferior, 2- to 5-locular, locules with 1 to many anatropous ovules. Fruit various, endosperm present or absent, embryo straight. Four families—Caprifoliaceae (honeysuckles), Adoxaceae (moschatels), Valerianaceae (valerians), and Dipsacaceae (teasels); about 40 genera and 1,100 species, with worldwide distribution but more abundant in Northern Hemisphere temperate regions.

ORDER GENTIANALES

Trees, shrubs, and herbs with simple opposite leaves, except in the family Menyanthaceae. Phloem (food-conducting tissues) intraxylary—positioned toward the centre of the stem—except in the Menyanthaceae and Rubiaceae. Flowers perfect and hypogynous (with a superior ovary) except in the Rubiaceae. Corolla (collection of petals) of fused petals with 4 or 5 radially symmetrical lobes. Pistil (female structure) of 2 carpels (ovule-bearing components or segments of the pistil) with placentation—ovule attachment—to the ovary walls (parietal) or along the central axis of the ovary (axile); ovules usually numerous with 1 integument (covering) and a 1-layered nucellus (interior). Eleven families, more than 1,000 genera, and more than 12,000 species, of which some 6,500 belong to the family Rubiaceae (madders); other large families include the Asclepiadaceae (milkweeds), the Gentianaceae (gentians), the Apocynaceae (dogbanes), and the Loganiaceae (loganias). Distributed mainly in the tropics and subtropics of the world.

ORDER POLEMONIALES

Flowering plants with mostly sympetalous (fused) corollas. Flowers generally 5-merous (in parts of 5—5 sepals, 5 petals,

etc.), actinomorphic (radially symmetrical), stamens 5 and alternate with corolla lobes, or numerous. Fruit a capsule or of 1 to 4 nutlets. Plants typically trees, shrubs, vines, or herbs, except for a twining parasite and a few root parasites. Primarily in North and South America, but some also in Eurasia and in Africa as well. There are 8 families, including the Polemoniaceae (phloxes), Convolvulaceae (morning glories and sweet potatoes), Cuscutaceae (dodders), Boraginaceae (borages), and Loasaceae (loasas); 208 genera and 4,446 species with worldwide distribution.

ORDER SCROPHULARIALES

Trees, shrubs, vines, or herbs, sometimes parasitic. Leaves simple or rarely compound, alternate or opposite, rarely whorled or rosulate. Inflorescence (arrangement of flowers) various, or the flowers solitary. Flowers complete (with sepals, petals, stamens, and pistil) or rarely incomplete, perfect (with both sexes) or rarely imperfect, actinomorphic (radially symmetrical) to zygomorphic (bilaterally symmetrical), hypogynous (superior ovary) or rarely epigynous (inferior ovary). Calyx usually of 4 to 6 sepals; corolla usually of 4 to 6 united petals. Androecium (male complex) usually of 5, 4, or 2 stamens that are joined to the inner side of the corolla tube (epipetalous) and are alternate in position with the corolla lobes. Gynoecium (female complex) of 2 or rarely 5 united carpels, with usually 1 or 2 locules (chambers); with ovule attachment usually axile, (along the central axis) or parietal (to the ovary wall). Ovules 1 to many, with a single integument (outer covering). Fruit usually a capsule or a berry, rarely a schizocarp (a fruit that splits into several 1-seeded pieces), nut, or drupe (stone-seeded fruit); seeds with or without endosperm (nutrient tissue for the developing embryo). Eighteen families, nearly 900 genera, and nearly 12,000 species, of which the families Solanaceae (potatoes), Scrophulariaceae (figworts), Gesneriaceae (gesneriads), and Acanthaceae (acanthuses) contain 1,800 or more each; the Plantaginaceae (plantains) and Pedaliaceae (sesame family) are also included. Worldwide in distribution.

ORDER LAMIALES

Herbs, shrubs, or trees; leaves nearly always opposite and simple; 5-parted flowers usually bisexual and with a gamopetalous (1-piece, of fused petals), irregular, or bilaterally symmetrical corolla; stamens 2, 4, or 5, arising from the inner surface of the tubular corolla; ovary superior (positioned above the attachment point of the calyx and corolla), usually with 2 carpels (ovule-bearing segments of the ovary) and 4 locules (chambers), ovules usually 1 in each locule; usually 1 style, forked at the apex, terminal on the ovary or arising from its base; fruit of 4 nutlets, a drupe that separates into 4 pyrenes, or rarely a capsule. Four families, about 260 genera, and more than 6,000 species, of which the family Lamiaceae (mints) contains some 3,500 and the Verbenaceae (verbenas) 2,600. Worldwide distribution.

ORDER CAMPANULALES

Plants usually herbaceous, often with septate laticiferous vessels. Leaves simple and without stipules. Inflorescence racemose with a tendency to form loose heads. Flowers actinomorphic (with radial symmetry) or zygomorphic (with bilateral symmetry), generally 5-merous (with parts numbering 5 each), with a fused corolla, usually with 5 stamens in a single whorl and 2-lobed anthers variously coherent to fused. Ovary 1- to 5-locular (chambered) with many (sometimes 1) ovules in each locule. Ovules with 1 integument. Endosperm cellular. Seven families, including Lobeliaceae (lobelias) and Campanulaceae (bellflowers); 105 genera, about 2,000 species, of which some 900 species belong to the family Campanulaceae; other families include Stylidiaceae, Goodeniaceae, Brunoniaceae, Donatiaceae, Lobeliaceae, and Sphenocleaceae. Distribution worldwide.

†*Order Calycerales*. One family, Calyceraceae.

ORDER ASTERALES

Individual flowers epigynous, perfect or unisexual, sympetalous, regular or irregular, commonly 5-merous, the calyx wanting or more often represented by a set of 1 to many hairs, bristles, or scales collectively called the pappus; stamens alternate with the corolla lobes, the filaments attached in the lower part of the corolla tube, the anthers generally elongate and united into a tube; ovary bicarpellate but unilocular, with a single, erect, basal, unitegmic ovule; style growing up through the anther tube, usually 2-cleft, the branches commonly with ventromarginal stigmatic lines that do not reach as far as the tip; fruit an achene; flowers sessile in a centripetally flowering head on a common receptacle, sometimes individually subtended by a small bract (chaff), and almost always collectively subtended by an involucre of few to many bracts; herbs, shrubs, or trees with the heads arranged in various sorts of basically cymose inflorescences. One family, Asteraceae (asters), about 900 genera, and about 15,000 to 20,000 species with worldwide distribution.

Class Liliopsida (*Monocotyledones*)

Plants with a single cotyledon in the seed. The lily is the type genus for which the class is named.

Subclass Alismidae

Herbaceous plants, aquatic or semiaquatic. Vessels absent or only in the roots. Stomata (when present) with 2 or rarely 4 subsidiary cells. Gynoecium mostly apocarpous. Pollen grains usually 3-celled, monocolpate, nonaperturate or 2-polyporate. Ovules with 2 integuments. Seeds without endosperm. Three orders.

ORDER ALISMALES

Aquatic herbs. Flowers superior (ovary positioned above other flower parts) with biseriate perianth usually differentiated into 3 sepals and 3 petals. Gynoecium (female component) of several or many free carpels (structures comprising the ovary). Placentation (attachment of ovules) laminar, ovules numerous and scattered. Mature seeds without endosperm, endosperm development helobial (later disappearing). Embryo with prominent basal cell and nucleus of high ploidy (multiples of the basic chromosome number), horseshoe-shaped or straight. Stamens numerous, pollen 3-celled, trinucleate, and multi-aperturate (except *Butomus*). Vegetative parts with laticiferous (latex-bearing) canals (except *Butomus*), paracytic (parallel-celled) stomata, specialized aerenchyma (cellular tissue with air spaces) with diaphragms, protoxylem canals, metaxylem tracheids, and restriction of vessels to roots. Three families—Butomaceae (flowering rushes), Limncharitaceae (water poppies), and Alismaceae (water plantains); 18 or 19 genera and 103 species found in the tropics and the north temperate zone.

†*Order Hydrocharitales*. Near to and derived from the Alismales. One family, Hydrocharitaceae (frog's-bit).

†*Order Najadales*. Near to the Alismales and probably derived from it. Ten families, foremost of which is Potamogetonaceae (pondweed).

Subclass Liliidae

Herbaceous or rarely arborescent plants. Vessels mostly in the roots only, rarely in the stems and leaves. Stomata mostly without subsidiary cells, rarely with 2 (some representatives of the order Liliales) or 2 or more subsidiary cells (Zingiberales). Gynoecium almost always coenocarpous (mostly syncarpous), very rarely almost apocarpous. Pollen grains usually 2-celled, mostly monocolpate. Seeds with or without endosperm. Five orders.

†*Order Triuridales*. One family, Triuridaceae.

ORDER LILIALES

Monocotyledonous plants usually with storage rootstocks. Herbs to trees. Leaves often clustered at base. Flowers usually showy and bisexual (having male and female parts); components in 6 (3 petals, 3 sepals) or 3 parts. The order includes 20 families, notably Liliaceae (lilies), Alliaceae (onions), Agavaceae (century plants), Amaryllidaceae (amaryllises), and Dioscoreaceae (yams); about 430 genera, and 8,000 species; distribution is worldwide, but members are concentrated in temperate and subtropical regions.

ORDER IRIDALES

Annual or perennial herbs. Leaves basal or on a definite stem, parallel-veined, linear. Flowers mostly bisexual, radially or bilaterally symmetrical; perianth (sepals and petals) of 6 segments in 2 whorls, mostly basally fused, petaloid (petallike in structure and appearance). Stamens 3 or 6, arising from the tepals; anthers 2-celled, splitting lengthwise or transversely; pollen mostly with 2 nuclei and 1 germinal furrow or pore. Ovary mostly inferior, 3-chambered, with axile placentation (ovules attach along central axis of ovary) or 1-chambered with ovule attachment to ovary walls; ovules few to many or numerous, mostly anatropous (inverted and straight); fruit a capsule. There are 4 families, about 77 genera, and about 1,640 species, of which some 1,500 belong to the family Iridaceae (irises). Distributed in the tropics and subtropics of both hemispheres.

ORDER ZINGIBERALES

Rhizomatous herbs, rarely arborescent. Leaves mostly with an open sheath, sometimes ligulate. Leaf blades entire with many lateral veins diverging from a common midrib region. One-half of the leaf blade completely rolled around the other in the bud. Inflorescence terminal or lateral, commonly racemose with conspicuous bracts; in the axil of each bract a monochasial cyme, sometimes reduced to a single flower. Flowers zygomorphic. Perianth consisting of separate calyx and corolla. Perfect stamens rarely 6, usually 5 or 1. Sterile stamens 1 to 5, often represented by staminodes of great diversity. Ovary inferior, usually trilocular, with 1 to many ovules in each locule. Seeds with abundant endosperm, often with an aril. Eight families, 89 genera, and about 1,800 species, of which some 1,000 belong to the family Zingiberaceae (gingers); the family Marantaceae

(prayer plants) contains about 400 species. Distributed mostly in the tropics.

ORDER ORCHIDALES

Perennial herbs; terrestrial, epiphytic, or saprophytic, sometimes vinelike. Stems leafy or scapose, of sympodial or monopodial growth. Flowers solitary or in spikes, racemes, or panicles; bisexual, rarely unisexual, zygomorphic, always bracteate, mostly resupinate; perianth typically of 6 segments in 2 series, the outer series of 3 sepals green or often coloured and petaloid and usually all similar, the inner series of 3 petals with the central petal usually larger, often highly modified in colour and shape. Ovary inferior, of 3 carpels, ovules very numerous and minute. Style, stigmas, and stamens variously adnate into a singly highly complex structure (the column). Stamens 1 and then terminal on the column, or 2 and lateral (rarely 3), each anther 2-celled and introrse, the pollen usually in pollinia of 2 to 8 per anther. Fruit a capsule. Seeds abundant, minute, without endosperm, the embryo undifferentiated. A large order, variously estimated at 400 to 800 genera with 15,000 to 35,000 species, all in the single family Orchidaceae (orchids). Distributed worldwide, but mostly in the tropics.

Subclass Commelinidae

Mostly herbaceous plants. Vessels in all vegetative organs, or restricted to roots. Stomata with 2, 4, or 6 subsidiary cells, very rarely without subsidiary cells. Flowers mostly bisexual, with more or less reduced perianth. Gynoecium coenocarpous (syncarpous or paracarpous). Pollen grains 2-celled or 3-celled, mostly monocolpate or monoporate. Ovules usually with 2 integuments. Seeds with usually mealy endosperm. Seven orders.

†*Order Juncales*. Probably had a common origin with the Bromeliales and Commelinales from the Liliales. Two families, Juncaceae (rush) and Thurniaceae.

†*Order Cyperales*. Evidently derived from the most primitive Juncaceae. One family, Cyperaceae (sedge).

ORDER BROMELIALES

Largely herbaceous perennials, rarely shrubby, the more advanced floral types largely epiphytic. Roots usually present, but their absorptive function often taken over by the leaves. Leaves spirally arranged, usually rosulate, and with distinct sheaths and blades, bearing peltate (shieldlike) scales that serve to absorb and transmit moisture. Inflorescence simple or compound, usually bearing brightly coloured conspicuous bracts. Flowers perfect (both sexes present) or sometimes functionally unisexual and dimorphic (male and female flowers exhibit different forms), radially symmetric or nearly so. Perianth (sepals and petals) of 2 unlike series, the sepals and petals free or connate (fused). Stamens 6 in 2 series; filaments free or variously joined. Ovary superior to inferior, 3-celled; placentae axile (ovule attachment to a central stalk in ovary). Fruit capsular or baccate. Seeds winged, plumose, or naked. Embryo small, located at the base of the copious, mealy endosperm. One family, Bromeliaceae (bromeliads), with some 45 genera and about 2,000 species, all but 1 confined to the New World.

†*Order Commelinales*. Probably shares a common origin with the Bromeliales. Four families, including Commelinaceae (spiderwort), Xyridaceae (xyris), and Rapateaceae.

†*Order Eriocaulales*. One family, Eriocaulaceae.

†*Order Restionales*. Probably shares a common origin with the Commelinales. Four families, including Restionaceae (restio), Flagellariaceae (flagellaria).

ORDER POALES

Anemophilous (wind-pollinated) herbs, rarely woody or of giant structure, with jointed, cylindrical, usually hollow stems; leaves 2-ranked (distichous), alternate, each composed of a sheathing base, a ligule, and a usually linear blade; root system fibrous, mostly adventitious; rhizomes or stolons frequent; inflorescences various (panicles, spikes, racemes, or racemes) but always bearing distinctive subunits, the spikelets. Spikelets diverse but typically consisting of a central axis, the rachilla, bearing at its base a pair of empty bracts, the glumes, and above these 1 or more florets. The floret consists of an outer bract, the lemma, an inner, or secondary, bract, the palea, and the reduced flower included between them. Flowers small, typically consisting of 2 reduced perianth segments (the lodicules), 3 stamens with anthers attached at the centre, and a pistil fundamentally made up of 3 united carpels or segments but usually with 2 styles bearing feathery stigmas; ovule 1; fruit a caryopsis. One family, Poaceae (Gramineae; grasses); number of genera estimated at 600 to 700; species 6,000 to 10,000. Distribution worldwide.

Subclass Arecidae

Herbaceous or arborescent plants mostly with broad, petiolate leaves. Vessels in all vegetative organs or restricted to root (Arales). Stomata with 2, 4 (often), or 6 (rarely) subsidiary

cells. Flowers mostly unisexual, usually small and numerous, aggregated into inflorescences generally subtended by more or less prominent spathaceous bracts. Perianth of 6 segments, reduced to bristles or scales, or absent. Gynoecium usually coenocarpous (syncarpous or paracarpous), rarely apocarpous (in some palms). Pollen grains 2-celled, rarely 3-celled, mostly monocolpate. Large ovules usually with 2 integuments. Seeds almost always with endosperm. Five orders.

ORDER ARECALES (Principes)

Woody Monocotyledoneae with plicate, paripinnate, imparipinnate, pinnately nerved, costapalmate, or palmate leaf blades, the pinnae or segments induplicate or reduplicate in bud. Inflorescence paniculate to spicate, always with a prophyll, often with sterile bracts on the peduncle, usually with bracts subtending all branches, bearing usually bracteate flowers arranged singly, in pairs, or in cincinni of 3 or more. Flowers perfect or unisexual, calyx and corolla each of usually 3 but sometimes only 2 or as many as 10 sepals and petals or rarely the perianth uniseriate and lobed, androecium of 3 (rarely) or 6 to many stamens, gynoecium of 1 to 3 or rarely up to 10 distinct or united carpels, locules uniovulate, seed with copious endosperm and small embryo. One family, Areaceae (Palmae; palms), with about 200 genera and 2,600 species in the tropics and subtropics of both hemispheres.

†*Order Cyclanthales*. One family, Cyclanthaceae.

†*Order Arales*. Most likely had a common origin with the Arecales. Two families, Araceae (arum), Lemnaceae (duckweed).

†*Order Pandanales*. Most likely had a common origin with the Arecales and Arales. One family, Pandanaceae (screw pine).

†*Order Typhales*. Probably had a common origin with the Pandanales, but the affinity is not very clear. Two families, Sparganiaceae (bur reed) and Typhaceae (cattail).

Alternate systems of classification. Since 1900, and until recently, the dominant system of classification was that proposed by the German botanist Adolph Engler and his associates. It is still widely accepted as the basis for arrangement of families in the majority of existing manuals and floras, and for the arrangement of specimens in many larger herbaria, though in British herbaria plants are arranged according to the system devised by George Bentham and Sir Joseph Dalton Hooker and published in three volumes of their *Genera plantarum* (1862–83). The Engler system won wide acceptance because of its thoroughness: it was applied by Engler and his associates to the whole plant world, at all taxonomic levels. It was based largely upon the system proposed in 1883 by August Wilhelm Eichler, with certain features of the systems of the French botanist Adolphe-Théodore Brongniart (1843) and the German botanist Alexander Braun (1864). Engler considered the monocotyledons to be more primitive than the dicotyledons, and the apetalous and catkin-bearing dicotyledons (willows, walnuts, birches, oaks, etc.) as more primitive than the others. The principal fault in the Engler system is that it equates simplicity with primitiveness, completely ignoring the significance of secondary reduction and simplification.

Braun later (1875) put forward some fundamental ideas that anticipated by several decades the basic tenets of phylogenetic angiosperm systematics. According to him, the primitiveness of the Magnoliaceae, Alismaceae, and similar families is apparent when the flower is considered as a strobilus substantially homologous with the cones of the cycads, and from this it follows that the petalless forms (Apetalae), characterized by small, simply constructed unisexual flowers, must be derivative, and that the simplicity of their flowers is not primitive. To Braun belongs the well-known aphorism: "In nature, as in art, the simplest may be the most perfected." Braun, however, died only two years later, without having undertaken the reform of the system in accordance with the new principles he had enunciated. The German botanist Karl Wilhelm von Nägeli, in 1884, and the French paleobotanist Gaston de Saporta, in 1885, came to hold similar views independently. But the credit for reforming angiosperm classification on an evolutionary basis belongs to the American botanist Charles E. Bessey and the German botanist Hans Hallier. Their first papers appeared in 1893 (Bessey) and 1903 (Hallier), but the most complete account of Hallier's system appeared in 1912, and of Bessey's in 1915. In 1916 the Russian botanist Christopher Gobi published the sys-

Classifica-
tion
systems of
the 19th
century

tem that he had already used in the late 1890s in lectures to his students at St. Petersburg University. These three workers came to the conclusion that the "Apetalae" were not only derivative and simplified but also heterogeneous, the different members thereof having arisen along different evolutionary lines within the dicotyledons. Later, the British botanist John Hutchinson proposed a new system of classification in his *Families of Flowering Plants* (1926–34; 2nd edition, 1959) based on many of the principles adopted earlier by Bessey and Hallier. One of the main differences is the division of the dicotyledons into two main groups, Lignosae and Herbaceae, the former embracing those families "fundamentally woody" and the later those that are "fundamentally herbaceous." This division leads to the wide separation of some obviously closely related families, such as the Araliaceae and Apiaceae or the Verbenaceae and Lamiaceae. The Hutchinson system rests mainly upon gross morphological data. In spite of deficiencies it has noticeably stimulated the development of the phylogenetic systematics of angiosperms.

The most recent systems of angiosperm classification are those of the Soviet Armenian botanist Armen Takhtajan and of the American botanist Arthur Cronquist. Takhtajan's system has gone through a series of modifications since its first appearance in 1942, its last version having been published in 1969 and 1970 in Russian and in En-

glish. Cronquist's system was published in part in 1957 (the dicotyledons) and appeared in its complete version in 1968. Both systems are synthetic in the sense that their authors have synthesized data from different fields of botany into one taxonomic whole. Both authors recognize, however, that knowledge of very many angiosperm groups is scanty, insufficient, and in many cases conflicting and that many details of classification are still uncertain. These two systems have much in common. They evolved independently in parallel fashion from a similar ancestry (that of Cronquist more nearly from Bessey, that of Takhtajan more nearly from Hallier), and have influenced each other, leading toward an increasing convergence of the two systems. The most recent published versions of these two systems agree in treating the angiosperms as a division Magnoliophyta, with two classes, the Magnoliopsida (dicotyledons) and Liliopsida (monocotyledons). These new names are the result of the extension of the type concept in nomenclature up to the rank of division. They also agree in the subdivision of the Magnoliopsida and Liliopsida into subclasses and in many other points. There have been also proposed two other modern systems of classification, by the Hungarian botanist R. Soó (1967) and by the American botanist Robert F. Thorne (1968); these systems have much in common with those of Cronquist and Takhtajan. (A.T./Ed.)

THE MAJOR ORDERS OF ANGIOSPERMS

The remainder of this article consists of a review of the major groups of flowering plants. Groups are here identified at the order level of scientific classification and arranged in accordance with the *Annotated classification*, above. (As noted earlier, further information about the orders indicated above by a dagger [†] may be found in the *Micropedia*.)

Magnoliales (magnolia order)

Ever since the emergence of Darwin's evolutionary theories in 1859, botanists have attempted to classify the members of the plant kingdom according to their presumed natural relationships. During the first part of the 20th century, most "natural" systems of classification of the flowering plants (angiosperms) were based primarily on similarities or differences in gross morphological (structural) features, and the emphasis was placed on the reproductive structures; *i.e.*, the flowers. More recently, however, considerable data have accumulated from investigations of wood anatomy, vegetative nodal anatomy (*i.e.*, the manner in which vascular bundles depart from stems to enter leafstalks), pollen morphology, chromosome analysis, comparative biochemistry, floral anatomy, seedling development, and embryology, which, when considered as a whole, give a much more reliable picture of the true relationships within the flowering plants. Based on the totality of these features, most students of plant evolution now regard the Magnoliales order as including the most primitive components of the angiosperms.

Magnoliales, a plant order belonging to the dicotyledonous group of flowering plants, contains 8 families, 166 genera, and about 1,800 species, all of which are woody shrubs or trees. The 8 families of the Magnoliales order include the following: (1) Magnoliaceae, with 12 genera and about 210 species; (2) Degeneriaceae, with 1 genus and 1 species; (3) Himantandraceae, with 1 genus and 4 species; (4) Eupomatiaceae, with 1 genus and 2 species; (5) Annonaceae, with 122 genera and about 1,100 species; (6) Canellaceae, with 5 genera and about 9 species; (7) Myristicaceae, with 16 genera and about 380 species; and (8) Winteraceae, with 8 genera and 88 species. These estimates indicate that approximately 80 percent of the total genera (122 of 166) in this order and 60 percent of the species (1,100 of 1,794) are included in the pantropical (*i.e.*, found throughout the tropics) family Annonaceae. The next two largest families, Myristicaceae and Magnoliaceae, include about 32 percent of the species in the

Magnoliales order, with the other 5 families comprising the remaining 8 percent. When this many small families are found to be classified together in the same order, it is usually assumed that they represent a group of relic families that have evolved together slowly over a long period of time—a linear evolutionary derivation of one family directly from another should not be implied.

GENERAL FEATURES

Structural diversity and distribution. All members of the order are woody; most are trees of small or intermediate size, though an exception occurs in the case of the tulip tree or tulip poplar (*Liriodendron tulipifera*, family Magnoliaceae), which reaches a height of over 150 feet (46 metres) and, in the Appalachian forests of the eastern United States, may have a base diameter of 10 feet.

Other tall trees are found in the genera *Mitrephora*, *Mezzettia*, and *Cananga* (all three of family Annonaceae) in the rain forests of Southeast Asia. The species of *Eupomatia* are shrubs, and many genera of the family Annonaceae are mostly shrubby, some being modified as climbers; *e.g.*, the genera *Ellipeia*, *Cyathostemma*, *Uvaria*, and *Phaeanthus*. Many species of Annonaceae are cauliflorous—*i.e.*, with flower buds formed from mature wood of the trunks and older branches; but the genus *Geanthium* is unique in this order in that floral structures form on subterranean branches.

Most Magnoliales are tropical in distribution, with the greatest speciation occurring in Southeast Asia and Africa. *Xylopia*, which includes about 160 species in the Annonaceae family, is the only genus in the order with pantropical distribution.

Genera with some temperate species include *Magnolia* and *Liriodendron* (Magnoliaceae family), with native species growing in China, Japan, and the eastern United States. Other temperate species include the papaw tree (*Asimina*, family Annonaceae), which extends northward into southern Ontario, Canada; *Eupomatia* from eastern Australia; and four genera of the Winteraceae family (*Drimys*, *Tasmannia*, *Pseudowintera*, and *Bubbia*) that range from eastern Australia and New Zealand to the southern Andes in Chile.

Economic importance. The wood of the tulip tree (*Liriodendron tulipifera*), sometimes referred to as American whitewood, is one of the most valuable timber products in the United States, where more than 800,000,000 board feet are cut each year. The wood is light yellow to tan, with a creamy white margin of sapwood. It is relatively

Growth
forms and
distribu-
tions

Representative plants from three of the largest families of the magnolia order.
Drawing by M. Pahl

soft, easily worked with tools, and takes paint well. Large, clear logs are well suited to the manufacture of rotary-cut veneers, not only for furniture and cabinetwork but also for berry and fruit boxes. Other uses are for millwork (sashes, doors, and blinds), hat blocks, and to a lesser extent, pulpwood for making paper (by the soda process).

The southern magnolia, or laurel magnolia (*Magnolia grandiflora*), has large, creamy-white flowers that, together with its dark green leaves and reddish egg-shaped fruit with pendent scarlet seeds, give it a striking appearance. The natural range of this stately tree (60 to 80 feet [18 to 24 metres] tall in the wild) is a strip about 100 miles (161 kilometres) wide, from North Carolina through northern Florida, along the Gulf Coast to eastern Texas. It is most abundant in Louisiana. A valuable ornamental, it is planted as far north as New Jersey on the Atlantic Coast and all the way to British Columbia on the Pacific Coast, where the winters are relatively mild. It also can be found in cultivation throughout most warm temperate regions of the world. Although its value as an ornamental far exceeds that as a timber producer, about 25,000,000 board feet are marketed annually in the southern United States. The majority of this wood is utilized in the manufacture of venetian blinds because of the wood's fine, uniform texture, hardness, and ability to resist warping.

The cucumber tree (*Magnolia acuminata*) reaches its greatest size (80 to 100 feet) in the narrow valleys of the Smoky Mountains of Tennessee and North Carolina. The fleshy fruit resembles a 2- to 3-inch- (5- to 7.5-centimetre-) long cucumber, which gives the tree its popular name. The timber is not as durable as that of the related evergreen magnolia or tulip tree, but is marketed to make crates, boxes, cheap furniture, and interior flooring.

About 80 species of magnolia have been described; because of their showy flowers, which usually appear before their leaves in deciduous types, many are in cultivation in the north temperate parts of the world. Forty-six species and varieties are being grown at the Arnold Arboretum of Harvard University. The Morris Arboretum of the University of Pennsylvania has numerous American and

Asiatic species, and the Royal Botanic Gardens, near London, has a magnificent living collection. Most American species have white to creamy-yellow flowers; many Asiatic species and their hybrids are characterized by pink to purplish-red flowers. A hybrid developed near Paris in 1820 is undoubtedly one of the most widely cultivated ornamentals—*M. soulangiana* is a large shrub or small tree of many varieties with large, cup-shaped, pinkish-purple flowers that appear early in the spring before the leaves. Some other well-known magnolia hybrids (indicated by the X) in cultivation are: *Magnolia loebneri* (*kobus* X *stellata*); *M. thompsoniana* (*tripetala* X *virginiana*); *M. watsonii* (*obovata* X *sieboldii*); *M. proctoriana* (*salicifolia* X *stellata*); and *M. veitchii* (*campbellii* X *denudata*).

Another genus of the Magnoliaceae family that is widely cultivated in tropical regions is *Michelia*. Although the flowers are not as grandiose as those of the genus *Magnolia*, they more than make up this deficiency by their abundance and extreme fragrance. They also differ from the flowers of *Magnolia* in that they develop in dense clusters in the axils of leaves (the point at which the leaf stalk joins the branch), rather than singly at the ends of branches. The champac (*Michelia champaca*) is supposedly native to India, Assam, and Myanmar (Burma), but it has been in cultivation for so many centuries that its original natural range is difficult to determine. This tree is a handsome ornamental with evergreen leaves and profuse, highly scented yellow flowers that are the source of champak, an exotic East Indian perfume. In addition, the timber from this species has some local uses in making light furniture and plywood. The banana shrub (*Michelia figo*) from southern China also is cultivated to some extent as a tropical ornamental with fragrant flowers.

Because the family Annonaceae is by far the largest in the Magnoliales order, it is not surprising that this group includes the most species that yield some type of economic product. Lancewood (*Oxandra lanceolata*), from northern South America and the West Indies, is undoubtedly the most important commercial timber source in this family. The wood is yellow to olive-yellow, hard, heavy (specific gravity 0.95), of fine texture, and with an extremely straight grain. These characteristics make the wood particularly suitable for use in scientific instruments, turnery (objects shaped by lathe), tool handles, and such sporting goods as billiard cues, archery bows, and fishing rods. Solera or Colombian lancewood (*Guatteria boyacana*) has most of the same properties and uses but is not as well known in the timber trade. Yellowwood (*Enantia chlorantha*) from Liberia, Côte d'Ivoire, and the Cameroons of West Africa produces a sulfurous yellow dye; the wood also is used locally to make unpainted furniture and veneers. Otu (*Cleistopholis patens*) yields a soft, light (specific gravity 0.40) wood from West Africa that finds some of the same uses as balsa wood—in buoys, life rafts, floats, etc. The fibrous inner bark is of some value for cordage and coarse netting.

Polyalthia longifolia is a tall, handsome tree with pendent linear leaves, which is cultivated in most parts of Sri Lanka and India as an avenue tree and around temples, where it has a religious significance. Although the wood is not very durable, it is utilized to some extent in making matches, boxes, and packing crates. Other woods of the Annonaceae family in India and Myanmar that have some commercial value are derived from the genera *Milium*, *Sageraea*, *Mitrephora*, *Saccopetalum*, and *Cyathocalyx*. Because of their tough and elastic qualities, these woods are utilized in the manufacture of tool handles, wheel spokes, and sporting goods.

The wood of *Xylopi aethiopia* is quite flexible and has some local use in west central Africa for masts, boat paddles, and rudders. It has been described as termite-proof and, accordingly, is used for house posts and beams. The dried black fruits of this species are called guinea peppers and were once of commercial importance in Europe as a tangy condiment and drug. At present, the fruits are reportedly used by some African tribes as a cough medicine and purgative. The bark of several other *Xylopi* species from Brazil (*X. sericea*, *X. frutescens*, and *X. aromatica*) finds some local use in cordage and rough textiles.

The most widely known economic products of the Annonaceae family in the tropics are its edible fruits. One of the most important of these is the West Indian custard apple or bullock's heart (*Annona reticulata*). The latter common name is suggestive of the shape and general appearance of the fruits. When the fruit is ripe and the skin has begun to blacken, its white to cream-coloured flesh becomes sweet and aromatic and resembles ice cream when chilled. It may be eaten with a spoon as a dessert. The sweetsop, or sugar apple (*Annona squamosa*), although native to northern South America, Central America, and the Caribbean region, is even more widely cultivated and highly esteemed in India and Pakistan. The conical fruits break into segments when ripe and expose a cream-coloured sweet pulp in which dark brown glossy seeds are embedded. Among the natives of the tropics the sugar apple tree is reputed to be of medical value. Tea made from the roots is highly purgative, while that made from the leaves is mildly laxative and is also considered to have a general tonic effect on the digestive tract. Poultices of the leaves are used in dressing infected wounds.

The cherimoya is the fruit of a rather small tree, *Annona cherimola*, which is native to the cool (but frost-free) mountain valleys of Peru. Although it is grown in southern Florida, it does not produce fruit well there because of the high humidity; it is currently commercially grown on a small scale in southern California. The fruits, however, are quite perishable and ferment readily. Like the sugar apple, it is now well-established in the Old World tropics. Although the fruit does not break into segments when ripe the way that of the sugar apple does, the flesh is of a more creamy consistency and has fewer seeds. Under ideal conditions, the fruit may attain a large size, weighing up to 16 pounds. The soursop, or guanábana (*Annona muricata*), also is native to the American tropics, but is now general throughout the Old World tropics as well. In Cuba the fruit is a favourite, and the tree may be found in almost every yard planting. The fruit is large (up to 10 pounds), tapering, and heart-shaped, and the green skin is covered with spiny protuberances. The aromatic flesh, white and somewhat fibrous, is strained to make custards and ice cream; the acidulous juice is usually extracted to make a refreshing drink, which has been described as a combination of the flavours of strawberries, pineapples, and cinnamon. The hybrid atemoya (*Annona squamosa* × *A. cherimola*) has been established in the Caribbean region; reputedly the fruit contains the best features of both parents. The alligator apple (*A. glabra*) grows plentifully in the Florida Everglades and on the Florida Keys, where its fruits have been described as "edible but not very palatable." The tree's prime use in Florida is as a rootstock in deep, sandy soils for the grafted custard apple and the sugar apple.

Other species of *Annona* that produce comparatively inferior fruit, but which are eaten locally, include: *A. montana*, the mountain soursop (West Indies and South America); *A. longiflora* (Mexico); *A. paludosa* (Brazil); *A. testudinea* (Honduras); *A. nutans* (Paraguay); *A. senegalensis* (East and West Africa); and *A. diversifolia*, the ilama, which was first cultivated long ago by the Aztecs of Mexico.

Two species of *Rollinia* (*R. mucosa* and *R. pulchrinervia*) have edible fruits that reach 4 inches (10 centimetres) in length and bear some resemblance to those of the soursop, except that the spines are softer and more blunt. *R. mucosa* is a large tree native to the West Indies and northern South America, whereas *R. pulchrinervia* is restricted in the wild state to the Amazon Basin. Both species are referred to by the common name biriba, and both are widely cultivated, particularly throughout Brazil, for their delicious fruits.

The papaw (*Asimina triloba*) of eastern North America produces a fruit that is sometimes eaten. The fruits of this species show considerable variability in size, colour, and palatability. Two general types have been observed: (1) large, yellow-fruited, highly flavoured, and early ripening; and (2) relatively small, white-fleshed, mild flavoured, and late ripening. A number of selected clones (groups of plants of identical genetic makeup that are vegetative divisions of one plant), propagated by grafting, are in cultivation,

principally in southern Pennsylvania, Ohio, Illinois, and Indiana (where the yellowish fruits are referred to as Indiana bananas). Sometimes an alcoholic beverage is made from the papaw.

Certain Asiatic species of *Polyalthia* (*P. cerasioides* and *P. korinithii*), *Uvaria* (*U. burahol*, *U. dulcis*, and *U. heterophylla*), and *Artabotrys* produce edible fruit, as do African species of *Uvaria* (*U. chamae* and *U. globosa*).

The ylang-ylang tree (*Cananga odorata*) has its natural range from the tropical parts of eastern India through the Malaysian regions to the Philippines and northern Australia. The name means "flower of flowers" because the yellowish-green, bell-shaped flowers yield an exceedingly delicate and evanescent fragrance that is highly valued in the manufacture of perfumes. Ylang-ylang or cananga oil is derived by simple distillation from the petals of fully opened flowers. Although the tree blossoms throughout the year, the flowers picked in May or June yield the highest amounts of the cananga oil. Long known to the peoples of the Far East, this oil first reached Europe about 1864. Although the Philippines are probably the chief producers of ylang-ylang oil, some production also comes from Malaysia, Java, the Mascarene Islands, and Madagascar. The related *Artabotrys odoratissimus* (climbing ylang-ylang) is cultivated in many tropical regions for the fragrance of its flowers, but the perfume has only localized uses.

In Ghana and the Côte d'Ivoire region of West Africa ethereal oils distilled from leaves of *Enneastemum capeus* are reportedly utilized in making perfume.

Cymbopetalum penduliflorum (Annonaceae family), a tree of Central America and Mexico, has flowers that, when crushed, yield an oil with a spicy odour similar to nutmeg or cubeb pepper; the oil has been used for several centuries to flavour chocolate and in cooking. According to one authority, this plant was called xochinacatzli—sacred ear flower of the Aztecs—because the inner petals bear some resemblance to human ears.

In the upper Amazon region, Indian tribes use an extract from the tree *Unonopsis veneficiorum* to tip their poison blowgun darts and arrows; this substance is said to have the same paralyzing effect on man and animals as that caused by curare poisons obtained from the genus *Strychnos* of the Loganiaceae family (order Gentianales).

Monodora myristica (family Annonaceae) is a large (up to 60 feet [18 metres] high) West African tree with big leaves and striking flowers; these features combine to make it an attractive ornamental in many tropical regions. Because the large ruminant (i.e., folded in undulate fashion) seeds of this tree bear some resemblance to those of the true nutmeg (*Myristica*, family Myristicaceae), the tree is referred to as the Jamaica nutmeg or the calabash nutmeg. The latter name refers to the orange-sized fruit that encloses the seeds, and which has a superficial similarity to a gourd when dried. In West Africa the seeds are used as a flavouring, as aromatic necklaces, in primitive medicinals, and (when pulverized) as a pomade.

Although many trees in the family Myristicaceae (nutmeg family) reach timber size, the wood is not of much value in world trade. Nevertheless, the following species from tropical regions of South and Central America find local uses in the manufacture of furniture, millwork, veneers, flooring, and general carpentry: *Dialyanthera otoba* (otobo), *Iryanthera lancifolia* (kirikawa), *Iryanthera sagotiana* (marakaipo), and *Virola koschyni* (banak). Wood of *Pycnanthus kombo* from West Africa is grayish-brown to pink, soft, and light (specific gravity 0.40), and is made into plywood for packing cases and low-grade interior woodwork. *Staudtia gabonensis* produces an orange to reddish-brown, moderately hard and heavy (specific gravity 0.90) wood used for cabinetry, tool handles, carving, and turnery in several West African countries. Chuglum (*Myristica irya*), from the Andaman Islands in the Bay of Bengal, yields light red to reddish-brown wood with darker streaks and high lustre which is used to make musical instruments and furniture.

Both nutmeg and mace are obtained from the seeds of *Myristica fragrans*, a native of the Moluccas or Spice Islands in the Indonesian Archipelago that is now grown in

Products
and uses
of the
nutmeg

the tropics of both hemispheres. Although some of these spices are still exported from Indonesia, the greatest production today is in the British West Indies, principally the island of Grenada.

The nutmeg tree is a handsome evergreen with dark leaves and reaches a height of 30 to 60 feet (9 to 18 metres). The small, yellow, fleshy flowers are unisexual, and the plants producing them are dioecious; *i.e.*, the male and female flowers are produced on separate trees. The ripe fruits are golden yellow and resemble apricots or pears. As the fruits dry out, they split open, revealing the single shiny brown seed covered with a bright red fleshy structure, called an aril. Inside the seeds are the kernels, which are the nutmegs of commerce; the aril is the source of mace. The pulverized seed finds much use for seasoning spiced fruits, sausages, pastries, puddings, eggnog, etc. Mace is one of the most delicately flavoured spices and is used in making baked goods, pickles, ketchups, and sauces. Two oils are obtained from the seeds of *Myristica fragrans*, a volatile oil obtained by distillation, and a fixed oil obtained by subjecting the nutmegs to heat under pressure. The volatile oil contains myristic acid and a narcotic, myristicin; it is used medicinally as a carminative and as a flavouring agent in dentifrices, tobacco, and perfumes. The fixed oil is known as nutmeg butter and is used in ointments and in candles.

The seeds of *Gymnacranthera farquhariana* have been used in India for candlemaking. Those of *Myristica malabarica* have been used for oil and for adulterating nutmegs; its aril is marketed as Bombay mace. *Myristica argentea*, the Papua or Macassar nutmeg, is also used in oils and soaps, but is useless as a spice. The seeds of *Virola surinamensis* are used to make a commercial wax.

The family Canellaceae is of relatively little economic importance. The leaves and bark of the wild cinnamon (*Canella alba*) from the West Indies still have some use as a condiment and for medicinal purposes. The small trees of this species are cultivated to a limited extent in southern Florida, as ornamentals prized for their reddish-purple flowers and blue-black berries. The scented wood of *Cinnamosma fragrans* is exported from Zanzibar to Bombay and Thailand where it is used for religious ceremonies. *Warburgia ugandensis* is a fairly important timber producer in Uganda; the bark is utilized as a purgative and the resin for cementing tool handles.

The sole economic product from the Winteraceae family is "Winter's bark" from *Drimys winteri* of South America; it still finds some use as an astringent and a stimulant.

EVOLUTION

The fossil record. Fossils representing four of the eight families of the Magnoliales order have been found. These include leaves ascribed to members of the Magnoliaceae family (*Magnolia* and *Liriodendron* from the Cretaceous Period of about 100,000,000 years ago and the Tertiary Period of about 60,000,000 years ago and *Talauma* from the Tertiary, all of North America). Seeds (*Magnoliaespermum*) are recorded from the Tertiary brown coals of Germany, and pollen belonging to the family is widespread in the Lower Cretaceous and Tertiary deposits of both hemispheres. Fossil leaves and seeds of the Annonaceae family are known from the Cretaceous and Tertiary of both hemispheres. These have been assigned to about 10 different modern genera. Seeds of the modern genus *Asimina* are known from the Tertiary brown coals of Germany, and petrified woods (*Annonoxylon*) have been found in Tertiary deposits of North America and Austria. Fossil woods (*Myristicoxylon*) of the Myristicaceae family are known from the Tertiary of North Africa. The Winteraceae family is represented by fossil leaves (*Drimys*) from the Tertiary deposits of Australia, South America, and North America. The remaining four families have no fossil record.

Unfortunately, the fossil record is of little assistance in attempts to determine which group of flowering plants appeared first on Earth. Although there are numerous scattered reports of putative angiosperm (flowering plant) fossils from pre-Cretaceous rocks—*i.e.*, deposits older than about 136,000,000 years—none of these finds has

ever been indisputably accepted as belonging to the angiosperms. Indeed, possibly the best evidence is that the angiosperms arose rather suddenly during the Lower Cretaceous, about 120,000,000 years ago. Because these are the epochs when undoubted angiosperm pollen grains (which, due to the chemical nature of their coats, are extremely resistant to decay) first appeared in the fossil record, the pollen evidence is believed to be more reliable than that based on compressed leaves or leaf fragments. Nevertheless, in the absence of floral structures (which are only very rarely preserved as fossils) it is difficult to assign the Cretaceous fossils to modern families, let alone genera. Although numerous "species" of *Magnolia*, *Liriodendron*, *Drimys*, etc., have been described from leaf remains dating back to the Lower Cretaceous, only in rare instances have any of these identifications been validated by concomitant cuticular studies (*i.e.*, arrangement and types of cells on the outer cell layer of leaves), descriptions of wood anatomy, pollen morphology, fruits, or seeds preserved in the same sediments. Accordingly, most of the identifications of these supposed early remains of the Magnoliales order remain suspect. Although undoubted representatives of magnolialean families were present by the beginning of the Tertiary Period (approximately 63,000,000 years ago), so were numerous representatives of structurally much more highly evolved angiosperms; *e.g.*, the families Salicaceae (willows), Juglandaceae (walnuts), Fagaceae (oaks and beeches), and Moraceae (mulberries). Thus, the known fossil record cannot establish which angiosperm family is the most primitive.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The features of most diagnostic value for determining family relationships within the order include the presence or absence of stipules (leaflike appendages at the base of leafstalks); presence or degree of fusion of the carpels (simple pistil or seed-bearing organs); modification of perianth parts (tepals, the leaflike, showy parts of a flower) into sepals and petals; spiral or whorled arrangement of floral organs; free or connate (joined, fused together) stamens; pollen uniaperturate (with a single aperture, or germ-pore) or modified; and rumination (folded, ridged pattern of growth) of endosperm.

Alternate systems of classification. As treated in the classification above, the eight families included in the Magnoliales order are believed to contain many more ancient and primitive structural features than can be found in any other order of flowering plants. Some of these features follow: vesselless woods in the Winteraceae family; *i.e.*, the water-conducting elements are all composed of primitive conducting cells called tracheids, such as those occurring in many ferns and some more primitive gymnosperms; flowers with numerous, spirally arranged, usually free parts on an elongated floral axis; the male organs or stamens often relatively broad and with pollen sacs embedded in their surfaces; the female organs or carpels often relatively unmodified from a leaflike structure; pollen grains usually with a single elongate germinal furrow such as that of the ancestral gymnosperm type; abundant ethereal oil cells in both floral and vegetative organs; and seeds bearing a small embryo embedded in copious endosperm (food storage tissue).

Pollination by beetles, believed to be a primitive condition among flowering plants, is normal for the Eupomatiaceae family and has been reported to occur commonly in many members of the Magnoliaceae, Winteraceae, and Annonaceae families. Ruminant endosperm—*i.e.*, endosperm that is fluted by the inward development of numerous ridges from the inner seed coat—is a normal feature in the Annonaceae, Myristicaceae, and Eupomatiaceae families, and at least one genus (*Cinnamosma*) in the family Canellaceae.

The classification presented in this article is a recent one that is gaining acceptance. By contrast, some authorities, in the treatment of the Magnoliales order, exclude four families recognized here (Eupomatiaceae, Annonaceae, Myristicaceae, and Degeneriaceae). Furthermore, they place the monotypic genus *Degeneria* in the Winteraceae family, the Annonaceae and Eupomatiaceae together in

Problems
in the
fossil
record

an order Annonales, and the Myristicaceae family in the order Laurales. To the Magnoliales order of these treatments are added the families Illiciaceae, Schisandraceae, Lactoridaceae, Trochodendraceae, and Cercidiphyllaceae, which receive no treatment here. Other authorities take an even broader view of the Magnoliales order, not only including the eight families recognized here but also adding 11 other families, which, under the treatment presented here, appear in the orders Laurales and Illiciales. Although there are grounds for criticism of all of these systems, the system presented here, circumscribing a smaller group, is probably more natural, if for no other reason than the fact that fewer genera are included, thus there are fewer "odd" morphological features to confuse the picture. (J.E.Ca.)

Laurales (laurel order)

Laurales is a fairly large order of flowering plants, consisting of 11 families with a total of about 70 genera and more than 2,500 species. The order is of interest not merely because of its abundance but also for its utilitarian, morphological (structural), and phylogenetic (evolutionary) importance.

GENERAL FEATURES

Economic importance. Of the 11 families, the laurel (Lauraceae) is the most useful to man. The leaves and bark of several species such as those of *Lindera* (benzoin), *Litsea*, and *Laurus* (laurel) are of medicinal value. Some, like the South African *Ocotea bullata* (stinkwood), yield useful timber. Most of the world's supply of natural camphor, used in the manufacture of collodion and explosives, comes from *Cinnamomum camphora*, a native of Japan and Taiwan. Essential oil containing up to 80 percent of safrole, used in the perfume industry, is obtained from the roots of *Sassafras officinale* and the wood of two Brazilian trees, *Ocotea preteosa* and *O. cymbarum*. Cinnamon spice is derived from the bark of *Cinnamomum zeylanicum*, a native of Sri Lanka and southern India. Cinnamon bark and leaf oil are also used in medicine and perfume. *Persea americana*, the avocado, an evergreen tree native to the rain forests of Central America, is economically important in the southern United States, Hawaii, Brazil, South Africa, and tropical Australia. Its edible fruits contain a higher percentage of protein than any other fruit.

Other families of Laurales are economically less important. *Peumus boldus* (family Monimiaceae), of Chile, yields boldo wood used in cabinetmaking. *Doryphota sassafras*, of the same family, is a source of essential oil. Some species of the families Calycanthaceae and Chloranthaceae are grown as ornamentals.

Size range and diversity of structure. Members of the order produce their own food by photosynthesis (i.e., are autotrophic) with the exception of *Cassytha*, a rootless, vinelike stem parasite without proper leaves; it grows on many species of flowering plants. Four of the families—Austrobaileyaaceae, Amborellaceae, Lactoridaceae, and Calycanthaceae—are exclusively shrubs; the other seven are predominantly trees. Some members of the laurel family (Lauraceae) attain great size; *Cinnamomum camphora*, for example, reaches a height of about 100 feet (30 metres), and *Persea americana* grows up to 60 feet (18 metres) or more.

The Laurales order shows great diversity in vegetative and floral structure. Unlike most other flowering plants, the wood in *Amborella* and *Sarcandra* (family Chloranthaceae) is devoid of vessels (water-conducting tissues made of special hollow cells). In *Austrobaileya* (family Austrobaileyaaceae), a woody vine, the wood has vessels but exhibits other primitive characteristics. On the other hand, the families Lactoridaceae, Calycanthaceae, and Lauraceae show some features considered to be advanced.

The plants of the genus *Austrobaileya* are more simple. Their phloem (the part of the vascular system that transports food), unlike that of other flowering plants, is devoid of companion cells—a characteristic of coniferous plants. Typical sieve tubes (the normal arrangement of phloem tissue) are also absent in this genus; instead, its long and overlapping phloem-tissue cells lack the characteristic ter-

minal sieve plates, with small holes that lead to the next cell. Further structural simplicity is seen in the phloem of *Austrobaileya*, and also the family Calycanthaceae, which lack sclerenchyma (thick-walled cells). On the other hand, the presence of sieve cells with single, transverse end plates is an advanced development in the Calycanthaceae family.

The order demonstrates considerable diversity in floral structure even though many families, particularly the Amborellaceae, Trimeniaceae, and Lactoridaceae are not completely described as yet. The genus *Austrobaileya* has probably the most primitive floral structure of the order. Its flower is bisexual and hypogynous (the flower parts are joined at the base of the female structure, or ovary, a condition sometimes called "superior ovary"), and its numerous floral parts are arranged spirally. The stamens (male pollen-producing structures) are laminar (flat, or petal-like), and the carpels (simple ovaries) each have numerous ovules, or developing seeds. In the families Gomortegaceae and Calycanthaceae, also, the flowers are bisexual (with both male and female organs). In *Amborella* (family Amborellaceae) the flower is unisexual (either male or female) and the plants dioecious (one plant with either male or female flowers); all other families are polygamous (with both unisexual and bisexual flowers on the same plant).

The flower form is usually hypogynous ("superior ovary") in the families Trimeniaceae, Lactoridaceae, and Lauraceae; rarely, as in *Hypodaphnis*, it is epigynous, or inferior ovary, with the petals, sepals, and stamens arising at the upper end of the ovary, which they enclose, forming what is called the floral tube. In all the other eight families the flower form is either perigynous ("half inferior") or epigynous.

In the family Lactoridaceae the stamens are laminar with

Stamens, carpels, and ovules

of the
laurel
family

primitive
and
advanced
structures

protruding connectives and the pollen is held in permanent tetrads (groups of four), as in the Winteraceae family and some members of the Annonaceae family (both of the order Magnoliales). In the families Hernandiaceae, Chloranthaceae, Lauraceae, and Gyrocarpaceae the gynoecium (female flower parts) consists of a single carpel with a single ovule. Other families have more than one carpel; in the families Trimeniaceae and Gomortegaceae they are united; in the others, free. In the Lactoridaceae family the ovule number per carpel is six, in the Calycanthaceae family it is one or two; all others have a single ovule.

The fruit is winged in the families Hernandiaceae and Gyrocarpaceae. In the families Trimeniaceae, Monimiaceae, Gomortegaceae, Chloranthaceae, and Lactoridaceae the seed is endospermous (*i.e.*, it contains endosperm, a nutritive starchy tissue for the developing embryo), and the embryo is small. In contrast, exalbuminous (without endosperm) seeds with large embryos occur in the families Hernandiaceae, Calycanthaceae, Lauraceae, and Gyrocarpaceae.

Distribution and abundance. Plants of the Laurales order occur generally in the tropics or subtropics. Some families are widely distributed; others in the order are restricted. Lactoridaceae, for example, is confined to the Juan Fernández Islands, 400 miles (645 kilometres) west of Chile, others to places like Chile, New Caledonia, Australia, or islands of the Pacific Ocean. A few species occur in warm temperate regions: in North America, extending to Canada; in Africa; and in southern Europe, where *Laurus nobilis* (family Lauraceae) extends to the Mediterranean.

NATURAL HISTORY

Life cycle. Very little is known about the life cycle in six of the families of the order (Austrobaileyaceae, Amborellaceae, Trimeniaceae, Gomortegaceae, Hernandiaceae, and Lactoridaceae), and such knowledge is far from complete in families like Monimiaceae.

The flowers of the Calycanthaceae family are remarkably adapted for pollination by beetles. The food provided by the tips of some of its tepals (similar-appearing flower petals and sepals) and the prolonged connectives of the stamens attract the beetles, which also eat the nectar secreted by the inner stamens (sterile stamens, usually flat and petal-like). In doing both, the beetles serve in pollination. It has been suggested that the position of the carpels on the concave receptacle might offer protection to the ovules from the foraging beetles.

The mode of secretion of nectar from the glandular appendages of the stamens in the Lauraceae and Monimiaceae families has been studied. In the Lauraceae family, the epidermis ("skin") and cuticle (a waxy coating) of the bud break down just before the opening of the flowers; the nectar then is secreted through the intercellular spaces of the flower tissues. In the Monimiaceae family, there is no secretion of nectar before the beginning of flower opening, and the epidermis is not as extensively damaged as in the Lauraceae family. Numerous bees, blowflies (*Calliphora*), and mites visit the flowers for the nectar.

There is little uniformity in pollination and other processes of the life cycle within the order. In some members of Laurales, such as species of *Beilschmiedia* (Lauraceae) and *Hortonia* (Monimiaceae), the staminal appendages do not function as nectaries. In *Persea americana* (avocado) the flowers open twice, and pollination is brought about by bees. In Sri Lanka (formerly Ceylon), *Cinnamomum zeylanicum* (Ceylon or true cinnamon) flowers in May, and fruits mature within two or three months; this is probably true of other tropical species.

Ecology. The Laurales order is mostly tropical and subtropical, and its species are mostly evergreen. Some members of the Lauraceae and Calycanthaceae families also grow in warm temperate regions, where they are deciduous. *Calycanthus fertilis*, *Sassafras albidum*, *Persea borbonia* (sweet bay), *Litsea aestivalis*, and *Lindera benzoin* (spicebush), for example, are among the characteristic species in the deciduous forests of eastern North America, where climatic conditions are similar to northwestern Europe and parts of eastern Asia.

Some species of the Lauraceae family, like *Cinnamomum camphora* (camphor tree), are not particularly demanding in their environmental and soil requirements. The camphor tree grows well at elevations of 3,000–4,000 feet (900–1,200 metres) and even up to 45° (latitude) north and south of the Equator. In contrast, *Cinnamomum zeylanicum* is sensitive and thrives best only on the white sandy soils of Sri Lanka.

FORM AND FUNCTION

Despite the great diversity of structure among families of the order, some structural features common to all serve to distinguish the Laurales from other orders. Like the related Magnoliales, the Laurales order is composed of species that are all woody and that have ethereal (aromatic) oil cells. Those species are further characterized by pollen grains with no more than two grooves and by a primitive nodal anatomy (arrangement of vascular bundles at the juncture of leaf and stem) of the type called unilacunar. The stamens have nectar-bearing appendages, and, in most species, the anthers split open when ripe by means of valves. The female structures usually consist of a single carpel. Unlike the Magnoliales order, which has generally primitive leaflike carpels and stamens, most Laurales species have more specialized floral organs.

EVOLUTION

The Laurales order occupies an important place in the phylogeny, or evolutionary history, of the flowering plants. Of the 10 genera of dicotyledons (plants with two "seed leaves") with primitive, vesselless xylem (water-conducting tissue), two are included in the Laurales order, the rest in the Magnoliales order. The only flowering plant species without companion cells and true sieve tubes (*Austrobaileya*) also belongs to the Laurales order. On the other hand, in several families, floral evolution has advanced to the level of epigyny (inferior ovary) and unisexuality. Thus, many of the evolutionary trends observed among the flowering plants as a whole are retained in this and in the related and probably more primitive order, the Magnoliales.

Furthermore, distribution of several members of this order is restricted to areas that are relatively little explored botanically. The living and fossil plants of such regions, when more completely studied, will yield valuable data for understanding the origin and evolution of the flowering plants. Well-preserved fossils resembling living genera of the Lauraceae family, such as *Sassafras*, *Cinnamomum*, and *Persea*, have been found in Lower and Upper Cretaceous rocks (about 65,000,000 to 136,000,000 years old) in several localities in Europe and America. Since those genera at that time were already as highly specialized as their modern counterparts, it may be inferred that they must have had a fairly long history of evolution before the Cretaceous Period. In the absence of fossil evidence, however, no reliable conclusions as to the origin and early phylogeny of the family can be drawn.

Pollen similar to that of the fossil genus *Clavatipollenites* from the Lower Cretaceous Period shows some tenuous resemblances to that of the family Chloranthaceae. The fossil history of other families is virtually unknown.

In view of the present paucity of information on the paleontology of the order, evolutionary interpretations must of necessity be based on comparative morphological studies of present-day groups. The Austrobaileyaceae family is thus placed lowest in the evolutionary scale because of the preponderance of its apparently primitive vegetative and floral characters, such as the absence of companion cells and typical sieve tubes, the primitive cambium and wood anatomy, numerous spirally arranged flower parts, laminar stamens, and numerous ovules per carpel.

The Amborellaceae family also manifests many primitive features, including vesselless xylem, spirally arranged perianth (sepals and petals), and stamens with a broad filament. At the same time, however, its members have advanced to the level of unisexuality. An uncertain affinity to the Monimiaceae family has been suggested.

Many authorities consider Lactoridaceae to be an isolated family. Some assign it a relatively primitive place, near the

Laurales compared with Magnoliales

Unusual mode of nectar secretion

Relationships of families within the order

Winteraceae family (order Magnoliales), while others give it a relatively higher place, assuming that it had a common origin with the family Chloranthaceae. Still others suggest that its mode of growth, stipules, and anatomy all indicate a relationship with the families Piperaceae (order Piperales) or Polygonaceae (order Polygonales). But without adequate data none of these views can be supported.

Of the Trimeniaceae family still less is known; all that can be said is that it exhibits a mixture of primitive and advanced features. Some authors, however, suggest an affinity with the Monimiaceae family.

The families Monimiaceae, Gomortegaceae, Hernandiaceae, Lauraceae, and Gyrocarpaceae have been found to be more specialized and more closely related to one another than other Laurales families. Of these, it has been suggested that the Monimiaceae family, with the greatest range in floral structure, constitutes the parent family from which the others have evolved. Its protoxylem strand patterns (developing form of xylem, or woody tissue), wood anatomy, and embryology all are similar to those of the other four families. In the five-family group, Gyrocarpaceae seems to be the most highly specialized. Its vessel cell end walls are inclined less, its medullary ray tissue (wood rays) is more specialized, its floral structure is generally reduced, and the family exhibits a peculiar type of embryo-sac development.

The floral hypanthium, a saucerlike structure formed from the fused bases of the petals and sepals, is common to the less specialized Calycanthaceae family and the parent Monimiaceae family. The subfamily Siparunoideae of Monimiaceae also resembles Calycanthaceae in the absence of staminal appendages. The Calycanthaceae family also shares numerous anatomical features with the Lauraceae family, but there is little morphological evidence to support its suggested affinities to the Rosales or the Magnoliales orders. Its pollination by beetles has been considered a primitive feature only because other types of insects appeared later in the geological time scale.

The affinities of the Chloranthaceae family have also been much disputed. Some authors have placed it in the order Piperales, but the nodal anatomy, opposite stipulate leaves, united petiole (leaf stalk) bases, and inferior ovary with its solitary pendulous ovule all put this family outside the Piperales order. Those features plus staminal appendages indicate an affinity with the Monimiaceae family. Thus, with the possible exception of the families Austrobaileyeaceae and Lactoridaceae, all other families in the Laurales order can probably be derived from a Monimiaceous stock.

Although the Laurales order is more advanced than the Magnoliales, it seems more probable that it originated independently, rather than from the Magnoliales order. Because the Lactoridaceae family possesses a combination of features of both orders, it has been suggested that both Laurales and Magnoliales had a common origin and early diverged along separate evolutionary lines.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. As early as 1950, the woody plant families having ethereal oil cells and monocolpate (single-furrowed), derived polyporate, or acolpate pollen were divided into two groups—one with unilacunar and the other with trilacunar or multilacunar nodal anatomy. The Laurales order as presented here corresponds to the unilacunar group. Certain other features are also characteristic of several members of the order, although a few families do not share them. These include the polygamous flowers, the presence of staminal appendages, anthers that open by means of valves, two pollen sacs per anther, and the single pendulous ovule per carpel.

Alternate systems of classification. The scope of the order Laurales as presented in the *Annotated classification* is a recent and authoritative treatment. The scope of the Laurales order varies in other systems of classification. Some authorities include the Myristicaceae family and exclude the Calycanthaceae and Chloranthaceae families, placing Calycanthaceae in the Rosales order and Chloranthaceae in Piperales. Others include the Calycanthaceae family. The Lactoridaceae family has often been placed in the

order Magnoliales near the Winteraceae family. Similarly, earlier authors have included all these families in the order Ranales or Magnoliales along with other woody families. Recently, however, most taxonomists have included the families Monimiaceae, Lauraceae, Gomortegaceae, Hernandiaceae, and Gyrocarpaceae in the Laurales order as distinct from the Magnoliales order. (R.L.N.S.)

Piperales (pepper order)

The Piperales comprises two families, the Piperaceae, or pepper family, and Saururaceae, or lizard's-tail family. In some systems of classification the family Chloranthaceae is also included within this order.

GENERAL FEATURES

Members of this order are mostly herbs or shrubs. The leaves are usually rather broad and alternately arranged on the stems. The densely aggregated flowers are quite small and lack petals and sepals. Reduced leaves, or bracts, are present below the flowers and in a few species are petal-like in appearance. The flowers are most often bisexual, with 1 to 10 stamens and usually a single superior ovary (*i.e.*, the ovary is above the other flower parts, the sepals, petals, and anthers, all of which attach at the base of the ovary). The ovary develops into a single-seeded or a few-seeded fruit.

Representative plants and structures of the two families in the pepper order.

Distribution and abundance. The family Piperaceae is composed of 10 genera, mostly shrubs, many vinelike, and largely confined to the tropics of both the Old World and the New World. The genus *Piper*, with centres of distribution in South America and Malaysia, contains around 1,000 species and is one of the larger ones in the plant kingdom. *Peperomia*, a genus of over 500 species, is also widely distributed in the tropics and subtropics of both hemispheres, a few species extending into Florida. A number of geophilous (ground-dwelling) species of *Peperomia* are found at high altitudes in the American tropics. Some taxonomists classify the genus *Peperomia*, along with a few other genera, as a third family, the Peperomiaceae, which differs from the Piperaceae proper by the absence of stipules (appendages at the base of leafstalks) and in characters of the stem anatomy and pollen. The family Piperaceae includes a number of species used by man, the most important of which is *Piper nigrum*, the source of the black and white pepper of commerce.

The family Saururaceae, which comprises three to five genera, depending on the authority followed, is made up of perennial herbs found in eastern Asia and North America. The genus *Saururus* (lizard's-tail) has one species in eastern North America and another in Asia. *Anemopsis* (*yerba mansa*) of the western United States and Mexico is the other member of the family found in the United States. Some species of Saururaceae often have a general resemblance to some of those of the family Polygonaceae (order Polygonales).

The two Piperaleae families are most readily distinguished from each other by the number of ovules, 1 in the Piperaceae and 2 to 10 in the Saururaceae. The Piperaceae family also lacks the showy bracts, or upper leaves, found in Saururaceae. The ovary and the stem anatomy of the two families also differ fundamentally.

Economic importance. Pepper, prepared from the fruits, called peppercorns, of *Piper nigrum*, is one of the world's most important spices. It sometimes is referred to as black and white pepper to distinguish it from red, chili, and cayenne peppers, which belong to the genus *Capsicum* of the family Solanaceae (order Scrophulariales). Pepper, one of the first spices known to man, was mentioned in Indian writings more than 3,000 years ago and was observed by Marco Polo to be in extensive use in China as a condiment in the 13th century; it later became one of the first articles of trade between the Far East and Europe. Although much appreciated by the early Greeks and Romans, pepper did not assume great importance in Europe until the Middle Ages. In addition to its use for seasoning food and in the preserving of meats, it also had considerable application in medicine at that time. Peppercorns were also once used as a medium of exchange to pay rent and taxes.

Pepper production. *Piper nigrum* is adapted to hot, wet tropical climates. It is said still to occur wild in Assam and northern Myanmar and apparently first became a cultivated plant in that part of the world. The plant, a woody climber, reaches 30 feet (9 metres) or more in height. The aerial portion produces roots that allow the plant to attach itself to the trees or poles on which it is usually cultivated. The shiny, ovate, prominently veined leaves are from 5 to 10 inches (13 to 25 centimetres) long. The inconspicuous, self-pollinated flowers hang in spikes, 4 to 5 inches (10 to 13 centimetres) long. Each spike produces from 50 to 60 single-seeded, berrylike fruits, which change from green to red or yellowish red when ripe and to a blackish colour when dry.

In commercial planting the pepper is propagated vegetatively from stem cuttings. Harvest begins in the third to fifth year, and the berries mature nine months after flowering. Plants continue bearing well for 12 to 15 years. Harvesting is done by hand when the berries are green but mature. For the manufacture of black pepper, the berries are allowed to dry in the sun after picking until they darken and are ready for shipment. The whole peppercorns are then ground to produce black pepper. For the preparation of white pepper, the fruits, often picked when fully ripe, are placed in water for several days to rot the fruit coat. Then the outer hull of the fruit is removed by trampling underfoot or by other means. After drying, the peppercorns eventually turn white and are ready to be ground into white pepper. Peppers contain the alkaloids piperine and piperidine, the latter in small amounts. A resin known as chavicine, however, is considered responsible for most of their pungency. An essential oil prepared from steam distillation of pepper flavours meat products and various sauces.

Until World War II, Indonesia produced 80 percent of the pepper for the world trade; since then India has become the chief exporter. Other countries exporting pepper include Malaysia, Brazil, Kampuchea (Cambodia), and Madagascar. Annual world exports amount to between 50,000 and 75,000 tons. The United States is the world's chief importer.

Various other Asiatic species of *Piper*, generally called long pepper, also have uses similar to those of *Piper nigrum*. The two most important are *Piper retrofractum*, or Javanese long pepper, which occurs wild in Malaysia, and *Piper longum*, Indian long pepper, native to India. Both

species are cultivated to a limited extent but do not enter world trade. In addition to their use as a spice, both are still employed in local medicine for a great variety of complaints. In early times among the Greeks and Romans, long pepper was more highly esteemed than black pepper.

Other products. Several other species of *Piper* are of economic importance. The leaves of the betel pepper, *Piper betle*, are chewed with the nuts of betel palm as a masticatory in much of the Old World tropics from Zanzibar to Oceania. Betel chewing is important at ceremonial occasions and acts as a mild stimulant as well as serving to sweeten the breath. This species also finds medicinal uses among native peoples of the areas where it occurs. Its cultivation is most advanced in India, where it is called *sireh*. Cubebe, *Piper cubeba*, native to Indonesia, is used as a medicine and formerly had some importance as a spice.

Kava, or kawa (*yagona*), made from *Piper methysticum*, has been referred to as the "national beverage" of Polynesians. It is widely cultivated in Oceania for its use as a ceremonial and social drink as well as for medicine. Peeled roots were once chewed, but for making the beverage scrapings from the root are fermented in water. Kava is a narcotic and is used primarily for its relaxing effects; excessive use can lead to intoxication.

The leaves of a few of the species of *Piper* occasionally are used as condiments. In both South America and Malaysia some species have been used as an ingredient of arrow poisons, apparently for their irritating effect, and as a poison to stupefy fish.

Other useful plants in the order include several species grown as ornamentals, especially *Peperomia*, of the Piperaceae family. The peperomias are mostly low herbs, occasionally epiphytic (*i.e.*, growing among the branches of trees), with fleshy leaves. Several species are cultivated as houseplants for their attractive foliage. *Saururus cernuus*, lizard's-tail, so named because of the shape of its inflorescence (flower cluster), is a plant of bogs and marshes of eastern North America and is occasionally cultivated in pool or bog gardens.

FORM AND FUNCTION

Little detailed information on the floral biology and natural history of the plants of this order is available. Many species have no obvious specialized means for dispersal of the seeds, but it has been suggested that seeds of many species are eaten by birds and thus disseminated. The small fruits of *Peperomia* are covered with a mucilaginous substance that allows them to adhere to objects. Thus, both birds and other small animals could serve as agents of seed dispersal.

CLASSIFICATION AND TAXONOMIC STATUS

The family Chloranthaceae is placed in the Piperaleae order in many systems of classification, whereas others assign it to the order Laurales. Chloranthaceae is readily separated from the Piperaceae and Saururaceae families by its opposite leaves, petioles that are somewhat connate (fused around the stem) at the base, small, free stipules, and more or less inferior ovary.

Modern authorities are generally in agreement that the Piperaleae is a rather primitive order, representing a slight advance over the Magnoliales order, from which it is thought to have been derived. (C.B.He.)

Nymphaeales (water lily order)

Nymphaeales is a plant order belonging to the dicotyledonous group of flowering plants. Its members are found in aquatic habitats, and its best known representatives are the water lilies, from which the order derives its common name, the water lily order. The aesthetic appeal of the water lilies, especially those of the genera *Nymphaea* and *Victoria*, enhanced by their aquatic habitats, has led to their worldwide cultivation and familiarity. There are four families, eight genera, and about 70 species.

GENERAL FEATURES

Plants of the Nymphaeales order are aquatic. In the genus *Ceratophyllum*, the plants are either rooted or free-float-

Ceratophyllaceae

Cabombaceae

Barclayaceae

ing but submerged; in the other genera, they are attached to pond or stream bottoms, but their leaves and flowers may be either submerged, floating, or standing above the water. They range in size from the small, fragile fanwort (*Cabomba*) that has floating leaves less than an inch (2.5 centimetres) in diameter, to the hornwort (*Ceratophyllum*) with small leaves and richly branched stems reaching 12 to 15 feet (3.5 to 4.5 metres), to *Victoria* with its floating, circular, shieldlike leaves 6.5 feet (2 metres) across and flowers 15 inches (38 centimetres) in diameter.

Distribution and abundance. Representatives of the order occur, often abundantly and frequently, in quiet fresh waters over most of the Earth. The genus *Cabomba*, for example, is found in the New World tropics and subtropics; *Brasenia*, the water shield, is native to all continents except Europe; *Victoria* is found in tropical South America; *Euryale* and *Barclaya* live in the tropics and subtropics of Asia and Indonesia; the genus *Nuphar*, consisting mostly of the large yellow-flowered pond lilies, ranges over most of the Northern Hemisphere; *Nymphaea*, consisting mostly of smaller, white-flowered water lilies, is cosmopolitan, except in the Pacific islands and New Zealand; and the hornwort, *Ceratophyllum*, is also cosmopolitan.

Economic importance. The leaves, the starchy, horizontal, creeping stems, and the protein-rich seeds of the larger species have been used as food by man throughout his history and are used today, commonly by primitive peoples, and even more widely during famines. The seeds are eaten by fish, and all parts are eaten by grazing or browsing hoofed mammals. Several genera supply cover for fish and attachment and protection for their spawn. Fruits and seeds provide food, and the plant parts extending above the water provide food and cover for aquatic birds.

Cabomba, *Brasenia*, *Ceratophyllum*, and *Nuphar*, and other genera less commonly, may grow so rankly as to clog lakes and irrigation ditches. The Figure illustrates some of the structures characteristic of the order.

NATURAL HISTORY

Life cycle. All genera are perennial (*i.e.*, they live through more than one growing season) in their natural habitats, although plants of *Victoria* persist for only a few years. Those genera with creeping, horizontal stems may multiply vegetatively as older branches die. Some species of *Nymphaea* produce detachable plantlets on their leaves.

The seeds of all genera are distributed passively. The fruits of *Nymphaea* species are thrust underwater by the arching growth of the floral stalk and are ruptured by the swelling of mucilage contained in the spaces around the seeds. The seeds of *Nuphar* species are released to float, in packets of soft tissue enclosing air, after the decay and opening of the fruit; the seeds eventually sink when released from the packets. Pulpy, bladderlike tissues produced by the seed stalks around the seeds of *Nymphaea*, *Victoria*, and *Euryale* carry the seeds until ruptured. In the genus *Ceratophyllum*, the spiny fruits are transported by submerged water currents or by fur animals, and the spines eventually anchor them in the substratum. Fish and seed-eating or fish-eating birds also distribute the seeds of various species.

Leaves, flowers, and young fruits of attached genera remain afloat or extend above water level, whichever is normal, even with rising water by means of continuing growth at the bases of leaf or floral stalks, respectively. Cutin and other waxes on floating leaves and flower parts prevent wetting of tissues and their sinking. A coating of mucilage covers the leaves and stems of species of the Cabombaceae family, probably as a protective mechanism. Sharp, strong prickles protect all exposed organs from animals in the genera *Victoria* and *Euryale*.

Ecology. The genus *Ceratophyllum* grows in stagnant or slow-moving water and may be either attached, by burial of the older end of the stem and its branches, or free-floating. All attached species characteristically grow in deep, silted, saturated soils, with little or no free oxygen, below quiet bodies of water. The creeping stems (rhizomes), submerged leaves, and roots are tolerant of oxygen-poor conditions. Air passages extending from floating leaves or leaves above the water into the roots provide for

Seed dispersal

Insect
associa-
tions

some gaseous exchange between atmosphere and tissues. *Nymphaea* and *Nuphar* are able to withstand fairly severe dehydration without injury and can flourish in semiterrestrial, moderately aerated soils.

Many plant-eating insects, all of them flying types in the adult form, visit Nymphaeales species for food and to deposit eggs. No insect that lives on submerged plants or parts depends on a single species of plant; but there are specific relationships between emergent or floating plant species and flying insects. Some insects, dependent on floating plant parts, are not associated with submerged plant species since they cannot deposit eggs on them. Injury is due to sucking of food materials by bugs (Heteroptera), insertion of eggs and subsequent decay by dragonflies and damselflies (Odonata), removal of epidermis and leaf mining by beetles (Coleoptera), and gross destruction by the caterpillars of moths and butterflies (Lepidoptera). The transfer of pollen by flying insects is the usual pollinating mechanism, except in the genus *Ceratophyllum*. Pollinating visitors, also often plant-eating, are primarily beetles and flies (Diptera), but bees (Hymenoptera) and bugs have also been recorded as pollinators.

Pollination
mecha-
nisms

Natural mechanisms insuring cross-pollination and hybridization have been described for *Nymphaea*, *Nuphar*, *Victoria*, and *Ceratophyllum*. The stigmas (female pollen-receiving structures) of a flower become receptive before the anthers (male pollen-producing structures) of the same flower shed pollen. In the flowers of *Nymphaea*, *Nuphar*, and *Victoria*, the inner stamens (the male structure of the flower consisting of the fertile anther and its supporting stalk) or staminodia (sterile, petallike stamens) form a closed cone over the stigmas, apparently preventing insect invasion after pollination and often trapping the insects that delivered pollen, causing them to drown in liquids present in the stigmatic cup. During the period when the female stigmas are receptive to pollen, nectar (sweet liquid in the stigmatic bowl), scent, and colour attract insects. Later, when the male anthers are ripe, pollen attracts the insects. In the submerged species of *Ceratophyllum*, male flowers are situated above female flowers. Pollen is released and sinks slowly through the water. Some of the pollen eventually slides down a groove contained in the pistil of the female flower and is thus deposited in a pit where pollen germination occurs, leading to eventual fertilization of the female ovules.

FORM AND FUNCTION

Vegetative characteristics. Some genera have extensive, buried or surface-creeping rhizomes (rootlike horizontal stem structures), especially the genera *Nuphar*, *Nymphaea*, and *Brasenia*; others have short, erect, buried stems with (in *Brasenia*, *Cabomba*) or without (in *Victoria*, *Euryale*) associated horizontal floating branches. The genus *Ceratophyllum* has long, largely floating stems with many lateral branches, but a plant may be anchored at its basal end. Branching is not understood in all genera. In the Cabombaceae family, branching is sympodial; that is, a vegetative apex is transformed into a flower, and a lateral branch continues vegetative growth. In others, branching is monopodial; that is, the main axis is continued and the flowers are laterals. In *Nuphar*, flowers arise in leaf sites, replacing leaves, but they are not directly associated with and located above leaves (the axillary position); vegetative buds arise at prospective floral sites and are axillary. In the genus *Nymphaea*, flowers and buds arise similarly, but neither is axillary. In *Victoria* and *Euryale*, the flowers arise in a successive, helical arrangement, alternating with a leaf helix. Roots, which are absent only in the genus *Ceratophyllum*, arise in clusters from the stem at leaf bases.

Vascular
systems

The vascular systems in the stems of the Nymphaeaceae and Barclayaceae families are extremely complex and have not yet been satisfactorily described. In the Cabombaceae and Ceratophyllaceae families, relatively simple vascular systems are present. Very little xylem (water-conducting tissue made of special hollow cells known as tracheids and vessels) is present in the vascular bundles. Tracheids (nonspecialized supporting and water-conducting cells) are present, although scarce in the Cabombaceae family, in the organs of all genera. Vessels (specialized water-conducting

cells) are usually reported as being absent, but recent studies have indicated that they may be present in the roots of some species of the Nymphaeaceae family.

Flower characteristics. Flowers are solitary in all genera of the order, except that in *Ceratophyllum* two flowers may occur in the axil of one leaf. Floral parts are arranged radially in each flower (i.e., they are "regular" or actinomorphic). Anatomical studies indicate that probably floral parts are attached in complex, multiple helical arrangements, although the helices may be nearly suppressed, and some organs appear externally to be arranged in whorls (cyclic). The flowers of the Nymphaeaceae, Barclayaceae, and Ceratophyllaceae families pose special problems in the study of their structures, which have been partly resolved by anatomical investigations. In the Nymphaeaceae and Barclayaceae families, the carpels (structures making up the female part of the flower, the ovary or pistil) are partially fused in some species of *Nymphaea*, or completely fused in a subwhorl around a central core except in the stigmatic (pollen-receiving) regions. The ovary is multilocular (has several chambers) with few to many ovules attached widely over the side walls. The stigmatic region occurs as an upwardly widening cone, with a basal conical projection in some genera, and it has prominent to reduced extensions of the carpels termed styler processes. The pollen-receptive stigmatic tissues occur on the inside surface of the stigmatic cone as laterally discontinuous, centrally grooved, radiating zones (rays), each above a locule (chamber of the ovary). Stigmatic-like tissue is continuous from the rays to the bottom of the inner lining of the locules, providing the pathway for pollen tubes. In *Nymphaea* and *Nuphar*, the perianth and stamens are hypogynous (attached below the carpels) and are free from one another, although some stamens are fused to the ovary in *Nymphaea*. In *Victoria*, *Euryale*, and *Barclaya*, the perianth and staminal organs are, reportedly, fused laterally and basally into a common tubular structure that is fused to, and indistinguishable from, the fused ovary wall. In *Victoria* and *Euryale*, therefore, the free lobes of the perianth and stamens are epigynous; that is, they arise from the top of the fused carpels. In *Barclaya*, the stamen-perianth tube extends above the fused carpels, and the free staminal parts are attached to the inner wall of the tube where they hang downward. The inner stamens of *Victoria*, which assist in the cross-pollination mechanism, are, however, sterile; their basal, fused parts arch over the recurved stigmatic rays and are fused with them, and their free upper parts stand erect after pollination.

The young female structure in *Ceratophyllum*, generally reported as being unicarpellary, is composed of two separate and unequal carpels, which fuse during development. The product is unilocular (single-chambered).

Biochemistry. Latex cells have been reported for most genera except *Ceratophyllum*. All genera have a reddish anthocyanin pigment that turns purple instantly on exposure to air or to acid. Recent investigations have revealed an insulin-like compound in *Nymphaea nouchalii*, minute quantities of a spasmolytic alkaloid in the rhizomes of *Nymphaea alba*, and ellagitannins (dark-coloured carbohydrates) in *Nymphaea* and *Nuphar*, characteristic of other primitive dicotyledons but absent in monocotyledons.

EVOLUTION

On the basis of widespread fossil deposits of rhizomes, leaves and fruits of the genus *Brasenia* from Cretaceous deposits (about 100,000,000 years old), and of *Euryale*, *Nymphaea*, and *Nuphar* from Tertiary deposits (about 50,000,000 years old), apparently the Nymphaeaceae family has enjoyed a wide distribution over the Earth since the early Tertiary Period and possibly since the early Cretaceous Period. Some of the oldest angiospermous pollens reported (reports not unchallenged, however) by paleobotanists are those of *Nuphar* and *Nymphaea* from the Jurassic Period (about 150,000,000 years ago).

Because of the relative lack of environmental stresses in their aquatic habitat, few striking structural changes from the ancient form have occurred in the Nymphaeales order during its long existence other than the evolution of fused carpels and enclosed ovaries (in some) to protect the seeds

Origin of
the order

against plant-eating insects, and the adoption of aquatic features, including reduction of the xylem, development of air canals, and the rhizomatous habit.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The following characters of the Cabombaceae, Nymphaeaceae, and Barclayaceae families contrast with those of the Ceratophyllaceae family: adventitious roots (roots arising in unusual places such as along stems) are present; flowers are bisexual (male and female parts present in the same flower) and generally with differentiated petals and sepals; embryos are small; endosperm (the starch- and oil-containing tissue of seeds) is mealy but scanty; perisperm (tissue surrounding the endosperm) is abundant.

Taxonomic problems. The delimitation of Nymphaeales, as presented with the exclusion of the genus *Nelumbo*, frequently placed with this order, seems to be sound. The order is considered to consist of related groups, derived from a ranalian (*i.e.*, a group of dicotyledonous flowering plants showing certain primitive characteristics) ancestor, but semiherbaceous, rather than woody and treelike. The two genera *Victoria* and *Euryale* of the Nymphaeaceae family, with their massive connation (fusion) of floral parts, epigyny (*i.e.*, ovary enclosure by the fused bases of the sepals, petals, and stamens), and petallike stamens, seem rather segregated from *Nuphar* and *Nymphaea* of the same family; on recent biochemical evidence this segregation is more justified than that of the genus *Barclaya* into its own family separated from *Victoria* and *Euryale*. Although *Ceratophyllum* seems closely related to the Cabombaceae family, the pollen types do not support such a relationship. Recent considerations based on biochemical, serological, and anatomical researches do not support the derivation of monocotyledons from the Nymphaeales order. (M.F.Mo.)

Ranunculales (buttercup order)

The Ranunculales order is a large group of plants comprising 10 families, about 140 genera, and approximately 3,000 species. It is a rather diverse grouping, including mainly herbaceous plants and climbers, though some are woody shrubs. They are of considerable interest because they are abundant in most temperate areas, often forming a characteristic element of the floras. They also include many species of great ornamental value, which are grown in gardens in many parts of the world. Several species belonging to the order are common and noxious weeds, particularly in Europe and North America; indeed, many species contain compounds (mainly alkaloids) that are poisonous to man or to livestock. Some of these compounds are also important in folk medicine. In evolutionary terms the group is of especial importance, as it is considered by many botanists to be an early offshoot from the Magnoliales (see above)—the order generally considered to be the most primitive among the flowering plants.

GENERAL FEATURES

Both vegetatively and florally the Ranunculales order is highly variable. There are, nevertheless, a number of features held in common by most members of the group. Among these are the herbaceous or softly woody habit and the usually alternately arranged leaves that lack the small leaflike appendages, called stipules, at the bases of their leaf stalks. In the flowers, the segments of the perianth (sepals and petals) are usually spirally arranged, and the stamens are usually numerous and they, too, are often spirally arranged. There are usually several free carpels (female flower structures) that are spirally arranged or sometimes whorled, but they are rarely united or reduced in number to one in this order. Alkaloid chemical substances are generally present.

Distribution and abundance. The Ranunculales order is a cosmopolitan group and is found everywhere; its species are, however, more common in temperate and subtropical regions than in the tropics. Only 1 of the 10 families of the order (Menispermaceae) is mainly tropical. Members of the order occupy a wide range of habitats, including

Some vegetative and floral diversity in the buttercup order.

From (*Ranunculus sceleratus*, *Aconitum napellus*) Baillon, Eichler, Fibas, Rassner, Troll, Warming and (*Podophyllum peltatum*) Eichler, A. Gray, Hegi, Maout et Decaisne, Schumann, Warburg, Warming, Wettstein in A. Engler, *Syllabus der Pflanzenfamilien II* (1964), Gebrüder Borntraeger, Berlin; (others) G.H.M. Lawrence, *Taxonomy of Vascular Plants* (1969), The Macmillan Company

fresh water, and the species are often very abundant. The barberry genus, *Berberis*, for example, is widespread in temperate South America and also in the Himalayas; the buttercup genus, *Ranunculus*, is common in Europe and North America, and the monkshood genus, *Aconitum*, is abundant in the Himalayas and East Asia.

Importance. The importance of the group is related to its botanical and economic interest. When considered as an early offshoot from the most primitive flowering-plant stock, the group is of considerable evolutionary interest. Related to this is the fact that the group exhibits a series of structural features that can be construed as showing the origin of flower petals from sterile stamens. Many of the intermediate stages are present in existing species, and almost the whole series is shown by the largest family (Ranunculaceae), with various segments of the series being shown by the other families.

The simplest stage in this series is shown by genera such as *Anemone* and *Pulsatilla*, in which the perianth consists of a single series (*i.e.*, sepals, or, as they are sometimes called, tepals); these are usually coloured and serve to attract insects. The stamens (male reproductive structures) are numerous, and all are fertile. Many species of *Clematis* are similar, but others have the outer stamens sterile and somewhat broader than the fertile inner ones. In the genus *Trollius* the outer stamens are more or less flattened and are sterile, the anther-bearing portion being represented by a nectar-secreting pit on the inner surface, near the base. These organs are coloured and very petallike, though the main insect-attracting function is still carried out by the larger and brightly coloured sepals. In the genus *Ranunculus* the process is carried further, the sepals being small and usually greenish, whereas the nectar-secreting organs are larger and coloured and take on the main insect-attracting function. Like those of *Trollius*, these organs each bear a nectar-secreting pit on the inner surface, near the base, often covered by a fold or flap of tissue. These organs, which are clearly homologous with sterilized stamens, occur in a close spiral between the sepals and the fertile stamens. They are generally few in number (usually five), alternate in position with the sepals, and are conventionally referred to as petals by most taxonomists, although the Berlin school prefers to call them "honey leaves" (*Honigblätter*).

In columbines of the genus *Aquilegia* the petals are more or less tubular structures, with an expanded and flattened forward portion and backwardly projecting spurs, at the base of which nectar is secreted. The petals are only slightly

Interpretation of the possible origin of flower petals

larger than the sepals, and both series are coloured and serve to attract insects. In *Helleborus*, *Nigella*, and related genera, the petals are again tubular but much smaller than the usually coloured sepals. They are often of very elaborate construction and serve only to secrete nectar. In those genera with highly zygomorphic (irregular or bilaterally symmetrical) flowers (*Aconitum*, *Consolida*, *Delphinium*), the petals are much-modified nectar-secreting structures, often enclosed in and hidden by the large coloured sepals.

Thus, there is a series of elaboration of nectar-producing structures and petallike structures. It must be emphasized, however, that this series cannot be directly interpreted as showing an evolutionary lineage. What it does show, however, is various stages of a process of stamen sterilization and nectary and petal formation that may have taken place in the earliest angiosperms or pro-angiosperms.

NATURAL HISTORY

Growth
forms

Life cycle. The life cycle of the Ranunculales order presents no great differences from that of other flowering plants. The group includes short-lived annuals (e.g., many species of buttercups), perennial herbs of longer or shorter duration, suffrutescent perennials (i.e., those with a woody base that lives from year to year but with branches that die back each year), and woody shrubs and climbers that may persist for long periods. Reproduction is mainly by seed, though various forms of vegetative reproduction do occur (e.g., rhizomes and stolons occur in many species, and bulbils are found in some forms of *Ranunculus ficaria*). Formation of embryos without fertilization occurs, but it is apparently rare in the group.

Ecology. A very wide range of habitats is occupied by the Ranunculales order, including fresh water (both still and flowing), waste ground, field margins, grassland, pasture, forest, moorland, bogs and marshes, mountain pastures, and mountain slopes. The Menispermaceae family consists of mostly climbers and lianas in tropical forests, whereas the rest of the families in the order tend to avoid tropical areas or to grow only on high mountains (where there is a more temperate climate) within the tropic zone. In general, it may be said that most species of the Ranunculales order are either adapted to average moist habitats or to very wet ones, including even aquatic situations; true dry-habitat species are rare, and desert is essentially the only major plant habitat in which the Ranunculales order is not strongly represented.

The aquatic species of the genus *Ranunculus* (*Ranunculus*, subgenus *Batrachium*) are an extremely variable group, difficult to classify, and some of them show the interesting phenomenon of heterophylly—the ability to produce leaves of different shapes depending, in this case, on the depth of the water in which they grow.

In *Ranunculus aquatilis* the plants may bear leaves of three different shapes, depending on the water levels; the submerged leaves are repeatedly divided on a pattern of thirds into threadlike segments; the leaves borne at the surface of the water are simple and palmately lobed, with more or less oblong, toothed segments; and the aerial leaves are divided two or three times by thirds into wedge-shaped segments. Thus, the precise type of leaves that is produced depends on the water levels: at times when the water is high, plants will mainly have leaves of the submerged type; when the water is low, most of the leaves will be of the aerial type. This variation causes difficulty in the classification of the aquatic buttercups.

Pollination. The Ranunculales order shows a very wide variation in methods of pollination, a variation that is reflected in the wide range of floral types found within the group. The mainly temperate families Ranunculaceae and Berberidaceae are the best known in this respect; the range of pollination types in the Ranunculaceae includes almost all of the types in the rest of the order.

In the Ranunculaceae family, as in the Ranunculales order as a whole, insect pollination is the general rule. It seems possible, however, that at least one or two species of *Thalictrum* may be wind pollinated, if not as a general and regular occurrence, then at least sometimes. Self-pollination may be the rule in many of the short-lived annual species in the family.

The insect-pollinated types may be divided into two broad classes—pollen flowers and nectar flowers, depending on what the visiting insect obtains from its visits to the flowers. In the first category are such genera as *Anemone*, *Pulsatilla*, and *Clematis*, in which no nectar is produced but from which the insects collect pollen. In the second category are such genera as *Aquilegia* (columbines), *Ranunculus* (buttercups), *Helleborus*, and *Delphinium* (larkspurs), which have well-developed nectaries.

In most cases insects are attracted to the flowers by the coloured perianths. The coloured parts may be sepals, as in *Anemone* and *Clematis*; petals (honey leaves), as in *Ranunculus*; a combination of the two, as in *Aquilegia*; or the very complex arrangements of sepals and petals containing nectaries in the strongly zygomorphic flowers of *Aconitum* (monkshood), *Delphinium*, and *Consolida*. In some species of *Thalictrum* (meadow rue)—e.g., *T. kiusianum*—the filaments of the stamens are swollen and coloured and appear to act as insect attractors.

In all these types the flowers may be obligate outcrossers either because the female ovaries mature before the male anthers of the same flower (protogyny) or because of the reverse situation, in which the anthers mature first (protandry), though these characteristics are usually only weakly developed. Both the male stamens and the female carpels are spirally arranged, and they mature from the margin toward the centre of the flower, so that both sets of organs may contain mature members at the same time. The stamens and stigmas (pollen-receiving surfaces of the female flower structure) are usually situated in such positions that a visiting insect has to touch them in order to obtain pollen or nectar, thus effecting pollination.

In the Berberidaceae family (at least in the two shrubby genera *Berberis* and *Mahonia*) a different mechanism is employed, involving sensitive stamens. Nectar is secreted in pits on the inner petals, and insects are attracted by the brightly coloured sepals and petals, which, in sunny conditions, are widely spreading. Each of the six inner petals has two nectary pits near the base. The stamens are opposite these petals, and, in sunny conditions, lie along them, the base of the filament thus lying above the line of junction of the two nectary pits. An insect visiting the flower to obtain nectar will necessarily touch the base of the filament. This area is sensitive to touch, and the stimulus causes the filament to spring rapidly into an erect position, thus depositing pollen on the body of the insect. The pollen may then be transferred to another flower by the insect, thus effecting cross-pollination.

Relatively little is known of the pollination mechanisms in the other families of the order, but certain structural modifications suggest that highly adapted mechanisms may be in operation. In the genus *Cissampelos* and other related members of the Menispermaceae family, for instance, the anthers of the six stamens are united into a ring. Cross-pollination is made more certain in this family by the occurrence of separate male and female flowers.

Seed dispersal. Seeds are dispersed in various ways in the Ranunculales order, depending on the nature of the fruit. In those genera with fleshy fruits (e.g., the genus *Actaea*, and many members of the family Berberidaceae) the seeds are mainly animal-dispersed, whereas in the majority of the order, in which dry fruits prevail, seeds are dispersed by more passive mechanisms. The seeds of many species of *Ranunculus* have a hard beak, formed by the persistent style, and often, also, a spiny or warty surface; these are dispersed by adhering to the fur of animals. The seeds of genera with single-seeded fruits show adaptation to wind dispersal—those of the genus *Thalictrum* often being winged and flattened, and those of *Pulsatilla* and *Clematis* bearing a long, plumose appendage. Genera with many-seeded podlike fruits usually have a spilling mechanism, by which the seeds are gradually shaken out of the open pods when these are agitated by the wind. In *Helleborus foetidus* and perhaps some others species of *Helleborus*, the pods, when ripe, are pendent, hanging near the ground surface. All the seeds from each pod are attached to a persistent, fleshy part of the placenta, which becomes detached upon ripening, causing the seeds to fall out, though still attached to the ribbon of placenta; this

Insect-
pollinated
flowers

fleshy tissue is attractive to ants; the ants drag about the strips of seeds, ensuring dispersal.

EVOLUTION

Very few fossil Ranunculales are known, and only a few forms from the Tertiary (about 50,000,000 years ago) have been certainly identified as belonging to the group. These reveal little of the evolution of the order but do indicate that the Menispermaceae family was formerly much more widespread than today, various leaf impressions having been found in Europe, North America, and Greenland.

Most phylogenists believe that the Ranunculales order is an early offshoot from a broadly conceived Magnoliales stock. Some authorities stress the close relationship between the Illiciales order and the Lardizabalaceae, Sargentodoxaceae, and Menispermaceae group of families of the Ranunculales order, and they also point out the close structural relationships between the Berberidaceae, Nandinaeae, Podophyllaceae, Ranunculaceae, and Menispermaceae families, suggesting a common origin for all of them from a possible ancestor of form similar to the order Illiciales. Other workers, however, believe that the Ranunculaceae family within the Ranunculales order could be ancestral to all the other families of the order and that all of the features in which the other families of the order differ from the Ranunculaceae family appear to represent evolutionary derivations from that family. It is to be doubted, however, whether many phylogenists would accept this latter view, because the Ranunculaceae family itself includes a wide range of types, some generally considered to be primitive, others showing characteristics usually considered to be advanced. In the present state of knowledge, the evolutionary pathways and relationships within the order remain obscure.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The Ranunculales order is distinguished from its allies by a combination of features, among which the most important is perhaps the widespread occurrence of nectar-producing petals. It differs from the Magnoliales and Illiciales orders by the herbaceous or softly woody habit, the absence of aromatic compounds, the usual absence of stipules, and various floral characters. It differs from the Nymphaeales and Nelumbonales orders by its predominantly terrestrial habit, leaf type, and various floral characters; and from the more advanced Papaverales order by the absence of a latex-conducting vessel system, the free carpels, and other floral characters. It differs from the Paeoniales order, which was included in the Ranunculales order in many older taxonomic systems, by the presence of nectar-producing petals, and by the sequence of stamen maturation.

Alternate systems of classification. The contents of this order are not generally agreed upon among taxonomists, and various alternative classifications have been proposed. Specifically, there is no general agreement as to precisely what groups should be included in the Ranunculales order and how the groups should be related to each other; and there is little agreement as to which groups of genera should be recognized at family level.

The following points of agreement should be noted, however. The core of the order consists of the families Lardizabalaceae, Sargentodoxaceae, Menispermaceae, Ranunculaceae, Glaucidiaceae, Hydrastidaceae, Circaeastraceae, Podophyllaceae, Nandinaeae, and Berberidaceae; that is, those families comprising the order as presented here. The other groups in the order in other classifications—viz., the families Paeoniaceae, Ceratophyllaceae, Cabombaceae, Nymphaeaceae, Corynocarpaceae, Coriariaceae, and Sabiaceae—are more often placed in other orders, although the exact relationships of many of them are still controversial.

Within the order as presented here, however, there is great variability, and it may be doubted whether or not it should be maintained as a whole. The division of it into two orders, Ranales and Berberidales, has been proposed, but this has not been widely accepted, and it may be an improvement to recognize its division into even three groups.

Regarding the placement of the Ranunculales among other orders, the close relationship of Magnoliales, Illiciales, and Ranunculales is generally agreed upon among phylogenists, as is a close relationship of the Ranunculales order with the Nymphaeales and Nelumbonales orders. A relationship with the primitive members of the flowering plant class Liliopsida (monocotyledons) is postulated by some authors, whereas others suggest that the similarities between Ranunculales and Nymphaeales orders of the dicots and the Alismales order of the monocots are the result of convergent evolution. A fairly close relationship between members of the Ranunculales order (particularly among the Berberidaceae, Glaucidiaceae, and Podophyllaceae families) and the Papaverales order is widely accepted; this is based mainly on structural features, strengthened, however, by the occurrence of the same, or closely related, alkaloids in both groups. A close relationship between the Ranunculales and the Paeoniales orders is not now generally accepted. (J.Cul.)

Papaverales (poppy order)

Papaverales, an order of flowering plants in the class Liliopsida, consists of three families: Papaveraceae, Fumariaceae, and Hypecoaceae. The order as a whole contains 45 genera and about 640 species.

GENERAL FEATURES

Economic importance. Most plants making up the order Papaverales are herbaceous (nonwoody), though there are some shrub and small tree species and a few with a climbing growth habit. The order occurs primarily in the temperate regions of the world, extending only sparingly into the tropics. Many different species are utilized as showy garden plants, and the genus *Papaver* (poppy) is the source of edible poppy seed, poppy-seed oil, and opium. The latter is a narcotic long derived from the dried juice that exudes from the cut, unripe capsules of the opium poppy (*Papaver somniferum*). A number of substances, including morphine, codeine, heroin, and other derivatives of opium, are in wide medical use for the relief of pain, and many are involved in drug addiction problems.

The family Papaveraceae is one of the important drug-producing families of the plant kingdom, and alkaloids are abundant in many species of the order. Some alkaloids, such as protopine, are widespread within the group but are little known outside of it. Morphine is found only in the opium poppy.

Distribution and abundance. Plants of the order Papaverales do not occupy as many different types of habitat as do many orders of angiosperms, but at the same time they are not restricted to a narrow range of ecological situations. Although there are genera with a marked preference for woodlands and forests, and some groups can be found occupying nearly every kind of terrestrial habitat, the most favoured sites are open and well drained. Habitats range from Arctic and Alpine settings to deserts, moist woods, and stream banks. There are, however, no strictly aquatic members. A number of species are found in deserts, semideserts, and arid areas. The California poppy (*Eschscholzia*), for example, is very abundant in open valley and desert lands of southwestern North America.

Many Papaverales species are weeds and are found in fields and waste places. The great abundance of poppies in the grainfields of Europe and elsewhere is well known; the weedy tendencies of the prickly poppies (*Argemone*) in the arid areas of the southwestern United States and in Mexico are no less marked. These plants occupy cultivated areas and spread deeply into overgrazed rangelands as well. Celandine, or swallow wort (*Chelidonium majus*), usually occurring in damp or shady places along roadsides, rock walls, and in wastelands, is a ubiquitous weed in Europe, Asia, and eastern North America.

Genera of both the Papaveraceae and Fumariaceae families display the disjunct eastern Asia-eastern North America distribution pattern that was used as a geographical test of evolutionary theory by Charles Darwin and by Asa Gray. The genus *Stylophorum* of the Papaveraceae family, for example, has species found only in eastern North

Split
distribution
pattern

America and eastern Asia, and the single species of *Adlumia* of the Fumariaceae is found in Korea and the eastern United States, with a tremendous gap between.

FORM AND FUNCTION

There is a natural and practical, although not absolute, division of the order Papaverales into those plants in which the sap is watery and those in which it is milky or coloured. In plants belonging to the families Fumariaceae and Hypecoaceae the sap is watery and acrid, and there is an abbreviated calyx (green leaflike sepals of the flower). These two characteristics serve to distinguish the two families from the Papaveraceae, in the majority of species of which the sap is milky or coloured and the calyx is well developed, fully enclosing the bud until the flower opens.

Taproots, rhizomes (rootlike stem structures), bulblets, and tubers make up the range of underground structures found in the order Papaverales. The stems are mostly herbaceous but may be woody and are erect or sometimes climbing. Although some leaves are entire (*i.e.*, smooth edged), they are mostly divided into pinnately (*i.e.*, the veins originate along a midrib, as in a feather) or palmately (*i.e.*, the veins radiate from a common point where the leafstalk attaches) arranged lobes or are more highly dissected. A common pattern is a group of petioled leaves arranged in a rosette at the stem base, without stem leaves or with stem leaves reduced from base to apex. The fern-shaped leaves of *Pteridophyllum* are unusual.

The inflorescences (arrangements of flowers) are diverse in form, ranging from a single scapose (stemmed) flower to a cymose or racemose (*i.e.*, clustered along a central axis on short lateral stalks, the cymose type maturing from the terminal blossoms downward, the racemose type maturing from the base upward) inflorescence in a terminal or lateral position. The flowers are of a hypogynous type or, rarely, perigynous (*i.e.*, the sepals and petals arise from a cuplike structure partially enclosing the ovary) and are fully bisexual. They are radially or bilaterally symmetrical and are complete (*i.e.*, they have all four basic flower parts: sepals, petals, stamens, and pistil), even though the two sepals present in the family Fumariaceae are much reduced and often drop early in development. In the family Papaveraceae the two to three sepals tightly enclose the buds until the flower opens, when they are shed. The sepals are usually free except in the genus *Eschscholzia*. The petals are similar to each other, in two whorls, and their number is twice as many as the sepals. In the family Fumariaceae the petals differ from each other, the four petals forming two pairs, the outer pair being somewhat saccate, or spurred, at the base.

The androecium (male complement) is made up of six stamens in two groups in the Fumariaceae family, but there are many stamens arranged in concentric whorls in the various species of Papaveraceae. *Pteridophyllum* is a special case with free petals and four stamens. Stamen development takes place centripetally (*i.e.*, from the flower margin toward the centre), which contrasts with the centrifugally developed stamens of the order Capparales, an order once held to be closely related to the Papaverales.

The styles (the upper part of the pistil), if present, may be either deciduous or persistent and sometimes become beaklike on the ultimate fruit. In many genera the style is virtually absent, and the stigmatic areas (pollen-receiving regions) are located directly upon the ovary. There is an unusually wide range of stigma types among various groups of the order Papaverales. The entire, or bilobed, type is common, but greatly expanded, recurved, crested or lance-shaped stigmas are present in *Glaucium*, among other genera, and elaborate stigmatic ridges and crests occur in a number of genera including *Cathcartia*, *Meconopsis*, *Argemone*, and *Papaver*. The basic gynoecial (female) structure is constructed of two or more fused carpels. In the family Fumariaceae, there are consistently two carpels, and the ultimate fruit produced is unilocular (*i.e.*, has only one chamber). On the other hand, the gynoecium of the family Papaveraceae, while having two or more carpels and usually being unilocular, in some taxa becomes multilocular in fruit. The fruit is two- to many-valved (*i.e.*, it has openings through which seeds are released).

Seeds of the order are most commonly kidney-shaped, obovoid, or spherical and are frequently pitted. In a number of genera, crestlike arils are present on the seed, but true seed wings are absent. The seeds are plump to somewhat flattened and contain an endosperm (nutrient tissue for the developing embryo) that is usually oily, in addition to the small, straight to somewhat curved embryo.

Plants of the order Papaverales are widely recognized for their medicinal and poisonous properties, and more than 200 alkaloids are known in the order. Most of these are found elsewhere among the higher plants, sometimes commonly so, but in some instances only in one or a few families. At least eight alkaloids are distinctive and are known only from this order of plants.

The widely known poppy flower is the most common flower type within the order. Even dwarf Arctic poppies and the giant matillia poppy, which is woody at the base and otherwise quite different from the common poppy, are quickly identified as poppies by the average person. At a divergent extreme are the flowers of bleeding heart (*Dicentra spectabilis*) and Dutchman's-breeches (*D. cucullaria*), which are laterally compressed and appear to be irregular in shape. Flowers of all members of the order are perfect (*i.e.*, have both pistil and stamens, the female and male flower parts) and hypogynous (the sepals, petals, and stamens attach at the base of the ovary) and have a compound ovary with parietal placentation (*i.e.*, the ovules attach to the ovary wall). An exception to the compound ovary is found in the genus *Platystemon*, in which 6 to 25 carpels are weakly united when young, but become free in fruit.

NATURAL HISTORY

Although the breeding system of many species has not been investigated, some species of *Fumaria* and *Corydalis*

Male
flower
parts

Some vegetative, floral, and fruiting structures representing two of the families of the poppy order.

Pollination

are known to produce cleistogamous (closed when mature) flowers and to produce fruit without fully opening. Self-pollination is known to occur in the order, but the prevalent mode as a whole is cross-pollination, and insects are the primary carriers of pollen between plants. The open, many-stamened flowers of the poppy type are inviting to many kinds of bees and similar insects; the more closed and spurred flowers of many Fumariaceae species provide for a narrower range of insect visitors. No flower type is known to be so insect-specific that only a single species is its pollinator. Even though some flowers are somewhat tubular because of the weak fusion of their petals and are more or less closed by the overlap and fusion of the inner petals, they are dependent on insects for the transfer of pollen from plant to plant to ensure a seed set. Frustrated short-tongued bees sometimes bite through the base of the corolla (flower petals) and gain direct access to the source of nectar without pollinating the flowers, however.

There are usually several to many seeds in each fruit, but some genera have single-seeded fruits, and in a few groups the fruits break into single-seeded joints. The seeds are shed from the fruits by the opening of valves, through pores, or by the breaking of the fruit into one-seeded joints. In a few species the valves open explosively, throwing the seeds some distance from the plant. In some, the fruits are one-seeded and indehiscent (do not open along definite seams). Seed dispersal is mostly unspecialized, and seeds are spread around by water, by moving soil, or by the movements of the mature plant after it is uprooted or broken off. Ant dissemination of the arillate seeds is common in certain members of the group.

Evidently, most plants of the order are little eaten by animals, and none is known to have edible vegetative parts. The juices are either acrid and bitter or milky and often narcotic, which apparently is the basis for avoidance of the plants by both animals and man. Poppy seeds, however, are sprinkled on pastries and other foods, made into pastry filling, or ground for flour. The narcotic principle is not present in the seeds of even the opium poppy.

EVOLUTION

Recorded fossils placed definitely in the order Papaverales are few and contribute little of significance to an understanding of the probable origin of the group. Based on evidence from present-day species, it is now agreed by the most recent authorities that the order is more nearly related to the order Ranunculales than to Capparales, as had been thought by earlier investigators. Within the Papaverales, the family Papaveraceae has more archaic features than the family Fumariaceae, and the Hypecoaceae family has been suggested as forming a connecting link between them.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The family Hypecoaceae, with but one genus, *Hypecoum*, is distinguished by free petals and four free stamens, except that these features are also shared by the controversial monotypic (one species) genus *Pteridophyllum*. The latter has been the basis for the family Pteridophyllaceae, but it is sometimes placed in the family Papaveraceae and at other times in the Fumariaceae. The genera *Hypecoum* and *Pteridophyllum* are distinctive, and a recent treatment gives subfamily rank to each in the family Fumariaceae.

The families Papaveraceae and Fumariaceae differ substantially in many characters, but the surest distinguishing features are the many regularly inserted stamens, large bud-enclosing sepals, and regular flowers of the Papaveraceae, as contrasted with the six stamens in two groups, small, scalelike sepals, the bilaterally symmetrical to irregular flowers of the Fumariaceae. Although some authorities recognize the Hypecoaceae as a family distinct from Fumariaceae and only questioningly include *Pteridophyllum* in Papaveraceae, others give subfamily rank to both *Hypecoum* and *Pteridophyllum* in the family Fumariaceae. Another possibility sometimes suggested is to place both of these genera in the family Hypecoaceae.

Alkaloid distribution supports the association of the families Papaveraceae and Fumariaceae together in the same

order. Protopine, for example, is found in all members of both families so far investigated but is almost unknown elsewhere, having been reported from only one species, *Nandina domestica*, of the family Nandiniaceae (order Ranunculales). The subordinate taxa (subfamilies, genera, species, etc.) of Papaveraceae mostly have their own combination of alkaloids, and different combinations appear to characterize different sections of the family. On the other hand, members of the family Fumariaceae possess a combination of isoquinoline derivatives different from anything found in Papaveraceae.

Taxonomic problems. Many of the Asiatic species of the Papaverales order have been little studied from modern points of view, and this is one of taxonomic needs in the group. Further research on *Hypecoum* and *Pteridophyllum* would help to better place these genera with respect to each other and with respect to the principal families Papaveraceae and Fumariaceae.

The great divergence of taxonomic treatments of certain genera is baffling and calls for a sound evaluation. For example, the recognition by one authority of 123 species of *Eschscholzia* (California poppy), mostly from California, is not compatible with the treatment by another, in which only eight species are given for the state. A third has recently suggested that *Eschscholzia* consists of about 14 species. A similar disparity of treatments exists for the genus *Platystemon*. (R.C.R.)

Sarraceniales (pitcher-plant order)

The Sarraceniales, or pitcher-plant order, consists of the single family Sarraceniaceae, a small group of low perennial herbs of bogs and wet savannas with pitcherlike leaves specialized for trapping insects and other tiny animals. The Sarraceniaceae is confined to the New World, where it ranges from the tropics to the southern rim of the Arctic; but it has a counterpart in the Old World pitcher-plant family, Nepenthaceae (see *Nepenthes*). The approximately 15 species, despite their relative homogeneity, constitute three distinct genera, which are endemic (native) to three widely separated regions.

Sarracenia, the largest genus (eight or nine species), occurs in the Atlantic coastal regions of North America. The South American pitcher plants, genus *Heliamphora*, number four to six species and are known only from isolated mountains of the Guiana Highlands of northern South America. The genus *Darlingtonia* includes only *D. californica*. This distinctive pitcher plant is endemic to Pacific North America, where it is highly localized in montane (mountain) meadows in northern California and adjacent Oregon.

GENERAL FEATURES

The pitcher plants are totally unlike any other plants in the Western Hemisphere. As a group, they take their common name from their hollow tubular leaves, which are shaped like urns, trumpets, or small pitchers. Some species have hooded pitchers. In *Darlingtonia californica*, for example, the overarching hood gives to the tall, upright, tubular leaf the appearance of a cobra raised in striking position, hence its local name, cobra lily, or cobra plant. The curious landing ramp protruding from the mouth even suggests a snake's tongue.

The hollow leaves of pitcher plants are carefully constructed pitfalls that entrap insects or other tiny prey lured to the mouth of the leaf by glistening surfaces or unusual light-transmitting patches. Downward-pointing (retorse) hairs in the throat of the pitcher and other devices prevent escape, and the exhausted prey fall into the digestive liquor at the bottom. The liquor is a mixture of digestive enzymes (biological catalysts) and other secretions involved in digestion, rainwater (in hoodless species), and decomposing bacteria. In all species the trapping mechanism is of this passive, pitfall type.

Distribution and abundance. Excepting *Sarracenia purpurea*, species of the genus *Sarracenia* are confined to the southeastern part of the United States, where they occur mainly on the Coastal Plain and adjacent Piedmont from southern Virginia to eastern Texas. The green pitcher

Drawing by M. Pahl based on (*Darlingtonia californica* section of fruit, androecium and gynoecium; *Sarracenia purpurea* section of flower; *Heliophora nutans* seed, section of fruit, entire leaf) Wunschmann, Warburg, and Hegi in A. Engler, *Syllabus der Pflanzenfamilien* vol. II (1964); Gebrüder Borntraeger

plant, *S. oreophila*, the only species whose geographic distribution is completely isolated from the other species, occurs in the Appalachian Mountains of northeastern Alabama and extreme west central Georgia. The greatest concentration of species, populations, and individuals is in the region from southern Georgia and northern Florida to the southern half of Alabama.

Sarracenia purpurea is the most widespread species, ranging from the sub-Arctic to the subtropics, from Labrador to Great Bear Lake, near the Arctic Circle in northwest Canada, southeastward over central and eastern North America to Georgia, Florida, Alabama, Mississippi, and possibly Louisiana on the Coastal Plain. The yellow pitcher plant, *S. flava*, probably the most common species of the genus in terms of numbers of individuals, ranges from southern Virginia to northern Florida and southern Alabama on the Coastal Plain and Piedmont. The hooded pitcher plant, *S. minor*, is relatively common on the Coastal Plain from South Carolina to southern Florida (east coast). The other species of *Sarracenia* all have very restricted distributions.

Darlingtonia occurs from the central Oregon coast through the southwest Oregon mountains southward to Nevada County in the Sierra Nevada Range of northern California. It is abundant in the Mt. Shasta region, where it may be found in at least 30 to 40 localities within a 15- to 20-mile (25- to 30-kilometre) radius. Thus, despite its localized distribution, the California pitcher plant is by no means rare. Distribution of South American pitcher plants is still poorly known, but they exist in Guyana and Venezuela.

Economic importance. The pitcher-plant order is of minor economic importance, even though species of *Sarracenia* have been cultivated as curiosities for many years. The species most commonly cultivated are *Sarracenia flava*, *S. purpurea*, and *S. rubra*. The common pitcher plant was introduced into culture in England at least as early as 1640. Since their discovery, both *Darlingtonia* and *Heliophora* have been grown in cultivation but on a much more limited basis; the latter is grown only

rarely, however, because of the inaccessibility of its native habitats. *Darlingtonia* is extremely difficult to grow and seldom survives long under artificial conditions, although it has done well when transplanted to New England bogs.

It is not unusual that such bizarre plants as the sarracenias would draw the attention of the American Indians and early explorers and settlers in North America as possible sources of medicines and drugs. Indians in Newfoundland used the root to treat smallpox, and the treatment enjoyed a short-lived popularity in England, beginning about 1865. Neither the root nor any other part of the plant has ever been proved to have real medicinal value.

Common names and lore. Pitcher plants have received many fanciful vernacular names through the years, some of which allude to a specific feature of the plant. The first English settlers in North America called the common pitcher plant (*S. purpurea*) the sidesaddle flower, apparently in reference to the peculiar umbrella-like expansion of the style (a portion of the female structure). This wide-ranging species has been called by a host of other interesting names: huntsman's-cup, Adam's cup, whip-poorwill's-boots, devil's boots, flytrap, northern pitcher plant, forefather's-cup; and, in Quebec, petits cochons and herbe-crapaud. Some of the common names given to other species are huntsman's-horn, flycatchers, trumpets, trumpet-leaf, biscuit flower, fiddler's trumpet, white-top pitcher plant, sweet pitcher plant, parrot pitcher plant, and calf's head.

Fantastic claims have often been made about pitcher plants—for example, that they will catch all the flies in a house—and the layman may find it difficult to separate fact from fiction. Carnivorous plants have excited the imagination of many popular writers; most stories involving so-called man-eating plants seem to be inspired by a vague knowledge of the tiny, harmless Venus's-flytrap (*Dionaea*; see *Nepenthes*) or of some other carnivorous species with an active trapping mechanism. There is no scientific fact to substantiate such stories.

NATURAL HISTORY

Life cycle. The pitcher plants are herbaceous perennials (i.e., nonwoody plants that live several years) with a round, horizontal, underground stem (rhizome or rootstock). An upright, above-ground stem is lacking, with the occasional exception of *Heliophora*. The mature rhizome, which is 3 to 12 inches (8 to 30 centimetres) long and of a typical form for each species, grows for 10 to 15 years (*Darlingtonia*) or as many as 20 to 30 years (*Sarracenia*). It forms new nodes (stem regions that give rise to leaves or other structures) at intervals. The nodes usually remain compacted and give rise to adventitious roots, rosettes of leaves, and flowering stalks. The interior of the rhizome is white from the abundant store of starch. During the life of the plant, the older end of the rhizome slowly decays; the middle part is covered with leaf scars and decaying roots; and the growing end (perhaps half of total length of rhizome) has functional roots and leaves, as well as older leaves in various stages of decay. A new set of roots forms and develops to maturity every season; the older roots continue to function as storage organs for six or seven years. During the years of rhizome growth, lateral underground buds may occasionally form; the buds develop into separate plants by forming new roots and leaf rosettes, after which the parent rhizome decays. In *Darlingtonia* but rarely in *Sarracenia*, the internodes (stem regions between nodes) elongate slightly, spacing out the new plants that are formed. This gives rise to gradual vegetative spreading in pitcher-plant colonies, particularly of *D. californica*. Thus, once established, pitcher-plant species slowly propagate themselves vegetatively.

Leaf forms. Two and sometimes three types of leaves are formed each year in *Sarracenia*. A crop of pitched, insect-catching leaves is produced in the spring, and a second crop, differing markedly in shape, may be produced in the fall. Half or all of the autumn leaves, depending on the species, may be swordlike and tubeless (phyllodia); phyllodia overwinter in the green condition. They may also develop in the summer in cool, shady places. The pitched leaves are evergreen in species in which they lie

Medicinal properties

Seasonal variation of leaves

close to the ground (*S. psittacina* and *S. purpurea*) but tend to die back in the fall in the upright species (e.g., *S. flava*). In addition, all species produce small, scalelike leaves.

The pitcher leaves clearly seem to be adapted to function like flowers in attracting the insects they trap. The leaves are flowerlike in their striking colour patterns and shapes, which are distinctive for each species, and may be easily mistaken for true flowers. During May and June, the active period of the leaves, glands over the surfaces of the flowerlike leaves exude nectar drops containing fruit sugar, which permeates the air with a fruity or honeylike fragrance. By early June the entire outer surface of the pitcher below the mouth in some species may glisten with almost continuous secretion. Heavy feeding activity by ants, wasps, bees, butterflies, moths, and other insects indicates the great attraction of the nectar and its sweet scent.

Flowering and seed germination. The flowers of all pitcher-plant species are showy and have a more or less agreeable scent. Most of the *Sarracenia*s produce their flowering scapes (leafless stalks) in the spring before the new leaves appear, but the common pitcher plant flowers after new leaves have begun to mature. Only a minority of the plants in a given population seem to produce flowers in any one year. Flower buds form the previous year in August and September and remain concealed in the leaf bases until March or April. In the southern states the *Sarracenia*s begin to bloom in March or April, continuing for a month or two or throughout the summer until August or September, depending on the species. *Sarracenia purpurea*, which has a wide latitudinal distribution, begins flowering during the first week of April in Florida but not until about the second week of August in Labrador. The petals of a *Sarracenia* flower wither after two or three weeks; the rest of the flower remains green until the capsule and seeds mature in four to five months.

The flowers, at first pendulous, may in some species become erect after pollination. The anthers (male reproductive organs) begin to shed pollen copiously as soon as the flower opens, and in *Sarracenia* the inverted umbrella-like style (a portion of the female structure) catches the pollen and holds it where insect visitors can find it readily. The nectar-scented flowers attract ants, bees, pollen-eating beetles, and other insects but especially bees, which seem to be the primary pollinators and tend, in the course of their nectar-feeding activities, to carry the pollen of younger flowers to the stigmas (female pollen-receiving areas) of older flowers. Glands on the ovary, sepals, or accessory leaves (*Heliamphora*) secrete the nectar that attracts insects, and the scent is more or less specific to each species. Cross pollination seems to be essential in *Darlingtonia* and *Sarracenia*, both of which have protandrous flowers—i.e., flowers in which the pollen is ripe before the stigmas are receptive.

Heliamphora pollination is poorly known. The floral structure suggests that insects, which are attracted by the nectar secreted by the sepals and ovary walls, effect pollination.

Seeds are shed from July to September, and in the warmer southern states germination may take place in three to five weeks; a recognizable seedling may form before winter dormancy sets in. Germination may be delayed until the following spring in the colder latitudes. The wide and sporadic distribution of some species suggests that migrating birds, by picking up seeds on their feet, may play a role in dispersing the seeds.

Hybridization and chromosome number. Species of *Sarracenia* have been known to hybridize freely, both in cultivation and in nature. Perhaps the most common natural hybrid is the cross between *Sarracenia purpurea* and *S. flava*, two species with overlapping ranges.

The chromosomes, which carry the hereditary material, have been counted in all species of *Sarracenia*, and the number has been found to be the same (26) throughout the genus. It is not surprising, therefore, that the species hybridize freely. The reproductive barriers between species are weak. Geographic separation and separation of flowering time seem to be the chief means by which the species are isolated. Bees, the most common pollinators,

visit different plants or species indiscriminately. Four to seven years are required for a *Sarracenia* hybrid to reach flowering stage.

The chromosome number of *Darlingtonia* is 30. There are no known reports of attempts to hybridize this genus with *Sarracenia*.

Carnivorous adaptations. **Trapping mechanism.** Insects are trapped in basically the same way by the various species of *Sarracenia*. They are attracted to the mouth of the pitcher by a trail of nectar-secreting glands on the leaf extending downward from the lip along the outside. The lip is provided with stiff, downward-pointing (retorse) hairs; below the lip, in the steepest part of the throat, is a highly polished area without hairs, from which digestive enzymes are secreted. Insects attempting to garner nectar around the lip almost invariably fall into the pitcher. Like a greased slide, the polished zone sends them tumbling into the liquor below, where they quickly become submerged and drown. Escape is prevented by the retrorse hairs at the mouth, which are too dense for the insects to crawl between and too stiff and downward directed for them to climb over.

Several species of *Sarracenia* have specialized luring devices that resemble those of the cobra lily, *Darlingtonia*. The cobra lily has a landing ramp from which insects can enter the pitcher. Because of the domelike hood, insects must enter from the side. The presence of the hood darkens the pitcher; this would discourage insects from entering if numerous translucent "windows" that permit light to penetrate were not present. The windows also serve to attract insects that have already entered the pitcher toward a point other than the true opening; they waste their energy trying to crawl through or fly against the translucent tissue, eventually tire, and drop into the liquid below. Retrorse hairs and a polished secretory zone are also present in this species.

The trapping mechanism of *Heliamphora* differs only in details from that of *Sarracenia*.

The quantity of debris—the undigested remains of the plant's victims—in any mature pitcher, especially in the fall, when the pitcher of some species may be half full of remains, illustrates the effectiveness of the pitcher-plant leaf as an insect-trapping mechanism. Ants are especially common prey, but flies, wasps, spiders, crickets, and other tiny animals often fall victim.

Digestive mechanism. *Sarracenia* species secrete digestive enzymes that accumulate in the bottom of the pitcher, where they become diluted with rainwater in species in which the leaves are not entirely closed off at the mouth by a hood or lid (e.g., *S. purpurea*). The liquid in the pitchers usually includes bacteria, and digestion is accomplished by the combined action of enzymes and bacteria. The insect that falls into this digestive broth is attacked almost immediately, and odours of decay are often evident. The end products, including nitrogen compounds, are absorbed by the leaves; the indigestible outer skeletons of the insects accumulate at the bottom of the leaf until it dies.

In *Darlingtonia* and *Heliamphora*, enzymatic glands are lacking, and apparently only bacterial digestion occurs.

Evidence suggests that the carnivorous habit is not essential to the survival of the pitcher plants but that they grow better and probably flower more profusely when provided with an animal diet. In the long run, young plants benefit more directly from an animal diet than mature ones, but carnivory helps the latter to produce more leaves and flowers.

Animals that exploit pitcher plants. Some animals, apart from the pollinators, have evolved methods of eluding the trap and using the pitcher plant for food, for shelter, or as a host for part of their life cycle. Certain insects parasitize the plant tissue; others rob the pitchers by parasitizing insects trapped there. In fact, some of these insects have lost the ability to survive under any other conditions. Birds often slit the pitchers to get at the insects inside, and tree frogs—which sometimes take shelter by day in the mouth of the pitcher by clinging to the inside walls with the suction pads of their feet—probably eat some of the insects visiting the traps.

Several moth species lay eggs in the pitchers, in which

Contents
of pitcher
fluid

Pollina-
tion

the caterpillars hatch and feed before they spin a cocoon and overwinter. The pitcher-plant moth (*Exyra* species) even passes its adult phase sitting inside the pitcher by day. Other moths parasitize the flowers and seed capsules and then spin a cocoon or tunnel into the stem to pupate; one moth larva is a root borer in *sarracenia*s.

Larvae (maggots) of flies of the genus *Sarcophaga* live within the pitcher's mouth; the larvae prey on flies captured by the plant and then bore through the pitcher wall to pupate in the soil. These larvae apparently do not have any structural adaptation for this dangerous habitat, but they do secrete an anti-enzyme that protects them from the otherwise destructive digestive enzymes produced by the plant. Like the pitcher-plant moth, the flies are able to go in and out of the pitcher without falling victim to it. Wrigglers (larvae and pupae) of the pitcher-plant mosquito, *Wyeomyia smithii*, thrive in the pitchers of *Sarracenia purpurea* and overwinter in them, emerging as adults in the spring. This northern species of mosquito, which belongs to an otherwise tropical group of mosquitoes, is rarely absent from a colony of the common pitcher plant, even at its northern limits of distribution in Canada.

Larvae of the minute gnat *Metriocnemus edwardsi* are found in the pitchers of *Darlingtonia*, where they hatch and feed in great numbers.

Ecology. The pitcher plants are hydrophytes—water plants—that commonly inhabit bogs, swamps, wet, sandy meadows, or savannas where the soils are water saturated, moderately to intensely acidic, and deficient in nitrates and phosphates. Some species can tolerate standing water, and a few may even thrive underwater for a time (e.g., *S. psittacina*). The montane species, *S. oreophila*, occurs in sands and gravels on stream banks, and other pitcher plants may be able to tolerate moderately well-drained acidic soils. On the Atlantic coastal plain, the pitcher plants characteristically inhabit wet, sandy areas in the pinelands, often over extensive areas. Frequently, several species occur together, and there may also be other carnivorous plants (e.g., sundews and flytraps—see *Nepenthes*). The most common plant associated with pitcher plants is sphagnum or peat moss. In Alabama, in both the bogs of the uplands and the boggy marshes of the coastal plain, *sarracenia*s form characteristic hydrophytic associations with sundews, pipeworts, orchids, and dichromenas. In the pine barrens of New Jersey, the common pitcher plant, sunken in the peat moss, helps to make the bogs and white-cedar swamps attractive. The *sarracenia*s usually demand full or partial sunlight, but at least one species (*S. rubra*) can grow in dense shade.

Grass fires often burn *Sarracenia* colonies to the ground during the summer months, but these plants are remarkably fire-resistant and usually can survive underground and make a comeback.

The California pitcher plant occurs in marshy or boggy habitats from near sea level to 6,000 feet (2,000 metres), ranging from the redwood forest zone to the red-fir forest zone. The soils in these regions are very acid, and the temperature never goes above about 65° F (18° C).

Heliophora grows under extremely humid and wet conditions; it occurs from the lower slopes to the exposed crests and cliffs of Mt. Roraima (Guyana) and Cerro Duida (Venezuela), two mountains about 400 miles (600 kilometres) apart at the eastern and western ends of the Pakaraima Mountains of the Guiana Highlands, which constitutes the known distributional range of the genus. On Mt. Roraima it reaches its full size and best development on the ledges of the cliff of Roraima. On Cerro Duida it occurs in association with various other plants, as part of the dense undergrowth in the forested valleys of the plateau, and as a cushiony growth in patches on practically all the adjoining ridge crests. In swampy depressions it mingles with sphagnum.

FORM AND STRUCTURE

Most of the pitcher plants are herbaceous, stemless (acaulescent) perennials consisting of a basal cluster (rosette) of leaves arising from a short, creeping rhizome. The hollow, tubular leaves curve outward and upward with their basal portion resting on the ground (e.g., *Sarracenia purpurea*)

or are erect (e.g., *S. flava*), with sheathing bases; the leaves widen gradually into pitchers. A prominent wing runs along the outer surface of the leaf from bottom to top on the side facing the centre (adaxial, or ventral, side) of the plant. At the top the wing forms a lip. On the back (dorsal) side a bladelike expansion forms a lid or hood over the mouth of the pitcher, in some cases effectively closing the opening to light and rain. The leaves of *S. purpurea* and of all the species of *Heliophora* are open at the mouth and collect rainwater. The strikingly coloured leaves vary from yellow green to dark green suffused with red to deep red, the intensity of red depending in part on the amount of sunlight in the habitat. One species is white with red and green reticulations (netlike patterns); other species have translucent-spotted leaves.

The height of the plant usually is determined by the height of the leaves, which in most species average 1 to 2 but may reach 4 feet (120 centimetres). By contrast with the North American pitcher plants, three of the six described species of *Heliophora* are stemmed (caulescent), branched, almost shrubby perennials, which attain a height of four feet. Their pitchers vary from 8 to 20 inches (20 to 50 centimetres) in length.

The inflorescence (flower cluster) of *Sarracenia* and *Darlingtonia* consists of a tall, leafless stalk (scape) with a solitary, nodding flower. The flowering scapes generally average about a foot in height but may vary from a few inches to four feet. Typically, the flowering scape more or less equals the length of the longest leaves, although in *Darlingtonia* and *Heliophora* species the scape may be as much as twice the length of the leaves (to four feet in *Darlingtonia*). In *Heliophora*, the inflorescence is several-flowered and one to two feet long; the flowers lack differentiated petals, the sepals being white to pink or rose purple and showy. The large flower (several inches across) of the North American species has five yellow, greenish-yellow, or pink to wine-coloured petals and five firm, green sepals, which persist long after the petals have fallen. The petals may be short or long and showy, as in *S. flava*, in which they hang down like a hound's ears. The *sarracenia*s have a unique, umbrella-like style, which has tiny stigmas on its five points.

Flowering
structures

EVOLUTION

No fossils have been reported for the pitcher-plant order. Phylogenetic relationships must be inferred from the morphological and biological relationships of the modern species, and such considerations, not surprisingly, have led to diverse views. Most authorities now agree that the carnivorous flowering plants form a more heterogeneous group than was traditionally thought and that, therefore, carnivory must have arisen independently in several more or less unrelated evolutionary lines. No two authorities agree, however, on the number or relationships of the lines, some assigning these plants to as many as six different orders. Furthermore, different authorities place the same carnivorous species in different orders.

On the basis of floral morphology, phylogenists at present have quite different views about the origin of the order Sarraceniales. Some regard the Sarraceniales as a very specialized order that has retained some primitive features that place it near the order Ranunculales (Ranales), from which it and the order Papaverales are derived. Others place the pitcher-plant order next to the order Violales and derive both orders from the Theales (Guttiferales). Still others propose different origins and alliances within the framework of their own phylogenetic systems.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The Sarraceniales is distinguished from other orders chiefly by its distinctive, highly modified leaves and to a lesser extent by features of the inflorescence and flowers. The more important distinguishing features used to separate the three genera within the single family are presence or absence of above-ground stem, form of leaves, number and arrangement of flowers, presence or absence of petals, coloration of sepals, number of carpels (simple ovaries or sections of a compound ovary), and form of style.

Characteristic
habitats of
pitcher
plants

Relationships of various plants disputed

Taxonomic problems. The order Sarraceniales, as presented in the *Annotated classification*, is defined in the strictest sense and includes only the family Sarraceniaceae. Unquestionably, the three genera named therein belong in the same family. So similar is the California pitcher plant to some of the eastern species that *Darlingtonia* probably could not be defended as a separate genus if it were not for its great geographic isolation from the eastern species.

The chief taxonomic problems of the family arise at two levels. First, there is no agreement about the relationship of the Sarraceniaceae to the families Droseraceae and Nepenthaceae of the order Nepenthesales. Some authorities continue to hold to the older view that the three distinct families form a natural order. This view rests on the theory that the leaves of the three families represent modifications from a common type. Authors have gone so far as to propose that the families Nepenthaceae and the Sarraceniaceae should be merged into a single family because *Heliamphora* seems to bridge the gap. Other authorities place greater weight on floral and pollen morphology, both of which suggest that the Sarraceniaceae stands apart from the other two families. Increasingly, evidence indicates that these families belong in two or three perhaps widely separated orders.

Second, within the family Sarraceniaceae there has never been agreement about the number of species in the genus *Sarracenia*, even though the group has been known for 400 years. Furthermore, there is reason to suspect that a similar problem of delineating species exists in *Heliamphora*, although knowledge of this genus is scant. The most useful taxonomic features in *Sarracenia* pertain to the form and habit of the pitcher leaves. The overall shape of the pitcher is generally constant and represents the single most useful feature, but colour and marking are important in some cases. Leaf size is quite variable within species and of itself is not useful. In combination, other characteristics (e.g., colour and shape of petals, odour, curvature of sepals, and presence and number of swordlike leaves) may be diagnostic. As with family relationships, specific relationships cannot be known any more definitively than they are without new lines of evidence.

(S.G.S.)

Hamamelidales

Hamamelidales is an order of woody flowering plants that includes three families, 30 genera, and about 80 to 150 species. Knowledge is still very incomplete concerning several genera; thus the actual number of species remains uncertain. The families and most of the genera are isolated both morphologically (*i.e.*, with respect to structure and form) and geographically, although the order as a whole is distributed worldwide. Thirteen genera contain only one species each and five genera only two species each. The order Hamamelidales is especially interesting from the standpoint of phylogeny because it apparently forms a link between groups with extreme types of floral organization; viz., the primitive woody plants with large, petalled flowers (the magnolias, buttercups, saxifrages, and roses) and the catkin-flowered plants (Amentiferae), which include the beeches, birches, alders, and oaks.

GENERAL FEATURES

All representatives of the order are woody: trees and shrubs, partly evergreen, partly deciduous; there are no herbaceous species. Most members of the order are medium-sized trees, but some are small shrubs (e.g., *Hamamelis*, witch hazel; *Fothergilla*, witch alder); others are giant trees up to 200 feet (60 metres) high (e.g., *Liquidambar*, sweet gum; *Altingia*; *Symingtonia*; and *Platanus*, plane tree).

Distribution and abundance. The actual distribution of the order is worldwide (except in Arctic regions), but most of the species and genera have very limited individual ranges of distribution, and it is possible that some of them will soon become extinct. Moreover, there are only a few species that grow in large pure stands. Several species are widely represented in northern fossil deposits.

Economic importance. Some genera are attractive for their early blossoming; some are even truly winter bloom-

ing as is especially true of *Hamamelis* (witch hazel) and *Corylopsis*. Others are known by their brilliant yellow, orange, or crimson leaf coloration in the fall (e.g., *Disanthus*; *Fothergilla*, the witch alder; *Hamamelis*; *Liquidambar*, the sweet gum; and *Parrotia*, ironwood) or for being impressive, large trees (*Liquidambar* and *Platanus*). All these genera are more or less hardy in temperate regions. *Rhodoleia*, which has showy, red, bird-pollinated flowers, can be cultivated only in tropical or subtropical regions. Parts of *Hamamelis* (witch hazel) plants have long been used as raw material for various purposes. The North American Indians used the fluid from boiled stems to stop bleeding and heal wounds. Today alcoholic extracts from leaves and bark are used for styptic (antibleding) remedies, and watery extracts are used for various cosmetics and liniments.

The wood of several trees is used as construction material or for furniture (e.g., *Altingia*, *Liquidambar*, *Parrotia*, *Symingtonia*, and *Platanus*). In other genera the twigs or bast (fibres) are used as a tough binding and plaiting material (e.g., *Molinadendron* and *Parrotiopsis*).

NATURAL HISTORY

Life cycle. The reproduction biology of the Hamamelidales shows some outstanding features. The range of pollination mechanisms is relatively wide. Pollination may be effected by bees or bumblebees (e.g., in *Corylopsis*), by flies (in *Disanthus* and *Hamamelis*), by birds (in *Rhodoleia*), or by wind (in *Liquidambar*, *Parrotia*, *Sinowilsonia*, *Sycopsis*, and *Platanus*). In certain members of the family Hamamelidaceae fertilization of the ovules occurs long after pollination—e.g., five to seven months in *Hamamelis virginiana*.

In the genera of Hamamelidaceae with one seed per carpel (structural unit of pistil), seed dispersal takes place by an ejecting mechanism. As the fruit opens, the bony endocarp (inner layer) bends in a characteristic manner and presses against the very hard and smooth surface of the seeds. The seeds are then forcibly discharged over distances of several metres. In contrast, the small, winged seeds of the many-seeded fruits of *Liquidambar* are distributed by wind. In *Platanus* the tufted nutlets are wind-dispersed. In many species of the family Hamamelidaceae, seed germination is usually delayed because of the very hard and impervious seed coat; the seeds sometimes take one or two years to germinate.

Ecology. The family Platanaceae and a large part of the family Hamamelidaceae occur in moist woodlands, especially on stream banks, and on steep woody slopes. Other species grow best on drier rocky soils. The exact ecological range is unknown for most species. Many members of the family Hamamelidaceae grow in tropical and subtropical mountain regions, particularly in undisturbed forest areas. In general, representatives of the families Hamamelidaceae and Platanaceae are not specialized for extreme habitats, but the species of Myrothamnaceae are quite remarkable in being among the most extremely drought-resistant of all seed plants and ferns—twigs and leaves can dry out and remain in a dry condition for several years without dying. They are found in the arid regions of tropical and southern Africa and Madagascar.

FORM AND FUNCTION

Vegetative characteristics. All species of the order are woody plants. The leaves are simple and have small appendages at the base of the leaf stalks called stipules (except in *Rhodoleia*). They are usually arranged alternately along the stems. The anatomical structure of the wood is relatively uniform; the small, angular vessel elements (water-conducting cells) mostly have very oblique end plates with many crossbars, the scalariform condition.

Flower and fruit characteristics. The individual flowers are usually medium-sized or small, but they often form dense inflorescences (flower clusters). Several genera bear unisexual flowers, but only the family Myrothamnaceae seems to be dioecious; *i.e.*, its species bear male and female flowers on separate plants. The perianth—sepals and petals—especially the petal portion, is often reduced or absent, and the number of floral parts sometimes varies

Medicinal uses

Adaptation to arid habitats

Vegetative, floral, and fruiting structures of three families of the order Hamamelidales.

Drawing by M. Pahl based on (*M. moschata*) *Beiträge zur Biologie der Pflanzen* (1966), Duncker and Humblot; and (*P. occidentalis* flowers) G.H.M. Lawrence, *Taxonomy of Vascular Plants* (1951), The Macmillan Company

considerably within one species. The stamens (male flower structures) are usually provided with a short or long anther-connective protrusion—an appendage on the pollen sacs. The anthers open by means of valves except in the family Myrothamnaceae and in some genera of Hamamelidaceae. The female flower parts (the pistils) are composed of fused carpels (structural units of the pistil), except in Platanaceae, in which they are not fused, but they always show free styles, the elongate upper parts of the pistils. Each carpel usually contains a single ovule except in Myrothamnaceae and some Hamamelidaceae. The fruits are capsules (nutlets in Platanaceae) that split open along a ventral (inner-side) line. In Hamamelidaceae, other modes of opening are also common. The seeds of the families Hamamelidaceae and Platanaceae contain no starch, but protein and oil are present.

EVOLUTION

Fossil record. The family Hamamelidaceae was widely distributed in the Northern Hemisphere, possibly in the Cretaceous Period (about 65,000,000 to 136,000,000 years ago), certainly in the Tertiary Period (2,500,000 to 65,000,000 years ago). In Europe the group is known at least from the Eocene Epoch (beginning about 54,000,000 years ago) until the lowest Pleistocene (about 2,500,000 years ago). *Liquidambar* is known from the Upper Cretaceous of North America. The Tertiary discoveries have been attributed with more or less certainty mainly to the genera *Corylopsis*, *Hamamelis*, *Liquidambar*, and *Parrotia*. Some other fossils have been described as separate genera; the oldest ones from the European Eocene are *Hamamelidan-*

thium and *Steinhauera*. The oldest remains of *Platanus* are known for America from the Upper Cretaceous, for Europe from the middle Oligocene Epoch (about 30,000,000 years ago). *Credneria*, known by leaves from the Cretaceous and long considered an ancestor of *Platanus*, has been transferred to the family Menispermaceae.

Phylogeny. The fossil record is too sparse to give sufficient information about the evolution of the group as a whole and about phylogenetic (evolutionary) relationships to other orders. Nevertheless, the characters of the living groups are interesting enough for certain phylogenetic conclusions. Floral structure, inflorescence morphology, leaf structure, wood anatomy, and chemical data show relationships to orders of the so-called "Amentiferae" (catkin bearers—catkins are elongate clusters of many small unisexual flowers), especially to the order Fagales (which includes the beech and birch families). Possible relationships are also indicated to the order Urticales (elm, mulberry, and nettle families), and less probably to the orders Myricales (sweet gale family), Juglandales (walnut family), and Casuarinales, but not to the Salicales (willow order—one of the catkin-bearing plant groups). *Corylopsis* and *Sinowilsonia* (family Hamamelidaceae) are the most interesting genera with respect to the relationships shown to the catkin-bearing plant orders. *Sinowilsonia*, for example, has reduced unisexual flowers arranged in catkins. There are connections, on the other hand, to certain groups of the order Saxifragales, especially to the family Cunoniaceae. Certain superficial resemblances are also seen to the primitive woody families Cercidiphyllaceae, Eupteleaceae, Tetracentraceae, and Trochodendraceae, but they are considered to be the result of convergent evolution and not close phylogenetic affinity. Thus, the family Hamamelidaceae is most interesting in being a sort of link between two quite different main groups of flowering plants. The order Hamamelidales, therefore, represents an ancestral tropical and subtropical stock for several plant groups that have an amentiferous life form, which mainly developed in the temperate regions. Moreover, this connection lends support to the idea of a monophyletic origin (*i.e.*, one evolutionary line of descent) of the flowering plants.

Key evolutionary position

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. Useful characters to distinguish the three families of the Hamamelidales include phyllotaxy (leaf arrangement), leaf form, hair types, structure of the inflorescences and flowers (particularly of the gynoecium—the female flower parts), and fruits.

Alternate systems of classification. Some authorities include additional families in the order Hamamelidales, among them Tetracentraceae, Cercidiphyllaceae, Eupteleaceae, Bruniaceae, Stachyuraceae, Daphniphyllaceae, and Buxaceae. All these families, however, occupy quite isolated positions. Furthermore, some of the subfamilies of the Hamamelidaceae, as presented here, have been raised to the status of separate families by some authors. These include Disanthaceae, Rhodoleiaceae, and Altingiaceae (= Liquidambaroideae). (P.K.E.)

Urticales (nettle order)

The flowering plant order Urticales, or nettle order, includes such important and well-known plants as the figs, breadfruit, mulberries, elms, stinging nettles, hops, and true hemp, or marijuana. Although the order is mainly tropical in distribution, many of its species are widely and abundantly dispersed in temperate regions, particularly in the Northern Hemisphere. The Urticales is distinctive morphologically and is considered to be among the more evolutionarily advanced groups of the woody flowering plants. It includes about 125 genera and about 3,100 species in four families.

GENERAL FEATURES

Size range and diversity of structure. Plants of the nettle order range from small herbaceous (nonwoody) species to large trees. The elm family (Ulmaceae) consists of shrubs and trees, including the elms (*Ulmus*) and hackberries (*Celtis*), some of which grow to 150 feet (45 metres)

in height. A great diversity of mainly woody plants is found in the mulberry family (Moraceae), which contains the figs, with about 800 species. Figs are great trees of the tropical forests; some are buttressed by wide-ranging, and often finlike, spreading roots, as exemplified by *Ficus elastica*, the well-known India rubber tree. Many figs grow at first as epiphytes, or air plants, upon the branches of other trees, from seeds dropped by birds or bats. As these young plants develop, they send aerial roots down along the trunk of the supporting host tree, and in time the ever enlarging roots gradually crush the host to death. These are the so-called strangler figs, vinelike in youth but self-supporting large trees at maturity. The banyan, or Bengal fig (*F. benghalensis*), is another wide-spreading tree, an old specimen of which comes to resemble a dense grove of trees by dropping thick prop roots from its spreading branches. Some of the tree species bear long, sharp thorns, for which feature these plants find use as hedgerow or fencerow trees to enclose livestock or discourage trespassers (e.g., *Maclura*, osage orange).

Representative plants of the (top left) elm and (others) mulberry families.

The nettle family (Urticaceae) is well known for its stinging hairs, which can cause severe pain on contact. Although the nettle family is most abundant in the tropics, where its species are shrubby and treelike, the temperate regions of the Northern Hemisphere contain large numbers of the herbaceous nettles, seldom more than a few feet tall and often weedy looking. The hemp family (Cannabaceae) is also herbaceous: one genus (*Humulus*, hop) is a vine and the other (*Cannabis*, hemp) a tall herb.

Distribution and abundance. The species of the order Urticales are unequally divided among the genera and families. One of the two largest families of the order is the mulberry family, with more than 1,400 species in about 54 genera. Of these genera the largest are *Ficus* (more than 800 species) and *Dorstenia* (about 170 species). *Brosimum*

and *Artocarpus* each contain about 50 species, which are distributed in the tropics. About 12 more genera in the mulberry family contain between 10 and 25 species each. The more than 30 remaining genera have fewer than four species each, and a third of these are known by a single species each.

The nettle family also contains about 54 genera, with more than 1,400 species of mostly herbaceous or soft-wooded plants. The largest genera are *Pilea* (400 species; the tropics), *Elatostema* (200 species; the tropics), *Boehmeria* (100 species; the tropics and northern subtropics), and *Cecropia* (100 species; tropical America). The next 20 genera, in numbers of species, all contain between 10 and 50 species each; the nettles themselves (*Urtica*) comprise a group of about 50 species. There is a large group of monotypic genera, about 14 in all.

The largest genus of the elm family is *Celtis* (hackberries), with about 80 species distributed in the Northern Hemisphere and in southern Africa. The elms (*Ulmus*) consist of about 45 species, north temperate in distribution but extending as far south as the Himalayas and Indochina in Asia and to Mexico in North America. Other genera in the tropics and subtropics include *Trema*, 30 species; *Gironiera*, 15; *Ampelocera*, 9; *Parasponia*, 6; and *Chaetachme*, 4. The genus *Zelkova*, with seven species, is found in the eastern Mediterranean countries eastward to the Caucasus and into Asia. *Lozanella*, with two species, is native to Central and South America from Mexico to Peru and Bolivia. *Planera*, with a single species (*P. aquatica*), is native to the southern United States.

The smallest family is the hemp family (Cannabaceae), which consists of only two genera and about five species. *Humulus* (hop) occurs in north temperate regions, especially in Europe and the northeastern United States. The genus *Cannabis*, with a single species (*C. sativa*), is thought to be native to Central Asia but is now widely cultivated and has escaped from cultivation as a weed throughout much of the Northern Hemisphere.

Economic importance. **Wood products.** Valuable timber trees include the elms, among which the cork elm, or rock elm (*Ulmus thomasii*), is considered superior because it grows to a great height before branching, thus producing long lengths of clear (knot-free) wood. The keyaki (*Zelkova acuminata*) of Japan is much appreciated for the beautiful colour and grain of its wood. Wood of the osage orange is used for railroad ties and fence posts and has been used to carve high-quality hunting bows in times past. Flexible, strong, and also durable, it has a bright orange colour that eventually turns brown. *Celtis occidentalis* wood, sold under the name beaverwood, is used for boxes, furniture, and gift items. The wood of the African oak (*Chlorophora excelsa*), of tropical Africa, is heavy, difficult to split, and resistant to termite attack. It has been used as a substitute for teak in shipbuilding and furniture making. *Chaetoptelea mexicana*, found in Mexico south of Panama, is a large tree, the wood of which is used as lumber. *Holoptelea grandis*, a tall tree of the Congo basin, Uganda, Cameroon, and Côte d'Ivoire, has hard yellow wood used for house interiors and small-boat construction. *Phyllostylon brasiliensis*—San Domingo boxwood, or West Indian boxwood, of the lumber trade—is a tree ranging from the West Indies to Argentina. It produces a fine-textured, lemon-yellow, straight-grained wood valued for the high polish it will accept; stained black, it is often used as a substitute for true ebony. The wood of *Planera aquatica*, called false sandalwood, is fragrant and is used in cabinetmaking. The lightweight wood of *Chaetachme microcarpa*, a shrub of central and southern Africa, is used for the manufacture of guitars and other musical instruments. *Brosimum aubletii*, source of the expensive letterwood of the lumber trade, is a tree of the Guianas (Guyana, Suriname, and French Guiana). Its reddish-brown or brown wood, bearing black marks that resemble printed letters or hieroglyphics, is used for cabinetwork and small items such as handles, drumsticks, and violin bows. *Bosqueia angolensis*, a tree of the Congo basin and Angola, produces yellow wood that turns pink on exposure to air; it is used in general construction and cabinetry. The wood of *Morus rubra*, the red mulberry

Letterwood

Representative plants of the nettle and hemp families.

From (female flower, stinging hair) A. Engler, *Syllabus der Pflanzenfamilien* (1964), Gebrüder Borntraeger Verlag Berlin-Stuttgart; and (cystolith) A.B. Rendle, *The Classification of Flowering Plants* (1967), Cambridge University Press

of eastern North America, although light and not very strong, is durable and rot-resistant, qualities that make it useful in fence construction and boat building. *Brosimum paraense*, the Pará breadnut tree of Brazil, produces wood called redwood or cardinal wood, used in fine furniture and fancy carpentry. Many *Ficus* species find use as lumber. *Ficus benghalensis* has wood that is durable in water. The wide, flat, finlike buttress roots of large specimens of *F. elastica*—the rubber tree grown as a houseplant—are used in tropical regions to make planks. *Ficus sycomorus*, a wood of great durability, was used by the Egyptians to make their mummy cases.

The hop and hemp. Among the most outstanding economically important plants in the Urticales is the hop (*Humulus lupulus*), the female flowers of which are used to flavour beer and to clarify it by precipitating protein materials that cause turbidity. The active principles of the hop also help prevent spoilage in beer by retarding the growth of bacteria.

The hemp, or cannabis (*Cannabis sativa*), used as a crude drug plant in Asia and Africa for centuries, has become increasingly widespread in Europe, North America, and South America since World War II. Parts of the plant are dried and offered under many names, including hashish, marijuana, pot, and grass. It is widely smoked, chewed, sniffed, or eaten to produce a mild euphoria (see DRUGS AND DRUG ACTION). The stems of the hemp plant also yield a fibre, called hemp, used mostly for rope, twine, bags, sacks, carpets, and other purposes suited to its coarseness. Hemp seeds are the source of hemp seed oil, which is used in paints, varnishes, soaps, and some edible products.

Fruits. Important fruits of the order are produced mainly by the mulberry family, Moraceae. The edible fig (*Ficus carica*), cultivated since antiquity, is eaten raw,

dried, preserved, or candied; when ground it serves as a substitute for tea or coffee. Numerous commercially grown varieties differ in flavour, size, colour, preserving qualities, appearance, and other features. Many other *Ficus* species also produce edible figs.

An important tropical tree is the breadfruit (*Artocarpus altilis*). One of the highest yielding of food plants, a single tree may have more than 800 grapefruit-sized, seedless fruits each season. Breadfruits, high in carbohydrates, constitute one of the staple foods in many tropical regions. The fruit is filled with a starchy, pulpy, white mass that is usually cooked before eating. Closely related to the breadfruit is the jackfruit (*A. heterophyllus*), which produces fruits up to two feet long and weighing 40 pounds (18 kilograms) or more; they are not highly esteemed, however, because of their inferior flavour and seed-filled interior.

A number of lesser fruits of the order are also eaten, such as the breadnut (*Brosimum alicastrum*), mulberries (*Morus alba*, the white mulberry; *M. rubra*, the red; and *M. nigra*, the black), and hackberries (*Celtis occidentalis* and others). In addition, fruits are eaten from the following plants: *Debregeasia edulis*, a Japanese shrub that produces yellow fruits resembling strawberries; *Pourouma cecropiaefolia*, a Brazilian tree with round, fleshy berries; *Cudrania javanensis*; *Celtis sellowiana* and *C. iguaneae*; *Myrianthus arborea*; and *Sahagunia streptocarpus*.

Fibres. Plant fibres for cloth, sacks, rope, and numerous other purposes are produced mainly by the nettle and the hemp families. The fibres of the hemp are similar to those of flax. A finer fibre is produced from the ramie, or China grass plant (*Boehmeria nivea*), also called the Chinese silk plant because its fibres make a cloth resembling silk. Ramie fibres, although eight times stronger than cotton fibres and much longer, are difficult to separate from the plant tissues. The fibres are also used to produce papers, cordage, and industrial bagging. Other plants with fibres like those of the ramie are sometimes used as substitutes for it; they include *Sarcochlamys pulcherrima* (duggal fibre) and *Pouzolzia occidentalis* (yaquilla). Olona (*Touchardia latifolia*) was formerly an important fibre plant of Hawaii, used for cloth, cordage, and especially fishnets because of its durability in water. Fibres are also obtained from the stinging nettle (*Urtica dioica*); *U. breweri*; *U. cannabina*; *Debregeasia hypoleuca*; *Villebrunea integrifolia*; and many others, including the wood nettle (*Laportea canadensis*), the fibres of which are claimed to be 50 times as strong as a cotton thread of equal diameter. Fibres extracted from the bark and aerial roots of many *Ficus* species are used locally.

Bark cloth, or tapa cloth, made from the inner bark of some trees, especially the paper mulberry (*Broussonetia papyrifera*), was once used by local populations mainly for clothing. It is still produced but now principally for religious purposes and for the tourist trade. Bark cloth is also made from the breadfruit tree, certain fig trees (*Ficus tinctoria* and others), *Pipturus albidus*, and several other genera, including *Antiaris*, *Sloetia*, and *Trema*. Paper is made from the inner bark of the paper mulberry and several other plants of the order (e.g., *Streblus asper*, *Ficus religiosa*, *F. petiolaris*).

Latex products. Among the earliest sources of rubber were species of the latex-bearing family Moraceae, especially *Ficus elastica*, but the Pará rubber tree (*Hevea brasiliensis*, family Euphorbiaceae) has largely displaced it. Among numerous other rubber-producing trees in the order Urticales, however, are the Mexican rubber tree (*Castilla elastica*), one of the most productive of wild rubber trees; *C. lactiflora*; *C. nicoyensis*; *C. costaricana*; *C. ulei*; *Ficus nekbudu*, the latex of which becomes red when heated; *F. gnaphalocarpa*, a source of rubberlike gutta-percha; *F. rigo*; and *F. vogeli*.

Latex is used in many other ways, as for birdlime, a sticky substance used to catch birds (from *Ficus anomani*, *F. glumosa*, and others); as indelible red ink (*Bosqueia angolensis*); as a red dye (*B. phoberos*); as a base for chewing gum (*Ficus platyphylla*); as a component in glue and caulking compounds (*Artocarpus altilis* and *Brosimum utile*); as a beverage (the cow tree, *Brosimum utile*); and as medicines (*F. indica* and *F. involuta*).

The breadfruit

Rubber-producing trees

Other uses. Silkworms are fed almost exclusively on mulberry leaves, *Morus alba* being preferred in Western countries. In Asia, the leaves of many species of *Morus*, some *Ficus* species, and *Maclura pomifera* are also used.

Ornamental plants of the order include about 50 species of *Ficus*, among which are *F. elastica* (the India rubber plant), *F. lyrata* (fiddle-leaf fig), *F. pumila* (creeping or climbing fig), *F. benghalensis* (banyan, or Bengal fig); *Ulmus* (elms); *Celtis* (hackberries); and *Morus* (mulberries).

NATURAL HISTORY

Pollination. Most members of the order Urticales are wind-pollinated, and some species have adaptations that enhance this process. *Pilea microphylla* (Urticaceae), the artillery plant, for example, ejects its pollen in tiny explosive puffs. Many genera, particularly in the family Urticaceae, exhibit the same phenomenon. In the flower buds of the nettles (especially species of *Urtica*), the stamens (male, pollen-producing structures) are bent inward and held under tension (inflexed) in the bud. When the flower opens, the stamens are suddenly released and spring out with such violence that the anthers, or pollen sacs, are turned inside out, ejecting their pollen in a cloud. The pollen is then carried by the wind to the large, brushlike stigmas (pollen-receptive regions of the female flower parts) of other flowers. The flowers, like most wind-pollinated flowers, are inconspicuous, greenish in colour, and lack petals.

The genus *Parietaria* (Urticaceae) also has explosive stamens, but unlike most other members of the family it has bisexual flowers—flowers with functional organs of both sexes. Self-fertilization is averted by the early maturing of the pistil (female structure), a condition called protogyny. The elongated upper part of the pistil (the style) projects from the tip of the unopened bud, ready to receive pollen from other flowers that have already matured. Later, when the flower opens, the stamens are fully developed and release their pollen explosively, but the ovules of these flowers have already been fertilized, and the style has dropped off.

Some species of the Moraceae are insect-pollinated, particularly the figs. Pollination is accomplished by small wasps called fig wasps or gall wasps (*Blastophaga psenes*). In the figs, separate male and female flowers are borne in a specialized inflorescence, or flower cluster, which consists of a hollow, pear-shaped stem tip with the flowers on the inside. This structure, called a syconium, ultimately becomes a fig at maturity. The male flowers are usually arranged near the small opening at the upper end of the syconium, and the female flowers, much more numerous, line the interior. The female flowers are of two types, long-styled fertile flowers and short-styled sterile ones. The long-styled flowers eventually produce a single, small, one-seeded, hard-shelled fruit called an achene. The fig itself is actually a collection of many of these achenes surrounded by the fleshy tissue of the syconium. The short-styled flowers are called gall flowers; they do not develop fruits but are used as egg-laying sites by the gall wasps, which pollinate the other flowers in the process of egg laying. The gall flowers then become a mass of pulpy, abnormal plant tissue, the gall, on which the wasp larvae feed and in which they develop.

The three flower cluster types—male, long-styled female, and short-styled female or gall flowers—are produced in three distinctive syconia. The first type of syconium, produced in the spring, contains male flowers and gall flowers; each of the latter may contain one of the fig wasp eggs, deposited there in the spring by wasps that had just emerged from overwintering in another type of fig. These eggs produce wingless male and winged female wasps later in the summer. The male wasp bites through the wall of a gall containing a female wasp and mates with her. On leaving the fig to search for a suitable place to lay eggs, the female wasp becomes covered with pollen from the male flowers near the small exit hole, at the tip of the fig. The second type of syconium, the true fig, bears only long-styled fertile female flowers. The female wasp, searching for egg-laying sites in summer, enters these figs and pollinates the flowers inside but does not lay eggs because the

styles are too long to suit the egg-depositing anatomy of the insect. The third type of syconium, produced in the autumn, contains only short-styled gall flowers. The eggs that are laid develop in the gall flowers and produce the next year's fig wasps.

Symbiotic relationships. The close interdependence of figs and the fig wasps can be considered a form of symbiosis, or living together for mutual benefit. The fig is pollinated by the fig wasp and in return provides specialized flowers suitable for the wasp's reproductive requirements. Another kind of symbiosis, involving ants, occurs in several species of the family Urticaceae, including the trumpet tree (*Cecropia peltata*) of tropical America. This plant has hollow stems that are inhabited by ants of the genus *Azteca*, which rush out and attack any intruder that disturbs the plant. They provide protection against leaf-cutter ants, and the plant in turn provides not only living space for the ants but also special food bodies for them on the lower side of the swollen bases of the leafstalks. As the food bodies are eaten, new ones grow to replace them. The plant also has special thin areas in the walls along the stems that make it possible for fertile female ants to burrow inside to lay their eggs. Some other *Cecropia* species, which do not harbour *Azteca* ants, are protected from leaf-cutter ants by a thick coating of wax on the stem that prevents the leaf cutters from climbing up.

FORM AND FUNCTION

Vegetative characteristics. *Stinging hairs.* About 12 genera in the family Urticaceae have stinging hairs. The principal ones include *Urtica* (50 species), *Urera* (35 species), and *Laportea* (about 25 species). In addition, *Girardinia*, *Obetia*, *Gyrotaenia*, *Parsana*, and *Hesperocnide*, all with fewer than 10 species each, have stinging hairs. In some species the hairs are found on all plant parts, but in others they may be restricted to the upper surfaces of leaves, to flowers, to fruits, or to the lower surfaces of leaves along the large veins.

The stinging hairs are hollow, glandular plant hairs tipped by a sharp-pointed, glasslike terminal cell that penetrates the skin at the lightest touch, like a hypodermic needle. The brittle tip breaks off in the skin, releasing an irritant liquid into the wound. The composition of this stinging fluid is not known in all cases, but in the wood nettle of eastern North America (*Laportea canadensis*) it is formic acid, and in the tree nettle of Australia (*L. photiniphylla*) it is a mixture of toxic substances, including 5-hydroxytryptamine.

Stinging nettles, such as *Urtica dioica* and the common nettle (*U. gracilis*), which are among the more widespread stinging species in temperate regions, usually produce an initial burning sensation that may disappear within an hour or may linger as an itch for hours or even days. The tree nettle of Australia, however, produces a sting so intense that the victim may dash about wildly, screaming in pain. Deaths from the tree nettle have been reported in a few cases; irritation can last for months. *Urtica holosericea*, in the western United States, has been reported to have a sting powerful enough to kill a horse.

Although the stinging hairs cause rashes and irritation when the plant is touched, some stinging species can be used for food. The young leaves of many nettle species, for example, are often boiled and eaten like spinach. The stinging juice is not poisonous, and boiling renders the hairs incapable of penetrating the skin as well. Wilted plants likewise have a greatly reduced capability of stinging because the hairs lack the rigidity needed to penetrate the skin.

In addition to the stinging members of the nettle family, a few other plants in the order produce skin irritations. Contact with the fruits or leaves of the osage orange, for example, produces dermatitis in susceptible persons.

Cystoliths. Another feature characteristic of the nettle family and many members of the mulberry family is the presence of cystoliths, deposits of calcium carbonate inside enlarged epidermal (surface) cells. They are visible as dots or variously shaped marks, especially in pressed, dried leaves. Their function in the plant is unknown.

Calcium carbonate deposits occur in another form in

Chlorophora excelsa (Moraceae), source of the iroko wood of commerce, which is very durable and practically immune to termites and wood-rotting fungi. About 3 percent of the trees carry streaks or lumps of calcium carbonate in the wood. These are called iroko stones and are hard enough to dull woodworking tools.

Fruit characteristics. The fruits of many members of the family Moraceae are multiple fruits; i.e., they are formed by the fusion of several different flowers. In the mulberry this results in a small fleshy fruit that resembles a blackberry but is actually the enlarged floral axis of a whole cluster (inflorescence) of flowers, instead of the developed carpels (ovule-bearing structures) of a single flower, as in the blackberry. Among the most extreme examples of this type of fruit are the breadfruit, breadnut, jackfruit, fig, and osage orange.

The jackfruit is unusual in still another way: it is produced along the main trunk of the tree, a condition known as caulicarp (cauliflory when considering the flowers). Such large fruits as the jackfruit could not be supported on the branches. The fig is a unique type of multiple fruit (syconium). Each "seed" in a fig is actually an individual fruit; the fig itself is the fleshy stem tip developed into a fruitlike structure.

In the family Ulmaceae the fruits are of two main types. Elms have dry, membranous, windblown fruit called samaras. In temperate regions, these fruits often mature early in the spring, before the leaves have fully expanded. The second type of fruit, found in *Celtis* and others, is a fleshy drupe, or stone-pitted fruit. These fruits are often eaten by birds and other animals, and the seeds are thereby spread.

EVOLUTION

Fossil record. One of the interesting observations to come out of the study of fossils of the earliest flowering plants, which appeared during the Cretaceous Period (from 65,000,000 to 136,000,000 years ago), is that most of them belong to plant genera living today and represent both primitive and highly evolved forms. Among the latter are many fossil members of the order Urticales, especially of the family Moraceae. It may be inferred from this that the highly evolved groups, at least, had experienced a long period of evolution and development before the great increase in flowering plants took place. So far none of this prior evolutionary history has been found in the fossil record. The earliest reliable fossils already show the differentiation of flowering plants into many distinct families.

Fossil leaves, fruits, and wood from the family Moraceae (including *Artocarpus*, *Morus*, *Artocarpidium*, *Ficus*, *Ficophyllum*, and *Ficoxylon*) are known from the Upper Cretaceous and show this group to be already firmly evolved into present-day forms. On the other hand, many fossils, particularly of leaves, have been called fig fossils with little basis for the designation except the resemblance of outline, and some records for this family may eventually be reassigned to other groups. The genus *Morus*, however, is well-known in the London Clay flora, a fossil deposit consisting mainly of fruits and seeds of some 500 species that lived during the Eocene Epoch (38,000,000 to 54,000,000 years ago). The late Eocene amber deposits in the Baltic region contain examples of plants belonging to the families Ulmaceae and Urticaceae. The family Moraceae is among the largest of about 18 families represented in the Wilcox flora of the early Eocene, a fossil deposit known from about 130 different localities in North America. Numerous fossils of the family Ulmaceae (including *Ulmus*, *Zelkova*, *Celtis*, and *Pteroceltis*) have been found in regions that suggest that these genera were formerly much more widely distributed than they are now. The genus *Ulmus*, for example, occurs in Eocene-age deposits in Spitsbergen and on the west coast of Greenland among other fossils that indicate a former cool temperate climate for these regions. The family Urticaceae is represented by flowers (*Forskohleanthium*) and fruits (*Urticarpum*) embedded in amber, both from the lower Eocene; fossil fragments of the genus *Urtica* date to the Pliocene (2,500,000 to 7,000,000 years ago).

Phylogeny. The fossil record has so far served mostly to show the great antiquity of several of the groups that

belong to the order Urticales, but it has not revealed links with any ancestral groups. Nevertheless, some hints of the course of evolution for the order (and within the order) are reflected in the form, structure, and growth of living members. At first sight the predominantly wind-pollinated families Ulmaceae, Cannabaceae, and Urticaceae seem primitive, especially the elm family. The small, relatively simple, mostly unisexual flowers are considered to be derived from a more complex condition rather than a primitive feature, however. This concept is supported by the presence of vestigial organs of the opposite sex in many functionally male or female flowers, indicative of a former bisexuality. Many members of the families Moraceae and Urticaceae show this feature. Based on these and other lines of evidence, the order Urticales is thought to be derived from the witch hazel order (Hamamelidales), or at least from some ancestor of that group.

Within the Urticales, the family Ulmaceae is considered to be the most primitive. The families Moraceae, Cannabaceae, and Urticaceae are more highly evolved. The Urticaceae is considered advanced over the Moraceae mainly because of its herbaceous growth habit compared to the predominantly woody habit of the mulberry family. The two families, however, are very closely related and are joined by a series of genera that are distinctly transitional. These genera (*Cecropia*, *Coussapoa*, *Poikilospermum*, *Musanga*, *Myrianthus*, and *Pourouma*) have sometimes been assigned to the Moraceae, sometimes to the Urticaceae. In the classification presented above they are considered as belonging to the Urticaceae.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The order Urticales is distinguished from other orders mainly by floral characteristics. The presence of mostly unisexual (separate male and female) flowers that are wind-pollinated and produce a single seed each is a unifying feature. In the female flowers the ovary is composed of two carpels (ovule-bearing structures), but there is only one ovary chamber (locule), containing a single ovule. The male flowers have only a few stamens (pollen-bearing structures). All flowers are characteristic in having few flower parts; all lack petals.

Within the order, the family Ulmaceae is characterized by its woody habit, unequal-sided leaves, paired stipules (basal appendages to the leaves), early-appearing flowers with stamens erect in the bud, and dry, winged fruits (samaras) or fleshy, stony-pitted fruits (drupe). The family Moraceae is distinguished by its woody habit, milky sap, multiple fruits, and stipules that fall early leaving a characteristic inflated scar. The family Cannabaceae is composed of aromatic herbs with watery sap and distinctive flowers. Features characteristic of the family Urticaceae include its herbaceous or softly woody habit, stinging hairs, cystoliths, fibrous stems, and inflexed stamens that release their pollen explosively.

Alternate systems of classification. The classification system presented in this article is widely recognized in its broader aspects, but viewpoints concerning the details differ among authorities; for example, the inclusion in the order Urticales of the four families recognized here is a feature of practically all systems. In some, however, particularly in older systems, the two genera here recognized as the family Cannabaceae (*Cannabis* and *Humulus*) are merged into the family Moraceae. There is also considerable difference of opinion as to which family—Moraceae or Urticaceae—should contain the genera *Cecropia*, *Coussapoa*, *Poikilospermum*, *Musanga*, *Myrianthus*, and *Pourouma*. These genera have characteristics intermediate between the two families.

Three small families have sometimes been included in the order Urticales by some authorities, singly or in various combinations. These are the Rhoipteleaceae (represented only by *Rhoiptelea chiliantha* found in southwest Asia), the Barbeyaceae (represented only by *Barbeya oleoides*, of northeast Africa and the Arabian Peninsula), and the Eucommiaceae (represented only by *Eucommia ulmoides*, found in China). The last two groups are sufficiently distinct, however, that they have been recognized as separate orders (Barbeyales and Eucommiales) in some of the most

Recogni-
tion
features
for the
families

Mulberry
fossils

recent taxonomic systems, as is done here. The Rhoipteleaceae are generally believed to belong more properly in the walnut order (Juglandales).

Opinions are divided on the numbers of genera and species in each family, particularly the two largest. Estimates for the Moraceae range from about 1,000 to 2,300 species and from about 50 to 75 genera. The genus *Ficus* alone has been considered to contain anywhere from 800 to more than 2,000 species. Estimates for the Urticaceae range from 500 to 1,900 species. These differences reflect, in part, the growing numbers of newly described species and, in part, differences of opinion concerning the placement of genera in particular families and the validity of recognizing some genera and species at all. (F.K.A.)

Fagales (beech order)

The Fagales, or the beech order, consists of the family Fagaceae, 10 genera that comprise about 1,000 species. The family, and hence the order, is made up exclusively of shrubs and trees, often forest-forming trees that lend character and beauty to the landscape over great areas. Because they supply timber and many other economically valuable products, the Fagales are of considerable importance to man.

GENERAL FEATURES

Size range

While some species are low shrubs, the majority are tree-like, often reaching mighty proportions. *Lithocarpus cyclophorus*, for example, attains a height of 150 feet (45 metres) and is held to be the largest tree of the Malay Peninsula. The stem girth of the English oak, *Quercus robur*, may reach 52 feet (16 metres), that of *Castanea sativa*, 90 feet (27 metres). The tropical-subtropical members of the order (*Lithocarpus*, *Castanopsis*, *Cyclobalanopsis*) are generally evergreen, with leathery-textured, usually smooth-margined leaves of uniform appearance. Outside the tropics the species as a rule are deciduous; that is, their leaves fall during unfavourable seasons. The leaves are usually lobed or toothed in different degrees around the margins. Many species of *Nothofagus*, usually known as southern beeches, that grow in the southern temperate zone have small, serrate or crenate (having rounded teeth) leaves that bear some similarity to birch leaves, often causing the popular Australian name "birches" to be applied to these trees.

Distribution and abundance. The beech order is mainly distributed over the Northern Hemisphere. Four of the most important distribution centres may be distinguished. One of these is situated in Southeast Asia: the Indochinese peninsula and the East Indian archipelago (islands of Indonesia). Here there is a centre for the genera *Lithocarpus*, *Cyclobalanopsis*, and *Castanopsis*, while the small genus *Trigonobalanus* is restricted to this area and a few oak (*Quercus*) species occur in the northern part. A second important distribution area, adjoining the first, is the East Asian one. The genera *Cyclobalanopsis*, *Castanopsis*, and *Lithocarpus* also occur here, though the species number decreases toward the north, while the oak species are here more numerous than in southeastern Asia and, moreover, some chestnut (*Castanea*) and beech (*Fagus*) species are added. A third distribution centre, though with a smaller species number, exists in the Mediterranean region together with Asia Minor and Caucasus. In this area there is especially a centre for section *Cerris* of the oak genus *Quercus*. A fourth and important centre is found in the eastern United States and Mexico, where the genus *Quercus* is richly represented.

In addition to these more important distribution centres, the order also occurs, though to a smaller extent, in other areas. In the western coast provinces of North America a number of oak species, one *Lithocarpus* species, and the endemic (restricted to that area) genus *Chrysolepis* are found. In middle and north Europe, the genera *Fagus*, *Quercus*, and *Castanea* are represented; only a few species occur, but they are important in the vegetation through their widespread occurrence. In the Southern Hemisphere there are isolated distribution areas for the genus *Nothofagus* (southern beeches) in western South

America, Australia, and New Zealand; and in the tropical region, the genus *Trisyngyne* is found on New Guinea and New Caledonia.

Economic importance. Numerous species of Fagales are of importance to man through supplying timber for different purposes. The lumber of European and American oaks (*Quercus*) is used for construction and carpentry, including shipbuilding; in America especially, the "white oak lumber," obtained from *Quercus alba*, *Q. macrocarpa*, *Q. prinus*, and others, is much appreciated and used for building purposes. The beeches (*Fagus*) and chestnuts (*Castanea*) of both continents are used for carpentry, piles, railroad ties, etc., though the chestnut blight has reduced the importance of the American chestnut (*C. dentata*). In East Asia, the oaks *Quercus crispula* and *Q. glandulifera*, among others, are used for carpentry and construction, as are the beeches (*Fagus sieboldii* and *F. chinensis*), the chestnuts (*Castanea crenata* and *C. henryi*), and *Cyclobalanopsis glauca*. Among the numerous species used in Southeast Asia are *Lithocarpus spicatus*, *L. platycarpus*, *L. pachyphyllus*, *L. costatus*, *L. cyclophorus*, *Castanopsis argentea*, and *C. indica*, the two latter being used for building purposes. In the Southern Hemisphere, the *Nothofagus* species are much used for the same purposes as the beeches of the Northern Hemisphere.

Among other products obtained from members of the beech order is cork, especially supplied by *Quercus suber*, the cork oak, occurring naturally and cultivated in the western Mediterranean countries. Cork, however, is also obtained from other oak species, notably *Q. occidentalis*, *Q. pseudosuber*, *Q. fontanesii*, and in China from *Q. variabilis*. The bark of several *Quercus* species and of *Lithocarpus densiflorus*, the Californian "tanbark oak," is used for tanning, and the "gall nuts" and cupules of some species are also sources of tannin. The "aleppo galls" of *Quercus infectoria* and "valonia," the cupules of *Q. aegilops*, are well known as sources of tannin. In older times especially, other chemical products were obtained; for example, from *Fagus* species methyl alcohol, acetic acid, creosote, guaiacol, and tar were extracted, and from *Quercus robur*, acetic acid. Oak manna was obtained from *Q. cerris*. Several species in the order have been used for dyeing; e.g., *Quercus velutina* in North America, *Q. incana* in India, and *Castanea crenata* in East Asia. The Mediterranean *Quercus coccifera* is host plant for a shieldlouse that supplies a pigment reminiscent of the red cochineal dye.

Many species of Fagales have edible fruits that have been used by man. The European chestnut, *Castanea sativa*, has been of special importance and has been cultivated to a great extent, as have some of the oak species, such as *Quercus ilex*, in the Mediterranean. In North America, the chestnut *Castanea dentata* and the chinquapin, *C. pumila*, have been used and also have been offered for sale in the local markets. Acorns of *Quercus alba*, *Q. prinus*, *Q. lobata*, of *Fagus grandifolia* and *Chrysolepis sempervirens* and others have been used for food, especially by the American Indians. In East Asia, the chestnuts *Castanea crenata* and *C. mollissima* are under much cultivation and their nuts are consumed to a considerable extent in Japan and China; and the nuts of several *Lithocarpus* and *Castanopsis* species have found use in their home countries, for instance, *Lithocarpus edulis* in Japan; *Castanopsis delavayi* in China; *Lithocarpus garrettianus* and *Castanopsis boisi*, *C. poilanei*, *C. piriformis* in Indochina; *C. hystrix* and *C. ferox* in India; and *C. schlenkeriae* in New Guinea.

Beechnuts and oak acorns have also been of importance as food for domestic animals, and in South America even the wood of *Nothofagus* species is used as cattle food, after decomposition by bacteria and fungi. Some oak species of East Asia are of indirect importance for human nourishment, the logs being used for the cultivation of the edible shiitake mushroom, *Lentinus edodes*, especially in Japan, and for other fungi. In Tierra del Fuego another edible fungus, *Cyttaria darwinii*, of great importance to the inhabitants, occurs on *Nothofagus* species.

Some species in the order are used for silkworm culture in Asia, for example, *Quercus aliena* and *Q. faberi* in

Edible
fruits

China; *Cyclobalanopsis glauca*, *Quercus acutissima*, and *Castanea crenata* in Japan; and *Quercus incana* and *Q. semecarpifolia* in India.

NATURAL HISTORY

Life cycle. The time from seed germination to flowering in the mature trees of the beech order is usually long, about 50 to 60 years for the English oak, and 40 to 50 for the European beech, if the trees are free-growing. As in the gymnosperms, the time between pollination and fertilization is also long and, in some, the fruit requires two years' time to ripen, as in several species of *Lithocarpus* and *Quercus*. The flowers develop in the deciduous species after the leaves appear, male and female flowers as a rule on the same tree (the monoecious condition); occasionally entirely male or female trees occur (the dioecious condition). In the *Fagus* group especially, the flowering is often periodical, with intervals of up to seven years between the "acorn years." In some evergreen species the leaves persist for several years; in others they live only a year. Individuals of some species attain great age; those of *Castanea sativa*, for example, may live more than 1,000 years, and those of *Quercus robur* may, under favourable conditions, attain a similar age. A tree of this species in Germany is reported to be about 1,500 years old. The common beech, however, will rarely reach more than 300 years in age.

Ecology. In the wide distribution area of the Fagales order, the ecological conditions are, of course, quite varied. In Southeast Asia, including the adjacent islands, favourable conditions are found especially on the mountain slopes with high humidity and frequent cloud cover, the temperature being tropical to subtropical. In East Asia and the northern part of the Indochinese peninsula, as well as in the Himalayas, the conditions are somewhat different. The temperature is not as high, and the precipitation and air humidity are varying, very high on the southern slopes of the Himalayas but low in some interior continental areas.

The special conditions in the Mediterranean area, summer dryness and winter rains, which also are found in part of western North America, give a dry-habitat character to members of the Fagales order occurring there, including such features as small leathery leaves that are spiny or hairy.

In the distribution areas of middle and north Europe and eastern North America, where temperate climate and rather great temperature variations occur, the Fagales, as a rule, are deciduous. While in Europe large forests are formed by a single species, in North America several species occur together mixed with other trees, and some species form low shrubberies on poor sand plains (*Quercus ilicifolia* and *Q. prinoides*). In Mexico, the Fagales, especially the oak genus *Quercus*, find favourable conditions for growth on the eastern slopes of the Mexican highland. Humidity and warmth there are high, and some *Quercus* species develop gigantic leaves. In the interior the conditions are dry and warm, and the species are adapted to existence where water supply is limited.

The distribution areas of the genus *Nothofagus* in the Southern Hemisphere are not only geographically but also ecologically widely separated from the others. The climatic character is oceanic, with small annual temperature change and great humidity. In parts of the South American district the mean annual temperature is very low and scarcely enough for cereal production; nevertheless, several *Nothofagus* species occur there and may reach up to the snow line.

FORM AND FUNCTION

Vegetative characters. Among the distinguishing characteristics of the Fagales order are the simple leaves, in the tropical species as a rule with entire unbroken margins and leathery texture, and in the temperate species often with lobed or toothed margins. Stipules, small leaflike appendages at the bases of leaf stalks, occur but fall soon after development. The leaves are, as a rule, alternate, either evenly distributed around the stem in a spiral or arranged in two rows. In the genera *Lithocarpus*, *Castanopsis*, and *Castanea* both possibilities occur in differ-

ent species, but in *Quercus* and *Cyclobalanopsis* only the evenly distributed spiral form is seen. In *Fagus*, on the other hand, the leaves are arranged exclusively in two rows along the branches, the rows being somewhat nearer to each other on the underside of the shoots. The same arrangement is found in most *Nothofagus* species, but the spiral distribution also occurs. An unusual arrangement is found in one species of *Trigonobalanus*, in which the leaves are in whorls on older shoots.

Flower and fruit characters. The flowers of the Fagales order are unisexual, though often with rudiments of the other sex present, and are usually arranged in dichasia (linear clusters branching into two axes) with three to seven flowers, which in their turn are collected in spikelike flower clusters, usually called catkins. With respect to the distribution of male and female flowers, three types of inflorescences (flower clusters) may be discerned: (1) all catkins are male in the upper, female in the lower part (some *Lithocarpus* species); (2) the upper catkins bear both male and female flowers, the lower being entirely male (*Castanea* and *Chrysolepis*); and (3) the upper catkins are wholly female, the lower male (*Quercus*, *Cyclobalanopsis*, *Castanopsis*). The genera *Fagus*, *Nothofagus*, and *Trisyn-gyne* differ from the usual condition in that the dichasia are not arranged in catkins but occur separately in the leaf axils, the points where leaf stalks join the stem.

Drawing by M. Pahl based on H. Hjelmqvist, "Studies on the floral morphology and phylogeny of the Amentiferae," *Botanical Notiser* suppl. 2:1 (1948)

Structure and diversity of forms within the Fagales order.

An important distinguishing feature of the Fagaceae family (and hence the Fagales order) is the occurrence of a so-called cupule, a structure so characteristic that it provided the origin of the old family name Cupuliferae for the present Fagaceae family. This cupule is a structure that surrounds the fruit (acorn, nut, etc.) as a cup and on the outer side bears modified leaf structures developed as scales, spines, or thin plates. It varies considerably from genus to genus. In the genus *Lithocarpus* each fruit is included in a cupule; the different cupules of a dichasium may, however, be more or less grown together. Similar cupules are found in the genera *Cyclobalanopsis* and *Quercus*, whose flowers, however, are solitary. In *Castanopsis* and *Castanea* the whole female dichasium is surrounded by a common cupule, which may burst at fruit-ripening. In *Chrysolepis* the cupule is a compound structure with separating walls between the fruits. In the *Fagus* group the cupule is divided into two to nine lobes; in some species of *Trisyn-gyne* it is much reduced.

The individual flowers of the Fagales order are simple and inconspicuous. In some genera, the perianth (the

The cupule

Geo-graphic isolation of the southern beech

combined set of petals and sepals, or both, in a flower) is, in both the male and female flowers, made up of six perianth leaves, which are comparatively well developed. In others, the perianth leaves of the male flowers are joined together, irregular in shape, and various in number, and the female flowers may also have a somewhat irregular perianth. Fusion of the flowers and reduction of the perianth is discernible in a few genera. In *Nothofagus* three diminutive perianth lobes may exist in the female flower, and in *Trisyngyne* the male perianth is often cuplike without discernible lobes.

The stamens (male flower parts) are in most genera about 12 in number, partly opposite the lobes of the perianth, partly alternating with them. In *Quercus* the number is reduced, often to five, but in some *Nothofagus* species, on the other hand, it is increased and may be 30 to 40. The anthers (pollen-bearing parts of the stamens) are in *Lithocarpus*, *Castanopsis*, *Castanea*, and *Chrysolepis* small, about as broad as high, attached at the middle, and movable. In *Fagus*, *Nothofagus*, and *Trisyngyne* they are oblong, attached at the base, immobile, and also much bigger, especially in *Nothofagus*. The different development of the stamens is possibly connected with the pollination method. Those genera that have stamens of *Lithocarpus* type are mainly insect-pollinated, while the others are wind-pollinated.

As with the stamens, the pistil (female flower part) is also of different development in different genera, and the pistil structure is probably connected with the pollination method. The wind-pollinated genera have a more or less enlarged stigma (sticky pollen-receiving area) surface, which, of course, provides a greater chance to catch the pollen suspended in the air.

Ovary (part of the female pistil) and fruit are rounded in shape in the *Quercus* and *Castanea* groups, except for *Chrysolepis*. Sometimes the nuts, however, are somewhat flattened through pressure of adjacent fruits, and in some *Lithocarpus* species, as *L. lindleyanus*, the fruits are weakly triangular. In *Chrysolepis* this triangular shape is more pronounced, especially in younger stages, and still more in *Trigonobalanus*, of which one species even has three-winged fruits. The nuts of *Fagus* and the fruits of *Nothofagus* are also decidedly triangular, while the dimerous (structure based on twos) top flower of *Nothofagus* and all female flowers of *Trisyngyne* develop flattened and more or less two-winged nuts, somewhat reminiscent of *Alnus* (alder) or *Betula* (birch) nuts. The ovules (developing seeds) are generally six in number, two in each of the chambers of the ovary; only one of them develops, however, into a seed.

EVOLUTION

Fossil record. Fossil Fagales show the great age of the order. *Quercus*, *Fagus*, and *Lithocarpus* are present in finds from Eurasia and North America, belonging to about the middle of the Cretaceous Period (about 100,000,000 years ago), as is the fossil genus *Dryophyllum*, which was apparently related to *Castanea*. In the Southern Hemisphere the genus *Nothofagus* also appears in the Cretaceous. In the Tertiary Period (25,000,000 to 65,000,000 years ago) *Castanopsis* and *Castanea* are reported from different countries, and the order on the whole shows a rich development. Fossil pollen of *Nothofagus* from the Cretaceous of New Zealand is known, and in Europe pollen from younger Cretaceous deposits is known that shows great similarity to *Trigonobalanus*.

Phylogeny. Since several genera thus appear in the same early period, the fossil finds give scarcely any guidance for a sketch of the evolution in the order. The problems of evolution and relationships are thus better approached through morphology (structure), especially the organization of the cupule. The inflorescence (flower cluster) type, the different style, stigma, and anther types (female and male structures), and other considerations are also important features determining relationships.

CLASSIFICATION AND TAXONOMIC STATUS

The family Fagaceae (hence, the order Fagales) has attracted the interest of many systematists (botanists who

study classification of plants), and opinions have been considerably divergent about the subdivision of the group. Sometimes a very great number of genera has been proposed, the sections of *Lithocarpus* and *Quercus* being given the rank of genera in these treatments. In other cases some of the genera have been united with each other, for example, *Cyclobalanopsis* has been joined with *Quercus*, and *Trisyngyne* with *Nothofagus*. The morphological differences between *Quercus* and *Cyclobalanopsis* are not very great, but the two groups are clearly distinct from each other and there are no transitional forms between them (as may be found between *Cyclobalanopsis* and *Lithocarpus*). They thus apparently belong to two different evolutionary lines, and on this account should be kept apart. Similar conditions are met with in the other case: *Nothofagus* and *Trisyngyne* apparently represent different evolutionary lines, which speaks in favour of the view that they are separate genera.

Among the groups related to the Fagales order, the order Betulales (birches) is the nearest. The two orders have, as a matter of fact, often been united into one. New genera have been added to the family from time to time. The American species formerly placed in the genus *Castanopsis* were in 1948 recognized as a distinct genus, *Chrysolepis*, and, in the 1940s, a great number of new species were discovered by an expedition to New Guinea. These, like some earlier known species from New Caledonia, are placed in the genus *Nothofagus* by some authorities but by others are regarded as a separate genus, *Trisyngyne*. In 1961 a new species was found in Borneo that, together with an earlier known but incompletely described species from Indochina, forms the new genus *Trigonobalanus*. (H.Hj.)

Betulales (birch order)

The birches and their close allies—the alders, the ironwoods, the hornbeams, and the hazelnuts—are a group of trees and shrubs that constitute an order of flowering plants, the Betulales or birch order. The group is predominantly of the north temperate and Arctic regions and long ago became deeply embedded in the folklore and ancient forest industries of primitive man. The tree birches are today major sources of cabinet woods and also provide handsome and graceful material for the landscape gardener. Ecologically, the alders especially have been found to be important soil-builders (“pioneers”) because of the nitrogen-fixing bacteria in their root nodules; and all of the shrubby members of the order provide important cover for wildlife. Scientifically, as one of the members of the catkin-bearing group of flowering plants (Amentiferae), they have shared centre stage with the oaks, the walnuts, the willows, and others in stormy debates concerning which of the flowering plants are in reality primitive.

GENERAL FEATURES

Size range and distribution. The birches range from trees to sprawling shrubs; the canoe or paper birch exceptionally reaches a height of 120 feet (37 metres) and a diameter of 3 feet (1 metre) on the northwest coasts of North America. The North American yellow birch and black birch, *Betula maximowicziana* of Japan, and *Betula albo-sinensis* of central and western China achieve heights of 90 to 100 feet (27 to 30 metres). Most of the remaining tree birches are modest in height, such as the gray or old-field birch of the eastern United States, whose clustered stems seldom become much over 30 feet (9 metres) high. Unusual flexibility in adapting to its environment is shown by the largest of the birches, the canoe birch, which assumes a depressed and shrubby form when it grows in exposed habitats at its northernmost limits near the tree line or at high altitudes. Among the dwarf birches, *Betula pumila* may grow as much as 15 feet (5 metres) high; other species that extend into the Arctic achieve a height of 5 or 6 feet (1.5 or 2 metres) in the lee of a protective rock, but in the open they creep on the surface of the tundra. One of these dwarf birches, *Betula michauxii*, is confined to southern Labrador; its slender twigs rise but a foot (30 centimetres) or so out of the shallow ponds in which it grows.

Tree
heights

The alders are commonly shrubs or small trees of medium size, but the black alder of Europe and northern Africa (*Alnus glutinosa*), the tree alders of western North America (*Alnus rubra* and *A. rhombifolia*), and *Alnus hirsuta* of northeastern Asia and northern Japan, are trees of up to 50 to 75 feet (15 to 23 metres) in height and 2 feet (0.6 metre) in diameter.

The various species of hornbeams and hop-hornbeams are small trees, some of which may be 50 to 60 feet (15 to 18 metres) tall but commonly reach a height of only 10 to 15 feet (3 to 5 metres). The very local genus *Ostryopsis*, with two species in China, is a small shrub up to 10 feet (3 metres) in height.

Among the hazels, a strictly tree-habit characterizes the Turkish hazel, which may reach a height of 80 feet (24 metres), while its close relative, the Chinese hazel of central and western China, is reported to grow over 120 feet (37 metres) high. The great majority of hazels, however, are modest shrubs, often forming coppices.

The members of this order are found chiefly in cool to cool-temperate areas of the Northern Hemisphere; only in the Americas do they extend along the mountains into the Southern Hemisphere. In the mountains of North America some species occur as endemics. Individual species are usually prominent members of the plant communities of which they form a part, but seldom occur in pure stands.

Most of the genera, with the exception of *Ostryopsis*, are widespread in their distribution today. Thus in *Betula* (birch), the white birches and dwarf birches are circumpolar and very nearly coincide in their areas, the dwarf birches extending farther into the Arctic. They now occupy most areas that were glaciated recently (until about 10,000 years ago). By contrast, other members of the genus are more disrupted in their distribution, tending to be centred on the geologically ancient areas of eastern North America and of eastern Asia, with extensions into the Himalayan and Caucasus regions. Some are even more limited in distribution, occurring only in northern China, Korea, and Japan.

In the genus *Alnus* (alders), many species occur generally throughout the range of the Betulales, except for the Himalayan region, where a small and distinctive group of species occurs. A few other species occur in Japan, across cool temperate North America, and in Europe. One small group of closely related species is limited to Szechwan in southwestern China.

Ostrya (hop-hornbeam) and a few species of the genus *Carpinus* (hornbeam or blue beech) share much the same areas, both groups occurring in central eastern North America, in the southern European region exclusive of the Iberian Peninsula, and in the southeastern portion of Asia. One small group of species of *Carpinus* is limited to temperate East Asia. *Carpinus*, however, has a somewhat wider range than does *Ostrya*, not only in southern Europe and southeastern Asia but also in the highlands of Central America, from which *Ostrya* is absent. The two genera are notably absent from recently glaciated regions except for limited incursions into the southern fringes of this area.

The closely related genus *Ostryopsis* is restricted to portions of the Himalayan region.

Corylus is another genus whose species occur around the Northern Hemisphere, projecting well into formerly glaciated areas, although not as aggressively as do the members of the dwarf birches of the genus *Betula*.

Economic importance. The primary economic members of the family are the tree birches of the Northern Hemisphere, whose fine-grained wood provides lumber used for flooring, trim, furniture, and high-quality veneers. The uniform texture of the wood of these birches and of the tree alders makes it excellent for buttons, spools, wooden shoes, shoe lasts, and similar objects. The wood of hop-hornbeam (*Ostrya*) and hornbeam (*Carpinus*) is so difficult to split that it was used in pioneer days for such items as tool handles and levers. All genera are used for fuel and charcoal.

The bark of various genera and also the mature female strobili (seed-bearing structures) of some species of alder are sources of high-quality tanning materials and have been so used by Eskimos, American Indians, and others.

The papery bark of the white birches was formerly used as a substitute for writing paper in Kashmir and for many kinds of utensils and containers by the American Indians and Ainu people of Japan. In the Lapland region of Norway and Finland and other places it is used, when finely ground, as an emergency food. Some of the birches produce a sugary sap, which is fermented to produce birch beer; the twigs of the cherry birch of North America are steam-distilled to produce an essential oil (oil of wintergreen) mostly composed of methyl salicylate. Leaves of some of the birches in combination with alum produce a green dye, or with chalk produce a yellow colour. There is a multitude of other minor and very local uses, ranging from the hooked sticks derived from *Alnus nitida* (Himalayan black alder) used in primitive rope bridges to extracts of the bark of *Alnus rubra* (of the west coast of North America), which have been recommended for scrofulous conditions, indigestion, and dyspepsia.

Hazelnuts and filberts (*Corylus*) have been harvested for food since the days of primitive man. Hybrids and selections have been produced by horticulturists and are widely used for food and as a source of oils used in food, painting, perfumes, and soap manufacture.

NATURAL HISTORY

Life cycle. The life cycle of these plants is basically like that of other flowering plants, but there are certain peculiarities, largely in the reproductive portion. All members of the family have developed the abundant, small (approximately 0.03 millimetre diameter), nonsticky, unornamented pollen grains that are well adapted to wind pollination. It has been calculated that one hazel bush produces 600,000,000 pollen grains, shed from the flexible male catkins (pendent clusters of male flowers) before or at the time of the opening of the leaves in spring. The stiff female inflorescences (flower clusters) contain many fewer pistils (female structures), one hazel bush producing only about 1,300 in 200 female inflorescences. Only the styles and stigmatic surfaces of the pistils (the pistil consists of stigma, style, and ovary—the stigma and styles being adapted to receiving the pollen, the ovary enclosing the ovules, which are immature seeds) are mature at pollination time, usually late in May. In most flowering plants the three parts of the pistil develop simultaneously. The stigma is ready to receive the pollen when the style is ready to serve as the pathway for the pollen tube, which then makes its way to the future seeds (ovules) located within the ovary. But in the Betulales the ovules are not yet formed when pollination occurs. It takes weeks for the ovules to develop. In the meantime, the pollen tube, which in most plants grows directly to the ovule, remains inactive within the tissues of the style. After the development of the ovule, the pollen tube resumes growth. It approaches the embryo sac by a most unusual path, through the basal or chalazal portion of the ovule, instead of by way of the micropyle (a small opening at one end of the ovule). This is termed chalazogamy. Subsequent events, including double fertilization, the development of endosperm, embryo, seed, and fruit are typical of flowering plants.

Ecology. It is unusual for members of the order to occur in pure stands, although this has been reported for birch in the northern Soviet Union, the black alder in central Europe, and *Carpinus betulus* in the Rhine Valley. Ordinarily, the members of the order Betulales in Europe are associated with pine, spruce, or aspen, especially along waterways; they also occur on the moors of the north European plain. Some shrubby species form part of the understorey in oak and beech forests.

In North America, the forest tree species are the red alder of the Pacific Coast region; the paper birch, which occurs from Alaska to New England; and the black birch and the yellow birch, both of which grow in the northeastern United States and extend southward in the Appalachian Mountains. Of these, the red alder is ecologically important in its contribution of great quantities of nitrogen to the soil. This characteristic is shared by the other species of the genus, too. The red alder forms forests in association with Sitka spruce, western hemlock, white spruce, Douglas fir, and others, although it may occasionally form

Delayed fertilization of ovule

Geographic distributions

Products and uses of bark

pure stands in stream bottoms and moist flats. Its small fruits germinate freely on mineral soil, and it is often the first tree species to become established, growing so rapidly for the first 25 years that it overtakes its associates, but thereafter is overtaken by its chief competitor, the Douglas fir. The paper birch characteristically occurs in regions where summers are short and cool and the winters are cold and snowy. It tolerates a wide range of moisture conditions, but grows best in fresh, well-drained, sandy loams. It rarely occurs in pure stands, but grows with jack pine, or red or white spruce, and balsam fir, or with aspen. Despite the vast number of winged seeds produced per tree, the fragility of the newly germinated seedlings contributes to a low rate of survival. Paper birch generally lasts but a single generation in natural succession and is replaced by other, more shade-tolerant species. While the black birch is a minor species in many forest types, the yellow birch is a major member of several types of forest, being associated with sugar maple and beech, or hemlock, or balsam fir and pin cherry. Its small fruits germinate well after logging, fire, and windthrow but not in the thick litter of the undisturbed forest.

The river birch, the gray birch, the American hornbeam, and the hop-hornbeam are small trees in the forests of cool temperate North America, the two latter thriving as members of the understory in the rich woods of bottomlands, coves, and protected slopes. The gray birch grows in the dry soils of the northeastern United States and Canada, is an outstanding pioneer, and is notoriously intolerant of shade.

Most shrubby members of the order Betulales occur among the alders, birches, hazels, and both species of *Ostryopsis*. Temperate American species such as *Alnus crispa*, *A. incana*, *Betula glandulifera*, *Corylus americana*, and *C. cornuta* are often thicket-formers, especially when they occur at the margins of woods or in the open. The arctic and subarctic species, notably among the birches, occur as low shrubs in the barren lands or in boggy or damp heath-covered areas.

FORM AND FUNCTION

The members of this largely temperate to arctic group are characterized throughout by their woody habit, which carries with it the necessity for surviving the winter above the surface of the soil. Direct concomitants to this requirement are adaptations that meet the need to conserve water during the winter, a period when water is largely frozen and thus physiologically unavailable. Three major morphological adaptations contribute to the survival of

Betulales species in such habitats: (1) the shedding of the leaves; (2) the envelopment of the extremely delicate embryonic cells of the growing point and the immature leaves of the next season with a system of tough, waterproof bud scales; and (3) the development of bark initiated by secondary changes under the original epidermis of the twigs and branchlets. In some species, continued growth of the woody portion of the stem is accompanied by the production of bark that is formed in highly distinctive paperlike layers, although the functional superiority of this peculiar type of bark is unknown.

The characteristic cylindrical male catkins, which are so prominent in most members of the family throughout the winter, are precocious inflorescences composed of a multitude of male flowers whose anthers require but a few days of spring warmth to mature and shed their pollen. This precocity of the male flowers is matched by the production of functional styles and stigmas in the female flowers, which are in small stiff catkins or in somewhat modified buds. The large quantities of tiny pollen grains shed before or at the time of leaf expansion in the spring provide the maximal opportunity to utilize the wind as a pollinating agent.

The fruits are also characteristic structures. In those alders and birches with winged fruits that are freely carried about by the wind, the fruits are so small that there may be over 1,000,000 to the pound (e.g., as is the case in paper birch). The process of dissemination in the birches is facilitated by the shattering of the mature female catkin, which leaves only the catkin axis still attached to the parent tree in the fall. In the alders the female catkin, or ament, does not shatter; instead the scales become woody and remain attached to the ament axis, separating sufficiently so that the little fruits may shake out. Some of the alders have substituted corky ridges for the filmy wings, the corky ridges serving as floats that aid in dissemination by water. In *Ostrya*, *Carpinus*, and *Ostryopsis* the fruits are nutlets that are attached to leafy wings or envelopes. These are shed in later summer, leaving the bare female axis on the tree; dissemination is presumably by small rodents or birds. In the hazelnut, the individual fruit is quite large, in *Corylus americana* averaging about 500 per pound, or each one averaging about 3,000 times the weight of an average paper birch fruit. Dissemination of this eminently edible fruit is by animals.

tion

EVOLUTION

The evolutionary origins of the Betulales, as in the case of flowering plants generally, cannot as yet be determined from the available fossil evidence, even though there is an abundance of leaf impressions, pollens, and woods. These appear suddenly in the sedimentary rocks of the Mesozoic and Cenozoic Eras (i.e., in rocks as old as about 100,000,000 years), very similar in form to the leaves, pollens, and woods of contemporary genera. In the absence of direct evidence, it is necessary to fall back on information obtained from living forms. Based on living species, the order Betulales is considered by most authorities to be a moderately advanced rather than a primitive flowering plant group. In fact, in some respects, with its often nectarless, odourless, wind-pollinated, unisexual, and very tiny flowers, it may be considered advanced as compared with the larger, bisexual flowers of the presumably primitive flowering plants. The order Betulales has stamens differentiated into anther (pollen sac) and filament (stalk), the latter sometimes split all the way to the base of the filament to form two independent stamen halves. The ovary is inferior (i.e., it is enclosed within the basal portions of the other flower parts, which appear to arise at its upper end), composed of two fused carpels, has but one or two functional ovules, and is crowned with a well-defined style (the elongated upper portion of the ovary). The tiny flowers are clustered together and often are fused with adjacent leafy bracts to form very complex inflorescences. The fruits are indehiscent (i.e., they do not split open along definite lines) single-seeded nuts or nutlets. The order Betulales consists of woody trees or shrubs and in this respect is considered to be only moderately advanced. The leaves are pinnately veined (i.e., with a midrib and branch

Representative plants from the tribes (top right) Carpineae and (others) Betuleae of the birch order.

Evolutionary predecessors

veins in the fashion of a feather), rather than palmate, and are trilacunar (*i.e.*, having three leaf gaps); there are no vestiges of the ancient double origin of the vascular supply such as is found in the floral organs and cotyledons ("seed leaves") of some flowering plants. The puzzling phenomenon of chalazogamy is difficult to assess from the evolutionary point of view, but the presence of only a single integument in the ovule and the long delay between pollination and fertilization are taken as being advanced. In the structure of the wood there are some examples of somewhat advanced features, but other quite primitive wood characters also occur. All of the above information taken together can be interpreted to indicate that the Betulales probably originated before the Cretaceous Period (*i.e.*, before about 136,000,000 years ago). Other families of flowering plants that may have had a hypothetical ancestor similar to that of the Betulales are found in the Fagales (beech order). A common ancestor for the two orders is difficult to determine, but various proposals have been made, the two plant orders Hamamelidales and Sapindales being favoured. The students of wood anatomy favour the Hamamelid hypothesis. Whichever of these is the more tenable, both schools of thought unite in the rejection of the proposal that the birches, oaks, and other wind-pollinated orders represent ancestral types for the insect-pollinated families.

CLASSIFICATION AND TAXONOMIC STATUS

Until recently the Betulales, as presented herein, was treated as one of two families (Betulaceae and Fagaceae) in the order Fagales, but many authorities now regard each former family as a distinct order. Some workers have applied the family name Corylaceae to the group here called Betulaceae, and a few have even divided the group into three separate families—Carpinaceae, Corylaceae, and Betulaceae (corresponding for the most part to the tribes named above). The order as presented here, consisting of one family divided into three tribes, is the most recently accepted classification, however. (E.C.A.)

Juglandales (walnut order)

This is a small but important order of flowering plants consisting of two families, Rhoipteleaceae, with one genus and one species, and Juglandaceae, the walnut family, with nine genera and about 58 species. The walnuts are common large forest trees, primarily of temperate areas but also of subtropical regions, mostly of eastern North America, Central America, western South America, and eastern Asia. Walnuts, hickories, and pecans have been appreciated for many years for their edible oily nuts and their valuable wood, and they are now cultivated in large numbers in most temperate regions of the world.

Some of the trees, at least in the early days before extensive cutting for lumber, grew to be 150 feet or even 175 feet high (46–53 metres). The black walnut, *Juglans nigra*, has been reported to reach 6 feet (2 metres) in diameter. The smallest member of the order is the Texas walnut, *J. microcarpa*, a shrubby tree of Texas and New Mexico only 20 to 30 feet (6 to 9 metres) high.

GENERAL FEATURES

Distribution and abundance. The trees are common throughout the deciduous forests of the eastern United States and in parts of eastern Asia. In Mexico and Central America they are only locally common in certain canyons in the mountains or in fog belts on the slopes of the mountains. One species, *Oreomunnea (Engelhardia) pterocarpa*, occurs in only one valley in Costa Rica. The black walnut, *Juglans nigra*, yields such valuable timber that most of the native trees in the eastern United States have been cut down; hickories (*Carya* species), too, have been greatly reduced in numbers from timber cutting. The fall webworm attacks the hickory and walnut leaves in many regions, and insect damage also seems to be reducing the numbers of the butternut (*Juglans cinerea*) in the northeast. In the United States and in Europe many walnut and hickory trees have become naturalized in the regions where they have been introduced.

Vegetative, floral, and fruiting structures of the walnut order.

From (left) American Journal of Botany, vol. 25 (1938) and (female flower, butternut) American Journal of Botany, vol. 27 (1940)

Economic importance. The most important and best known member of the order is undoubtedly *Juglans regia*, the Persian walnut, also known as the English walnut and Circassian walnut. This was originally native to China, the Himalayan mountains, and from Iran to Greece. The wood and nuts have been used and prized for over 2,000 years; the Persian walnut is probably the most important of all nuts. Orchards and individual trees have been planted in warm temperate areas in many countries. The pecan, *Carya illinoensis*, native of the southeastern United States and northern Mexico, though not as valuable for its wood, is important for its valuable nuts; more and more orchards are being planted not only in the southern United States but also in other countries. The black walnut, *Juglans nigra*, native in the eastern United States, is well known for its valuable wood used in fine furniture and in cabinetwork, interior panelling, and gun stocks. The tree has become so scarce as a native tree that lumbermen have been known to try to buy yard trees from private homes. Even single trees can be extremely valuable because the wood can be extended considerably if used as thin veneers. Black walnut meats are very tasty and are used in candy and cakes, but the hard-shelled nuts are difficult to crack. Important primarily locally for their nuts are the American butternut, *Juglans cinerea*; Japanese butternut, *J. ailantifolia*; shagbark hickory, *Carya ovata*; and the big shellbark hickory, *C. laciniosa*. The wood of the hickories is extremely valuable because of its toughness, hardness, strength, and resistance to shock and is used for tool handles, wagon axles, and agricultural implements. The fresh husks of the butternut have been used as dye (khaki); the fruits of *Platycarya* have been used in China as a black dye for cotton cloth. The meats of the Persian walnut have been used for a drying oil. Several members of the temperate genera have been planted for dooryard trees or park trees. The Japanese butternut, a rapidly growing tree, is very hardy and is increasingly being planted in the United States; the nuts of the heartnut variety are easily cracked. The woods of the Asiatic members other than walnuts and hickories have local uses, but none of these trees has edible nuts. Leaves of various species have been thrown into the water for use as fish poisons by primitive people. A toxic substance, juglone, is given off by the leaves and roots of the black walnut and under certain conditions injures vegetable crops growing near the trees.

Natural history. The trees are adapted to wind polli-

Uses of the black walnut

nation; thus the stamens of staminate (male) flowers are very numerous and the stigmas (female flower structures) are enlarged to catch the pollen. Adaptations for seed dissemination have developed in two different directions. All members of the order have one-seeded fruits, and the seed remains inside the fruit for dissemination. Some genera have developed small fruits with wings for wind dispersal; others have developed large fruits, or nuts, for animal, primarily squirrel, dissemination. The seeds are typically viable for only one winter season in the northern regions and must not dry out; squirrels plant them underground, where it is moist. The nuts have an adherent husk for protection, but it is not known whether its principal function is to prevent drying out or injury in falling from the trees.

Many interesting natural hybrids are known among the hickories and the walnuts, but most of these are not used commercially. Some of the species of *Carya* (hickories) are diploids—i.e., they have the normal two sets of chromosomes per cell; some are tetraploids, with four sets of chromosomes in the nucleus of each cell.

Ecology. Many of the trees in the walnut order grow in the forests of the temperate regions; others grow in the mountains of the tropics; a few are subtropical or even grow near the seashore in the tropics, but none of them is strictly alpine. Most of the members have deciduous leaves, even in the tropics, but a few are evergreen. All appear to require moisture in the soil. A few grow in swamps, some in rich bottomlands; others prefer dry hill-sides, but only where rainfall is sufficient; a few grow in arid regions, but then only along streams in canyons or in the fog belts in the mountains. Members of the order rarely occur as solid forests but are mixed with other trees, especially oaks. An oak-hickory forest covers much of the deciduous forest of the eastern United States and part of eastern Mexico. *Engelhardia* is occasionally dominant in eastern Asia.

Distinguishing features. All members of the order are trees. The alternate or, rarely, opposite leaves are pinnately compound (i.e., each leaf is composed of several leaflets arranged along both sides of a central axis). The lower surfaces of the leaflets, and often the buds, flowers, and young fruits, are dotted with yellow or sometimes pale several-celled resinous scales. The inconspicuous flowers lack petals, and at least some occur in catkins or elongate slender spikes. Catkins are long and scaly, and usually drooping, spikes of unisexual flowers; that is, the male or staminate flowers occur in one catkin, the female or pistillate flowers in another. The ovary is two-celled or incompletely two-celled (that is, with one or two ovarian cavities or locules), but there is only one ovule. The one-seeded fruits are either winged nutlets or nuts, which are enclosed in husks. The seeds are oily and lack endosperm, a starchy nutrient tissue for the developing embryo.

EVOLUTION

Fossil record. There is no fossil record for the rare Chinese and Indochinese family, Rhoipteleaceae, but the walnut family, Juglandaceae, is abundantly represented in the fossil record in the form of leaves, nuts, and pollen grains. Members of this family appear first in the Upper Cretaceous Period (about 75,000,000 years ago), along with the earliest flowering plants, and by then had already evolved into essentially modern genera. This indicates a long previous history, which is also true of many other flowering plants. As early as the Eocene Epoch (about 50,000,000 years ago) the walnut family had spread over much of the Northern Hemisphere, with a much wider distribution than in modern times, and continued to spread through the rest of the Tertiary Period. Trees, therefore, occurred in regions where modern members are no longer native, such as Europe, North Africa, Alaska, Greenland, and the northwestern United States. Thus, in north central Oregon, in the Clarno Formation of the Eocene, of about 50,000,000 years ago, 75 recently discovered petrified fruits strongly resemble the living Arizona walnut, *Juglans major*. The species is, however, much more primitive than any modern one and apparently is intermediate between modern species. Furthermore, some of the genera now restricted to eastern Asia, such as *Pterocarya*, *Platycarya*,

and *Engelhardia*, once were to be found over much of the United States as well as Europe.

The range has since become much restricted, due to a general cooling of the climate in the north and to mountain building, resulting in present-day drier conditions. Furthermore, glacial activities in the Pleistocene Epoch of the last 2,000,000 years completely wiped out the trees in Europe, where they could not survive south of the glaciers because of the extensive east-to-west oriented European mountains that blocked their southward range extensions as the glaciers advanced. In the eastern United States and in China the mountains run largely from north to south, and during periods of approaching glaciation the trees were able to move south by means of seed dispersal along the valleys, encountering no physical barriers, and move back north after the glaciers had retreated.

Phylogeny. Juglandales is one order of a group formerly known as the Amentiferae. All members of this group are woody plants, with inconspicuous wind-pollinated flowers that lack petals and are arranged in elongated clusters known as catkins (aments) or spikes, such as are found in the willows, bayberries, birches, oaks, and beeches. The catkins superficially resemble the cones of the gymnosperms (pines, spruces, firs, etc.). Some botanists believe that all of these orders are related, are very primitive, and have evolved directly from ancient gymnosperms, perhaps even the seed ferns. This belief is due partly to the resemblance of catkins to cones and especially to the separation on the same tree of the male catkins from the female ones; partly to wind pollination and lack of petals as in the gymnosperms; and partly to the early appearance of the plants in the fossil record. While most botanists no longer believe that the Amentiferae group gave rise to more advanced flowering plants, some still believe that they are primitive and possibly had a different origin and line of evolution from the rest of the flowering plants. One European botanist, for example, has found features about the ovule of *Engelhardia*, a primitive genus of the family Juglandaceae, to be different from other angiosperms and highly reminiscent of certain fossil seed ferns.

Most present-day botanists, however, now believe that the families of the Amentiferae are not primitive but advanced, having had ancestors with conspicuous, insect-pollinated flowers that had petals and bisexual flowers (with male stamens and female pistil together in the same flower). Thus, the presence of an abortive female pistil in a few male flowers in various species of the Juglandaceae family indicates that the ancestral flowers were bisexual. In addition, the compound pistil with inferior ovary (i.e., located below the attachment point of the other flower parts) in several families of the Amentiferae group suggests an advanced rather than a primitive nature. The ancestral bisexual flowers have been reduced, the sexes separated, the petals lost, and the flowers crowded into catkins with specialization for wind pollination. Furthermore, the catkin and the cone are technically not equivalent; each flower of a catkin (for example, a staminate flower) is equivalent to a complete cone (for example, a staminate cone) in the gymnosperms. Thus, theoretically, a catkin could be considered equivalent to a large number of massed cones. There is also a difference of opinion among present-day botanists as to the nature and evolution of the primitive flower itself and as to the type of plant, and its reproductive structure, from which the angiosperms arose. Since truly primitive angiosperms have not yet been located in the decidedly incomplete fossil record, the presence of early fossils of the Amentiferae group does not necessarily prove them to be the most primitive of flowering plants.

The Juglandales order itself, in turn, has stood apart from the other orders of the Amentiferae group because of its compound leaves, and the Juglandaceae family itself lacks the stipules (small, leaflike appendages at the base of leaf stalks) present in the other orders.

It has often been suggested that the Juglandaceae family has been derived from the Sapindales order, which includes the sumacs. These are woody plants with pinnately compound leaves also lacking stipules, some of them having resinous dots on the leaflets as do the members of the Juglandaceae family. They also have panicles of flowers

Restriction of distribution during recent geologic time

Scattered occurrence of trees

but, unlike the walnut family, petals are present. A few members even have reduced crowded flowers arranged in spikes. The wood anatomy and pollen structure, however, indicate that not only is the Juglandaceae family unrelated to the Sapindales order, but it is even more primitive than the latter in several features. Thus, the walnut family was probably derived from some other more primitive group. It now seems likely, though not proved, that the family was derived with the bayberries, oaks, and birches through the Hamamelidales, the witch hazel order, from the Magnoliales, the magnolia order. It is generally agreed that this last order is the most primitive living group of flowering plants, having, as it does, extremely primitive gymnosperm-like wood structure as well as other primitive features.

Relatives
of the
walnut
family

There have been differences of opinion about which families are related to the walnut family. The families Julianiaceae, Picrodendraceae, and Rhoipteleaceae have been considered to be close to the Juglandaceae family because of their compound leaves and general flower and inflorescence (*i.e.*, the flower cluster) structure. Studies of wood anatomy and pollen grain structure have shown that the first two are much more likely to be related to the Sapindales order. The stipules, flowers, and flattened winged fruits of the Rhoipteleaceae family strongly suggest the elms in the order Urticales, though the latter have simple leaves. Again, wood anatomy indicates that the Rhoipteleaceae family is more closely related to the walnut family, especially to the more primitive genera of that family, *Engelhardia* and *Alfaroa*. The flower and inflorescence structure of the genus *Rhoiptelea* fit exactly the proposed hypothetical ancestor of the Juglandaceae family. In the Amentiferae group the bayberry family, Myricaceae, considered by many to constitute a distinct order, has been placed by some in the order Juglandales. This family has catkins and one-seeded nutlets that are often winged. Once more the bayberries have simple leaves and stipules, but they could still be close to the Juglandales order. The compound leaves of the Juglandaceae (walnut) family, however, separate it from the oaks and birches and even from witch hazels and magnolias.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The two families of the order are quite distinct in position of the ovary (superior or inferior) and internal structure of the ovary (two-celled or one-celled; that is, two-loculed or one-loculed), and in having bisexual (perfect) flowers in long slender spikes or unisexual (imperfect) flowers in true catkins. Within the Juglandaceae family itself the subfamilies, tribes, and genera are separated on the basis of the modification of the primary and secondary bracts (scales) in the fruiting condition into wings or into husks for the nutlets or nuts. In addition, the presence or absence of sepals (the outer whorl of flower structures, similar to flower petals but usually smaller and coloured green), type and position of inflorescences, variation in position of the carpels (ovule-bearing leaves of the pistil), type of stigma, wood anatomy, and pollen structure are of value.

Taxonomic problems. The classification used in this article for dividing the Juglandaceae (walnut family) into subfamilies and tribes is a recent one of recognized authority. Most of the former classifications divided the family merely on the basis of the appearance of the fruits; for example, one group of genera has small, winged fruits, the other has larger fruits, most of which have husks. Yet various studies in wood anatomy, pollen structure, inflorescence type and position, floral structure, and nature of primary and secondary bracts show that the traditional classification schemes bring together unrelated members.

Tremendous advances have been made within the past 50 years, primarily in the family Juglandaceae, in the knowledge of inflorescences, flower structure, wood anatomy, pollen-grain structure, seedling type and its anatomy, number of genera and species, number of fossils, relationship within the family, and relationship to other families and orders. Much still remains to be done, however. Opinions differ as to what genera and how many species should be recognized. Relationships among the genera are still open

to question. Knowledge of fruit and seedling structure is still incomplete. Better knowledge of the relationships of the order to other orders is still needed as is indicated in the lack of a satisfactory explanation for the compound leaf. Intensive studies are now going on in an attempt to obtain a better natural classification of the flowering plants as a whole. The location of the Juglandales order in this classification is still in doubt. (Wa.E.M.)

Caryophyllales (pink order)

The order Caryophyllales includes many dicotyledonous plants (plants whose embryos have two leaves), ranging from garden subjects and vegetables to bizarre succulent plants that resemble stones. The garden plants include carnations, pinks, four-o'clocks, amaranths, portulacas, and Madeira vines. Vegetables in the order include beet, spinach, rhubarb, and buckwheat. The carpetweed family (Aizoaceae) includes ice plants, sea figs, and living stones. Some authorities include the cacti (as the family Cactaceae) in this order as well; however, in view of evidence to the contrary and because the cacti are of such general interest, they are dealt with separately (see *Cactales*).

GENERAL FEATURES

The name of the order is derived from that of the pink family, Caryophyllaceae, which was based upon a pre-Linnaean genus, *Caryophyllus*. The number of species in the order has been estimated between 6,500 and 8,500, depending upon the interpretation of the order; *i.e.*, which families are included in it and particularly whether the cactus family (Cactaceae) and the buckwheat family (Polygonaceae) are included. In this treatment of the order, the Cactaceae are excluded and the Polygonaceae are included.

Representative plants from the three largest families of the pink order.

The Caryophyllales include mostly herbs, but various families have shrubs, vines, and trees. On the whole, the order is not noted for the size attained by its members. Commonly, the species are most prevalent in moist temperate or tropical environments, but many members of the goosefoot family (Chenopodiaceae) are restricted to salty, alkaline soil. In some salt-tolerant species, the leaves are succulent (fleshy). Leaf succulence is also common in the family Aizoaceae and remarkably so in its numerous South African members.

NATURAL HISTORY

The most striking single ecological feature in the order is the dominance of the Chenopodiaceae in alkaline situations and the prominence of succulent Aizoaceae in the deserts of southern Africa. The other members of the order occur in any of several types of habitat, but in general none is conspicuous. Even the Aizoaceae in the southern African deserts are not conspicuous except when they are in flower.

Characteristic geographic distribution patterns occur in individual families, but none is typical of the order as a whole. The poke family (Phytolaccaceae) and the Madeira-vine family (Basellaceae) include plants primarily of the American tropics. The amaranth family (Amaranthaceae) is most highly developed in tropical America and tropical Africa. The four-o'clock family (Nyctaginaceae) is common throughout the tropics but occurs also in the warmer temperate regions. The carpetweed family (Aizoaceae) occurs over most of the Earth, but its chief centre of distribution is in desert and temperate latitudes of southern Africa. The Caryophyllaceae (pink family), the Portulacaceae (portulaca family), and the Polygonaceae (buckwheat family) are characteristic of temperate regions. The goosefoot family (Chenopodiaceae) occurs throughout the

world, but its greatest development is in salty or alkaline areas, particularly those of coastal salt marshes and deserts.

FORM AND FUNCTION

Vegetative characteristics. The external vegetative characteristics of the plants in the Caryophyllales vary greatly; no specific feature can be singled out as indicative of the group. Certain tendencies are noteworthy but not distinguishing. Only rarely do the leaf bases bear stipules (leaflike tabs). Succulents occur in the Aizoaceae and in the Didiereaceae (a small Madagascan family), as well as in some of the Portulacaceae, Chenopodiaceae, Basellaceae, and Phytolaccaceae. Absence of stipules is almost a distinguishing characteristic of the order, but the presence of succulent tissues is not.

Two internal vegetative features characterize many members of the Caryophyllales. Eight of the families have some members in which conductive tissues (xylem and phloem) are produced from generative tissue called cambium at various depths inside the stem or the root, rather than only at the position of this tissue in most other plants. This produces additional cambial layers, as readily seen in a cross section of a beet root. Despite the commonness of this feature, it has not been proved to occur in all members of the order.

The second internal feature is the chemical uniqueness of pigmentation in many of the Caryophyllales. In most flowering plants colours ranging from nearly red to nearly blue (*i.e.*, from violet to purple) are dependent upon the presence of chemical compounds called anthocyanins; colours ranging from yellow to reddish orange are dependent upon compounds called anthoxanthins. A distinct but parallel series of pigments occurs only in a large number of Caryophyllales and the cacti. These substances, known as betalains, include betacyanins, which produce colours from near red to near blue, and betaxanthins, which produce colours in the yellow to reddish-orange series. The presence of betacyanins especially, rather than anthocyanins, is presumed to be of taxonomic significance. Betacyanins have been found in many of the Caryophyllales but not in any members of the family Caryophyllaceae or the Molluginoidae (a group sometimes considered to be a separate family but included here as a subfamily in the Aizoaceae). Their presence also in the cacti is an indication of the relationship of these plants to the Caryophyllales and has led some authorities to include the cacti in this order.

Pigments

Reproductive characteristics. Throughout most of the order, the flowers have true sepals (modified petallike structures) but no true petals (that is, not embryologically derived from petal primordia). Some families that display what appear to be petals, such as Portulacaceae and Nyctaginaceae, are thought to have greatly modified sepals, in which case the sepal-like appendages are then interpreted as bracts (specialized leaves subtending flowers). The Caryophyllaceae, however, apparently have true petals developed by the usual means—that is, through modification of individual stamens (the male parts of a flower) or portions of them. Caryophyllaceae is the only family in the order that, so far as has been determined, has ordinary petals.

In most members of the order, the stamens are in one or two series (concentric circles around the central axis of the flower) or sometimes in three series of three; in some cases, however, as in many of the Aizoaceae, there are numerous stamens.

The carpels (specialized leaves each forming all or part of a pistil, the female part of the flower) are united and commonly enclose a single seed chamber, but there may be 3 to 12, one for each carpel. Usually, there are as many styles—extensions above a plant ovary bearing stigmas, structures that receive pollen grains at their tips—as carpels, and they are not united. The structure and positioning of the ovule in most members of the Caryophyllales differ from the common type in the flowering plants in being curved or coiled in a special way. The ovule is surrounded by two coverings (integuments), the inner being longer than the outer. The embryo lies toward the outside of the ovule, surrounding the food-storage tissue,

Ecological patterns

Representative plants from three medium-sized families of the pink order.

which usually is not formed from a nutritive tissue (endosperm) during fertilization, as in most flowering plants. Commonly, most of the food is stored in the perisperm. The features of the ovules, embryos, and seeds are similar to those of the cacti, which further strengthens the case for a relationship of the two groups.

The placenta (the tissue that bears the ovules) in many Caryophyllales is either basal and low or forms a column arising from the base of the ovary. This type of placenta is rare in other orders of flowering plants. It does occur in the Primulales, probably indicating some relationship of these two orders.

EVOLUTION

As is true of most other chiefly herbaceous orders of flowering plants, the Caryophyllales have left virtually no fossil record. Any evidence, therefore, of phylogeny must come primarily from a consideration of the living members of the order. The origin of the Caryophyllales, in consequence, is largely a matter of speculation. The order was presumably derived from the ancestral complex of the buttercup order (Ranales), but the present relationship of these orders is not close, and the lines of origin of the Caryophyllales are obscure.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. Consideration for inclusion in the order rests primarily upon such matters as absence of stipules (basal appendages of leafstalks), an unusual arrangement of cambial tissue, and the wide occurrence in the order of betalains, a unique class of pigment compounds. Disposition into families is based chiefly upon floral features such as numbers of parts and position of the ovary with regard to the floral envelope. Of taxonomic significance also are the number and position of ovules and the type of fruit.

Alternate systems of classification. In some classifications six additional families are included as follows (their disposition in this discussion follows in parentheses): Gyrostemonaceae (Phytolaccaceae), Bataceae (Phytolaccaceae), Molluginaceae (Aizoaceae), Tetragoniaceae (Aizoaceae), Halophytaceae (Chenopodiaceae), and Hectorellaceae (Portulacaceae). The Polygonaceae are separated by some as the order Polygonales. The families Batiaceae and Thelygonaceae are sometimes grouped with the Caryophyllales but may be separated under orders of their own. The proposed alliance of the cacti with certain succulent members of the Aizoaceae (subfamily Ficoideae) is based on similarity of pollen grains, the presence of betacyanins, and distinctive common features of the ovules and embryos. The differences that serve to separate the cacti are dealt with in the section *Cactales*. (L.Be.)

Cactales

The cacti are curious, often spiny, fleshy-stemmed plants constituting the family Cactaceae, order Cactales, characteristic of and well adapted to dry regions. Although the cacti are native to the Americas—with one possible exception (see below)—they are cultivated widely throughout the world for their bizarre forms and often striking blossoms. Cacti are easily grown from cuttings or from seeds; they are adapted to warm, arid indoor conditions and require little care once established.

GENERAL FEATURES

Importance. Cacti are economic plants in Mexico, parts of Central and South America, and the Caribbean region. Various species are cultivated for food, including vast complexes of prickly pears, especially of *Opuntia ficus-indica*, and torch cacti (*Cereus*). Drinks prepared from some cactus fruits have been a popular native medicine for fevers. In Mexico, leaves of chollas, resembling string beans, are eaten. In Latin America, species of *Opuntia*, *Cereus*, and other genera are planted around houses, often forming an impenetrable barrier. Barrel cacti (*Echinocactus* and *Ferocactus*) are a source of water in emergencies.

Cacti are cultivated chiefly for their ornamental features and general hardiness. They can be grafted easily, and

many rare species are propagated by grafting upon more vigorous stocks. Many small cacti are suitable for home cultivation. Without water, most cacti persist but do not grow. Some species, however, do require periodic drought. Many species grow well in warm weather in full sun, provided there is adequate soil moisture, but others require some shade.

Size range and diversity. Most cacti are composed of stems and have no leaves. The leaves, when present, are usually greatly reduced; they may occur only temporarily at the growing end of the plant. Only in the genera *Pereskia* and *Pereskopsis*, restricted to the tropics, do the leaves fit the popular conception of leaves.

Cacti vary greatly in size and general appearance, from buttonlike peyote (*Lophophora*) and low clumps of prickly pear (*Opuntia*) to upright columns of barrel cacti (*Ferocactus* and *Echinocactus*) and the imposing saguaro (*Cereus giganteus* or *Carnegiea gigantea*) trees. Some of the climbing tropical species—such as those of the leaf cactus (*Epiphyllum*) and some species of *Rhipsalis*—have thin, flattened stems. Regardless of its shape, degree of elongation, or branching, the cactus stem is succulent (having fleshy, moisture-conserving tissue) and greatly enlarged as storage tissue. The appearance of the plant varies also according to whether the stem surface is smooth or ornamented with protruding tubercles, ridges, or grooves.

Distribution. The Cactaceae are native through most of the length of North and South America, from British Columbia and Alberta southward. The northernmost limit is along the Peace River in Canada; the southernmost limit extends far into Chile and Argentina. The only representatives of the family possibly native to the Old World are members of the genus *Rhipsalis*, occurring in East Africa, Madagascar, and Sri Lanka. Whether these plants are native or were introduced in these tropical areas is a matter of disagreement, as is the possibility of dispersal of this

Representative cacti.

highly specialized group from the Western Hemisphere to the Eastern Hemisphere.

Various species of *Opuntia* and some other genera have been introduced into the Mediterranean region, and some have grown wild there since shortly after the discovery of America. Species of *Opuntia* are widely naturalized in India, the Malayan region, Hawaii, and Australia. In Australia and eastern Cape Province in South Africa, they have become pests difficult to eradicate.

NATURAL HISTORY

Life cycle. The characteristic feature of cactus seedlings is the pair of large seed leaves (cotyledons), which tend to be succulent, sometimes markedly so. From seed some species reach the flowering stage in two or three years, and both flowers and fruits may be developed even on stems that still retain juvenile characters. (This curious feature led to the naming of many supposed species on the basis of plants that seemed to be mature because of reproduction but that did not have the expected type of spines.)

Usually within a few years the succulent stem assumes the characteristic form and appendages of the species. In the prickly pears, in which the adult stem is composed of flattened joints arranged end to end, the portion developed in the first year of growth is cylinder-like for several months, the upper portion gradually becoming flattened, and the joints developed later being flat.

Most cacti reach a considerable relative size within 5 or 10 years, but some grow much slower. Information concerning the age of older plants usually is lacking because the woody parts are very thin; counting of growth rings requires sectioning and careful study with a compound microscope. The saguaro, or giant cactus, is estimated to attain ages in the hundreds of years.

Pollination is mostly by insects or birds, though sometimes by other animals such as bats. Because there is no precise mechanism governing the pathway of pollinators, the process of pollination tends to be haphazard, at least in most of the larger flowers of the open as opposed to the tubular types. Most flowers open in the daytime and are visited by day-flying insects or birds, but many, and especially such species as the saguaro and the various species of *Cereus*, open at night. As with other night-pollinated plants the night-blooming cacti tend to be white-flowered.

Ecology. Cacti are admirably adapted to dry environmental conditions through such features as the thick water-retaining stem, extensive root system, and lack of leaves.

The stems of prickly pears concentrate water over the flat surfaces of the joints that either drips or streams from the curved lower margins, thereby increasing the amount of water in the soil just under the plant. Some species of cacti have spines that point downward; water collected on the spines, even from light mists, is directed in droplets to the ground. The saguaro's downward-pointed spines during its earlier years of growth collect water and repel rodents that might eat the succulent stems to secure water. In older saguaros the stem above the approximately 4- or 5-foot (1.2- to 1.5-metre) level produces another, not downward-directed, type of spine. For plants growing near the lower edge of a rock or a crack between rocks, the amount of water available from a relatively light rain may be greatly increased, as it would be for a plant living under the edge of a roof.

The root systems of cacti are shallow and wide-spreading. They remain receptive to moisture through many months of dry weather and immediately soak up even the scantiest rainfall. Substances from the roots of some desert plants, and perhaps some of the cacti, prevent the invasion of any other plants nearby, thus increasing the chance of continued survival. The absence of leaves reduces the ratio of plant surface to internal plant volume, as does the thickening of the stems, thus aiding water retention.

Within their natural range, cacti occur in a wide variety of soil types. Frequently, a species is restricted to a particular type of rock formation, such as limestone or igneous rock. A few species are confined to localized rock outcroppings, a limitation particularly striking in the genus *Pediocactus*, in which 8 of its 11 taxa are found on special rock ledges on the Colorado Plateau or on gypsum-rich soil.

Some species are associated with tropical rain forests, as in the Everglades in Florida, where species of *Opuntia* and *Cereus* occur at points at which the water table may be only a few inches below the surface. Most species are sensitive to cold, but many grow in regions with cold winters, as in the United States on the Great Plains and in the Great Basin and the Rocky Mountains.

FORM AND FUNCTION

Vegetative characteristics. Many other plants, succulent and essentially leafless, are often confused with cacti. A large group of spurges (*Euphorbia* species) occurring in Africa includes many plants with long cylindroid stems similar in appearance to cacti. These plants, common in cultivation, are distinguished readily by their milky juice, a feature rare in cacti and supposedly absent in cacti with elongated stems. Yuccas and the century plants (*Agave* species) often are confused with cacti, but they are distinguished readily by succulence of the leaves rather than the stems.

Cacti can be distinguished from all other succulent plants by the presence of spines in areoles, special clearly defined areas, each developed from a lateral bud of the stem. Areoles are universal in the cactus family (at least in the juvenile phase) and have so far not been found in any other plant family. Almost all species of cactus have tufts of stiff sharp spines. In some species the mature plant may not have spines, but it does have areoles, which are filled with hair or sharp, barbed structures called glochids. The more obvious characters of the cactus family, in combination with areoles, are reduction or lack of leaves, unusual floral formation, and distinctive fruits and seeds.

The leaves, if discernible, are reduced in size (except in *Pereskia*, as indicated above). In *Opuntia* they appear only on young joints of the stem and fall off after a month or more of growth. They are relatively small and succulent and range from conical to elongated and cylindroid. In most genera the leaves are not visible to the unaided eye but are represented by a hump of tissue just below a spine-bearing areole.

Reproductive characteristics. Frequently the flowers are large, attractive, and white or brightly coloured. All the genera have a floral tube that invests the ovary, and, except in *Pereskia*, adheres to its surface. The portion of the tube covering the ovary usually develops small, inconspicuous scales, which increase gradually in size upward on the free portion of the floral tube above the ovary. They grade into sepaloid flower parts and, farther up, into petaloid parts. There are many conspicuous stamens (pollen-bearing organs) and 3 to 20 or more stigmas (parts that receive pollen) arising from a single style. In some groups, especially *Opuntia*, there is only a short floral tube above the ovary, but in others, as with some species of *Cereus*, the tube may be very long. The fusion of the floral tube with the surface of the ovary occurs in all species of cacti except *Pereskia* and in many other flowering plants. A flower which has this feature is described as epigynous, and its ovary is said to be inferior.

The ovary and the investing floral tube may develop into a fleshy and often edible fruit. It is one-chambered, and the numerous ovules borne on the walls give rise to numerous seeds. The ovules usually are campylotropous; that is, curved between the hilum (point of attachment to the stalk) and the opening through which the pollen tube enters (micropyle).

The flowers usually are associated with a spine-bearing areole, but in *Mammillaria* (fishhook cacti) they may be produced in a special areole between the elongated tubercles of the stem surface or they may be in this position but have no visible connection with an areole. The flowers develop either inside the spine-bearing part of the areole or in an area either merging with it or remote from it and connected by an isthmus.

EVOLUTION

Because of the lack of fossils, the evolutionary course of the cacti is difficult to trace. One *Opuntia*-like fossil has been uncovered, but evidence suggests that it may not represent a cactus at all. Primitive living cacti may

Distinctive structure

Adaptations to arid conditions

Origin of
cacti

suggest lineage. The greatest number of primitive features is preserved in *Pereskia*. The flowers of some species are perigynous (floral tube surrounds the ovary) instead of epigynous; the stems are only moderately succulent; the leaves, though succulent, are similar to those of many other plants. The wood and reproductive parts reveal other primitive features. Of particular significance is the similarity of the carpels of *Pereskia pittitache* to those of the primitive tropical woody plants of the buttercup order of other taxonomic systems (Ranales). The carpels are unsealed, which may indicate origin of the cacti from a very primitive stock and an early separation in evolutionary development from the Ranales or from developmental lines ancestral to the Ranales and to related groups. One of these lines of development may have branched off long ago to the ancestors of the order Caryophyllales, as indicated by the features held in common between that order and the cacti. The numerous differences between these two groups indicate that they separated as far back as the Late Mesozoic Era (about 130,000,000 years ago).

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The features used in separating cacti from other succulents are listed above (see *Form and function*). The family Cactaceae apparently is not closely related to any other plant family.

Taxonomic problems. The Cactaceae are considered by some authorities as the sole family of the order Cactales, as in this article. Thus, the cacti stand alone, not being related closely to any other group of flowering plants. They do share some features in common with the orders Ranales, Myrtales, Rosales, and others, but the relationship to any of them is not close.

Similarities to
other
plant
groups

The order Cactales, consisting of the single family Cactaceae, has been included recently by several plant taxonomists in the Caryophyllales. This proposed alliance first arose from the obvious succulence of the Cactaceae and a subfamily of the family Aizoaceae. These families are similar to the cacti in features of the pollen grains, in the development of the embryo sac (megagametophyte), and in the campylotropous ovules with the food in reserve in the perisperm. In the cacti, however, the ovules may be in a variety of positions other than the campylotropous condition. Betacyanin pigments occur in the Caryophyllales as well as in the Cactaceae, indicating a link between the groups; they have been assumed to occur in no other groups of plants.

The Aizoaceae, despite similarities, lack a number of the characteristic features of the cacti. Leaves of the Aizoaceae usually are opposite; those of the Cactaceae are alternate. The leaves are conspicuously succulent, while in cacti the stems are succulent. The Aizoaceae do not have spines in areoles, as do cacti. The flowers are superficially similar, but in the Aizoaceae there are no leaves on the floral cup (tube) and leaves do not grade into sepaloid and petaloid parts. In the Aizoaceae the fruit has partitions at maturity, unlike the cacti. There is more than one style instead of the single style in the Cactaceae.

Similarities of the cacti and other groups, accompanied by numerous differences, indicate the derivation of these groups from a common ancestry. The major taxa and even the species of living flowering plants were mostly derived from ancestors that were wholly or partly displaced and that usually have become extinct, leaving no recognizable remains behind.

(L.Be.)

Theales

Theales constitutes one of the larger orders of the flowering plants, consisting of 21 families, with approximately 155 genera and 2,550 species. Theales plants vary in form, structure, and range of habitats and are related to many other plant orders. Some authorities suggest that at least a few of the related orders evolved from an ancestor that, if still extant, would be included within the Theales. From this viewpoint, therefore, the order is of considerable interest.

Another feature of interest is the distribution of the species within the families. Five families contain 400 or

more species; one has about 120 species; and the other 15 are of somewhat equivocal status—none contains more than 45 species. Many authorities merge the 15 small families with one or another of the larger families or place them in other orders.

GENERAL FEATURES

The order Theales is predominantly tropical in distribution, occurring in rain forests or in upland evergreen broad-leaved forests; few species occur in temperate regions. Members of the order are found almost worldwide; however, the centre of distribution is in Southeast Asia.

Members of one family, Dipterocarpaceae, are characteristic of the Malaysian rain forest, where species form the upper canopy at heights up to 250 feet (about 80 metres). Many species of this family are of economic importance for their timber; others produce valuable resins. *Camellia* (*Thea*) *sinensis*, the tea plant, is the most important economic species in the order. It has been cultivated for a long period of time in eastern India (Assam), Tibet, and China, the area to which it is probably native. Tea is also grown in several other areas (e.g., Sri Lanka, Turkey, and the Soviet Union).

Other species of *Camellia* (e.g., *C. japonica*) are widely cultivated as ornamentals in gardens in the temperate zone. *Gordonia*, *Stuartia* (both of the family Theaceae), *Hypericum* (Hypericaceae), *Ochna* (Ochnaceae), and many other genera are used as horticultural ornamentals.

Edible fruits include the souari nut (*Caryocar nuciferum*, family Caryocaraceae), the mammee apple (*Mammea americana*, Clusiaceae), and the mangosteen (*Garcinia mangostana*, Clusiaceae).

NATURAL HISTORY

Pollination. Not much is known about the pollination mechanisms in the order, but a number of notable structural developments seem to be related to pollination.

The most simple is the uniting of the stamens (male parts) either in a ring, as in the cultivated camellias, or in bundles, as in the common Saint-John's-wort (*Hypericum*) and in many tropical members of the order. In some members of the family Clusiaceae the stamens are united into very condensed groups known as phalanges. A further adaptation, presumably effective in pollination, is the extreme elongation of the stamens of the family Caryocaraceae; these project considerably beyond the petals and are also united at the base.

The most remarkable pollination adaptations are found in members of the Marcgraviaceae, in which the floral bracts, small leaflike structures located just below the flowers, are transformed into nectar-secreting organs of various shapes, but always hollow and somewhat pitcherlike. In the simplest case (found in three genera), a bract subtends each flower. In the genus *Marcgravia*, however, the flower cluster is pendulous and umbellate—the flowers are on stalks that radiate from a common point, umbrella fashion. The central flowers of the umbel are sterile, and their bracts are enlarged to form erect, pitcherlike structures, superficially very like the insectivorous pitchers of *Nepenthes*, which hang below the outer ring of fertile flowers. These nectar-filled pitchers attract hummingbirds, which were once thought to pollinate the fertile flowers as they hovered, drinking the nectar. In at least two Guyanese species, the hummingbirds approach the pitchers from above the fertile flowers and do not come into contact with the stamens or the stigmata (female parts). In these two species, the stamens open in the late bud stage, and the flowers are actually self-fertilized.

Seed dispersal. Various dispersal mechanisms occur in the order, but only two are noteworthy. In most families, the aging sepals persist around the ripening fruit, and in various groups, notably the families Dipterocarpaceae and Lophiraceae, two or more of them enlarge above the fruit, producing a two-winged structure that is distributed by the wind.

The most remarkable development connected with the seeds occurs in the family Dioncophyllaceae. In this group the fruits open before ripening, and the developing seeds are pushed out from the fruit by the lengthened and hardened funiculi—the stalks on which the ovules grow within the ovary. The seeds continue to develop in this exposed position until ripe, when they fall, leaving the remains of the fruit and the funiculi. The function of this strange process, which is unique among flowering plants, is unknown.

Ecology. The order is extremely diverse in its habitat requirements. There are trees of the tropical rain forests (the family Dipterocarpaceae and others), climbers in the same forests (Marcgraviaceae), mangrove growth forms in coastal tidewaters (Pellicieraceae), trees and shrubs of the mountain evergreen broad-leaved forests (Theaceae and others), herbs and shrubs of various temperate habitats (Theaceae, Hypericaceae), and aquatics of tropical and temperate freshwaters (Elatinaceae). The morphological variability of the order is thus reflected in its ecology.

FORM AND FUNCTION

Vegetative characteristics. The order Theales is not well distinguished from other plant orders, and there are no conclusive diagnostic characters that will consistently serve to distinguish it. The following features occur frequently in the order, however, and, in combination, serve to characterize it in a general way.

The plants are usually woody, often with evergreen foliage. The leaves are usually simple, and resins are often present in the tissues. The bisexual flowers are mostly hypogynous; *i.e.*, the sepals, petals, and male parts (stamens) arise at the base of the ovary, a condition in which the ovary is described as superior. The calyx consists of free sepals and the corolla of free petals, and the flower is radially symmetrical. The stamens are usually numerous, with a tendency to be united, either in a ring or in a

number of separate bundles. The ovary is composed of two to many usually united segments called carpels, each of which bears ovules—developing seeds—attached along the central axis.

Resins are found in many members of the order, and some are of economic importance. In the family Hypericaceae, the resins occur in distinct, often globular glands, which may be yellow, orange, red, or black; similar glands occur in some of the smaller families (*e.g.*, Dipterocarpaceae and Tetrameristaceae). In the family Dipterocarpaceae, the resins are more generally distributed throughout the tissues.

Although most species of the order are evergreen trees or shrubs, the family Marcgraviaceae, found in the forests of tropical South America, is composed of climbers. These have a number of structural modifications, particularly in the genus *Marcgravia*, which shows shoot dimorphism, a condition that consists of two distinct types of vegetative growth patterns. The climbing shoots bear small leaves without stalks that are arranged in two rows (distichous) on the branches. Short adventitious (aerial) roots develop along these shoots and enable them to climb. The upper shoots, which bear pendulous flower clusters at their ends, have much larger, stalked, spirally arranged leaves and lack the adventitious roots of the climbing stems. The transition between one shoot type and the other is often quite abrupt. The cause is unknown, but it is thought that the increase in the amount of light received by the shoots as they climb higher may be involved.

The family Dioncophyllaceae also shows remarkable vegetative modifications. In two of its genera, the leaves have two forms, one being "normal," the other terminating in two leathery hooks that presumably enable the plant to scramble over other vegetation. In the third genus, the

flowers

leaves are of three forms, two as just described plus a third type with an elongation of the midrib, projecting beyond the blade and bearing glandular hairs. The function of the elongated part, which is called a rhabdode, is unknown, but the glandular hairs borne on it are very similar in structure to the "tentacles" of the insectivorous genus *Drosophyllum* of the order Nepenthales. The leaves of the Dioncophyllaceae have been compared both to the leaves of the Droseraceae and to the pitcher-bearing leaves of the family Nepenthaceae, but botanists agree that they are not insectivorous.

Floral characteristics. The flowers are exceptionally variable, and a wide range of structures occurs. There are usually distinct sepals and petals, though in some cases (family Dipterocarpaceae) the petals may be rather leathery and not brightly coloured. The sepals are usually four or five in number, free, and overlapping. In some groups, however, there is no sharp distinction between the sepals and the floral bracts and bracteoles—small green appendages just below the flowers—and the calyx appears to consist of a compressed spiral of several segments. This condition of the flower buds is called perulate. The petals vary from two to many, though four or five occur most commonly. They are normally free but may be fused to the ring formed by the united bases of the stamens.

The stamens are usually numerous (more rarely 5 to 10) and are centrifugally arranged (*i.e.*, they ripen from the centre of the flower toward the circumference). They are usually united, either into a ring, to which the petals are sometimes joined, or into distinct bundles. The anthers (pollen sacs) usually open by slits, but terminal pores occur in some groups (*e.g.*, Ochnaceae). The connective between the anthers is sometimes prolonged into an appendage (as in Dipterocarpaceae and Oncothecaceae).

The ovary consists of two or more (frequently five) carpels that are united, or, if apparently free, have a united style—the narrow upper portion. The ovules have two integuments, or coverings, and endosperm, a starchy nutrient tissue for the developing embryo, may be present or absent in the seed.

EVOLUTION

Fossil record. As with most flowering plant groups, the fossil record of the Theales order is both scanty and of little value in deducing the evolutionary history of the group. Noteworthy features include the occurrence of fossils from families that are at present entirely tropical (Dipterocarpaceae and Clusiaceae) in deposits of Tertiary age (beginning about 65,000,000 years ago) in Europe and in the Mediterranean area.

Phylogeny. The difficulty of deducing evolutionary relationships of such a variable group is revealed by extreme affinities that have been suggested for it. It has been suggested by some authorities, for example, that the order is derived from early members of the family Dilleniaceae (order Dilleniales). Others stress this relationship by merging the Theales and Dilleniales, either completely or in part. Again, the similarity between the orders Theales and the Ericales leads to the view that the order Ericales was derived from the Theales. Some authorities, in fact, place the order Theales in a crucial position in their systems, suggesting that the origins of several other plant groups are to be found in a "thealaceous" ancestor. These groups are the orders Capparales, Primulales, Diapensiales, Salicales, Violales, Sarraceniales, and Malvales, and the family Lecythidaceae of the order Myrtales, as well as the Ericales already mentioned.

The problem of the precise meaning of phylogenetic origins occurs with this group. It cannot be denied that similarities exist among the orders mentioned, but many botanists are skeptical that all or even most of them arose from the Theales.

Within the order the problems of phylogeny are similar. A few indications as to the evolutionary relationships of the families emerge, however, even though they do not give a clear picture of evolution within the order.

The family Ochnaceae, for instance, appears to be linked to the Dipterocarpaceae through the family Lophiraceae. Similarly, the families Theaceae and Clusiaceae are linked

by the Bonnetiaceae. Many of the smaller families included in the order are sufficiently similar to various of the larger families for them to be merged by various workers. Thus, the family Lophiraceae is usually included in the Ochnaceae; Bonnetiaceae, Asteropeiaceae, Tetrameristaceae, and Pellicieraceae in the Theaceae; and Hypericaceae in the Clusiaceae (the resulting large family, in the last instance, is often called Guttiferae). The remaining smaller families—Strasburgeriaceae, Ancistrocladaceae, Dioncophyllaceae, Diegodendracheae, Marcgraviaceae, Pentaphylacaceae, Caryocaraceae, Quiinaceae, Medusagynaceae, and Oncothecaceae—form a mixed group. Some of them are clearly allied to the large families within the order, whereas others are of more controversial status.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. Some of the characteristics used in distinguishing the families have been mentioned. The curious bracts of the Marcgraviaceae and the enlarged and persistent calyx of Lophiraceae and Dipterocarpaceae, for instance, serve to diagnose these families. Because the group is so variable, many other characters are used in its classification; these include variations in habitat, leaf position and form, presence or absence of stipules, and floral characters.

Alternate systems of classification. The order Theales is a variable group with a large number of unusual modifications. Thus, it is not surprising that taxonomic treatments of the 21 families included here vary.

Comparisons reveal a wide diversity of opinion as to which families the order Theales should contain, which groups should be regarded as families, and which orders are related to the Theales. The main conclusion arising from this lack of agreement is that the order Theales, as presented here, is variable and shows relationships in many directions; for example, more than 60 plant families have been placed in the order Theales or have belonged to other orders that include genera at some time placed in the Theales as defined here. This represents about 13 percent of all flowering plant families, an impressive number to be related to the 21 families. This large group is understandably difficult to divide so that all assumed relationships take their proper place.

Certain groups, however, show more or less clear affinities with the Theales; these are the orders Dilleniales, Ericales, and Violales, with which the Theales are closely associated in all of the most authoritative classification systems.

When the content of the group is considered, it is clear that it may be viewed as one order, as is done here, or divided into a number of separate orders. Because there are no objective standards for satisfactorily defining orders, no final decision can be made. It seems, however, that within the large and variable Theales, as presented here, some eventual subdividing is likely and would be useful.

Some of the authors of the various taxonomic systems dealing with the Theales recognize a large number of relatively small families, while others recognize a smaller number of relatively larger families. In view of the extreme variability of the group and its multiple relationships, the former treatment—the one followed here—seems to be a more accurate reflection of the natural situation, and it seems likely to gain wider acceptance.

Further study of the group, however, from many points of view, is likely to result in modifications. Many of the families comprising the Theales are small, tropical, and not well known. Detailed studies of them may reveal unsuspected similarities or differences that will result in altered viewpoints. The habitats of many species in the group are in danger of extinction as a result of human activities, and it is extremely important that they be preserved for study.

(J.Cul.)

Violales (violet order)

Violales is an order of nine families of flowering plants. The nine families are the Bixaceae, Cistaceae, Cochlospermaceae, Flacourtiaceae, Lacistemataceae, Peridiscaceae, Scyphostegiaceae, Stachyuraceae, and Violaceae. With the

The problem of determining relationships

Central evolutionary position of the Theales

exception of the Cistaceae (rockrose family) and the Violaceae (violet family), the order Violales is restricted to the tropical regions of the world. The majority of the members of these families are trees and shrubs, though many herbs are found in the families Cistaceae and Violaceae. Rarely, if ever, dominant in vegetation, members of the Violales order are usually found as low vegetation beneath the higher trees of forests.

GENERAL FEATURES

Economic uses of the plants of the Violales order are limited, although some provide man with food, dyes, and ornamentation. A member of the Bixaceae family (*Bixa orellana*) is used to produce a red "annatto" dye, which is extracted from the pulp around the seeds. It is native to tropical America, but it has been widely planted elsewhere in the tropics. Three members of the Flacourtiaceae family are used as food in the tropics. The governor's plum (*Flacourtia indica*), a small tree, has maroon-coloured, juicy fruit 1 inch (2.5 centimetres) in diameter. Kei-apple (*Dovyalis caffra*), a small tree from South Africa, has bright yellow fruit. The fruits of both these species are used in jams and preserves. In addition, the Ceylon gooseberry (*Dovyalis hebecarpa*), which is cultivated in south Florida and California, produces edible fruit; and a fourth species of the family, *Azara microphylla*, from Chile, is cultivated for its orange berries.

The family Cistaceae provides many species of small ornamentals for rock gardens, especially from the genus *Cistus* (rockrose). At least 20 species native to the Mediterranean region have been introduced into North American gardens. Another genus of this family, *Helianthemum* (sunrose), also is occasionally planted.

Of all the families of the order Violales, the violet family (Violaceae) has the longest history of uses by man, particularly in Europe. Violets are widely grown as ornamentals, and there are, for example, several nurseries in the United States that deal exclusively in wild violets or in cultivated

varieties of wild forms. Over 100 species are offered for sale. Pansies, sweet white violets, and johnny-jump-ups are common names of some of the varieties most widely grown. The confederate violet is a gray-flowered form popular in Southern states of the United States in cultivation and as a wild flower. Many large-flowered forms of the genus *Viola* have been bred by hybridization (crossing different species), a phenomenon found frequently in wild species of the family.

Wild violets are also used, in a variety of ways, as food. They may be eaten raw, in salads, or cooked in many ways. Wine and sugar syrups are made from them. They have been used in making candy, especially in France, and large violet plantations in southern France obtain perfume from the petals.

FORM AND FUNCTION

Floral structure in the Violales order is varied, but flowers most frequently are constructed on a plan of five, generally five sepals and five petals, either with radial or bilateral (left- and right-sided) symmetry. All the families, except the Stachyuraceae, have true parietal placentation—i.e., with the seeds attached to the inner wall of the fruit. This is perhaps the most constant characteristic of the order. The fruit is also varied, but usually it is a capsule, a dry fruit with two or more openings that release the seeds. With rare exceptions, the species of the nine families are perennial, living for three or more years. Except for the Cistaceae and Violaceae families, members of the order are shrubs and trees. They have simple or lobed leaves, arranged alternately and spirally on the stems, almost always with pairs of small leaflike appendages (stipules) at the bases of their stalks.

EVOLUTION

Evolutionary relationships among the nine families of the Violales order and among other closely related orders of flowering plants are obscure and have been variously interpreted and described by different authors. Because of the absence of any meaningful fossil record, the evolutionary relationships among the flowering plant orders must be inferred from their present structural similarities. Characteristics of the flowers, such as numbers, fusion of parts, and placement of parts, are generally used to judge relationships. Using weighted combinations of such morphological features, it is held by some recent authorities that the Violales order is closely related to the order Theales and that the order Dilleniales has also arisen from the Theales. The classification presented in this article is, however, considered to be more reliable and useful than previous ones.

CLASSIFICATION AND TAXONOMIC STATUS

The order Violales, as presented, consists of nine families. Some authorities include as many as 21 families. All of the families of the Violales, as described, have been placed in other orders by various authorities, and most of these nine families have been divided into additional families or lumped into fewer families. The history of the classification of these families is not such as to inspire confidence, either in any existing scheme of classification or indeed in any future scheme as presently conceivable. The Cistaceae, Flacourtiaceae, and Violaceae families have had the greatest permanence of identity in the shifting classifications of 19th- and 20th-century phylogeneticists and may be considered as the most natural groupings. (N.H.R.)

Begoniales (begonia order)

The Begoniales, or begonia order, consists of two families of flowering plants: Datisceae, distributed mostly in the northern tropics and subtropics, has three genera and three or four species; Begoniaceae, mostly of the moist tropics, has three to five genera, depending on the authority consulted, and about 1,000 species. There is little resemblance between plants of the two families, members of the Datisceae being mostly trees (except for *Datisca*, an herb) and those of the Begoniaceae mostly succulent herbs or subshrubs.

Economic
importance

Vegetative, floral, and fruiting features of the violet order.

GENERAL FEATURES

Size range and diversity of structure. Begonias vary in size from a few inches in height (such as *Begonia steyermarkii* of Venezuela, an herb) to the 16- to 20-foot (5- to 6-metre) height of somewhat woody shrubs or what are virtually small trees (such as *B. pentaphylla* and *B. digitata* of Brazil).

The growth habits of the plants of the order vary as widely as their size. Included in the family Begoniaceae are plants with stems that are upright, creeping, or developed into underground rhizomes (horizontal rootlike stems); stemless plants with basal tubers; and plants that climb by means of true roots or prop roots or by hooks developed from bent and elongated axillary buds—buds located in the upper angle between stems and leafstalks.

The leaves of begonias vary from simple to compound (i.e., single bladed or with several leaflets, respectively) and essentially are smooth margined to much lobed. They generally have one lobe noticeably larger than the other. Characteristically, all leaves on one side of a branch have the larger lobe on the same side of the leaf, and those on the other side have the larger lobe on the opposite side; the leaves, in effect, form mirror images of each other.

In the family Datisceae, *Tetrameles* and *Octomeles* are large trees, 100 feet (30 metres) or more in height. *Datisca*, the other genus in the family, is a perennial herb resembling *Cannabis* (hemp), for which one of its two species, *D. cannabina*, is named.

Distribution and abundance. The family Begoniaceae is distributed generally throughout the moist tropics—being noticeably absent only from Australia and from Fiji to the Galápagos Islands. Some species of Begoniaceae are abundant in moist, cool tropical areas, such as occur in Central America to altitudes of 6,500 feet (2,000 metres) or more and in the wet eastern Himalayas to 12,000 feet (3,600 metres). Others, with thick hairy leaves or stout tuberous bases, occupy niches in drier areas that are sandy or rocky. The plants may be found singly, in small colonies, or, occasionally, covering valleys or new road cuts.

The only species of *Tetrameles*, *T. nudiflora*, is found in India, Sri Lanka (formerly Ceylon), Java, and elsewhere in deciduous forests of medium rainfall, such as those in the Western Ghāts; the region from Sikkim to Tenasserim, Myanmar; the Andaman Islands; and the middle and eastern portions of Java in teak forests.

Two species of *Octomeles* have been described, but they are considered synonymous by most botanists. Specimens of *Octomeles* are among the tallest trees in the moist evergreen ebony forests of the Malay Archipelago and Papua New Guinea, where they are locally abundant.

The two species of *Datisca* are perennial herbs that are widely separated geographically. *D. cannabina* is a native of the Old World, ranging from western Asia to the south side of the Himalayas, where it is found in the dry western portion, as well as in the temperate damp parts of the middle Himalayas. *D. glomerata* (durango root)

is known from California to northwestern Mexico but is not common.

Economic importance. The family Datisceae is of minor local importance and is of scientific interest chiefly because of its greatly reduced floral structure and its interrupted geographic distribution. The wood of *Tetrameles* and *Octomeles* is used in making packing cases, especially for tea. The root of *Datisca cannabina* contains a compound, datiscin, used in the Orient as a yellow dye for silk.

The family Begoniaceae is of considerable horticultural interest, many species and hybrids being prized as house or garden plants. The leaves of some African and Asian *Begonia* species are eaten; in South America, some species are eaten to prevent scurvy. Rhizomes of certain species in South America are used for their medicinal qualities as astringents, as treatment for fever, as antisiphilics, and as laxatives. The family Begoniaceae is also of evolutionary interest. The family seems to be the end point of a line of development that has involved the structure of its various organs. Patterns of evolutionary progression, apparent from the diversity of the species, may be traced in the floral parts and the fruits.

The ornamental value of the plants is also based on diversity in growth habit; leaves, including colour patterns; inflorescence (flower-cluster) type; flower size and colour; and length of blooming period. Classifications of begonias for horticultural purposes are quite different from those for botanical studies. In fact, the species are valued for their potential in producing hybrids. Three groups of species are of interest to horticulturists. One is cultivated for its leaves (including especially *Begonia rex*). Another, valued for its flowers, is subdivided into a group of small-flowered plants centred on *B. cucullata* (more commonly called *B. semperflorens*) and a group of large-flowered plants, including the tuberous begonias such as *B. rosae-flora*, *B. veitchii*, and *B. boliviensis*. A third group has both ornamental flowers and decorative leaves and includes *B. scharffiana* and *B. metallica*, from which was produced the hybrid *B. × credneri*, now more widespread than either of its parents.

Modern growers use four group classifications for begonias: (1) fibrous-rooted, including the wax (*B. semperflorens*), the cane stemmed, and the hirsute, or hairy; (2) the rhizomatous; (3) the rex; and (4) the tuberous rooted. Such horticultural classifications are not used by botanists because they often separate related taxa (genera, species, groups of species, etc.).

NATURAL HISTORY

Because of the comparative rarity of the family Datisceae and because two genera of the family are tall trees with flowers at great distances from the ground, not many observations have been made on pollination mechanisms. Both *Tetrameles* and *Octomeles* are dioecious (i.e., male and female flowers on separate plants) and have unisexual flowers. An abundance of flowers suggests that pollination

Botanical and horticultural features

Characteristic begonia leaf shapes

Representative plants from the two families of the begonia order.

by wind is most likely in *Tetrameles*. Wind pollination is indicated in the other two genera because of their smooth ovoid pollen grains, but the possibility of insect pollination cannot be excluded. *Datisca glomerata* is also wind-pollinated.

Flowers of all the Begoniaceae are unisexual. There are almost no records of abnormalities in nature involving abortive members of one sex appearing in flowers of the other. The plants are usually monoecious—with flowers of both sexes developing on the same plant—but normally the two sexes come to maturity at different times. In some cases the plants are dioecious. In monoecious plants, flowers of both sexes may, depending on the species, develop on the same inflorescence (flower cluster), or the inflorescences may bear flowers of only one sex.

Pollination Even though flowers of both sexes are often borne on the same plant, self-pollination does not usually occur because of the difference in the flowering time of the sexes. Some inflorescences are protandrous (*i.e.*, the male flower parts mature before the female of the same inflorescence), and the pollen is completely shed by the time the female flowers are receptive. Other inflorescences, however, which have the staminate (male) flowers on upper branches and carpellate (female) ones on lateral branches, are protogynous—the female parts mature first—and the fruits are completely mature before the pollen is shed.

Few records have been made of pollinating agents, though three different genera of bee visitors (*Apis*, *Bombus*, and *Podalirius*) have been reported. In cultivation it is thought that self-pollination may occur occasionally by a trickling down of pollen to the stigmas (the sticky pollen-receiving surfaces of the female flower parts).

Mature seeds, mostly less than 0.04 inch (1 millimetre) long, are borne in large numbers, usually in capsules, which become dry and split open. The small, characteristically patterned, lightweight seeds seem not to be transported over very great distances, though there are some records of bird dispersal.

Many members of the Begoniaceae contain free organic acids (including oxalic and malic) in the cell sap. It has been suggested that the presence of these acids may be an active deterrent to insect attack. Other cell contents of interest include crystals of calcium oxalate.

EVOLUTION

No unanimity has been reached on the actual relationships of the family Datisceae, so that evolutionary theorizing has been impractical and unsatisfactory. Affinity to the Begoniaceae has been rather generally accepted, with the seeds perhaps the most uniform character in the two families.

The interrupted distribution of *Datisca* has been suggested as an evidence of its former occurrence in Europe, but a fossil record is lacking.

Based on the present distribution of the family Begoniaceae, the present-day representatives of the probable prototype of the genus *Begonia* are the American and Asiatic members of *Begonia* (section *Begoniastrum*). From this group have originated the other numerous, highly specialized, endemic (*i.e.*, restricted to one region) members. The two chief centres of distribution are from Brazil and the Andes mountains to Mexico; and in the eastern Himalayas, the mountains of Indochina, the Malay Archipelago, and especially the Philippines and New Guinea. Smaller numbers of species have reached other areas. Representatives of the family are absent in Europe and are relatively scarce in Africa, but distribution patterns are thought to indicate an earlier worldwide dispersal. Fossil evidence, however, is nonexistent, and proof, therefore, is lacking.

CLASSIFICATION AND TAXONOMIC STATUS

basis of
begonia
classification
system

Distinguishing features. At present the genus *Begonia* consists of more than 60 sections to which its hundreds of species have been assigned. The primary divisions are geographic, and the sections, though distinguished by morphological characters, are rather strictly confined by geographic limits. Since many species are narrow endemics, the system of subdividing the genus into sections is more satisfactory in *Begonia* than it might be in many other

genera. Even here, however, many true relationships are obscured, and some species have been described numerous times from different localities.

Twelve sections are described from Africa, 20 from Asia, 27 from America; one with three subsections is American-Asiatic. A few additional sections of uncertain relationship from each area have also been designated.

Although the plants vary in size, habit, and floral structure, they are usually recognizable as begonias because of their generally succulent (fleshy, thick) leaves and stems and the slightly to markedly oblique leaf outline characteristic of most species.

Botanically the family Begoniaceae offers many taxonomic problems of interest. No complete modern monograph is yet available, the most detailed studies having been prepared for particular geographic areas, usually as parts of more inclusive floras. Phytogeographic (plant distribution) studies would produce many interesting and worthwhile results because of the high percentage of endemism in the family. If combined with monographic work, such research would probably result in a reduction of the number of species now recognized.

Taxonomic problems. The order Begoniales is presented in this article in a form generally accepted by botanists; *i.e.*, including two families, Begoniaceae and Datisceae, the latter containing the genera *Datisca*, *Tetrameles*, and *Octomeles*. In 1965, however, the last two genera were accorded family status (Tetramelaceae) and thus were separated from the Datisceae. This newer arrangement seems to be a more satisfactory classification than any previously proposed.

Nonetheless, problems remain concerning the relationship of the families Datisceae and Begoniaceae and the true affinity of each in the general classification system. Casual observation of the plants in the two families does not give much insight into their possible relationship because of the enormous differences in the habit and aspect of their members.

A need exists for more detailed observations, utilizing modern techniques and on a family-wide basis, of trichomes (plant hairs), pollen, chromosomes, and seeds. A broad-scale anatomical survey might serve to clarify and perhaps to modify relationships between species groups.

(B.G.S./L.B.Sm.)

Capparales (caper order)

Capparales, the caper order of flowering plants, consists of eight families, 427 genera, and 4,000 species. The type family, Capparaceae, derives its name and importance from *kapparis*, the Greek name used by Dioscorides for *Capparis spinosa*, which is the source of the caper of commerce. The genus *Capparis* is often confined to arid regions of the tropics and subtropics and includes diverse growth forms such as trees, shrubs, and stragglers. In addition to this dominant genus, the order has several other genera that provide food and flowers to mankind. The cabbage, cauliflower, knol kohl (all three are varieties of *Brassica oleracea*), turnip (*B. rapa*), and radish (*Raphanus sativus*) are important vegetables, rich in sulfur compounds and vitamin C. The edible mustard oil is from the seeds of *Brassica juncea* and *B. campestris*. The well-known horseradish tree (*Moringa oleifera*) is cultivated for its edible roots and fruits and for ben oil, used as a lubricant for watches. The mignonette (*Reseda odorata*), stock (*Matthiola incana*), wallflower (*Cheiranthus cheiri*), and candytuft (*Iberis* species) are garden plants widely cultivated for their flowers.

The two so-called crucifixion thorns (*Koeberlinia spinosa* and *Canotia holacantha*) together constitute an interesting growth form characterized by leafless, thorny thickets found only in the southwestern deserts of North America.

GENERAL FEATURES

Diversity of structure and habit. The members of the order exhibit diverse growth features. Some, such as *Craeteva nuxvula* and *Moringa oleifera*, are small, deciduous trees, cultivated in the tropics and subtropics. Many others are armed or unarmed (*i.e.*, thorny or not) shrubs.

Thorns

The arms are the paired, stipular (located at the base of leafstalks), recurved thorns, as in *Capparis spinosa* (capers), *C. micrantha*, and *Apophyllum anomalum*, which are distributed in the Mediterranean region, Africa, and Australia, respectively. The arms may also consist of the tips of the branches in *Zilla myagroides* of the Nubian Desert of Africa and *Koeberlinia spinosa* and *Canotia holacantha* (crucifixion thorns) of the southwestern deserts of North America. The leaves are short-lived in many of these species. The order is also rich in stragglers (sprawling, vine-like forms), such as *Capparis sepiaria* of India, *C. cucurbitina* and *C. scortechinii* of Malaysia, and woody lianas, such as *Maerua arenaria* of India, *Roydsia parviflora* and *R. scortechinii* of Malaysia, and *Ritchiea frangrans* of tropical Africa. The Australian *Emblingia calceoliflora* is a prostrate undershrub with a hispidulous (hairy) stem. *Cleome* (bee plant) and allied genera are mostly glandular, annual (short-lived) herbs; *Isomeris arborea* (burro fat), a close ally, is a shrub in the Mexican desert. The herbaceous annuals are also represented widely by *Capsella bursa-pastoris* (shepherd's purse), the herbaceous perennials (plants that continue to grow season after season) by *Cheiranthus cheiri* (wallflower) and *Cochlearia officinalis* (scurvy grass), and the woody perennials by *Alyssum spinosum* and *Vella spinosa*, all of the above belonging to the north temperate zone. The common aquatic forms are *Rorippa palustris* (marsh cress), *Cardamine pratensis* (cuckoo flower), *C. rotundifolia* (mountain watercress), *Nasturtium officinale* (watercress), and *Subularia aquatica*, which are all found in temperate regions and on tropical mountains. *Nasturtium officinale* has spreading stems that root at the nodes ("joints" of a stem) and pinnate leaves (i.e., leaves with either veins or separate leaflets arranged

along either side of a central axis). *Subularia aquatica* has long, narrow, centric (shieldlike) leaves; its flowers either project above water or remain submerged and then rely on self-fertilization, because they remain closed. There are tufted xerophytes (plants adapted to dry habitats) such as *Erophila verna* and *Anastatica hierochuntica* (rose of Jericho) of Europe and the Mediterranean region, which have hairy or fleshy leaves and grow on sand dunes. Saline (salty-habitat) succulents, such as *Cakile maritima* (sea rocket) and *Crambe maritima* (sea kale), are found along the Atlantic and Baltic shores and in the Mediterranean region.

Economic importance. Examples from the family *Capparaceae*. The pickled flower buds of *Capparis spinosa* are the commercial European capers. The root bark is bitter and has been used to treat rheumatism, paralysis, toothache, and disorders of the liver and spleen. The fruits and flower buds of *C. decidua* are edible and are often preserved in salt vinegar. The flower buds are used as potherbs. The fruit is astringent and has been used to treat heart disorders. The hard, heavy wood is used to make tool handles and boat knees (a bent piece of wood used as a brace in boat construction) because it is resistant to termite attack. *C. sepiaria*, the Indian caper, is planted as a hedge. It has been used to decrease fevers and to treat skin diseases. *C. zeylanica* fruits are edible and used in curries. The root bark has been used as a sedative and is effective against cholera. *C. mitchellii* fruits are edible and are consumed in Australia and Tasmania. *C. corymbifera* flower buds are preserved in salt vinegar and eaten. The pounded leaves and twigs of *Cadaba farinosa* are made into cakes, puddings, and cereals; as food, the plant is called *forsa* or *balambe* in the Arabian Peninsula and tropical Africa. The leaves and seeds of *Cleome icosandra* are useful as external applications for wounds and ulcers. The seeds are also used in curries. *C. spinosa* (spiderflower) is grown as an ornamental. The ashes from the stems and leaves of *Courbonia virgate* are used as a source of salt in parts of The Sudan and Arabia.

Edible and useful products

Examples from the family *Brassicaceae*. *Alliaria officinalis* (garlic mustard) is used to treat gangrenous infections. *Armoracia lapathifolia* is the well-known horseradish, whose roots are used for flavouring food. *Barbarea verna* (Belle Isle cress) is used as a vegetable. *Brassica campestris* variety *sarson* (yellow sarson, or Indian colza) provides seed oil, which is used for cooking, and oil cake, which is used as cattle feed; the tender leaves and shoots are eaten as a vegetable. *B. campestris* variety *toria* (Indian rape) has similar uses. The tender leaves and shoots of *B. hirta* (white mustard) are used as a vegetable; the seeds yield a fatty oil. *B. juncea* (Indian mustard) seed oil is used for cooking. *B. napus* (rape) leaves are used as vegetables. The seeds of *B. nigra* (black mustard) are used as a spice and condiment. *B. oleracea* variety *acephala* is the vegetable borecole, or kale. *B. oleracea* variety *botrytis* is cauliflower or broccoli, which is grown all over the world for its edible inflorescences (flower clusters). *B. oleracea* variety *capitata* is cabbage. *B. oleracea* variety *gemmifera* is Brussels sprouts, a bud-bearing cabbage, the young shoots, buds, and leaves of which are edible. *B. oleracea* variety *gongylodes* is kohlrabi, or knol kohl, the short, swollen stem of which is edible. *B. pekinensis* is Chinese cabbage. *B. rapa* is the turnip. *Raphanus sativus* is the well-known radish.

Plants related to cabbage

Representative plants from six of the eight families of the order Capparales.

NATURAL HISTORY

Adaptations for pollination. The perpetuation and spread of this order is facilitated by the efficient adaptation of its flowers, fruits, and seeds for pollination and dispersal. In the family *Capparaceae*, the pollination is by insects, which are attracted by nectar secretion, dense aggregation of the flowers, and the bright colours of the petals. Dichogamy, the maturing of the male and female organs of the same flower at different times, favours cross-pollination in many cases, as does, in *Cleome spinosa* (spiderflowers), the production of male flowers alternating with female and bisexual flowers in succession. In the family *Brassicaceae*, both cross- and self-pollination of the flowers occur. The twisting of stamens (male pollen-producing structures) to one side may favour cross-pollination.

nation. In such instances, however, the slightest irregularity in the movement of the visiting insect may cause self-pollination because of the close proximity of the anthers (pollen sacs) to the stigma (sticky, pollen-receiving surface of the female structure). In *Cardamine chenopodifolia* and *Subularia aquatica*, the flower remains submerged and closed (the cleistogamous condition) when the water is high. *Pringlea antiscorbutica* (Kerguelen Island cabbage) is wind-pollinated in the absence of insects suitable for its pollination. The flowers are without petals but have exerted (long, extended past the end of the flower) anthers and long, filiform (threadlike), stigmatic pollen-catching structures. In *Cardamine pratensis* (lady's smock), self-sterility favours cross-pollination. In mignonette (*Reseda odorata*) of the family Resedaceae, different parts of the flower play different functions in the process of pollination. Nectar is secreted by the large, posteriorly projected petallike disk. The white, fringed edges of the petals, the red anthers, and the strong odour attract the insect visitors. The pistil (female structure consisting of stigma, style, and ovary), with terminal, papillose (nipplelike) stigmas, projects from the centre, and the stigmas receive the pollen carried by insect visitors. If the insects fail to visit the flowers, the stigmas, which lie directly below the anthers, eventually receive pollen from them and achieve self-pollination.

Adaptations for dispersal. The dispersal of fruits and seeds in the Capparales order is caused by a variety of agents. The wind is the chief agent of dissemination in the desert. In North African deserts, fruits and seeds are either winged or are light or hairy; a pair of wings usually surrounds the fruit in *Zilla macroptera*, and the seeds are velvety in *Cleome arabica*. In *Morettia phileana* of the Nubian Desert and *Sisymbrium altissimum* (tumbling mustard) of Europe and North America, the withered plants and their inflorescences (flower clusters) are blown about, scattering the fruits and seeds. In *Anastatica hierochuntica* (rose of Jericho) of the deserts of Asia Minor and North Africa, the plants curve into balls, or "roses," in drought and are blown along by the wind until they reach a wet spot; there the balls unfold along with the valves of the fruit, dispersing the seeds. In *Biscutella californica* the fruits are edged with hairs. In *Cochlearia*, the four- to six-seeded locules (ovary chambers) are dispersed by the valves acting as wings. In *Draba verna* (whitlow grass) the thin septum of the dried fruit sends the small, light seeds away like tennis balls from a racket. The fruits of *Crataeva nurvala* and *C. macrocarpa* in Malaysia, Myanmar, and Indochina and the seeds of *Mathiola incana* (stock) and *Nasturtium officinale* (watercress) are dispersed by river waters. The seeds of *Cakile maritima* and *Crambe maritima* and the fruits of *Raphanus maritimus* are disseminated by sea tides. In *Nasturtium lacustre* and *Cardamine pratensis* (cuckooflower) the leaves with bulbils or adventitious buds float and develop into new plants elsewhere. Animals act as agents for the dispersal of seeds in the order Capparales through their excreta. Seeds of *Sisymbrium sophia* and *Capsella bursa-pastoris*, for example, are distributed through the excreta of cattle; fruits of *Draba alpina* and seeds of *Cardamine bellidifolia* and *Cochlearia arctica* are dispersed in the excreta of birds; and fruits of *Draba verna* are carried in the excreta of earthworms. The seeds of Capparales may also be dispersed by simple adhesion to the feet of man or cattle and to the wheels of carts. The mucilaginous seeds of *Capsella bursa-pastoris* stick to the feet of gulls and those of *Cardamine* (white top), *Senebiera heleniana*, and *Lepidium perfoliatum* (peppergrass) to seashore birds.

Adaptation to environment. The propagation of plants by seeds is strongly handicapped in saline and arid conditions because of incomplete seed ripening in mother plants at times; low soil moisture; hard, nonabsorbing soil crusts; high concentrations of soluble salts; or destruction of seedlings due to various factors such as irregular rainfall, animals, wind erosion, and deposition of mud. Large seeds with large food supplies may be advantageous in establishing seedlings in spite of competition for light and moisture, eating by animals, wind erosion, and other factors. The large seed of *Crambe maritima*, for example,

sends down an extensive root at an early stage of development, enabling the species to colonize adverse habitats in the early phase.

Delayed germination. Many of the desert seeds possess germination-inhibiting substances. The seeds of *Eruca boveana* and *Carrichtera annua* of the dry Mediterranean, Arabian, and Persian regions contain inhibiting factors; as much as 4 to 8 inches (10 to 20 centimetres) of rain wash away these factors, thereby considerably improving the percentage of germination of such seeds. The fruit valves of *Sinapis alba* contain a blastokoline substance that suppresses the germination of the seeds. Some desert annuals from Arizona sprout only after a long period of ripening. *Lepidium lasiocarpum* is ready to germinate after one year and *Streptanthus arizonicus* after 26 months. The presence of inhibitors and the habit of germinating only after a long period of ripening are believed to be adaptations that enable a proportion of the seeds to get established at times when favourable external conditions exist. Many annuals seem to counterbalance the danger of extermination in dry habitats by profuse seed production. Even the tiniest ephemeral, such as *Erophila verna* of the Mediterranean region, sets numerous fruits and ripens large numbers of seeds.

Sexual versus vegetative propagation. The natural propagation of plants by seeds is observed mainly in crop plants. In ornamentals, however, the propagation is by both seeds and vegetative means.

In an environment that is favourable for growth and flowering, such as the damp woodlands of the British Isles, profuse vegetative propagation takes place as an alternative to low seed production. Although plants of *Cardamine pratensis* (lady's smock) flower profusely, seed production is scanty, and 70 percent of them reproduce vegetatively by means of buds developed at the base of the terminal leaflets. In *Dentaria bulbifera* (coralroot) reproduction is exclusively or mainly by means of bulbils that replace the lower flowers on the inflorescence. The upper flowers rarely produce fertile seeds. The bulbils, about 0.04 inch (1 millimetre) in length and thrice that in thickness, normally develop near the parent plant. Vegetative spreading is also by rhizomes, horizontal, rootlike stems. The species is restricted to certain woods in Great Britain, although many other woodlands appear to be suited for its growth. Similarly, *Nasturtium sylvestris* (wood cress) rarely produces fertile seeds in spite of free flowering. It spreads profusely by means of prostrate stems that root at the nodes.

Ecology. Members of this order grow in varied ecological conditions. Trees, shrubs, and climbers of *Crataeva*, *Maerua*, and *Capparis* grow in tropical rain forests. In tropical deserts the undershrubs and shrubs such as *Farsesia aegyptiaca*, *Zilla myagroides*, *Capparis spinosa*, *C. decidua*, *Apophyllum anomalum*, *Koeberlinia spinosa*, and *Canotia holacantha* grow in rock clefts and on sandy hillocks.

Plants such as *Crambe maritima*, *Cakile maritima*, and *Cochlearia anglica* grow along the seashore, enduring low concentrations of salts and the consequent physiological dryness. *Draba alpina*, *Cochlearia nudicaulis*, and *Cardamine bellidifolia* grow in Arctic regions, withstanding continuous light during summer and low temperatures and dry winds in winter. *Cochlearia fenestrata*, along with its flowers and fruits, resists low temperature without protection.

FORM AND FUNCTION

Morphological features. The order consists of herbs, shrubs, small trees, and lianas. The leaves are alternate or opposite, simple or palmately compound, and they have stipules. In *Capparis*, *Apophyllum*, *Koeberlinia*, and *Canotia*, the leafless shrubs form dense thickets either by recurved stipular spines or thorny-tipped branches.

The flowers have petals, are bisexual, and are hypogynous (i.e., the sepals, petals, and stamens arise at the base of the ovary) or perigynous (sepals, petals, and stamen partly enclose the ovary), with numerous to few stamens and an ovary of two or more fused carpels. The fruit may be a fleshy berry or drupe or a dry silicle, silicle, or capsule—

Dry
habitat
adapta-
tions

fruits that open along one or more sutures. The seeds are curved or straight, winged or nonwinged.

Physiological features. In desert species such as *Caparis decidua* and the crucifixion thorns, spiny, leafless, green stems form thickets, and there are strongly developed taproots. *Apophyllum anomalum* of Australia is also leafless but is covered with a thick coat of plant hairs. In *Zilla spinosa* and *Ochradenus baccatus* the leaves of the rainy season are replaced by smaller summer leaves. The seaside *Cakile maritima* and the dune-inhabiting *Cochlearia officinalis* are succulents; by storing water in their stems and leaves, the former resists high salt concentrations and the latter drought.

The Arctic and alpine *Draba alpina*, *Cochlearia nudicaulis*, *C. fenestrata*, and *Cardamine bellidifolia* have thick, small, cushionlike stems and short, leathery leaves with concealed stomata (pores).

EVOLUTION, CLASSIFICATION, AND TAXONOMIC STATUS

The families Capparaceae and Brassicaceae form the core of the order Capparales. They have many common vegetative and floral features and cells. Other shared features suggest that the family Capparaceae is ancestral to the Brassicaceae.

There are many taxonomic problems in this order. The orders Capparales and Violales are regarded by some authorities as parallel offshoots of the order Theales. Others, however, consider the Capparales to have originated from the most primitive members of the order Violales, similar to the family Flacourtiaceae of that order.

The Cleomoideae, a subfamily of the Capparaceae, closely resemble the family Brassicaceae in their herbaceous habit and capsular fruit with central partitions. Some authorities raise the Cleomoideae to the rank of family, called Cleomaceae, which is considered to be closely related and basic to the family Brassicaceae. This treatment needs support from other enquiries into floral anatomy, embryology, and pollen morphology, however.

The resemblance and position of the family Tovariaceae with respect to the family Capparaceae could be better understood if the vascular anatomy of the axile placentation and eight-parted flower were better known.

The systematic position of the family Emblingiaceae is disputed. It shows resemblances to the families Capparaceae, Goodeniaceae, Scrophulariaceae, and Verbenaceae and Polygalaceae. More information on the floral and vegetative anatomy, embryology, and other details of this family will be necessary to establish the exact relationship of this group. (H.S.N.)

Ericales

The Ericales is an order of about 2,700 species of plants, largely shrubs or small trees, arranged in 10 families and about 135 genera.

The number of species used as ornamentals is inordinately large when compared with other plant groups of similar size. Many of the most beautiful and prized horticultural plants throughout the world are found in the Ericales, notable examples being azaleas and rhododendrons. Blueberries and cranberries are among the economically important members of the order.

GENERAL FEATURES

Structural diversity and distribution. Although predominantly woody shrubs and small trees, the order includes herbs, undershrubs, vines, epiphytes (plants that grow upon other plants), herbaceous saprophytes (nonphotosynthetic plants that obtain nourishment from dead organic matter), and root parasites. A few tree species attain heights of 75 to 100 feet (20 to 30 metres).

Ericads are very widely distributed in the tropics and throughout temperate regions of the Northern and Southern Hemispheres and are a significant component of the subarctic circumpolar flora. A few extend into the Arctic and the Antarctic regions. A number of genera are indigenous to southern Africa, and the large family Epacridaceae is in a sense the Australian segment of the order.

It has been customary to think of the species of the

Worldwide
distribu-
tion

Representative plants from three of the principal families of the order Ericales.

Drawing by M. Pahl based on (Epacridaceae, Ericaceae all but ovary) G.H.M. Lawrence, *Taxonomy of Vascular Plants* (1951); The Macmillan Company, (Ericaceae ovary) J. Hutchinson, *The Families of Flowering Plants*; The Clarendon Press, Oxford

Ericales as inhabitants of temperate and cooler regions, with tropical representatives being confined to the cool, high mountainous regions. A majority of species do occupy these areas, but the recent inclusion of the families Actinidiaceae and Saurauaceae in the order has extended the group's range into typically tropical situations of Asia and America. As a general rule, ericalean plants prefer acid soils.

Economic importance. Ericads have served as tea substitutes; early explorers of Canada and the eastern and northern regions of the United States, for example, brewed tea from the leaves of Labrador tea, or bog tea (*Ledum palustre*); Lapland rosebay (*Rhododendron lapponicum*); and checkerberry, or teaberry (*Gaultheria procumbens*). The Ojibwa Indians similarly used bog rosemary (*Andromeda glaucophylla*) and leatherleaf (*Chamaedaphne calyculata*).

For centuries the best material for making briar pipes has been wood from burls of *Erica arborea* or related Mediterranean species.

Ericalean plants have been and still are most important to man as foodstuffs and as cultivated ornamentals. Checkerberry (*Gaultheria procumbens*), certain of the bearberries (*Arctostaphylos* species), and creeping snowberry (*Chionogenes hispidula*) produce edible fruits. In Asia the fruit of the tara vine (*Actinidia arguta*) is much sought after, and the kiwifruit, or Chinese gooseberry (*Actinidia chinensis*), is commercially important in New Zealand. But it is the huckleberries, the blueberries, and the cranberries that are most prized as fresh fruits or as jellies or preserves.

Cranberries (*Vaccinium macrocarpon*) are cultivated in

Edible
berries

Massachusetts, especially on Cape Cod; in New Jersey; in Wisconsin; and in the Pacific Northwest. They are also harvested from wild stands in these areas. The tart fresh berries are processed with sugar and sold as cranberry sauce or jelly. Cranberries, first cultivated in New England in the early 19th century, are still one of the leading exports of Massachusetts. Cranberry sauce and jelly have come to be thought of as uniquely American, but the Scandinavians hold in high esteem their own native cranberry (*V. vitis-idaea*), the berry of which is spicier than the American fruit.

Huckleberries (*Gaylussacia baccata*) are harvested only from wild stands in the eastern United States and Canada. Although the flesh of the fruit is generally considered to be sweet and delicious, the "berry" is actually a drupe, or stony-seeded fruit, with 10 large, hard nutlets, making it less desirable and marketable than blueberries.

Blueberries of many types are harvested from wild stands in New England and the eastern states and from northern California into western Canada. Several species of *Vaccinium* are involved. They range from lowbush to highbush species and from diploid to hexaploid forms (i.e., genetic variants with two to six sets of chromosomes, respectively). Blueberries, with their small and insignificant seeds, are widely considered a delicacy, and their production is economically significant, especially in New England.

Ornamen-
tal uses

The other major use of ericads is as ornamentals. In Asia some of the vinelike forms (*Actinidia arguta* and *Clematiclethra* species) are cultivated for their deep green foliage. Several species of sweet pepper bush (*Clethra*) are used horticulturally to take advantage of the highly fragrant summer flowers. The leatherwood (*Cyrilla racemiflora*) and buckwheat tree (*Cliftonia monophylla*) are used similarly and also are desirable for their showy autumn coloration of foliage. The sourwood (*Oxydendrum arboreum*), one of the few trees in the order, is also cultivated because of the brilliant colour of its foliage in autumn. In Europe and New England, the heather (*Calluna vulgaris*) and some of the low bushy heaths (*Erica* species) are used as garden border plants. Many ericads are planted in gardens as novelties or to provide variation in foliage colour and texture.

The most important ornamentals in the entire order, however, are found in the genus *Rhododendron*, the azaleas and the rhododendrons, about 850 species of which are or have the potential to be ornamentals. Some of the most spectacular flower clusters known are produced by these shrubs, and they are widely used not only for the beauty of their blooms but also for the value of the many evergreen species as effective background shrubs. Natural species are cultivated, and many hybrids have originated in cultivation; it is thus difficult to develop a classification that includes all species, varieties, and forms. It is safe to say, however, that there are at least 1,000 varieties of rhododendrons and azaleas in cultivation.

Noxious ericads. The order contains a few species harmful to humans or animals. Some contain a toxic substance identified as andromedotoxin. This compound is known to occur in certain species of *Rhododendron*, *Leucothoe*, *Menziesia*, *Ledum*, and *Kalmia*, and it is probably more widespread in the order than is now known. Humans can be poisoned by chewing on leaves and twigs or by sucking nectar from the flowers of these plants. Poisoned honey has been reported in areas in which bees visit large *Rhododendron* or laurel (*Kalmia*) stands, but the honey is so bitter that very little of it can be eaten. The poison causes watering of the mouth, eyes, and nose; vomiting; slow pulse; and depressed blood pressure. Massive ingestion of andromedotoxin results in convulsions and slow and progressive paralysis until death; fatalities, however, are rare.

Several species of laurel (*Kalmia*) long have been known to be poisonous to domestic animals. *Kalmia angustifolia* is known colloquially as sheepkill, lambkill, or calkill, and one common name of *K. latifolia* is poison laurel. Sheep and cattle may become ill and die from eating foliage of these plants, but deer do not seem to be affected. The course of the disease parallels that in humans who have taken massive ingestion of andromedotoxin—convulsions, progressive paralysis, and death. Laurel poisoning is not a serious problem in sheep or cattle, however, probably be-

cause the tough, leathery leaves are not desirable except in the absence of more palatable foliage. Cases of poisoning are more frequent in sheep than in cattle.

NATURAL HISTORY

Pollination. Compared with some of the very highly specialized plant groups, such as the orchids, few unusual or unique features exist in the life cycle of the ericads. There has been only the slightest tendency toward development of irregular flowers, and highly involved and complicated methods of pollination are rare.

Probably most ericads may be pollinated in more than one way, but studies on pollination in the Ericales have been sketchy. In the heather (*Calluna vulgaris*), the nectary in the flower is a continuous, fleshy ring around the base of the ovary (female structure), and the lower parts of the petals and stamen filaments (basal parts of the male structures) are also succulent. An insect forcing its proboscis into the flower shoves the anthers (pollen sacs) apart. Anther chambers open laterally, and hornlike appendages attached to the anthers help deposit pollen on the insect's proboscis by acting as levers. Pollen is carried to another flower by the insect and deposited upon the stigma (pollen-receptive surface of the female structure) as the insect probes for nectar in the flower.

Insect
pollination

Nectar production decreases near the end of the pollination period. The filaments then elongate and extend the open anthers beyond the confines of the flower; thereafter wind pollination occurs.

Another kind of pollination also takes place in the same heather flower. Certain small insects (*Taeniothrips ericae* [Thysanoptera]) appear to be present at all times in *Calluna* flowers. These tiny insects are very lively, move about actively, and reach parts of the flower inaccessible to larger insects. Pollen discharged during their activity adheres to their bodies, which become sticky with nectar.

The males of *T. ericae* are much rarer than the females and cannot fly. Females, therefore, take the aggressive role and fly from flower to flower searching for males. They depart from projecting stigmas, their bodies heavily laden with pollen, and presumably land on stigmas, thereby probably being able to effect both self- and cross-pollination.

The laurels (*Kalmia* species) have two pouches in each of the five partly fused petals. Anthers are retained under tension in these pockets until the flower opens; then the filaments snap the anthers up, and pollen is forcibly ejected. Laurel flowers are visited by bees that almost certainly effect pollination. Presumably elevation of the anthers above the saucer-shaped flowers of *Kalmia* also permits wind pollination.

Mycorrhizal relationships. Mycorrhizae are structures formed by plant roots and the fungi that live in close association with them. Mycorrhizal associations are common and widespread in the Ericales. It has been suggested that probably all ericads are in some mycorrhizal relationship. Although considerable research has been done on the nature of the relationship, much of the work has been challenged and is of doubtful validity. In most instances, the species with an obligate relationship and those without cannot be identified with certainty; the relationship is obligate, however, in the few members of the family Pyrolaceae that occasionally lack chlorophyll and in the family Monotropaceae, all of whose members lack chlorophyll. In addition to these families, mycorrhizae have been reported in the Clethraceae, Epacridaceae, and Empetraceae. The phenomenon, which is widespread in the Ericaceae, probably occurs in all families of the order.

The structure of the ericalean mycorrhiza has been described as being intermediate between the conditions called ectotrophic and endotrophic, and the term ectendotrophic has been used to describe the mycorrhiza of *Monotropa*. Host roots are enveloped by masses of fungal hyphae (filaments of fungus cells) as in ectotrophs, but hyphae penetrate the cells of the host root tissues, as in endotrophs.

The fungi involved in the relationship are members of the fungal classes Deuteromycetes and Basidiomycetes. A number are of the genus *Rhizoctonia*. Little is known

as yet of the physiological relationships between the fungus and the plant. The view that species of *Phoma*, a deuteromycetes associated with some ericads, serve to fix free atmospheric nitrogen appears to be unfounded. There are advocates of a theory that fungi may serve in some capacity to synthesize various carbon-containing materials from the soil, which are then passed along to the host plant. This explanation is especially attractive in explaining saprophytic situations of nongreen ericads. It must be assumed that the fungus utilizes organic compounds from the soil and transfers its products in forms useful to the plant.

EVOLUTION

Fossil records of ericads are not numerous, especially considering the number of species in the order. All have been found in deposits of the Tertiary Period (2,500,000 to 65,000,000 years ago) and mostly from the Oligocene Epoch (26,000,000 to 38,000,000 years ago) and the Miocene Epoch (about 7,000,000 to 26,000,000 years ago).

Fossil leaves of *Saurauia* have been found in Alaska, and *Actinidia* leaves have been recovered from California. Miocene layers in Oregon have yielded leaves of *Arbutus trainii*, which closely resemble those of the living madrona (*A. menziesii*) of the Pacific Coast. Fossil records of *Arctostaphylos*, *Vaccinium*, and *Andromeda* also have been reported.

Fossil
pollen
grains

Many fossil pollen grains have been taken from Miocene deposits at Rypin, Poland. In some cases, some of them have been assigned to the Ericales because of structural resemblances; in other cases, they have been so assigned because of structure and the fact that they occur in tetrads (groups of four), a condition common in living ericads. *Cyrilla* appears to be represented by three species. Several pollen tetrads have been assigned to the Ericaceae, but only those of the genus *Rhododendron* are clearly identified.

The fossil record is of little help in tracing phylogenetic relationships within the order or between the Ericales and other orders. Relationships must be determined largely from comparative morphological studies of living forms. Close affinities between the order Ericales and the order Diapensiales are recognized, and a common ancestry for the two is postulated in the order Theales. A close relationship of these groups has been recognized for some time.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. Although there are exceptions to most features, ericads generally are shrubs with alternate, simple, leathery leaves. Their flowers have functional structures of both sexes and are regular (radially symmetrical) with a four- or five-parted corolla (collection of petals) of partly fused petals. Stamens number twice the number of corolla lobes and usually are attached directly to the receptacle (expanded stalk tip that carries the flower parts). Anthers open by terminal pores, and pollen is discharged in tetrads. The pistil (female structure) is compound with one style (upper, narrow, elongated part of pistil). The ovules are numerous and are attached along the central axis of the ovary. The only characteristics shared by all ericad species are that the ovule has but one integument, or covering cell layer, and the nucellus (central part of ovule) is a single cell layer thick.

Variations in the above characteristics provide the bases for establishing families and for determining relationships between them. Major variables of taxonomic significance are: number of floral parts, degree of fusion of floral parts, degree of fusion of floral parts with the ovary, type of anther dehiscence (opening), structure of pollen, structure of ovary, and type of fruit.

Taxonomic problems. Close relationships among the families Clethraceae, Pyrolaceae, Monotropaceae, Ericaceae, and Epacridaceae have been recognized for many years, although taxonomists have not agreed in their treatment of the families. The family Monotropaceae frequently is combined with the Pyrolaceae, and both families are sometimes included in the Ericaceae. The family Vacciniaceae, which is composed of those species of the Ericaceae that have partly to wholly inferior ovaries, is sometimes recognized.

In any of these manipulations, however, the five "core families" comprise some 2,200 species, or more than 80 percent of the approximately 2,700 species of the order.

Inclusion of the family Empetraceae in the Ericales has become almost universally accepted in recent years, although one important taxonomist retains it in the order Celastrales.

Fairly recently the family Cyrillaceae has been placed in the Ericales, an arrangement that is gaining acceptance. Previously, it was assigned to the Celastrales, and, in some systems, it remains there.

The families Actinidiaceae and the Saurauiaceae are obviously closely related to each other, and it is common to find the Saurauiaceae within the Actinidiaceae. These families have affinities with both the orders Dilleniales and Theales, and modern taxonomic treatments are about equally divided in placing them in one or the other order. Referred to the Ericales, as is done here, they are the most primitive families in the order and may be regarded as near ancestral to the families more traditionally comprising the Ericales.

Inclusion of the family Grubbiaceae in the Ericales has been to date quite widely rejected. The family consistently has been placed in the order Santalales for a great many years. The main stumbling block to general acceptance of the Grubbiaceae in the order Ericales is the structure of the pistil. The ovary is inferior and, as it begins its development, is more or less two-locular (chambered). As the ovary continues to mature it becomes unilocular with a standing, free-central placenta that bears two pendulous ovules. This ovular structure is so typical of the order Santalales and so completely atypical of the order Ericales that few taxonomists consider the ericad characteristics of the Grubbiaceae to outweigh the santalalean structure of the ovary. (H.T.C.)

Ebenales (ebony order)

The ebony order of flowering plants (Ebenales) consists essentially of woody trees or shrubs growing in the tropics. They have simple, smooth-margined leaves arranged alternately along the stems and bear radially symmetrical flowers that display diverse floral plans. The sepals and petals usually number four or five, and they are always fused. The male reproductive structures, or stamens, are variable in number and are arranged in one or more whorls. The female structure, or gynoecium, is superior—i.e., positioned above the point of attachment of the sepals, petals, and stamens—and it is usually composed of many sections called carpels. The ovules, or seed precursors, are attached to a central axis in the ovary. Glandular, or secretory, cells are often present in the flowers.

Five families are included in the ebony order. Only three of these are of numerical or economic importance, however. They are the Ebenaceae, the Sapotaceae, and the Strycaceae.

GENERAL FEATURES

Distribution and abundance. The family Strycaceae contains about 150 species, which are grouped into 10 genera; these plants grow mostly in hot climates. The most important genus, *Styrax*, contains about 100 species, of which one is found in the Mediterranean area (*Styrax officinalis*).

The family Ebenaceae contains only four to six genera, although it has a total of some 450 species. The genus *Diospyros* (persimmon and ebony) is the most important one in the family both numerically (350 species) and economically. The present-day distribution of the family Ebenaceae is largely pantropical. One-third of the species are found in Asia (India, Indonesia, Indochina, and the Philippines); another third are in Africa and Madagascar; and, of the remaining third, one-half are in Central and South America and the rest in Oceania (including Australia). There are, of course, a few species in subtropical climates, and four are found in warm temperate zones (North America and Asia). Ecologically, 85 percent of the tropical species grow in forests, with 60 percent in the evergreen forests. The zone of distribution of different species

Representative plants from the three principal families of the ebony order.

Drawing by M. Pahl based on (*Diospyros* flowers) J. Hutchinson, *Families of Flowering Plants*, The Clarendon Press, Oxford

of the family Ebenaceae varies enormously; for example, *Diospyros virginiana* (persimmon) extends from Texas to Florida and northern Connecticut, but *D. mafiensis* is known only from a very small area in East Africa.

The family Sapotaceae contains 63 to 126 genera, depending on the authority consulted, and more than 600 species, whose features contrast sharply depending on whether the species is found in the New World or the Old World. For example, no genus with a two-whorled calyx or with more stamens than petals is to be found in the Americas. Genera of plants with ovaries of three or fewer chambers occur very frequently in the Americas but are exceptional in the Old World. The same contrast applies to the relative distribution of unisexual—separate male or female—flowers. In Africa the area from Guinea to the Congo basin is richly endowed with species of the family Sapotaceae, particularly in Cameroon and Gabon. Madagascar has both pantropical and endemic (strictly native) genera. The island of Mauritius has an endemic genus (*Labourdonnaisia*). The genus *Northea* is found only in the Seychelles. The dry forests, savannas, and steppes that range from The Sudan to the Zambezi River are poor in Sapotaceae species, apart from a few endemics, of which *Butyrospermum parkii* is of economic importance—its oily seeds are pressed to obtain shea butter. New Caledonia is outstanding in the Australo-Papuan zone for the number of endemics of this family. Several regions of tropical America also have particular genera, in addition to genera with more extensive distributions.

Economic importance. *Family Styracaceae.* Economically, the best known representative of the family Styracaceae is the Malayan *Styrax benzoin*, a tall tree that is the source of the resin benzoin. The resin forms in cavities caused by the destruction of tissues in the wood of stems and branches. *Styrax tonkinensis* is also a source of resin;

deep incisions are made in the trunks, and the drops of resin that form in the cuts are collected about two months later. The resins contain vanillin, benzoic acid, and cinnamic acid. The Arab benzoin trade dates back before the Christian Era and provided incense to the Middle East and China. In the Western world it is used for perfumes and as a balsam and antiseptic. Several plants of the family Styracaceae are also used for ornamental purposes (e.g., *Halesia*, *Styrax*).

Ebony family. The family Ebenaceae is of economic importance especially for its timber, which is used in cabinetmaking. The wood, which is denser than water and hence sinks, has a hard, fine grain and is difficult to work, but it takes a magnificent polish. The heartwood of a number of species of *Diospyros* is used to provide a variety of colours: green in *D. chloroxylon* from India; red in *D. rubra* from the Mascarene Islands; white in *D. chryphyllus*, also from the Mascarene Islands; and variegated from *D. hirsuta*. Finally, the black woods, the true ebonies, are obtained from *D. dendo* and *D. mespiliformis*, which grow in equatorial Africa; *D. crassiflora* in Gabon and Cameroon; *D. ebenum* in Sri Lanka; *D. melanoxylon* in India; *D. perrieri* and *D. haplostylis* in Madagascar; and *D. celebica* in the Celebes. There are also other species that produce true ebonies. The quality of the wood is related to chemical changes in the cell walls that occur with respect to the formation of gums. As a result of abusive and indiscriminate exploitation, natural stands of these trees have been considerably diminished.

The fruits of some species of *Diospyros* are edible. The name itself signifies “celestial fruit” or “fruit of the gods.” The best known of these is the kaki, or Japanese persimmon, *Diospyros kaki*, cultivated in Japan. About 800 varieties of this species have been developed, some of which have been acclimatized to the Mediterranean area. The fruits, large orange-red berries, are very astringent until fully ripe, at which time the tannin content is completely transformed into insoluble crystals. The juice is then sweet and palatable.

Edible
fruits

Although *D. kaki* has been cultivated in Japan for several centuries, it originated in China, where it is also highly valued. The fruits of *D. virginiana*, the common persimmon of the United States, are used in jam making or dried like prunes. *D. ebenaster*, the black sapote, is a popular fruit, but little known outside Mexico. The dark colour of the flesh may make it unattractive to the uninitiated, yet it is considered to be equal in quality to the Japanese persimmon. *D. lotus*, a native of Central Asia and the Middle East, is grown in the Mediterranean area of western Europe as an ornamental tree. *D. mespiliformis* from Africa not only has edible fruit but its leaves, roots, and bark possess bactericidal properties. The bark of *D. multiflora* is used in the preparation of arrow poisons.

Family Sapotaceae. There are many species of the family Sapotaceae that are important as sources of timber, fruit, and gamboge (a resin). The heavy, hard, and long-lasting woods of some species of *Pouteria* (white balata) and *Manilkara* (red balata) are harvested in the Guianas and in Brazil, as is *Chrysophyllum pruriens*, also from the Guianas, and *Mastichodendron* species (ironwoods) from the Antilles. In Africa among the commercially important species are *Tieghemella heckelii* from Côte d'Ivoire and Gabon and *Autranella congolensis* of Central Africa. In tropical Asia several species of *Palaquium* are cut for timber, as is *Sideroxylon zwagei* in Indo-Malaya.

The fruits of some Sapotaceae species are edible. The sapodilla (fruit of *Manilkara zapota*, sometimes called *Nispero achras*) has been described as luscious, cool, agreeable, and fragrant. This plant, a native of southern Mexico, not only furnishes an excellent fruit but also a gum, known even to the early Aztecs, who chewed it. Now the milky latex is extracted from the trunk and from unripe fruit, boiled with aromatic ingredients, and made into chewing gum. This useful tree has been cultivated in many hot regions: West Bengal in India, the Hawaiian Islands, and parts of Africa. The sapote (*Calocarpum mammosum*) is another useful fruit from Central America. It is said that Hernán Cortés, the Spanish conqueror of Mexico, and his army were able to stay alive by eating this fruit during

their march from Mexico to Honduras. It is also cultivated in the West Indies, South America, and the Philippines. In the West Indies the sapote is called marmalade plum; in Cuba, mamey colorado. The star apple (from *Chrysophyllum cainito*) is another fruit of Central America and the West Indies.

Other fruits of the family Sapotaceae with local popularity are the canistel (*Lucuma nervosa*), grown in Cuba and Florida; the abia (*Pouteria caimito*) in Peru; and the gambeya (*Synsepalum dulcificum*) in Africa.

Economically valuable oils from seeds

The seeds of many Sapotaceae species contain useful oils, and those of several species of *Madhuca* from India are used both locally in the production of mohwra and illipe butter and exported for the manufacture of edible fats. The oil cakes made of these seeds are rich in saponins (glucose-containing substances that produce soapy lathers) and toxic substances, which have to be eliminated before the cakes can be used as animal fodder. The *beurre de Karité* ("butter of Karité") of The Sudan and the Nile River area across to Senegal is extracted from the seeds of *Butyrospermum paradoxum* (now *Vitellaria paradoxa*), a variously shaped tree native to the savannas of the area. This oil is an important element in the nutrition of the native populations of those areas. In southern Morocco the seeds of *Argania spinosa* yield an oil totalling about 50 percent of the weight of the kernel. The oil, of strictly local use, is an important item in the diet of the tribes of the area.

Other species of the family Sapotaceae furnish latex for commercial use. Gutta-percha, related to rubber but not elastic, is used to insulate submarine electric cables and in the manufacture of golf balls; the substance is found in several species of *Palaquium* from Malaysia (e.g., *P. gutta* and *P. leiocarpum*). In tropical America *Manilkara bidentata* provides a latex known as balata gum, which goes into the manufacture of diving belts.

NATURAL HISTORY

Little is known about the biology of the family Ebenaceae. The aromatic flowers of many species open at night, and the petals fall the next morning. Parthenocarpy, the production of fruits without fertilization, has been observed in *Diospyros kaki*, from which seedless fruits have been obtained. The dormancy of the seeds in some species has been shown to result from the mechanical resistance of the seed coats.

Sapotaceae as keys to the ages of forests

Ecologically, the family Sapotaceae is represented most abundantly in damp forests, where they give an indication of the age of the forest by their quantity relative to other species. They are usually large-sized trees. Members of this family are also fairly numerous in the coastal thickets of tropical seas and along river banks. Although they are practically lacking in the arid zones, spiny representatives grow in semi-arid areas, and small trees less than 10 feet (3 metres) high occur in thickets in New Caledonia.

Only the cultivated species have really been studied. It has been observed, however, that certain species (e.g., *Butyrospermum paradoxum*) are a particular attraction to bees and that others are pollinated at night by bats.

FORM AND FUNCTION

Family Styracaceae. The family Styracaceae is composed of small trees or shrubs with alternately arranged leaves that lack stipules, small leaflike appendages at the bases of leafstalks. The leaves are characterized by a hairy covering of stellate (branched in starlike patterns) plant hairs or scales. They have five-parted flowers with a calyx that is often fused.

The petals of the corolla are usually nearly free; i.e., not fused together. The male reproductive complex is usually composed of two whorls of stamens (diplostemony), although single whorls sometimes occur. The gynoecium (female reproductive complex) is located above the attachment point of the other flower parts or is partly enclosed by the bases of the sepals, petals, and stamens—its position is thus said to be superior or semi-inferior. It is composed of three to five segments called carpels, which form the same number of interior chambers, or locules. The partitions between the locules, however, are incompletely

formed and exist only in the lower half of the ovary. One or more erect or pendulous ovules are present in each locule. The fruits are drupes (stony-seeded, nonsplitting fruits) or capsules containing one or more seeds.

The ebony family. The family Ebenaceae consists of trees and shrubs with alternate (rarely opposite) simple, smooth-margined leaves that lack stipules. The plant hairs are generally formed of single cells but sometimes occur in tufts, or at times are branched into two parts. Glandular hairs also occur.

The solitary flowers occur in leaf axils (upper angles between leafstalks and stems) or form restricted, few-flowered inflorescences (clusters). They occasionally occur even on the trunk or older branches (cauliflory). They are radially symmetrical, and their parts occur in basic numbers of three to seven. The plants are dioecious—the male and female flowers occur on separate plants—but both flower sexes often have vestigial or sterile organs of the opposite sex in their structure. The stamens are generally attached either to the inner surface of the tubular structure formed by the joined lower portions of the petals (corolla tube) or at its base. They are either equal in number to the corolla lobes (petals) or two to four times as many (up to 120). In the female flowers the superior ovary is composed of two to eight carpels with as many locules or more, because of the formation of false septa, or walls. Each locule contains one or two ovules suspended from its summit. The fruit is usually a berry containing 1 to 16 seeds.

Family Sapotaceae. The family Sapotaceae consists mainly of large trees that are easily recognizable by the sticky latex throughout the plant. Their branched plant hairs also are distinctive, but the arms, or branches, of the hairs may not always be equal. The leathery leaves are simple and lack stipules; foliation is dense, particularly at ends of branches where the leaves form tufts.

Sapotaceous flowers may be solitary, grouped in axillary inflorescences, or cauliflorous. They are usually small, regular in shape, and bisexual. Each flower has a calyx of four to eight overlapping sepals in a single whorl. The corolla has as many parts as has the calyx, but the overlapping petals are always more or less fused. The stamens occur in two, three, or even more whorls; their arrangement is characteristic: attached, singly or in groups, opposite the petals. The superior ovary is composed of fused carpels with one to 30 locules, each containing one ovule attached along the central axis of the ovary.

The fruit is usually a hardened berry containing one to five seeds (rarely more), which are liberated after the fallen fruit rots on the ground. The seeds characteristically have a thick, smooth, and shiny seed coat and a large, dull, basal scar (hilum). The position, size, and shape of the hilum is often used to delimit groups within the family. The seeds contain a well-developed endosperm (nutrient tissue for the developing embryo) and are frequently rich in oil.

EVOLUTION

The order Ebenales is thought to have had its origin in the order Theales, especially the family Theaceae. The family Styracaceae is considered to be the most primitive within the order. *Styrax officinalis*, which grows today in the Mediterranean region, is known as a fossil from the Eocene Epoch (38,000,000 to 54,000,000 years ago) from areas where it is now lacking (e.g., central Germany).

Fossil members of the genera *Diospyros* and *Royena* have been uncovered in strata of the Upper Cretaceous (about 65,000,000 years ago and earlier), and wood samples of the family Ebenaceae have been taken from Oligocene rock (26,000,000 to 38,000,000 years ago) in Hungary.

Members of the family Sapotaceae lived during the Upper Cretaceous, according to the fossil record, with representatives of the genus *Sideroxylon* in Europe as late as the Oligocene Epoch. The family is now pantropical, with one-third of its genera in Central and South America, one-third in Africa, and one-third in India and the Pacific.

CLASSIFICATION AND TAXONOMIC STATUS

A considerable difference of opinion continues on the subdivision of the family Sapotaceae into tribes or subfamilies, as well as on the delimitation and position of its

Fossil specimens

genera. One authority, for example, in his treatment of the order included 63 genera; another, 126. The lack of complete herbarium material complicates the task of placing the various taxonomic groups (genera and species) within such a homogeneous family. The characteristics available for separating genera and species are, according to some workers, a continuous network of smoothly intergrading features that do not permit easy separation into smaller groups. As a result, it is almost impossible to assess the evolutionary trends of the family.

Some authorities remove the family *Styracaceae* from the order *Ebenales*. The pollen is similar to that of the family *Ebenaceae*, however, but is also rather like that of the *Cornaceae* and *Nyssaceae*, both of which are families of the order *Cornales*. (J.Mi./C.E.B.B.)

Primulales (primrose order)

The primrose order of flowering plants (Primulales) contains three families, about 64 genera, and nearly 2,000 species. The group has long been of popular interest because of the attractiveness of many of the wild plants, such as shooting star (*Dodecatheon*) and loosestrife (*Lysimachia*), and the beauty of the cultivated members, such as cyclamen (*Cyclamen*) and primrose (*Primula*).

Two of the families (*Theophrastaceae* and *Myrsinaceae*), which contain about half of the species in the order, are composed entirely of trees or shrubs. A few species of these families are climbers or epiphytes (plants that grow upon other plants instead of being rooted in soil). The order is worldwide in distribution, although the two woody families have a much more restricted range than the third, the primrose family (*Primulaceae*), which is composed of herbaceous (nonwoody) plants.

The economic importance of the order lies almost en-

tirely in its ornamental value. Very few of the woody representatives are in cultivation and then only infrequently. In the tropics some of the woody species are used to poison fish and as a tapeworm remedy (e.g., the pea-sized fruits of *Myrsine africana*).

NATURAL HISTORY

In the wild the plants reproduce mostly by seed, and in cultivation this method is also common. Cross-pollination in the woody families is attained by the occurrence of species with separate male and female flowers. In some species of the family *Primulaceae*, however, cross-pollination is effected by heterostyly, a condition in which some flowers have differently sized or positioned sexual structures (male stamens and female pistils) than others of the same species. Heterostylous flowers appear superficially identical, but some have short styles (the narrow, upper part of the pistil) and elevated anthers (the saclike pollen-producing part of the stamen); others have long styles and anthers near the inner base of the tubular corolla (fused petals). Self-pollination is almost entirely prevented by the different lengths of styles and stamens. Cross-pollination is practically ensured when an insect visits the flowers because it transfers pollen only between male and female structures of similar length, which are in different flowers. An insect (usually a bee) visiting a short-styled flower, for example, could encounter long stamens and pick up a load of pollen from them. This pollen would then be deposited on the stigma (the sticky, pollen-receiving region at the tip of the style) of a long-styled flower on a subsequent flower visit, but not on a short-styled flower because the pollen is not carried in an appropriate place on the insect to reach the stigma of a short-styled flower. A similar restriction operates when an insect picks up pollen from the short stamens of a long-styled flower. The pollen can only be deposited on the stigma of a short-styled plant. The centre, or "eye," of the corolla is often a different and brighter colour than the rest of the flower and is thought to function as a guide for the insect.

The family *Primulaceae* occurs primarily in cool climates and damp, usually acidic soils. A large number occur in mountainous regions, and many grow in the arctic tundra or in alpine communities at high elevations. The two woody families are subtropical and tropical.

FORM AND FUNCTION

Few morphological characters other than the flowers and fruits make the order readily distinguishable. The leaves are simple, lack the small basal appendages called stipules, and are generally alternately arranged along the stems; but this combination of traits is by no means unique. The location of the stamens in front of the corolla lobes, rather than in the usual position of being alternate with them, and the unusual free-central placentation—the attachment of the ovules to a short column that arises from the interior base of the ovary—make the order completely distinctive. The pistil is composed of five carpels, or ovule-bearing segments, which is not unique but is sufficiently unusual to make it useful in recognizing members of the order.

The two woody families differ morphologically from each other in two characters. The *Theophrastaceae* has, in addition to the five stamens, five petallike staminodes, or sterile stamens, that lie alternately with the corolla lobes. The seeds of this family are large and yellowish. The family *Myrsinaceae* lacks staminodes—at least petallike ones—and the seeds are small and dark coloured. In both families the fruits are more or less fleshy. The family *Primulaceae*, being herbaceous (rarely a little woody at the base), is readily differentiated from the other two families. The fruit, a capsule, is not fleshy.

EVOLUTION

The two woody families, which are included in the order chiefly because of the structure of the flower and fruit, may have had a different evolutionary origin from that of the herbaceous family. The form and structure of the flowers in the three families, however, are so striking and similar that their placement in one order is widely accepted.

There is strong evidence that the more or less immediate

Cross-pollination ensured by flower structure

Representative plants from the three families of the order Primulales.

ancestors of the order had 10 stamens and a five-celled pistil. Loss of the five outer stamens and of the septa forming the five cells readily explain the present type of flower. The carpel number of five contrasts with the usual two-carpelled condition of other plants with petals fused into a tubular corolla (sympetalous plants). On the widely held supposition that the larger the number of parts a flower has the less evolved it is, this order is considered primitive within the sympetalous group. Sympetalous plants are, however, considered to be evolutionarily advanced over most plants with free-petalled flowers.

Similar-
ities to
other
plant
orders

The primrose order, seems to be related to the ebony order (Ebenales), but neither is considered to have been derived from the other, and the two orders may have had a common origin. The origin has been sought among flowering plant groups with separate, free petals. The Caryophyllaceae (pink family), consisting primarily of herbaceous plants, has several characters remarkably similar to the Primulaceae, including the unusual free-central placentation. For this reason there is widespread opinion that this group is ancestral to the Primulaceae. Because woody plants are considered to be more primitive than herbs, however, and therefore the woody families of the order would not likely be derived from herbaceous families, it has been considered logical to look for a woody ancestor. Some authorities have recently suggested relatives of the woody, free-petalled tea or camellia order (Theales) as likely ancestors. A classification has been proposed that derives the families Theophrastaceae and Myrsinaceae from the order Theales and removes them from the Primulales. This arrangement leaves the family Primulaceae in the primrose order; it is considered to be derived from the Caryophyllaceae.

The evidence from chemical studies of plants is not definitive. Leuco-anthocyanin pigments occur in the order Theales and in the family Myrsinaceae but not in the Theophrastaceae. Although infrequent in sympetalous families, the pigments do occur in the Primulaceae and in the possibly related family Plumbaginaceae (leadwort family). But in the putative ancestor, the Caryophyllaceae, they do not.

Fossil leaves and flowers have been found representing the family Myrsinaceae in the Northern Hemisphere from Tertiary (2,500,000 to 65,000,000 years ago) and upper Oligocene (about 26,000,000 years ago) deposits. These are from regions in which living species of the family no longer occur.

CLASSIFICATION AND TAXONOMIC STATUS

The following descriptions are generalizations; some are true in all instances and some have exceptions, usually rare ones. The superior-fruit (*i.e.*, an ovary positioned above the attachment point of the other flower parts) character finds an exception in the genus *Samolus* (family Primulaceae) in which the capsule is half-inferior, or partly enclosed by the basal parts of the sepals, petals, and stamens. The genus *Coris*, of the same family, with a single species in the Mediterranean region and northeast Africa, has a bilaterally symmetrical corolla. It has been suggested that this aberrant species does not belong in the order Primulales.

There are serious differences of opinion concerning what families ought to constitute the order Primulales. The most widely accepted viewpoint is that presented here, which recognizes the three families described in the annotated classification section above.

Another taxonomic system, gaining in acceptance, recognizes the families Myrsinaceae, Theophrastaceae, and Aegicerataceae (consisting of the single genus *Aegicerata*, here placed in the Myrsinaceae) to constitute a separate order, the Myrsinales. In that system the primrose order contains the two families Primulaceae and Plumbaginaceae. The main division between the two orders is based on woodiness versus the herbaceous habit, the Myrsinales containing the woody plants, and the Primulales containing the herbaceous ones.

Still other systems accept all the above mentioned families (and sometimes also the family Plantaginaceae) into a more broadly defined primrose order.

The order is thus distinctive morphologically; its evolutionary origins and whether or not its families came from one or more than one ancestral stock still are not clear.

(G.J.G.)

Malvales (mallow order)

Malvales, the mallow order, is a relatively small order of flowering plants containing nine families and about 3,000 species, most of which are woody plants, though some are herbaceous. The order is found throughout the world, except in the Arctic, in nearly all types of habitats, especially in the warm temperate and tropical regions.

A number of plants in this order are economically or aesthetically important; for example, the cotton genus (*Gossypium*), the source of chocolate (*Theobroma cacao*), and plants cultivated for their beautiful flowers (*Hibiscus*, *Althaea*, and others).

Fruits of a large number of species of the Sterculiaceae family are rich in caffeine, and those of *Theobroma cacao* also contain the alkaloid theobromine. West African kola nuts from species of the genus *Cola* also contain the heart-stimulating glucoside kolanin. In addition, alkaloids have been detected in numerous other species, including *Waltheria indica* (family Sterculiaceae), several species of *Elaeocarpus* and *Sloanea* (Elaeocarpaceae), a number of genera of the family Malvaceae, and *Corchorus* and *Grewia* (Tiliaceae).

GENERAL FEATURES

Size range and diversity of structure. The forms exhibited by plants in the order Malvales are diverse, including plants with a size range from small herbs to large trees. None, however, is parasitic or normally epiphytic (not rooted in soil but living among tree branches), nor are there any particularly succulent species. In the family Bombacaceae the trees often develop swollen trunks, a feature particularly well exemplified in the baobab (*Adansonia digitata*) of tropical Africa (with related species in Madagascar and one in northwest Australia), a tree noted

Some
exceptions
to general
character-
istics of the
order

not for its height but for its remarkable girth, which may reach 80 feet (25 metres) or more.

Importance. *Ochroma pyramidale* (family Bombacaceae) is the source of balsa wood, the lightest of all timbers. The trees are natives of the area from Mexico to Bolivia, in Brazil, and in the Antilles.

source of
kapok

Ceiba pentandra (Bombacaceae), the silk-cotton, or kapok, tree, is a widely buttressed tree up to 200 feet (60 metres) high, native to tropical America but now widely distributed throughout the tropics. Kapok, the resilient water-resistant hairs from the fruit capsules, is used for upholstery, lifesaving equipment, quilts, and other products. *Bombax ceiba*, the cotton tree of tropical Asia, produces an inferior kapok.

Durio zibethinus (Bombacaceae), a large buttressed tree native perhaps in Sumatra and Borneo, is now cultivated and often naturalized throughout tropical Southeast Asia for its fruit, the durian, which is famous for its delicate flavour but disagreeable odour.

The family Elaeocarpaceae contains no plants of great economic importance, although a few are sometimes grown for their horticultural merit; for example, *Muntingia calabura*, often cultivated, and naturalized in parts of Florida. Other horticultural plants include species of *Elaeocarpus* and *Crinodendron*, especially *C. hookeriana*, a native of Chile, the lantern tree. The fruits of *Aristotelia macqui*, the macqui, are eaten in Chile.

Abutilon theophrasti (Malvaceae) is cultivated in northern China for its bast fibres, Chinese jute, which are used to make ropes, twine, and other fibre products.

Althaea rosea (Malvaceae), the hollyhock, a native of the eastern Mediterranean region, is widely cultivated in temperate gardens. The well-known *Hibiscus rosa-sinensis* (Malvaceae) is grown throughout the tropics for its flamboyant flowers. *H. esculentus* (also known as *Abelmoschus esculentus*), okra, is widely cultivated in tropical regions for its edible, mucilaginous, immature fruits, much used in soups. *H. sabdariffa*, the roselle, is used for its sweet calyx or as a potherb.

Cotton is obtained from species of the genus *Gossypium* (Malvaceae) and consists of the hairs that have developed on the seeds. In addition, cottonseed oil is extracted from the seeds themselves and cottonseed-oil cake, the residue, is used to feed cattle. There are about 20 wild species of *Gossypium*, perhaps 3 in Australia, 7 in Africa and Southwest Asia, and 8 in the Americas. All of them are lintless; that is, the individual seed hairs, even when well developed, are without convolutions. They are perennial shrubs that occur naturally in open habitats of dry regions of the tropics and subtropics, especially on banks of creeks or stream beds that are dry during most of the year. Such habitats are preferred because the seedlings are highly susceptible to competition from other plants. The domesticated cottons, two species, bear seeds with lint that may be spun. They have double the number of chromosomes found in the wild species and arose by hybridization some time in the past between Old and New World species. At first perennial, they later developed an annual habit, as shown in the modern races.

source
of kola
flavouring

The genus *Cola* (Sterculiaceae), *C. nitida* and *C. acuminata* especially, is the source of kola nuts. These two species are forest trees native to West Africa, and there they are often cultivated beyond the area of their natural distribution. Kola nuts constitute an important article of trade in West Africa and are a rich source of caffeine. They also contain the glucoside kolanin and when chewed confer considerable ability to withstand fatigue.

The species *Theobroma cacao* (Sterculiaceae), cacao, is one of about 22 species in the genus and is native from the central part of the Amazon Basin and Guyana westward and northward to southern Mexico. Its fruits are the source of cocoa, chocolate, and cocoa butter. There are two main types of cocoa trees, their distributions separated by the Isthmus of Panama. The subspecies *cacao*, from Mexico and Central America, corresponds to the "Criollo" cultivars, while the subspecies *T. cacao sphaerocarpum* of South America contains the "Forastero" varieties. The large, tough, berrylike fruits containing the seeds, or beans as they are called, are often borne directly on the tree

trunks. Cocoa butter is obtained from the beans by pressing and cocoa by roasting them.

The genus *Tilia* (Tiliaceae), the lindens or limes (not to be confused with the unrelated tropical limes, *Citrus aurantiifolia* [family Rutaceae, order Rutales]), particularly *T. americana* and *T. × europaea*, are valuable as timber trees and for the fibre below the bark, the bast fibre, which has been much used in country districts. The nectar secreted at the base of the sepals in the sweetly scented flowers is much sought after by bees and produces highly prized honey.

Corchorus capsularis and *C. olitorius* (Tiliaceae) constitute the chief source of jute or gunny and—especially *C. capsularis*—are much cultivated in India and Bangladesh and, to a lesser extent, elsewhere. The plants form sparsely branched annuals up to about 10 feet (3 metres) high. When ready, the stems are cut and retted in water, and the fibre is extracted by beating. The leaves and young shoots are also eaten as a vegetable or potherb; *C. olitorius* has been cultivated for this purpose from ancient times, especially in Egypt. The seeds, however, are poisonous and contain glycosides of the type found in the genus *Digitalis* (family Scrophulariaceae, order Scrophulariales).

NATURAL HISTORY

Pollination. Although little is known about the majority of the genera and several of the families in the order Malvales, it appears that the flowers, with their bright colours and nectaries, are generally adapted to pollination by insects or birds. A number are pollinated by bats, especially in the family Bombacaceae. Wind pollination is rare and perhaps of only secondary importance. Flowers are commonly protandrous; that is, the male stamens develop and mature before the styles (female structures that receive the pollen) of the same flower, an adaptation that favours cross-pollination. In some weedy species in the family Malvaceae, however, the styles eventually bend over to touch the withered stamens, still bearing some pollen, and effect self-pollination, thus ensuring fertilization in case pollen from some other source has failed to reach the styles.

In the African genus *Sparmannia*, the showy flowers contain numerous fertile and sterile stamens that are sensitive to touch; they bend outward from the centre when stimulated, presumably to aid pollination.

Elaborate adaptations to insect pollination are found in many members of the family Sterculiaceae. The flowers of the genus *Abroma* are a good example of "lantern-flowers," which have small "windows" in the petals that permit light to shine through, thus attracting insects. In many genera, especially *Sterculia* itself, dark-purple or chocolate-coloured flowers with a fetid odour attract flies. *Theobroma cacao*, the source of cacao and of chocolate, is pollinated by diverse types of small insects; thrips, ants, midges, and aphids have been recorded.

Pollination by hummingbirds, sunbirds, and others is widespread in many tropical species. The red flowers of *Malvaviscus*, which have a relatively narrow tube formed by the overlapping petals and have protruding stamens and styles, are an excellent example of adaptation to pollination by hummingbirds.

Hibiscadelphus, a rare native Hawaiian genus, two of four species of which are already extinct, is adapted to bird pollination. Here the natural pollinating bird may be extinct or nearing extinction too, and hand-pollination by man of the few remaining trees is necessary to ensure a good seed set.

Pollination by bats is widespread in the family Bombacaceae. In the genus *Adansonia*, for example, the drab-coloured flowers with their numerous stamens hang down below the foliage where bats can easily reach them. This association of characters is typical of flowers adapted to pollination by bats. Bat pollination has also been recorded for *Ochroma*, *Ceiba*, and *Durio* (of the family Bombacaceae).

Seed dispersal. Methods of seed dispersal are not particularly remarkable in the order Malvales. Fruits usually take the form of dry capsules or schizocarps (fruits that separate into pieces at maturity), which are sometimes

Insect
pollination

hooked for dispersal by attachment to animals' coats. Drupes (stone-seeded fruits) and berries also occur; the latter are large and leathery, as in the genus *Theobroma*, or juicy, as in *Malvaviscus*.

FORM AND FUNCTION

Distinguishing characteristics. The family Bombacaceae is distinguished by a combination of characters of which the most diagnostic is perhaps the unilocular (single-chambered) anther containing smooth pollen, which distinguishes it from the very closely related family Malvaceae.

The diagnostic characters of the family Elaeocarpaceae include flowers without an epicalyx (a series of bracts close to, and resembling, the sepals), petals that are often characteristically fringed or divided at their ends, and anthers that usually open by two apical pores (small openings in the end of the pollen sac).

The family Malvaceae is identified by the characteristic combination of a united column of stamens with unilocular anthers containing spiny pollen grains, especially when combined with the possession of an epicalyx and petals convoluted in the bud.

The Huaceae is a small and little-known family in which the petals are stalked and more or less persistent. There is a single basal ovule in the genus *Hua* and six in *Afrostryax*; the seeds in both genera smell strongly of onions.

The family Rhopalocarpaceae (Sphaerosepalaceae) has flowers with imbricate (overlapping) petals densely streaked with short resinous lines, and the numerous stamens are dotted as well.

The family Sarcocaulaceae (Chlaenaceae) has flowers with large petals that are convolute in the bud, similar to those of many other members of the order Malvales. The stamens are usually numerous and are borne inside a disk or a cupular ring of staminodes (sterile stamens). The fruit is often surrounded by lignified (woody) bracts.

The family Tiliaceae has flowers of a somewhat generalized type for the order, with five valvate (*i.e.*, touching edge to edge in the bud; not overlapped) sepals, five convolute, imbricate, or valvate petals, usually numerous stamens that are free or united into groups, a superior ovary of united carpels, and seeds with endosperm (a starchy nutrient tissue for the developing embryo).

The family Scytopetalaceae has leaves that lack stipules (basal appendages) and that are often asymmetrical at the base. In the flower the valvate petals are either reflexed at anthesis (flower opening) or do not separate but fall as an entire cap when the flower opens. The seeds are sometimes covered with agglutinated mucilaginous hairs.

The family Sterculiaceae has leaves that are often digitately divided. The flowers are sometimes unisexual and may be without petals, the stamens are free or united into a column, and the pollen is nonspiny.

Anatomical characters indicate a very close affinity between the families Malvaceae, Bombacaceae, Sterculiaceae, and Tiliaceae, and, to a slightly lesser degree, the family Elaeocarpaceae. Mucilage cells are found in the tissues of all five of these families, and mucilage cavities and canals are found in the tissues of most of them. Pericyclic fibre bundles are characteristic of most families in the order. Many of these fibres are of great economic importance—*e.g.*, jute and various hemps.

The presence of stellate hairs (hairs branched in a starlike pattern) on leaves and young stems is often characteristic, especially of the families Malvaceae, Bombacaceae, Sterculiaceae, and Tiliaceae.

Pollen. Pollen grains in the order Malvales are generally three-pored (tricolpate), often with the pores sunken or sometimes with several apertures. In shape, the pollen grains are generally more or less flattened spheres. The surface is generally ridged, but in the family Malvaceae the grains are characteristically spiny. In fact, one of the factors that helps to place the genera around *Hibiscus* and *Gossypium* in the Malvaceae rather than in the Bombacaceae (in which, on fruit characters, they have been classified by some authorities) is their possession of spiny pollen.

Nonspiny pollen of a basically similar kind is common

to members of the families Tiliaceae, Bombacaceae, Sterculiaceae, and Scytopetalaceae. The pollen of the Elaeocarpaceae is somewhat like that of the Tiliaceae but much smaller; however, grains that are very similar indeed are found in the family Flacourtiaceae of the order Violales, the group suggested by some as being the nearest family outside the order Malvales.

The pollen of the family Sarcocaulaceae is somewhat remarkable and has been investigated in detail. In all of the genera of that family the grains are united in firm tetrads (groups of four), sometimes with individual grains more or less degenerate and therefore smaller than the others. At first sight they appear quite dissimilar from any others in the order Malvales, yet the fine reticulations of the surface pattern show some affinity with the family Tiliaceae.

EVOLUTION

The earliest fossil remains, the petrified wood *Hibiscoxylon niloticum*, recognizable as belonging to the order Malvales date from Cretaceous deposits (about 100,000,000 years ago) in Egypt. Elsewhere, leaf impressions resembling the present-day genus *Sterculia* have been recorded from the Upper Cretaceous.

From the Eocene (about 50,000,000 years ago) numerous leaves and some fruits have been recognized as belonging to families in the order Malvales. A species of *Echinocarpus* (Elaeocarpaceae), for example, has been described from fruits in southern England, but other remains, not attributable to present-day genera, have been given fossil names—*e.g.*, *Sphinxia* (Sterculiaceae), and *Cantitilia* (Tiliaceae). From later Tertiary beds (about 20,000,000 years old, or less) numerous Malvacean fossils have been reported from many different parts of the world, including Europe, North and South America, Central and eastern Asia, and Australia. Leaf remains have been attributed to several modern genera—*e.g.*, *Elaeocarpus*, *Vallea*, and *Sloanea* (Elaeocarpaceae); *Bombax* and *Hampea* (Bombacaceae); *Sterculia*, *Byttneria*, *Pterospermum*, *Melochia*, and *Theobroma* (Sterculiaceae). From the Pliocene (about 5,000,000 years ago) even more numerous and recognizable leaf and fruit remains are recorded.

Fossil pollen attributed to the genus *Tilia* has been recorded from as far back as the Upper Cretaceous Period (about 65,000,000 years ago), and Bombacaceae-like pollen from Upper Cretaceous or Early Tertiary deposits in Brazil.

CLASSIFICATION AND TAXONOMIC STATUS

All recent classifications agree on the close relationship between the families Bombacaceae, Malvaceae, Sterculiaceae, and Tiliaceae, although a few authorities maintain two related orders, the Tiliales and Malvales, the latter containing only the family Malvaceae. Careful revisionary work on the order is highly desirable, and it should consider recent evidence from cytology, pollen studies, etc., and may perhaps lead to some rearrangements of a few genera among these families. The family Elaeocarpaceae, which is retained by some workers within the Tiliaceae, is separable from this close group on a number of characters and appears to be the most primitive family in the order, with a more generalized flower structure and a more primitive wood anatomy. A relationship with the family Flacourtiaceae (order Violales) is postulated by most authorities and supported by evidence from both floral and pollen-grain morphology.

The families included in this article in the order Malvales follow a recent classification system. Knowledge of the four smaller families is still inadequate. They are all confined to Africa, and two of them, the Rhopalocarpaceae and Sarcocaulaceae, are restricted to Madagascar. Some authorities classify them in an order called the Ochnales. All four are little represented in collections, and, for most of them, knowledge of their comparative anatomy, pollen morphology, and comparative biochemistry is meagre or nonexistent. Clearly, they are less closely related to the larger families of the order, and the inclusion of the family Huaceae is somewhat speculative. Some evidence of affinity exists, but more work is required to support it or to point to true affinities. (P.S.G.)

Basis of relationships between families

Fossil record

Uncertain relationships of smaller families

Euphorbiales

The Euphorbiales order is a large assemblage of dicotyledonous flowering plants (*i.e.*, it is a member of the class Magnoliopsida) consisting of seven families and about 315 genera and 8,000 species. Fifteen genera have more than 100 species each; the largest include *Euphorbia* (over 1,600 species), *Croton* (700), *Phyllanthus* (500), and *Acalypha* (430). One of the three flowering-plant groups that have the interesting cactuslike growth form and that inhabit very dry places is a member of this order. Many plants of the order are useful to man. The complex inflorescence (flower cluster) and the variation found throughout the order in the female flower are botanical features of special interest.

GENERAL FEATURES

Size range and diversity of structure. The Euphorbiales order includes plants having many diverse growth forms, including prostrate and erect herbs, shrubs, and trees. Many members are broad-leaved. The shieldlike leaves of *Macaranga gigantea* are among the largest simple leaves (up to three feet, or one metre, across) in the plant kingdom. Many different tree shapes occur in the order. In the genus *Elateriospermum*, the monopodial (or single, centrally stemmed) state is found with a conical crown, the trunk reaching the vertex and the leaves spirally set on twigs. In the genus *Embllica*, the twigs appear as doubly pinnate leaves (*i.e.*, they are compound, not from a central point, like a fan, but from either side of an axis, like a feather; in this case the subdivision is repeated twice), and the crown is inclined to be flat-topped. Intermediates between these two conditions are frequent. Some species of the genus *Euphorbia* growing in the desert regions of Africa and the Canary Islands closely resemble cactus plants in having fleshy stems of different shapes armed with spines. A number of Australian species are suffrutescent—that is, woody and living over from year to year in the lower parts of the stem just above ground level—and they have small, ramified stems and narrow leaves similar to those of the Ericaceae family (order Ericales), a growth form known, therefore, as the ericoid habit. Several members possess flattened stems or branches known as phylloclades that function as leaves (*Phyllanthus*). A few are lianas. In the genus *Picrodendron*, the bark is peculiar and peels off in long strips. Several kinds of hairs are present in different members of the order—stinging hairs in the genus *Tragia*, glandular in *Acidodendron* and *Macaranga*, nonglandular in *Mabea* and *Phyllanthus*, and numerous others.

Distribution and abundance. Euphorbiales species are found chiefly in tropical regions but are spread over the whole Earth with the exception of the Arctic and cold alpine zones. Two major centres of distribution are tropical America and Africa. Few species have a very wide range, and some genera have very restricted distributions, such as *Simmondsia* (California and neighbourhood), *Picrodendron* (West Indies), and *Panda* (west tropical Africa). The most widely ranging genus is *Euphorbia*.

Economic importance. Several species of the order have abundant milky juice (latex) and attendant complex secretory tissue; in certain cases, the juice is economically important. The genera *Mabea*, *Manihot*, and *Sapium* are the source of caoutchouc (a form of rubber), and the highest grade of rubber is obtained from *Hevea brasiliensis*. In some cases, the latex is medicinal, but in many species it is poisonous, as in the manchineel (*Hippomane mancinella*) of South America. *Manihot esculenta*—manioc, or cassava—the source of tapioca, is one of the most important tropical food plants, its large tuberous roots being very rich in starch. Tung oil and wood oil are important commercial oils obtained from the seeds of *Aleurites fordii* and *A. cordata*, respectively. The solid oil of *Sapium sebiferum* is used for making candles in China, and it is also considered to be a good substitute for lard. Castor oil is extracted from the castor bean, *Ricinus communis*. *Croton tiglium* is the source of croton oil, and resin is obtained from species of *Euphorbia* and *Croton*. The dried resin-containing latex of *Euphorbia resinifera* of Morocco is a well-known commercial drug, gum euphorbium. The fruits of

a few species, such as *Cicca*, *Beccaurea*, *Antidesma*, and others, are edible, as are the seeds of the candlenut, *Aleurites*. Fruit of *Embllica officinalis* is very rich in vitamin C and is used in several medicines. Excellent jams and wines are prepared in the Philippines from the fruits of *Antidesma bunius*. Timber of some species, such as boxwood (*Buxus*), is valuable. Candelilla wax is obtained from *Euphorbia antisiphilitica* and jojoba wax from *Simmondsia chinensis*. Species of *Tragia*, *Mercurialis*, *Euphorbia*, *Phyllanthus*, and *Croton* are medicinal. Many are toxic to cattle and sheep, notably the leafy spurge (*Euphorbia esula*), sun spurge (*E. helioscopia*), and eyebane (*E. maculata*). The African plant *Dichapetalum toxicarium* contains poisonous levels of fluorine (as fluoro-oleic acid). This plant accumulates and concentrates fluorine from the soil. Species of *Plukenetia* are used as potherbs in the East Indies, *Euphorbia* in Africa, and *Claoxylon* in Malaysia. Many are ornamental plants: the poinsettia (*Euphorbia pulcherrima*), the crown of thorns (*E. mili*), the scarlet plume (*E. fulgens*), the copper leaf and red hot cattail (*Acalypha*), crotons (*Codiaeum*), and others. Trees such as *Daphniphyllum macropodum* are grown for their large and handsome foliage.

NATURAL HISTORY

Life cycle. Some species are annuals of the wet season (*Micrococca*, *Sebastiania*, and others). Some, such as *Macaranga*, are rapidly growing, short-lived trees. Most members of the order are deciduous, dropping their leaves during seasons of unfavourable growth. Evergreen plants occur in the genera *Daphniphyllum*, *Buxus*, and others. Some, such as *Euphorbia nerifolia*, have leaves only during the wet season. In many other species of *Euphorbia*, the leaves are dropped early, and the stems not only perform the functions of the leaves but also act as water-storage organs. Some species begin flowering early in life, but others bloom only after five or six years.

Ecology. When certain species of *Euphorbia* that have a cactus-like growth habit are encountered in dry habitats, it is very difficult to determine from the external appearance whether the plant is actually a *Euphorbia* or a cactus unless it is in flower. The presence of latex, however, distinguishes the spurge. It is a matter of great interest to find how similar conditions of life have brought forth, in three different and widely separated families, such a close similarity of habit (*i.e.*, the cactoid growth form) as is met with in the families Euphorbiaceae (genus *Euphorbia*), Asclepiadaceae (genus *Stapelia*), and Cactaceae (numerous genera).

Many species prefer open land, but some members form an integral part of the tropical and subtropical forests of the world. Arborescent (treelike) cactoid species of *Euphorbia* are common in savannas. Plants such as *Bischofia javanica*, when growing on seashores, possess a peculiar oblique, condensed, one-sided habit (wind forms) and always show a decreased leaf size owing to the desiccation of buds. *Excoecaria parviflora* and *E. agallocha* prefer tidal marshes and saline flats. Some species are inhabited by ants, as in *Endospermum moluccanum*, in which the ants bite their way into stem sections, remove and eat or carry away the pith, and live inside the cavity thus formed. Other ant plants of interest are *Drypetes*, *Macaranga*, and *Agrostistachys*. Many species of the order are botanical nomads (widely distributed moving weeds having several methods of dispersal)—*e.g.*, *Croton bonplandianum*.

FORM AND FUNCTION

Vegetative characteristics. Leaves of the Euphorbiales order are mostly alternate but are sometimes opposite; they are extremely variable in shape, ranging from simple, in the genera *Euphorbia*, *Buxus*, *Daphniphyllum*, and others, to deeply cut (palmate) in *Ricinus* and *Manihot*, trifoliate in *Picrodendron*, and palmately compound in *Hevea*. Stipules (small, leaflike appendages at the base of leafstalks) are absent in the families Buxaceae and Daphniphyllaceae but are usually present in most of the other families. The stipules may be minute and persistent, as in *Picrodendron*; or deciduous (falling); or they may be represented by branched, hairlike bodies (*Jatropha*), glands,

by ants

or spines (*Euphorbia*). Extrafloral nectaries are present in several members of the Euphorbiaceae family.

Floral characteristics. Flowers in the order are mostly unisexual, except in the family Dichapetalaceae, in which they are predominantly bisexual. Bisexual flowers are also found in the family Buxaceae. When unisexual, male and female flowers may be borne on the same plant (bisexual plants, the monoecious condition), as in *Hevea*, or on different plants (unisexual plants, the dioecious condition), as in *Daphniphyllum* and *Panda*. The arrangement of the flowers (the inflorescence) shows great variation, and almost all types occur—heads, spikes, racemes, clusters, catkins, panicles, and others. In mixed types, often the first branching is racemose (*i.e.*, having a main axis with flowers borne on short secondary branches, the lower flowers maturing and blooming first) and all subsequent ones cymose (*i.e.*, similar to racemose, but with the terminal flowers blooming first). In bisexual plants seven types of flower arrangement can be seen: (1) male and female flowers in the same cluster without any order (*Cicca*, *Bridelia*); (2) one female flower to each cluster of males (*Euphorbia*); (3) male flower clusters toward the base of the leafy twigs, female toward the ends (*Breynia*, *Emblia*); (4) male flowers at the base of the inflorescence with female in the upper parts (*Ricinus*); (5) female flowers at the base of the inflorescence, male in the upper parts (*Croton*, *Sapium*); (6) female flowers singly at the ends of the main branches of the inflorescence, surrounded by the males on the smaller side branches (*Aleurites*, *Hevea*, *Jatropha*); and (7) female flowers on one raceme, male on another, the female raceme usually paired with a male (*Codiaeum*). The partial inflorescences of *Dalechampia* and *Euphorbia* are so condensed as to give the appearance of single flowers. In *Dalechampia* the inflorescence is very complex. In the centre is a cushion of 9 to 14 male flowers subtended by four small bracts. Anterior to this is a cyme of three female flowers in the axil (angle) of a larger bract. All these are enclosed in two large pink or white outer bracts. In *Euphorbia*, the partial inflorescence is a cyathium, which is a flowering group containing a central terminal female flower consisting of only the gynoecium (*i.e.*, the female parts or pistil, consisting of ovary, style, and stigma; there are no petals or other flower parts) and four or five bracts below that unite to form a cup-shaped involucre (whorl) resembling a calyx. Each bract subtends a small cyme of male flowers, the oldest of which is arranged near the centre. Each such cyme has a distinctive joint halfway up the stalk. Between the segments of the involucre are large oval or crescent-shaped glands, often brightly coloured, forming petallike structures. The cymose umbels (flower clusters radiating from a common point reminiscent of an umbrella and maturing from the centre outward) in some species of the Dichapetalaceae family are fused to the leaves (epiphyllous).

The form of the flowers also shows variation, and the shape and size of flowers of different sex may differ widely, as in *Hevea*. Regular (radially symmetrical) hypogynous (*i.e.*, with a superior ovary—the other flower parts attach at the base of the ovary) flowers occur in almost all the species, except in some of the members of the family Dichapetalaceae, in which the ovary may be inferior. The perianth (the collection of petals and sepals) is mostly in fives or fours, sometimes distinguished into sepals and petals; more often there is only one whorl of tepals, and frequently the flowers are naked, as in several members of the Euphorbiaceae family. When a corolla (the collection of petals) is present, the stamens are usually as many or twice as many as the petals. In naked flowers, the number of stamens is reduced to one (*e.g.*, in the family Euphorbiaceae), or several stamens may be loosely clustered, forming a globose head, as in the genus *Picrodendron*. In *Ricinus* the stamens are branched. In *Phyllanthus cyclanthera* the stamens are united by means of a ringlike common anther (synandrium). Both extrorse and introrse (*i.e.*, opening away from or toward the flower axis, respectively) anthers are present in the group. In the male flowers of several species, a rudimentary ovary is sometimes present. The ovary of female flowers is generally two- to five-chambered, the three-chambered condition

being most frequent. Each chamber of the ovary contains one or two pendulous ovules that are usually anatropous (*i.e.*, the body of the ovule is bent back along its supporting stalk) with a ventral raphe (ridge). Placentation (ovule attachment) is mostly axile (along a vertical central axis of the ovary). There are two coats (integuments) for each ovule, and both or either one of them may take part in the formation of the micropyle (a small opening in the ovule). Both of them persist in the seeds of many genera.

Pollination. Cross-pollination is the usual pollination method in the Euphorbiales order. In *Mercurialis* and other genera with inconspicuous flowers, pollination is by wind. Insect pollination takes place in almost all the other members. The flowers being small, insects are attracted to them by the large, brightly coloured bracts, as in *Dalechampia* and *Euphorbia*, or by coloured calyx, as in *Manihot*. Honey glands, present in several members, as on the involucre of the cyathium of *Euphorbia*, are frequently an attraction. Many species are sweet-scented of honey or citronella or have a fetid-wax smell, as in *Elateriospermum*, by which means they also attract small flies, beetles, honeybees, wasps, and plant bugs, which pollinate them.

Vegetative and floral structures from four of the families of the order Euphorbiales.

Fruits and seeds. The fruit is a capsule in most members of the families Euphorbiaceae and Buxaceae. They are sometimes prickly, as in *Ricinus*. The fruit may be a drupe (*i.e.*, a fruit with a single-seeded stony pit) or a berry. The capsular fruit often splits into three parts (cocci) from the central column, and at the same time each coccus opens ventrally, letting the seeds escape. Some fruits, such as those of the sandbox tree and rubber tree, split with explosive violence, hurling the seeds away. The seeds of some are distributed by animals, either because they have pulpy edible coats or because the fruits themselves

Complex
flower
clusters

are berries. The seeds of several members have a caplike outgrowth called a caruncle. This spongy structure attracts ants, and the seeds carried away by them effect dispersal. The seeds, with the exception of those of the families Picrodendraceae and Dichapetalaceae, contain abundant endosperm (a starchy nutrient tissue for the developing embryo), generally rich in oil. The embryo is usually very large in all but the family Daphniphyllaceae. The cotyledons (seed leaves) are generally flat and emerge above the surface of the ground at the time of germination (epigeal germination) and turn green.

EVOLUTION

The Euphorbiales order appears to be evolutionarily highly specialized, as is evidenced by the very reduced flowers in many members. It has been presumed that this group evolved from some ancient group intermediate between the family Flacourtiaceae (of order Violales) and the Malvales order. The nonhomogeneity of the order does not support the view that it is monophyletic, however. It is thought that the Euphorbiales order is not a natural assemblage derived from the same ancestors in the distant past but is a synthetic group made up of derivatives from several ancestors brought together merely because of a superficial resemblance and want of knowledge of the true evolution of the groups.

This order does not seem to have fossil representatives below the Upper Cretaceous Period (about 65,000,000 years ago), and those from that period are few, although such names as *Euphorbiophyllum*, *Crotonophyllum*, and others are occasionally encountered in literature as having been obtained from Upper Cretaceous and Eocene deposits (about 50,000,000 years ago). Tertiary (2,500,000 to 65,000,000 years ago) deposits of *Euphorbia*, *Acalypha*, *Mallotus*, and others are known from various parts of the world.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. It is impossible to give a set of characters by which the Euphorbiales order can be distinguished absolutely from all other dicots, for there are many exceptions even among the common members. Nevertheless, combinations of certain features are used by taxonomists to set limits to the order and to determine relationships within the groups. Such features include habit, presence or absence of latex, nature of indumentum (hairs on the surface of leaves, stems, and other organs), nature of leaves, presence or absence of stipules, sexuality, nature and arrangement of the flowers, nature and position of the ovary, presence or absence of endosperm, nature of fruit, features of embryo, and others.

Alternate systems of classification. There is much disagreement among taxonomists regarding the systematic position of the families included in the Euphorbiales order. Some authorities retain only the family Euphorbiaceae in the order, the remaining families being variously placed—Dichapetalaceae in the order Rosales, Buxaceae (including Simmondsiaceae) and Daphniphyllaceae in Hamamelidales, Pandaceae in Celastrales, and Picrodendraceae in Juglandales. Other authorities treat Euphorbiaceae, Daphniphyllaceae, and Dichapetalaceae as families in the Geraniales order; Buxaceae in Sapindales; and Pandaceae in an independent order, Pandales. Picrodendraceae as a family is not recognized in these systems, and the genus *Picrodendron* is then included in the family Simaroubaceae. Similarly, *Simmondsia* is included in Buxaceae. Three genera of the family Euphorbiaceae—*Micrantheum*, *Pseudanthus*, and *Stachystemon*—have been united by some workers into a special family, Micrantheaceae, but this separation is not widely recognized. Some taxonomists have even elevated many individual genera of the Euphorbiaceae family to the rank of family—e.g., the families Androstachyaceae (from the genus *Androstachys*), Stilaginaceae (*Antidesma*), Bischofiaceae (*Bischofia*), Hymenocardiaceae (*Hymenocardia*), Uapacaceae (*Uapaca*), Peraceae (*Pera*), and others. All these differences of opinion among competent taxonomists probably reflect the polyphyletic (origin from various unrelated ancestors) nature of the order. (N.C.N.)

Saxifragales

Saxifragales is a large and diverse order of flowering plants containing 28 families and over 3,000 species. They may be large forest trees, shrubs, stout woody vines, or delicate herbs. Plants belonging to this order are distributed throughout the world; they grow on all continents and on many islands in the Pacific Ocean. Their distribution ranges from cold temperate regions to the tropics and from sea level to the high mountains, and they grow in habitats as diverse as deserts and tropical rain forests. Some species produce medicinal products; a few produce edible fruits; and one genus is an alternate host for a serious disease-causing organism that attacks pines. Certain groups of the order Saxifragales are reputed to capture and utilize the bodies of insects as a source of nitrogen. Flowers and fruits are borne directly on the leaf blades in one small group of trees and shrubs. Exceedingly fleshy, thick, and succulent leaves characterize hundreds of species in one section of the order.

GENERAL FEATURES

Economic importance. *Ornamental plants.* Brexias (family Brexiaceae) are trees from Madagascar that are sometimes grown as specimen plants in greenhouses or outdoors in the subtropics or tropics. Indoors, brexias seldom become trees but grow to the size of tall shrubs. Both greenhouse specimens and those grown outdoors produce characteristic greenish or white, waxy-petalled flowers.

Species of several genera of the family Bruniaceae are widely grown as horticultural plants. Among them are *Berzelia*, *Brunia*, *Raspalia*, *Staavia*, and *Thamnea*. These plants are all natives of southern Africa and reflect the characteristic bushy, evergreen, heathlike nature of all members of the family Bruniaceae. In cooler temperate climates they must be grown under glass.

Among the most important and familiar perennial garden plants of temperate, subtropical, and tropical regions are members of the family Crassulaceae (stonecrop or orpine family). Many are grown as pot plants, especially in cooler climates, and a few are favoured for rock gardens and open border plantings in climatically suitable regions. The family Crassulaceae is native in many parts of the world, but the plants are often characteristic of arid and semi-arid regions and rocky places, particularly in southern Africa. They are typically fleshy-leaved plants, often with handsome, prevailing red or yellow flowers. The genera *Rochea*, *Crassula*, *Cotyledon*, *Bryophyllum*, *Kalanchoë*, *Pachyphytum*, *Urbinia*, and *Echeveria* are frequently grown under glass or in the home in temperate or cold climates. *Sedum* (stonecrop), however, is used as an outdoor plant for rock gardens in temperate lands. Generally, flowers of plants in the family Crassulaceae are small, but the clusters are particularly showy, especially in *Sempervivum* (houseleek), *Gormania*, *Graptopetalum*, and *Oliveranthus elegans*. Other garden genera are *Monanthes*, from Morocco and the Canary Islands, and *Byrnesia weinbergii*, which is Mexican.

The Crassulaceae, although easily propagated from seeds, also root readily from stem and leaf cuttings. Some species regularly produce offsets from the bases of parent rosettes. In *Kalanchoë* and *Bryophyllum* young plants appear in notches around the margins of leaves still attached to the parent plant; these plantlets either drop off naturally and become established below the main plant, or they can be removed from the parent leaf and planted.

The tree *Geissois racemosa* (of the family Cunoniaceae) of New Caledonia has leathery leaves and showy, crimson flowers borne in elongated clusters. Strictly tropical, it is grown only in greenhouses in temperate climates. *Cunonia capensis* of southern Africa is a small tree or large shrub with leathery leaves and dense clusters of small, white flowers. It is occasionally grown as a greenhouse plant.

Davidsonia pruriens (of the family Davidsoniaceae), the Queensland itch tree, is sometimes grown in greenhouses for its 2-foot- (60-centimetre-) long leaves, which are covered with bright-red, pungent hairs when young, and for its long-stalked clusters of flowers. It is native in north-eastern Australia.

Representative plants from five of the largest families in the order Saxifragales.

From (Saxifragaceae and Hydrangeaceae) A. Cronquist, *An Integrated System of Classification of Flowering Plants*, copyright © 1981 The New York Botanical Garden; (Cunoniaceae) J. Hutchinson, *The Families of Flowering Plants*, Vol. 1, © Oxford University Press 1959; (Grossulariaceae) G.H.M. Lawrence, *Taxonomy of Vascular Plants*, copyright, The Macmillan Publishing Company, 1951

Although several genera of the family Escalloniaceae have been introduced into ornamental horticulture—e.g., *Abrophyllum ornans* of New South Wales, Australia; *Anopterus glandulosus* of Tasmania; *Carpodetus serratus*, the putaputawheta of New Zealand; *Corokia cotoneaster* of New Zealand; the New Zealand species *Quintinia acutifolia* and *Q. serrata*, tawhewheo; and *Valdivia gayana* of Chile—none has achieved the importance or interest of the various species and cultivated varieties of *Escallonia*. Escallonias are mainly shiny-leaved, evergreen shrubs or small trees native only to South America, where they are found mostly in the Andes mountains and eastern Brazil. White, pink, or red flowers are frequently present in large clusters; sometimes they are pleasantly aromatic. In the United States these handsome shrubs are very popular in California, where their late-autumn or winter bloom is most welcome.

Eucryphia (of the family Eucryphiaceae) is a small genus of glossy-leaved, evergreen trees and shrubs native in the Southern Hemisphere. *Eucryphia pinnatifolia*, a small tree of Chile, is grown outdoors in parts of England and Scotland—e.g., the Royal Botanic Garden, Edinburgh. The flowers, which are produced in late summer and early fall, are large and white-petalled, with a central cluster of conspicuous yellow stamens giving the whole the appearance of camellia flowers.

Francoa (of the family Francoaceae) is a genus, native in Chile, of several perennial herbs with horizontal underground stems (rhizomes). The plants bear deeply cut, hairy leaves and long-stalked clusters of pure-white, pink, or deep-rose-coloured flowers.

Although the gooseberries and currants (genus *Ribes*, of

the family Grossulariaceae) are known chiefly for the edible fruits produced by some species, a number of strikingly handsome, sometimes thorny shrubs are available for the ornamental garden. Species of *Ribes* abound, particularly in western North America and in temperate Eurasia and South America. Among those most attractive as flowering plants are *R. odoratum* and *R. aureum*, both of which have fragrant, yellow flowers; *R. sanguineum* with white or reddish flowers; *R. viscosissimum* with sticky, greenish-white or pinkish, aromatic flowers; and *R. lobbbii* with velvety, purple-red flowers. Often the fruits are attractive, some species having translucent scarlet or deep-red fruits and others bearing powder-blue fruits. *Ribes roezlii*, of central and Southern California, has both handsome flowers, which are purple and white, and attractive reddish-purple fruits, which are clothed with reddish, bristly spines.

Probably the most important family of woody ornamental plants in the Saxifragales is Hydrangeaceae. The family is widely distributed in nature, and representatives occur in all parts of the world except Africa, Australia, New Zealand, and the coldest parts of both the Northern and Southern Hemispheres. Species of the family Hydrangeaceae are trees, shrubs, or woody vines, and at least one genus is composed of rhizomatous herbs (i.e., nonwoody plants with underground stems, or rhizomes). Among the plants that have been introduced into ornamental horticulture in greenhouses, gardens, and homes, are the following: *Cardiandra* from China and Japan; *Carpenteria californica*, a native shrub from California; *Decumaria*, a woody climber with two species, one of which occurs in southeastern United States and the other in central China; *Deutzia*, a genus of mostly Asiatic shrubs;

Gooseberries and currants

Dichroa febrifuga of the Himalayas, Malaysia, and China; *Fendlera*, a genus of western American shrubs; *Hydrangea*, a genus of trees, shrubs, and woody vines of North and South America, the Himalayas, and central and eastern Asia; *Jamesia americana* (waxflower, wild mock orange), a shrub of semi-arid and mountainous parts of west central United States; *Kirengeshoma palmata*, a perennial herb of Japan; *Philadelphus*, a genus of shrubs of northern Asia and Japan, western America, the southern Atlantic Coast of the United States, and Mexico; *Pileostegia*, a genus of climbing or prostrate evergreen shrubs of the Himalayas and eastern Asia; *Platycrater arguta*, a prostrate shrub of Japan; *Schizophragma*, a genus of climbing shrubs of Japan and China; and *Whipplea*, a genus of low, barely shrubby plants endemic (native) in Oregon, California, Utah, and Colorado. Of the horticulturally important members of the family Hydrangeaceae, the most widely planted and best known to gardeners are species of *Philadelphus*, *Hydrangea*, and *Deutzia*.

Philadelphus (mock orange, sweet syringa) species are shrubs with solid, white pith and often flaky bark. The flowers are showy and usually white-petalled, with clumps of bright-yellow stamens. These shrubs and their many cultivated varieties, which are widely planted in shrubbery borders, bloom late in spring.

Hydrangea
owers

Hydrangeas are known to most gardeners as shrubs, although some are woody vines—e.g., *Hydrangea petiolaris*, climbing hydrangea—and others are small trees, such as *H. arborescens* (mountain hydrangea, sevenbark). *Hydrangea macrophylla* (hortensia), which is the common hydrangea of florists, is sold as a pot plant for household adornment in many northern cities in the early spring. *Hydrangea paniculata* and its varieties, particularly *grandiflora*, comprise the most commonly grown group. Variety *grandiflora*, a treelike shrub, is probably the best all-around hardy (cold-resistant) hydrangea now in cultivation. Many garden hydrangeas are not entirely hardy in the north, and the aerial stems may die partially or completely to the ground each winter, new flowering stems being produced at the beginning of the next growing season. Hydrangea flowers, white, blue, or pink in colour, are produced in large, showy clusters. Flower clusters of *H. paniculata* often remain on plants for long periods of time, providing colour during midsummer in temperate regions when other garden plants are not flowering. In some species of *Hydrangea*, flower colour seems to be related to soil acidity. The pink-flowered hortensias, for example, show a tendency to turn blue when iron filings or alum are added to the soil to increase acidity. Flowers of *H. paniculata* are white when young, later changing to pink and purple.

Deutzias are shrubs that bear white flowers mostly in terminal clusters. Blooms in some horticultural forms are "double flowered"; that is, they have more than the usual single whorl of petals. Like the mock oranges, *deutzias* often have shreddy bark, but the stem is hollow and does not have the white pith of the mock oranges. *Deutzias* are very easy to cultivate and provide a fine floral display, mostly in the spring, even on small shrubs 12 inches (30 centimetres) tall. The best known, *Deutzia gracilis*, is a rather bushy shrub that produces numerous white flowers in loose clusters.

Virginian willow (*Itea virginica*) is one of several species of the genus *Itea*. Most species occur in tropical and subtropical Asia. *I. virginica*, the only American species, occurs southward from Pennsylvania and New Jersey to Florida and Louisiana. It is a slender-leaved, deciduous (i.e., the leaves fall in winter), low shrub, 2 to 3 feet (60 to 90 centimetres) tall. The white, fragrant flowers, which are individually tiny and not particularly showy, occur in terminal clusters. In autumn, the foliage becomes brilliant red. *Itea yunnanensis* is a large, stout shrub, 9 or 10 feet (about 3 metres) tall.

The family Parnassiaceae contains two genera, only one of which, *Parnassia* (grass-of-Parnassus), has any horticultural interest. The low-growing plants are moisture-loving, hardy, perennial herbs of tufted growth habit. The flowers, usually white, greenish white, or yellow, appear between June and September. Species of *Parnassia* occur through-

out the Northern Hemisphere, but *P. palustris* is the only one common in Europe.

Penthorum sedoides, the Virginian stonecrop (Penthoraceae), is one member of a small family of plants native in North America and eastern Asia. The leaves of the Virginian stonecrop, which is a branched perennial herb that attains heights of 2 feet (60 centimetres), are pale green, becoming bright orange with age. These hardy plants, which are used for waterside or shallow-water planting, have flowers that are pale greenish yellow.

Species of several genera of the family Pittosporaceae have achieved horticultural importance, namely, *Billardiera*, *Marianthus*, *Sollya*, and *Pittosporum*. The first three genera consist of low subshrubs (shrubby forms that are woody only at the base or also very small shrubs) with rather slender, twining or climbing branches. *Pittosporum* is a genus of stout evergreen shrubs and small trees. All species of the Pittosporaceae are natives of the Old World: *Billardiera* and *Sollya* occur in Australia; *Marianthus* in Australia and Tasmania; and *Pittosporum* chiefly in Australia but also in tropical and subtropical Africa, Asia, New Zealand, and the Pacific Ocean islands. A number of endemic species occur on the Hawaiian Islands. Greatest horticultural interest is centred in *Pittosporum*, certain species of which are hardy or half-hardy plants frequently grown outdoors in California and Florida. Several species, including *P. tobira* (tobira) of China and Japan, are excellent hedge plants. *Tobira* is also used to decorate the lobbies of hotels and office buildings. Most species of *Pittosporum* have fragrant flowers that may be white, red, yellow, purple, or greenish. *Pittosporum crassifolium* (karo) of New Zealand is a tall shrub or small tree sometimes reaching heights of 30 feet (10 metres). Planted in rows, it is suitable as a windbreak or shelter near the sea because it is resistant to strong winds and salt spray.

Among the herbaceous families of the Saxifragales, Saxifragaceae, perhaps with the exception of Crassulaceae, is the most important horticulturally. The genus *Saxifraga* (saxifrage, or rockfoil) has the largest number of species in cultivation. They occur in temperate (principally alpine) and boreal regions. They are rare in Asia, few in South America, and totally absent from southern Africa and the islands of the Pacific Ocean. Other genera or species of more or less horticultural importance include *Astilbe*, *Bergenia*, *Bolandra*, *Boykinia*, *Heuchera* (alum-root), *Leptarrhena*, *Lithophragma*, *Mitella* (bishop's-cap, mitrewort), *Oresitrophe rupifraga*, *Peltiphyllum peltatum* (umbrella plant), *Rodgersia*, *Suksdorfia violacea*, *Sullivania*, *Tanakaia radicans*, *Tellima*, *Tiarella* (false mitrewort), *Tolmiea menziesii* (pickaback plant), and *Zahlbruckneria paradoxa*.

Practically all Saxifragaceae species are perennial except for a few species in the genus *Saxifraga*. Saxifrageous plants of ornamental value have a variety of uses in the garden. *Heuchera*, *Astilbe*, and *Rodgersia*, for example, are best suited to the open garden. Wild garden genera include *Boykinia*, *Heuchera*, *Mitella*, *Tellima*, and *Tiarella*. *Saxifraga*, *Tolmiea*, and *Lithophragma* do well in rock gardens. Species of *Bergenia* are often utilized in garden borders because of their ornamental foliage and very early blooming pink or white flowers.

Flowers in the Saxifragaceae range from greenish to white and yellow and from pink and red to purple. Leaves are often thick, almost leathery, shining, and evergreen.

Medicinal and folk uses. A number of saxifragean plants are used in native medicine and ceremony in different parts of the world. Although several remedies have been ascribed to these plants, it is doubtful that more than a few are of therapeutic value.

Kalanchoë laciniata is used as an external medicine in India. *K. paniculata* is said to have occult uses in Africa. *K. laciniata* is used by Malaysians to attract good spirits; twigs of the plant are placed in houses to encourage the return of good spirits after a death. The same process is used to drive away evil spirits and to ward them off during serious illnesses such as cholera and smallpox. Children are bathed in water containing leaves of the plant. Leaves are also used to make a poultice for application to the chest of persons with coughs or colds. A compound lo-

The
saxifrage
family

tion made of the leaves of *K. laciniata*, *Costus speciosus*, *Stachyphrynium* species, *Drymoglossum heterophyllum*, and *Psophocarpus tetragonolobus* is used to treat smallpox. Pulped leaves of *K. laciniata* are used in the Philippines to treat chronic ulcers, sores, and headaches.

Bryophyllum pinnatum is widely used in Malaya; life-giving properties are attributed to it because of the production of plantlets by the leaves. It is used medicinally by the natives of India, Malaysia, and the Pacific islands. Poultices are prepared from the crushed leaves to relieve headache, coughs, and chest pains. Poultices are used to treat sore eyes in Java, and in Singapore the leaves are sometimes pounded in water, the resulting infusion being drunk to reduce fevers. As a ceremonial plant *B. pinnatum* is employed in connection with fishing—its twigs make up the besom (a brush made of bundled twigs) that is used to sprinkle yellow gruel during incantations designed to improve fishing. Leaves of this species are also used in Malaysia during the ceremonial washing of newborn infants.

It has been reported in South Africa that the fresh juice of *Cotyledon orbiculata* is occasionally used beneficially to treat epilepsy even though the plant is considered toxic. Various species of *Sedum* are also employed medicinally; *S. acre* is sometimes used as a laxative; the juice of *S. dendroideum* is employed in Mexico as an astringent to harden the gums and to relieve hemorrhoidal discomfort. Leaves of *Sempervivum tectorum* are chewed in parts of Europe as a home remedy for toothache and to relieve the pain of bee stings. A decoction (extract produced by boiling) of the leaves is employed to cure intestinal worms.

The bark of *Weinmannia pinnata* is considered astringent; the same plant secretes a gum that is used in some parts of Cuba as an adulterant of quinine. Similarly, the bark of *W. seloi* is a strong astringent and is used in parts of Brazil to treat wounds. The bitter bark of *Belangera tomentosa* is used as a tonic in some parts of Brazil.

Wood of the Javanese *Polyosma longipes* is said to be useful in treating epidermal scaling (scurf), and the steam produced by boiling the leaves of this species is employed to relieve sore eyes. An extract from the leaves of *Corokia buddleioides* is used in some parts of New Zealand to treat stomachache.

A decoction of the shoots and bark of *Dichroa febrifuga* is taken in the Himalayas as an antipyretic (fever-controlling agent). In Indochina, a decoction of the leaves is used for the same purpose. In Java, the leaves are pounded finely and taken without cooking, together with certain other substances, for fever. In one prescription, the powdered leaves are taken with wormwood (*Artemisia absinthium* and other species of *Artemisia*) as an anthelmintic (intestinal-worm treatment). In another prescription, the powdered leaves are used externally, apparently for intestinal difficulties following childbirth. Fresh leaf and root juices cause vomiting; after the leaves and roots have been soaked in wine and boiled, however, the juice no longer causes vomiting but becomes a gentle purgative.

The dried rhizomes (horizontal underground stems) and roots of *Hydrangea arborescens* of northeastern United States are used medicinally as a diaphoretic (a substance that promotes perspiring) and diuretic. The active principle, hydrangin, is an organic compound known as a cyanogenic glucoside; apparently hydrangin is present in all species of *Hydrangea*. Hydrangin occurs in rhizomes, roots, leaves, and buds. Accidental ingestion of any plant part, under certain conditions, may cause nausea, vomiting, and diarrhea. Treatment consists of washing out the stomach or inducing vomiting.

Penthorum sedoides is employed medicinally in a variety of ways, some of which are quite contradictory—e.g., as a demulcent (a medicine used to soothe irritated mucous membranes) and astringent (a substance that contracts tissues); as a laxative and to treat diarrhea. It reportedly has been used to treat hemorrhoids and gastric ailments.

Phyllonoma laticuspis is known as *hierba de la viruela* (smallpox weed) in parts of Oaxaca, Mexico. It is administered with sugar as a syrup prepared from the green leaves.

An aromatic decoction brewed from the leaves of *Pit-tosporum pentandrum* in the Philippines is used by women

in their baths following childbirth. The powdered bark is employed in small doses to reduce fever. If taken in larger dosages, it is considered a general antidote. It is also effective in relieving bronchitis. The Malaysians use poultices of both leaves and roots of *P. ferrugineum* to treat malaria. The leaves and fruit are used as a fish poison in Malaysia; the toxic action is probably related to the presence of such complex compounds as saponins, tannins, and alkaloids.

Leaves of *Astilbe philippinensis* are used in northern Luzon, Philippines, for smoking. Sometimes a little tobacco is mixed with the leaves. The rhizome of *Bergenia purpurascens* is used in Chinese medicine to stop bleeding and as a tonic. *Tiarella cordifolia* of North America is considered useful as a diuretic and tonic; in particular, it is said to be beneficial in relieving cases of urinary-bladder stones and other urinary complaints. *Saxifraga sarmen-tosa*, a native of China and Japan, is used in Java to treat earache. In Vietnam and in various parts of China it is also used for complaints of the ear. It is also employed in China for attacks of cholera and to treat hemorrhoids. To treat the former, administration is internal; to treat the latter, application is by steaming.

Timber and other forest products. Timber from trees of *Brunellia* is only of limited importance in tropical America. The light wood is rather soft, finely textured, easy to work, and perishable when in contact with the ground. The hard, durable wood of *Crypteronia paniculata* trees is used extensively for house building in Malaysia and the Philippines. It is also used for fuel. The sapwood is white, the heartwood reddish brown.

Several trees of the family Cunoniaceae produce timber and other forest products. The bark of *Belangera* of southern Brazil, Paraguay, and Argentina is used in tanning. The light-pinkish-brown wood is easily worked. The principal use of *Caldcluvia paniculata*, a small tree of southern Chile, is as fuel.

Trees of several species of *Weinmannia* occur in both Old and New World tropics. The bark is rich in tannins, and the timber is suitable for furniture and for interior construction. Timber of *W. blumei* from Malaysia is fairly hard but easy to work; red and lustrous, it is moderately resistant to decay. *W. benthami*, the brush mahogany of Australia, produces a timber that is useful in construction and is occasionally used for cabinet work, handles of small utensils, brush backs, and veneer and plywood. *W. lachnocarpa* (rose marara of Australia) is noted for its straight-grained, hard timber, which is employed for turnery, machinery bearings, chisel handles, mallets, and printer's blocks. Timber of *W. racemosa* finds limited use in New Zealand for cabinet work, interior trim, fencing, and mine timbers. Wood of *W. descendens* (encinillo) is imported into the United States from northern South America. The timber, light brown to pinkish and reddish brown, is of medium lustre, moderately heavy, and fine textured; it is employed for general construction, furniture, cabinets, joinery, turnery (such as brushes, broom handles, dowels, shoe heels, bobbins), and sporting goods.

Tanning substances are extracted from the bark of *W. racemosa* of New Zealand, *W. luzoniensis* of the Philippines, and *W. tinctoria* of Mauritius. Bark of the last named imparts to animal skins a red hue, hence *tinctoria*, which means "used in dyeing."

Ceratopetalum apetalum, the coachwood, or rose mahogany, of Australia, is sometimes imported into the United States, where it is used for the same purposes as *Weinmannia descendens*. Red elms, or red alder, *Cunonia capensis* of southern Africa, produces a light, soft timber that is durable underwater. It is suitable for furniture, wagon building, and for construction. Species of *Pancheria* of New Caledonia produce wood that is locally important for cabinetwork and turnery. The wood of *Spiraeanthemum samoense* has been used by natives of the Samoa Islands for canoe construction and war clubs.

The timber of *Escallonia* apparently has no commercial possibilities, owing mostly to the small size of the trees. Locally, however, where trees of sufficient size occur, the wood is utilized for building purposes. The moderately hard and heavy wood is easy to cut and tough to split and appears to be fairly resistant to decay. Fresh wood of

the family
Cuno-
niaceae

Escallonia floribunda has a peculiar odour, and, in certain localities in the Venezuelan Andes, it is called *cochinillo* or *puerquito*, both of which mean "little pig."

Eucryphia lucida, Tasmanian leatherwood, produces a fine-textured, tough, durable, brownish wood that is not in general use but is suitable for tool handles, furniture, and heavy construction. *E. moorei* of Australia is sometimes called coachwood because it has been used for frames and bodies of wooden vehicles. Ulmo trees, *Eucryphia cordifolia* of Chile, produce fine-textured timber with good working qualities but not very resistant to decay. The lustrous heartwood is brown and variable. In Chile, ulmo wood makes excellent flooring, and, in the nitrate-mining areas, it is used for railway cross-ties and for poles that support power lines. Other uses of ulmo are for furniture manufacture, vehicle parts, oars, and pilings. An extract of the bark, which contains about 15 percent tannins, is used in commercial tanning.

The fine-textured, whitish wood of *Deutzia scabra* is used in Japan for marquetry (delicate inlaywork) and for wooden nails. *Hydrangea paniculata* produces a hard, fine-textured wood prized in Japan for walking sticks, umbrella handles, tobacco pipes, and wooden nails; the bark is used to manufacture paper. The wood of *Itea nutans* is attractive and is used in Malaysia for small articles of turnery.

Pittosporum crassifolium of New Zealand furnishes a very tough, whitish wood favoured for marquetry. In the Philippines, fruits of *P. resiniferum* are known as "petroleum nuts" because of the fancied resemblance of the odour of the oil to that of petroleum and because even the green, fresh fruits burn brilliantly. The oil contains two organic compounds, a dihydroterpene and considerable quantities of heptane. The white, fine-textured wood of *P. resiniferum* is not durable; it is sometimes used in Malaysia for house rafters and for firewood.

Fruits, seasonings, and other edible products. *Sedum album* is sometimes used as an herb in salads; leaves of *S. reflexum* are occasionally consumed in salads or soups; and the leaves of *S. roseum* are eaten fresh, soured, or in oil by Eskimos in Alaska. Young shoots of *Crypteronia paniculata* are eaten as flavouring with rice in Indonesia. Flowers of *Eucryphia cordifolia* of Chile are rich in nectar and are prized as a source of honey.

Many species of *Ribes* bear edible fruits of considerable commercial importance. Among the important fruit-producing species is the European gooseberry (*R. grossularia*), which is used in desserts, in pies, and in jams and wines. The European black currant (*R. nigrum*) is eaten fresh or in jams or puddings. *R. rubrum* produces both red and white currants that are used for desserts, pastries, and wine. *R. vulgare*, an American currant, is eaten fresh or in desserts and pies. Other species of less importance for their edible fruits include the buffalo, or Missouri, currant (*R. odoratum*) and some American gooseberries, such as *R. hirtellum*, *R. cynosbati*, *R. oxyacanthoides*, *R. setosum*, and *R. inerme*. The most important fruit-bearing species of *Ribes* are available in many improved and selected varieties.

Young leaves of *Hydrangea thunbergii* from Japan are gathered, steamed, rolled between the hands, dried, and used as a substitute for tea; the preparation is called amacha, or ama-tsja (tea-of-heaven).

Plants of *Saxifraga erosa*, mountain lettuce, or deer-tongue, are used in salads by mountain people in southern Pennsylvania. The thick, fleshy leafstalks of *S. peltata* (Indian rhubarb) were peeled and eaten raw or boiled by Indians of the west coast of North America. Succulent leaves of *S. punctata* (dotted saxifrage) are consumed by Eskimos either raw or after being kept in oil. *Chrysosplenium alternifolium* (golden saxifrage), a perennial herb of Eurasia and North America, is occasionally used in salad and as an emergency food in the Vosges mountains (France). The leaves of *Bergenia crassifolia* (badan) are used by the Mongols as a substitute for tea called tschager tea.

Role in white-pine blister rust disease. Among the most serious and widespread diseases of forest trees is the white-pine blister rust. This disease is caused by a parasitic fungus, *Cronartium ribicola*, which spends part of its life cycle as a parasite of a susceptible five-needled pine and

the other part on certain species of *Ribes* (currants and gooseberries of the family Grossulariaceae). *Ribes nigrum* is the most susceptible species.

The fungus overwinters as a mycelium (filamentous vegetative body) in the stems of *Ribes*; spores (reproductive bodies) are produced by the first week in April, depending upon climatic conditions. The wind-borne spores may be carried several miles. They germinate on moist leaves of *Ribes* plants, and the fungal germination tube enters the leaves through stomates (pores) on the lower surface. Following growth of the fungus in the tissues of the leaves, pustules form on the leaves; from them, other wind-borne spores are released that carry the disease to the pines. The spores germinate on the pine needles, entering through stomates. Eventually, the rapidly growing fungus enters the water- and food-conducting system of the pine and then moves into the bark, on which externally visible cankers form. After about two years, pustules appear on the surfaces of these cankers. Wind-borne spores from the pustules can infect only species of *Ribes*, not pines. Thus, both *Ribes* and pines must be present together within a favourable environment in order to perpetuate the fungus. When control measures proved insufficient to halt the spread of the disease after its introduction from Europe in the early 1900s, programs for the systematic eradication of *Ribes* plants, including wild, nursery, and crop plants, were begun in regions in which white pines are of commercial and economic importance. Thus today, in many places in the United States where *Ribes* was once native, wild plants are very difficult to find in nature.

NATURAL HISTORY

Insect-trapping plants. The families Cephalotaceae, Byblidaceae, and Roridulaceae have been reported to be insectivorous. Insectivorous implies the ability of plants to "eat" insects, which, of course, they do not; rather, by a series of mechanisms, insectivorous plants trap insects and externally digest parts of them. Although insectivorous plants doubtless receive some nutrition from the bodies of insects, most can exist quite well without an insect diet. Insectivorous plants usually grow in soils that are deficient in nitrogen salts, which are used by plants in the manufacture of amino acids and proteins. Therefore they require a supplementary source of nitrogen, which they obtain by digesting the proteins in captured insect bodies.

Of the three families of Saxifragales noted above, only Cephalotaceae and Byblidaceae are truly insectivorous in the sense that they both capture and digest insects. Plants of the Roridulaceae, a family restricted to southwestern Africa, are found with insects caught in the resinous secretions of their leaves, but there is no evidence that any form of digestion takes place or that the plants benefit from these accidentally ensnared insects.

Roridula dentata, for example, is known not to digest the insects, which, by incidentally coming into contact with the leaves, become stuck on the plants. Even though these insects apparently do not benefit the plant, they are used as food by a spider of the genus *Synaema*. This spider, which has become adapted to life on *Roridula* plants, is immune to the sticky secretions and is thus able to move without difficulty. The spiders generally hide among the dried leaves or in nests that they build there, awaiting the vibration of a twig, indicating the presence of an ensnared insect, which the spider kills. There thus appears to be a symbiotic relationship between the spider and the plant; clearly the spider benefits from the relationship, but whether the plant is benefitted or not is unknown.

The insectivorous nature of plants of Byblidaceae and Cephalotaceae is more firmly established; apparently, a true capture-and-digest system exists. Byblidaceae consists of one genus, *Byblis*, and two species in western Australia. Plants of *B. gigantea* are shrublets, attaining heights of 20 inches (50 centimetres) and consisting of a woody rhizome bearing in any one season the dying parts of the previous growing season and the growing parts of the present season. These parts consist usually of a main stem, which is sparsely branched near the base. The long, linear, yellow-green leaves of the stems are covered with numerous mucilage glands, which give the leaf a glistening

mily

dible
xifrages

surface. Plants of *B. linifolia* are more delicate than those of *B. gigantea*, and the annual stem and its branches arise from a slender rhizome. These parts are also clothed with mucilage-secreting glands.

The glands are of two kinds, stalked and unstalked. Experiments have shown that minute cubes of coagulated egg albumen—a proteinaceous material such as might be found in insect bodies—placed in contact with the unstalked glands completely disappear after a period of from two to eight days. When this material is placed in contact with the stalked glands, there is no evidence of digestion.

In other observations, when trapped insects came in contact with unstalked glands, the latter produced a secretion that was much less viscous than that of the stalked glands. The actual mode of digestion of insects by these plants is still not completely known.

Plants of *Byblis* are sometimes infested with a small wingless capsid (members of a family of the insect order Heteroptera). Although other small insects are ensnared in the mucilage, capsids appear to be able to move unhindered over the surface of *Byblis* leaves.

The family Cephalotaceae consists of one species, *Cephalotus follicularis*, the west Australian pitcher plant, which occurs only in the southwestern corner of Australia. The plant has an underground rootstock from which two kinds of leaves are produced, foliage leaves and pitcher leaves. Foliage leaves and pitcher leaves are produced in a seasonal rhythm: the foliage leaves develop in the autumn, reaching full size and abundance in spring; pitchers grow in winter and spring and are fully formed and functional in summer when the insects they capture are most plentiful.

Foliage leaves attain a maximum length of about 5 inches (13 centimetres); the blade is ovate and pointed at the apex and is equally as long as the petiole (leafstalk). The thick, leathery, and smooth foliage leaves are studded with nectar glands. Pitcher leaves are about 2 inches (5 centimetres) or more long when fully mature. They measure about 1 inch (2.5 centimetres) across and are somewhat compressed front to back. There is an oval opening, wider crosswise than from back to front. The petiole, or leafstalk, is approximately at right angles to the axis of the pitcher; it is attached dorsally below the “hinge” of the lid at about the level of the opening. The mouth of the pitcher is surrounded by a thickened corrugated rim, each ridge of which forms a clawlike tooth that extends into and is directed downward toward the base of the pitcher. Each pitcher has a lid that overhangs the opening and is more or less open, depending upon the age of the leaf. The lid is traversed radially by narrow patches of green tissue between which are clear patches devoid of chlorophyll. The clear patches have the appearance of windowlike areas framed in green. To entrapped insects, the clear patches probably appear to be open spaces, and they attempt to escape through them until, eventually exhausted, they fall into the depths of the pitcher.

The interior of the pitcher has two zones. The upper zone forms a ridge around the mouth of the pitcher and arches over the internal cavity. The epidermis (surface) of the upper zone is studded with downward-pointing hairs, as is the inside of the lid. A smooth, glassy surface characterizes the interior zone of the pitcher, which has a glandular surface. The flask-shaped glands have been reported to be digestive in function. Within the pitcher a shelflike bolster projects inward but is not apparent externally; it contains glands, among which are many “water pores,” or hydathode-like (water-secreting) structures. The water pores resemble stomates, but the orifice between the guard cells is continuously open. Presumably, the fluid that fills the pitcher is produced from these pores. This action, however, has not yet been proven conclusively.

Some botanists have demonstrated that fluid taken from virgin, or unopened, pitchers can digest animal substances. Others, however, have not been able to find any fluid in unopened pitchers and have reported the presence of fluid only in opened pitchers. In any event, it has repeatedly been observed that pitchers do capture insects, notably ants. Small pitchers catch small insects. That the soft parts of these insects undergo dissolution of some sort is evident. There is some question, however, as to whether this

dissolution is the result of digestive enzymes secreted by the pitcher glands, by extraneous microorganisms, or both.

Although pitcher fluid, sterilized to kill any microorganisms, will digest proteinaceous material in the laboratory, it still cannot be concluded that this digestive process actually takes place in pitchers under normal circumstances. It is presumed, nevertheless, that digestion by pitcher fluid may take place very slowly in the pitchers; available evidence indicates that both the secretions of the pitchers and the actions of microorganisms contribute to the digestion of insect proteins. Plants grown under laboratory conditions without the presence of insects thrive and flower. The question, therefore, remains concerning the usefulness or necessity of insect protein to insectivorous plants.

Reproductive biology. *Epiphyllous flowers.* Flowers that are borne on or produced from leaves are termed epiphyllous flowers. Flowers and fruits of plants in the genus *Phyllonoma* are borne directly on the upper surface of leaf blades. In *P. ruscifolia*, all stages of flower and fruit development may be found on one plant at any time. The cluster of flowers is produced from the midvein well toward the tip of the mature leaf. From the point of attachment of the cluster of flowers, the leaf narrows rapidly toward the pointed apex. Not all leaves bear flower clusters. There has been some question about the morphological nature of the flower-bearing green leaves. Some botanists have thought them to be expanded stems (cladodes) modified for both photosynthesis and reproduction; others have proposed that the leafstalk and flower stalk represent fused structures. Studies of the minute structure of the leaf indicate, however, that they are true leaves and that a separate flower stalk is not fused to midvein of the leaf.

Pollination processes. Before fertilization can take place in flowering plants, it is necessary for viable pollen to be transferred from stamens (male reproductive organs) and deposited on receptive pistils (female structures). If this transfer takes place within the same flower, it is called self-pollination. Self-pollination, however, is not always accompanied by fertilization and the setting, or producing, of seed, because some plants are not self-compatible; that is, some plants do not have the genetic capacity to produce seed even when the style (the narrow upper portion of the pistil) is dusted with pollen from the same flower. When seed is produced as a result of fertilization by pollen from the same flower, the term self-compatible is used. Cross-pollination refers to the transfer of pollen from flowers of one plant to the pistils in flowers of another plant of the same species in order to effect pollination and subsequently fertilization and the setting of seed.

Species of the family Saxifragaceae apparently have mechanisms that prevent self-pollination. Dichogamy, for example, is a condition that involves the separate maturing, in terms of time, of stamens and pistils in the same flower. It results when the anthers do not release their pollen at the same time the stigmas (pollen-receptive surfaces of the pistil) are receptive. There are two variations of this arrangement, protandry and protogyny. In protandry, the anthers are ready to liberate their pollen before the stigma of the same flower is structurally and physiologically receptive; in protogyny, the stigma matures before the anthers of the same flower are ready to shed pollen. In the Saxifragaceae that have been studied, protandry is predominant. This condition has also been reported for *Parnassia*, of the family Parnassiaceae. As with many groups of plants, biological phenomena of this kind have not been studied in detail in most families of the order Saxifragales.

Heterostyly is another reproductive phenomenon that has been observed in members of the Saxifragaceae. Heterostylous plants have bisexual flowers of two or three different kinds. They are distinguished from each other by the size and behaviour of the reproductive structures; for example, *Jepsonia heterandra*, a very locally distributed native plant of California, has distylous flowers. Some plants produce long-styled (called pin) flowers, and others produce short-styled (thrum) flowers. Pin flowers also have large stigmas and short stamens that produce many small pollen grains. Thrum flowers have small stigmas and long stamens that produce fewer but larger pollen grains.

Flowers growing from leaf surfaces

Pitcher-shaped, insect-trapping leaves

Cross-
pollination
ensured
by flower
structure

Heterostyly is one of the most extraordinary reproductive devices by which cross-fertilization is ensured in higher plants. Even though a heterostylous flower contains complete and functional structures of both sexes, the plants, because they contain a genetic factor that inhibits self-fertilization, must be cross-pollinated. Although the flowers are bisexual, functionally they are either male or female, and cross-pollination is as obligatory as in species with separate male and female flowers.

Pollination agents. Pollination in saxifragalean families is usually by insects. The following account of pollinators in *Jepsonia heterandra* is typical of other species with similar breeding systems. Soon after the opening of anthers in the morning, flowers of *J. heterandra* are visited by flies, especially by several genera of syrphids, as well as by small bees, especially the species *Dialictus ornduffi*. The male insects visit flowers to obtain nectar (but not pollen) and to mate with females. In the course of these activities, pollen occasionally adheres to the bodies of the bees and is consequently available for transfer to other flowers. The females, which visit flowers to gather both pollen and nectar, collect abundant quantities of *Jepsonia* pollen on the posterior pair of legs.

Syrphid flies drink nectar from *Jepsonia* flowers but do not crawl into the flowers as do female *Dialictus ornduffi*; rather, the flies remain at the entrance to the floral axis and on the styles. From this position the proboscis (elongated mouthparts) is extended down to the nectaries at the base of the petals. When this happens, pollen from the anthers is transferred to the underside of the fly's head, and the proboscis also becomes coated with pollen. During grooming activities, pollen from the head and proboscis is transferred to the forelegs. Flies visiting other flowers transfer the pollen to them, effecting cross-pollination.

Other pollinators of saxifragalean plants have been recorded, and flies have been observed transferring pollen of certain species of the family Crassulaceae and *Parnassia*. Most flowers of *Parnassia* have conspicuous nectar-secreting staminodia (sterile, or aborted, stamens), which act as glands and secrete glistening droplets of nectar; flies feeding on this nectar may become dusted with pollen. Pollination in *Roridula* appears to be carried out by small Heteroptera. When the sensitive anthers in *Roridula* are touched by a suitable visitor, they suddenly spring upright, scattering pollen over the insect. The brightly coloured tubular flowers of some Crassulaceae—e.g., *Bryophyllum*—are pollinated by birds. Pollination of *Escallonia* has not been observed in the wild, but the abundant nectar makes insect pollination very likely. Flowers of *E. rubra* growing in England have been observed to be visited both by honeybees and bumblebees, the latter even biting their way into closed flowers to secure the nectar (see REPRODUCTION AND REPRODUCTIVE SYSTEMS: *Pollination* for additional information about the mechanisms involved in the process).

Ecology. Plants belonging to the order Saxifragales inhabit almost the complete range of environmental conditions on Earth. They are to be found growing in deserts and semideserts, under mesic (moist) conditions, and in water; they occur at sea level and in the mountains above the tree line; they grow in humid and dry tropical atmospheres, in the cold of the Arctic and Antarctic, and in the snowy reaches of the European Alps, the Andes, and the Himalayas.

Escallonia, the largest in numbers (60 species) of the 7 genera of the family Escalloniaceae, is confined to South America except for one species that reaches Costa Rica. The genus is found predominantly in mountainous regions, but in the southernmost portion of its range in South America, it grows in a temperate climate near the sea. In the cordilleras of Bolivia, Peru, Ecuador, and Colombia, plants of *Escallonia* grow as low shrubs at an elevation in excess of 13,000 feet (4,000 metres), extending above the tree line. The Valdivian rain forests of Chile contain several species of *Escallonia*. In the dry scrub vegetation of central Chile, *Escallonia* grows in company with *Araucaria* (monkey-puzzle tree), *Alnus* (alder), and sclerophyllous shrubs—typically leathery-leaved plants of dry habitats. In such dry areas of Chile, and from Ar-

gentina to Venezuela, *Escallonia* species occur at the bases of valleys near sources of underground water. In south-east Brazil, Uruguay, and portions of adjacent Argentina, *Escallonia* occurs in the forest. In other regions of Chile and Brazil, some species of *Escallonia* grow in flooded areas and swamps, but they are rarely found in the shrub-covered *campos* (level, grassy plains areas with scattered trees or shrubs). In the high cordilleras from northwestern Argentina to Peru, *Escallonia* plants are not scarce on the upper cloud forest border, and farther north in Colombia they penetrate the *páramos* (high, treeless plains). The highest cloud forest sites that support the growth of *Escallonia* occur in parts of the southeastern Brazilian coastal ranges and in Costa Rica, where species live in subalpine meadows together with numerous members of the family Ericaceae (heaths).

Brunelliaceae, consisting of the single genus *Brunellia*, is another strictly tropical American group of plants. It is distributed along the western side of America from about 23° North latitude in Mexico and the Greater Antilles south to 18° in Bolivia. Like *Escallonia*, most species of *Brunellia* grow in mountain forests, from elevations of about 2,000 feet (600 metres) to 12,500 feet (3,800 metres). One group of *Brunellia* species occurs at low elevations, from 2,000 to 6,500 feet (600 to 2,000 metres). Another group inhabits cold regions and is usually found between 9,200 and 10,500 feet (2,800 and 3,200 metres) elevation. In contrast, *B. hygrophilica* is part of the sea-level vegetation, where temperatures range between 86° and 102° F (30° and 39° C) and the rainfall amounts to 320 inches (8,000 millimetres).

The family Crassulaceae is of cosmopolitan distribution, but species are particularly concentrated in the dry regions of southern Africa, the Macronesian islands (Azores, Canary Islands), and in western North America. Most plants of the Crassulaceae are characterized by their moderate to extreme succulence—thick, fleshy stem and leaf growth—and most members of the family are remarkable for their dry-habitat-adapted structure, particularly mucilaginous water-storage tissues in the leaf and stem. Some species are believed capable of absorbing water directly from the air through special hairs, surface cells, or aerial roots. Bladder hairs of *Crassula falcata*, for example, can take up moisture from the atmosphere. Many plants of the family are of the rosette growth habit. Their crowded, basally disposed leaves are able to retain moisture in the form of dew; absorption of this moisture may take place directly through the leaves or through special hairs. The viviparous habit (*i.e.*, the production of plantlets directly from leaves of the parent plant) of *Bryophyllum* species may be an adaptation to arid conditions; the plantlets are ready to grow in the presence of the slightest moisture.

The family Saxifragaceae illustrates the entire range of adaptation to differing moisture conditions found in the order. *Saxifraga nutans* is a true aquatic plant, *S. pennsylvanicum* is a bog plant, and *S. micranthidifolia* grows in cold mountain streams and on wet rocks. Other species are more or less adapted to dry conditions (*i.e.*, they are xerophilous), among them *S. tridactyloides*, which stores moisture in small bulblike bodies on the stem (bulbils). Similarly, *S. trifurcata* has a strongly cuticularized (wax-coated) epidermis, *S. globulifera* produces membranous bud scales and hairy stipules, and *S. aspera* stores moisture in its fleshy, heavily cuticularized, long-persistent leaves; all are examples of adaptations to dry habitats. In some saxifrages, leaf rosettes are produced. The bases of the lower leaves in the rosettes are only weakly cuticularized, so that dew accumulating there may be absorbed by the leaves in sufficient quantity to enable the flowering shoot to develop.

Species of the genus *Saxifraga* are known for their tenacious ability to grow and thrive on exposed rocky crags and in fissures of rocks. The name *Saxifraga* literally means "rock breaker." Thus saxifrages grow high in the Alpine regions of the mountains of Europe, in places that are covered with snow and ice for long periods of the year. The plants have tough, wiry root systems and deeply penetrating taproots. In the same harsh environments, some saxifrages (*e.g.*, *S. hirculus*) develop as cushion plants.

Escallonia
at high
elevations

Saxifrages
growing on
rocks

This involves a considerable reduction in leaf surface (that is, a diminution of the evaporating surface) and a shortened shoot. These low cushion plants are also often adaptable to bog conditions.

Most Saxifragaceae species, however, grow in moist, shaded woodlands. Among these are species of *Saxifraga*, *Astilbe*, *Rodgersia*, *Astilboides*, *Peltiphyllum*, and *Boykinia*.

FORM AND FUNCTION

The several families that make up the order Saxifragales are held together by a pattern of overlapping similarities, rather than by characteristics held in common by all families. Perhaps the order is best described by its internal heterogeneity instead of by its homogeneity. Practically all growth forms of plants are found, including trees, shrubs, and woody climbers among the woody types; and annual and perennial herbs among the herbaceous types. Leaves are alternate or opposite, with or without stipules (basal appendages). Sometimes the flowers contain elements of both sexes—that is, stamens (male) and pistils (female)—but in some groups the flowers may be either entirely male or female. The flowers are almost always radially symmetrical. Generally the petals are free—that is, separate and not fused to each other. Stamens vary from few in each flower to many and indefinite in number. The ovule-bearing segments of the pistil (carpels) may be separate, but more often they are fused to each other. All conditions of ovary insertion are present, ranging from ovaries positioned above the other flower parts (superior ovaries) to those wholly enclosed by the fused bases of the sepals, petals, and stamens (inferior ovaries) as well as various intermediate conditions. Seeds usually have abundant nutrient tissues for the developing embryos (endosperm). More homogeneity exists among the anatomical features. The pollen grains, for example, are usually tricolpate, which means they have three germinal grooves. Among the woody families, vessel elements (water-conducting cells) have end openings predominantly with ladderlike crossbars (scalariform perforations), whereas among the herbaceous families, the vessel elements usually have simple perforations.

Several of the families are very distinctive in certain features. The family Phyllonomaceae is characterized by flowers borne directly on the leaves. The family Crassulaceae is well known for its extreme succulence and the presence of crassulacean acid metabolism. Byblidaceae is insectivorous, and Cephalotaceae is distinguished by its remarkable urn-shaped leaves and its insectivorous nutrition. The family Francoaceae is distinctive in having a diacytic stomatal apparatus (*i.e.*, stomates, pores in leaf surfaces, with two epidermal cells enclosing the pore so that their common wall is at right angles to the long axis of the stomate). The family Davidsoniaceae is characterized by its irritant hairs. In addition to normal phloem external to the water-conducting xylem, the family Crypteroniaceae also has internal phloem—*i.e.*, food-conducting tissues located within the stem interior, between the pith and the inner surface of the xylem. The families Roridulaceae and Byblidaceae are characterized by the circinate vernation of their leaves; the leaves are rolled lengthwise in the bud, like those of ferns. Pittosporaceae has secretory canals in the axis.

EVOLUTION

Fossil record. Although many species of fossils have been described and assigned saxifragalean names and relationships, it is impossible in many cases to establish with any degree of certainty the accuracy of these assignments as far as the real relationships of the fossil plant material is concerned; thus the following examples should be viewed with an understanding of this qualification.

The family Saxifragaceae is represented in the fossil record by *Saxifraga*, found in many European localities in deposits as old as the Tertiary Period (65,000,000 to 2,500,000 years ago), but most have come from the Pleistocene Epoch (which began about 2,500,000 years ago) and more recent deposits. Various fruits and leaves from England, Czechoslovakia, and Germany in Eocene

(54,000,000 to 38,000,000 years ago) and more recent deposits, and *Chrysosplenium* from the middle Pliocene of England, are also known from the Saxifragaceae. The family Hydrangeaceae is represented by *Philadelphus*, known from Canada in deposits as old as the Upper Cretaceous; and by *Deutzia*, *Schizophragma*, *Decumaria*, and *Hydrangea* from many European, central Soviet Union, Japanese, Alaskan, and North American localities of Tertiary age. *Ixerba* of the family Brexiaceae has been found in the Pliocene of New Zealand. *Itea* of the family Iteaceae occurs in Tertiary deposits of Italy. The family Escalloniaceae is known from the Pliocene of New Zealand and Bolivia (*Quintinia* and *Escallonia*, respectively) and is also known from the Pleistocene of New Zealand (*Carpodetus*).

The family Grossulariaceae is known in fossil form by *Ribes*, found in European and North American Tertiary deposits, and by *Riboidoxylon* (wood) from the Upper Cretaceous in California. The family Cunoniaceae is represented by the fossil genus *Cunonioxylon* (wood) from Upper Oligocene deposits in the eastern Alps of Europe. Leaf and stem fossils of the family Crassulaceae are known from France and The Netherlands in Tertiary deposits. A flower of *Billardierites* of the family Pittosporaceae has been found in amber of Miocene age (26,000,000 to 7,000,000 years ago) from the Småland Peninsula of the Baltic coast.

Several conclusions can be drawn from the above data. Members of the Saxifragales have been present at least since the beginning of the Tertiary Period—that is, from the Paleocene Epoch (which began about 65,000,000 years ago)—and probably even earlier. There are several reports of saxifragalean plants from earlier strata (*e.g.*, *Philadelphus* and *Ribes* from Upper Cretaceous sediments). The occurrence of the wood of *Ribes*, represented by the form genus *Riboidoxylon*, is well dated and based on modern methods. It can probably be accepted as the earliest documented discovery of a saxifragalean plant. The Late Upper Cretaceous deposits of the Panoche Formation, in which *Riboidoxylon* occurs, are dated at between 70,000,000 and 80,000,000 years ago.

A comparison of the geographic distribution of fossil forms with modern representatives of the same genera is instructive. Modern species of *Philadelphus* grow in southern Europe, Asia, and North and Central America. The fossil occurrence of *Philadelphus* in what is today northern Germany is thought to indicate a recent contraction of an originally broader range for the genus. Today, species of *Hydrangea* occur from India to Japan, in the Malay Archipelago, in North and Central America, and in western South America. The fossil range of *Hydrangea* in northern, central, and southern Europe provides evidence that the genus was more widely distributed in geologically earlier times than it is now.

More difficult to explain are the occurrences of other fossil saxifragalean plants in northern latitudes, for example, the Cunonia-like wood in the eastern European Alps and the *Billardiera*-like flower in the Baltic region of present-day Germany. The family Cunoniaceae is mostly southern in distribution today and the Pittosporaceae, to which family *Billardiera* belongs, is fundamentally Australian, eight of its nine genera being found on that continent.

These outstanding disjunctive distributions must be viewed with considerable prudence pending other forms of corroborative evidence such as a reexamination of the identifications and a search for other southern plant forms in the beds containing these reputed saxifragalean ancestors. Overall, however, the conclusion that is drawn from presently available data and observations is that present-day distributions of saxifragalean plants are remarkably similar to those that existed as long ago as the Upper Cretaceous Period.

Phylogeny. The fossil record of the order Saxifragales is too fragmentary to enable any conclusions to be drawn concerning its early origins and relationships. All that can be stated with any assurance is that saxifragalean plants appeared in Late Upper Cretaceous times contemporaneously with representatives of many other families of flowering plants. Doubtless, the actual progenitors of plants with saxifragalean relationships were in the process

family

Ancestry of
the order
Saxi-
fragales

of evolving long before Saxifragales are recorded in fossil-bearing strata. Nothing is known about the real relationships of these ancient plants of saxifragalean alliance nor from which plants they may have evolved.

Information from comparative studies of present-day Saxifragales species seems to point to an origin from ancestors of the order Dilleniales. The order Saxifragales is closely related to the order Rosales, and perhaps its nearest affinities are with members of this group. Although the anatomy of the wood of several families in the Saxifragales is more primitive than that of the most primitive representatives of the Rosales, floral structure in some saxifragalean families reaches a higher level of specialization than that found in any rosalean families. It appears, then, that both the Rosales and Saxifragales owe their origins to forebears of the Dilleniales, perhaps to ancient plants of magnolialean (*i.e.*, the order Magnoliales and its relatives) alliance.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. In flowering plants, floral characteristics provide the major bases for family delineations. To a lesser extent, vegetative features are used—*i.e.*, the morphology of leaves and twigs, growth habit of the plant, texture of the bark, and sometimes microscopic structure and chemical constituents. Some plant families have unique or almost unique properties, such as insectivorousness or epiphyllous flowers, which enable the plant taxonomist to characterize the family. Usually, however, this is not the case, and families are established on a combination of characteristics; it is this combination of characteristics that sets the family apart from other closely related families.

The generalizations above hold true for the families that comprise the order Saxifragales. Some families have evolved very specialized structural innovations, but most owe their distinctiveness to a combination of characters rather than to any single character. Because the elements that make up the order Saxifragales can be interpreted in various ways, plant taxonomists over the years have assembled different schemes of arrangement; usually the schemes are influenced by their creators' ideas of the features that are the most reliable indicators of relationship and whether larger or smaller groups of plants are more reflective of natural conditions. Nevertheless, the several schemes of arrangement are more or less based on the same data and raw materials. The manner in which these are employed and weighted gives rise to some of the differences in systems of arrangement of saxifragalean families.

Among the useful characters employed to subdivide the order Saxifragales into families is the predominant habit (growth form) and duration of the plants—that is, whether the plants are woody or herbaceous, and, if herbaceous, if they are annual or perennial. Using these criteria, the order is divided into two main groups of families, those with mostly woody, perennial plants and those made up mostly of herbaceous species. Herbaceous Saxifragales are usually perennials, but annual plants predominate in a few families. Useful characteristics of the leaves concern phyllotaxy—that is, whether the leaves are alternate, opposite, or whorled on the stem. All three dispositions occur in different parts of the order. The presence or absence of stipules (basal appendages on leafstalks) and of simple or compound leaves have been useful in separating families. Fusion of sepals and petals, and of the carpels (the ovule-bearing segments of the ovary), are pertinent criteria in distinguishing among the families. The number of stamens, whether they are definite or indefinite in number, is also a meaningful character for delineating saxifragalean families. Position of other floral parts in relation to the pistil (female organ)—that is, whether sepals, petals, and stamens are attached below, at, or above the attachment to the floral axis of the ovary—is an important means of segregating families in this order. The kind of fruit produced is indicative of familial cohesiveness, as is the number of coats on the seeds.

Basic of the classification system. The classification of the order Saxifragales into families as presented in this article incorporates both traditional information from floral

structure and vegetative morphology and ancillary data on the microscopic anatomy of plant parts. This classification, in its broader aspects, conforms to others published in recent years. Unlike some systems, however, which separate the families Philadelphaceae and Hydrangeaceae, these two are united here, and the combined group is considered under the name Hydrangeaceae. Because of the many overlapping characters between the two groups, relationships are better preserved and expressed by joining rather than by separating them.

The family Paracryphiaceae (with *Paracryphia* as the only genus) is included provisionally within the order, but the relationship is not wholly certain. *Lepuropetalon*, considered as the basis of a separate family (Lepuropetalaceae) by some plant taxonomists, is tentatively included within the family Parnassiaceae (which has two genera, *Parnassia* and *Lepuropetalon*). Unlike the situation with *Paracryphia*, *Lepuropetalon* has long been included in the family Saxifragaceae, and it seems to be related to this general alliance of plants. Its inclusion as a second genus of Parnassiaceae, however, is a departure from traditional treatments.

A number of the taxa here considered as families are assigned merely to generic status by some taxonomists. In treatments by other taxonomists, all or some of the families included here in the order Saxifragales are put into different orders along with another variety of families. Such dispositions reflect valuation and weighting by different taxonomists and are not to be considered "wrong" on this basis alone; rather, they are legitimate expressions of personal predilections.

Alternate systems of classification. In older taxonomic systems, the family Saxifragaceae is placed in the order Rosales along with other families traditionally placed there, such as Hamamelidaceae, Rosaceae, Platanaceae, Crassulaceae, Cunoniaceae, and others. More recent authorities have placed the plant groups included in the traditional Saxifragaceae in different categories and have given different taxonomic importance to the categories themselves.

In one recent system of classification the order Saxifragaceae (treated as a family in the order Rosales) is placed in two different orders: Saxifragales, consisting of the families Crassulaceae, Cephalotaceae, Saxifragaceae, Eremosynaceae, Vahliaceae, Francoaceae, Donatiaceae, Parnassiaceae, and Adoxaceae; and Cunoniales, containing the families Pterostemonaceae, Cunoniaceae, Philadelphaceae, Hydrangeaceae, Grossulariaceae, Oliniaceae, Greyiaceae, Escalloniaceae, Baueraceae, and Crypteroniaceae. In another recently proposed system, the saxifragaceous groups of traditional classification systems are all included in the order Rosales under four families: Hydrangeaceae, Grossulariaceae, Cunoniaceae, and Saxifragaceae. Woody taxa are concentrated in the first three families, the majority falling into Grossulariaceae. The order Rosales in that system contains 17 families and nearly 20,000 species.

Thus, among the several recently proposed systems of classification, there is considerable diversity of opinion as to the taxonomic values and the composition of the groups comprising the Saxifragales.

All of the recombinations, re-evaluations, and reinterpretations appear to be based on little more than a reworking and re-sorting of presently available evidence. Such activities are not productive; a better approach would be taxonomies based on new evidence, thus reducing or even eliminating conjectural aspects. New data can come from intensive studies in plant anatomy, from comparative plant chemistry and cytotoxic studies, intensified paleobotanical investigations, and other nontraditional means.

(W.L.St.)

Rosales (rose order)

In comparison with other orders of flowering plants, the rose order (Rosales) is not particularly large in terms of either the number of families it includes (three) or in the number of its species (about 3,200). It is, however, one of the most frequently encountered flowering plant groups in the temperate zones of the world, especially in cultivation. Some of the most important food plants occur in the or-

der, and numerous ornamentals are of this alliance, among them roses (*Rosa*), flowering cherries (*Prunus*), mountain ash (*Sorbus*), spirea (*Spiraea*), firethorn (*Pyracantha*), hawthorn (*Crataegus*), and various species of cinquefoil (*Potentilla*). Members of the order are most characteristic of the upper latitudes or higher altitudes, being common in the temperate zones of both the New and Old World, but there are also important tropical species.

GENERAL FEATURES

Woody
nature of
the order

Structural diversity, distribution, and abundance. The order is extremely diverse, ranging from small herbs (strawberry and cinquefoil) to shrubs and woody climbers (roses and spirea) to small trees (mountain ash) and giant tropical trees (*Parinari*, *Licania*). There are many more woody or partly woody species than there are herbaceous kinds. Tropical lowland representatives in the New World are mostly woody shrubs to quite large trees, some more than 100 feet (30 metres) tall, with extremely hard, often useful wood. These woody kinds are especially characteristic of the family Chrysobalanaceae.

Members of the rose order have a natural distribution over much of the world, but the group is especially abundantly represented in eastern Asia (Japan and China), North America (north temperate areas), and Europe. The largest genera are *Rubus* (blackberries and raspberries), with several hundred species; *Crataegus* (hawthorns), with a like number of species; *Potentilla* (cinquefoils), with 300 species; and *Rosa* itself, with about 150 natural kinds. The precise size of these genera is very difficult to state, especially in the blackberry and hawthorn groups. In these, there have been widespread hybridization and recombination of species formerly isolated from each other ecologically. With the destruction of forests and other barriers to interbreeding, two or more species have often come together, bred with one another, and the hybrids have backcrossed with the parents. The consequence is that estimates, for example, of blackberry-raspberry species range from 25 to 1,000 or more different kinds, depending upon the taxonomic recognition given to the many forms. If each variant is considered a species or a subspecific unit of some rank, the number of kinds becomes almost infinite, and such a classification system serves no useful purpose.

Economic importance. Numerous economically important food plants belong to the rose order, including apples (*Malus*), pears (*Pyrus*), peaches, apricots, and plums (all three, *Prunus*). That is, most of the more important fruits produced in the temperate areas belong to this one order and to one of the families, the rose family (Rosaceae). Apple culture, based on crosses and selection from the common crab apples, is the economic base for several parts of the United States, including the northwestern states and New York, Michigan, and Virginia. In the southern U.S., strawberries (*Fragaria*) and peaches replace apples as the major fruit crops of the rose order.

Besides the many food plants of the order, there are also large numbers of ornamentals in temperate gardens. Of these, none is more widespread, appreciated, or diverse in form than the cultivated roses. There are numerous wild species, but, except when planted for livestock enclosures, they are seldom used. The hundreds of cultivated varieties, however—climbers and bushes, dwarfs and standards, singles and doubles, and those with petals of every hue—grace the gardens of cottage and castle, ghetto and suburb. The damask rose is widely grown in Bulgaria for the valued perfume, called attar of rose, and rose water, which are distilled from the fresh flowers. An uncommon but historically interesting economic use was recognized and began to be exploited during World War II, when the fruits of wild rose species were gathered for their very high vitamin C content. The practice has continued among present-day advocates of herbs and health foods.

Many members of the Rosales order have less well known values. Ninebark (*Physocarpus*) is a shrub that in dense stands helps to prevent soil erosion and provides shelter for birds. Mountain ash trees (*Sorbus*) produce orange fruits that feed many birds and can even be used for jelly making. Shadbush (*Amelanchier*) bears fruits used by birds, and its leaves, bark, and young twigs feed deer and

rabbits. Hawthorns (*Crataegus*) provide excellent cover for wild animals, and the fruits make up a substantial part of the diet of some birds. The wood of the black cherry (*Prunus*) is important in cabinetmaking. The heavy, hard, close-grained wood of the hawthorn makes excellent tool handles, canes, and charcoal.

Contributions of the order for medicinal purposes are numerous, especially among the herbaceous species. Agrimony (*Agrimonia*), for example, was looked upon in past ages as a general cure-all for any sort of wound, for snakebites, and even for removing warts. It has also been used commonly as a substitute for or as an additive to tea, and the entire plant yields a pale- to intense-yellow dye, depending on the season it is collected. It is still believed to be useful in the treatment of diarrhea and liver ailments and as a gargle. The active principle is a tannin.

The petals of certain rose species are strongly odorous by virtue of a volatile oil they produce. This property gives rose petals value as flavouring for cough syrups and candies. Dried rose petals are often kept in potpourri jars or among clothing items, where their fragrance is slowly released. Fresh rose petals impressed in the surface of butter contained in a tightly covered container overnight in a cool place impart a delicate rose odour and taste to the butter. This, spread on small thin shapes of bread and garnished with a fresh rose petal, makes rose-petal sandwiches, often served with tea.

The leaves of hawthorn have been used as an adulterant of tea. Its flowers and fruits have astringent properties, which form the basis of their medicinal use as a cardiac tonic and as a diuretic for some kidney ailments. The fruits added to brandy produce a highly regarded liqueur.

In addition to the temperate-zone fruits of the rose family, there are also a few now widely cultivated species from the tropics and subtropics. The loquat (*Eriobotrya*) originally came from China, but it grows easily in warm places from southern Florida south. The coco plum (*Chrysobalanus*), a native fruit in the tropics and subtropics, grows along sandy shores from Florida through the West Indies, south to Brazil. The sweet, dry, but rather tasteless fruits are borne on small shrubs or low trees of the strand and riverbanks. In Mexico, the bark, leaves, and roots are used medicinally as an astringent; the leaves and fruits are the source of a black dye; and the oily pits are used for food, or they are strung on sticks to serve as candles. Oiticica oil is a product expressed from fruits of one of the species of the family Chrysobalanaceae that grows in northeastern Brazil, where it has long been used medicinally and for illumination. Large quantities of the oil are imported by the United States for use in place of tung oil in paints, in making printing inks, and in making linoleum.

NATURAL HISTORY

Life cycle—reproductive features. The evolutionary success of the rose order rests on a variety of adaptive advances over its progenitors. The embryo, for example, uniformly fills the seed and is not dependent on an enveloping endosperm (nutrient tissues in the seed), as are the embryos of some less advanced families.

The wide range of fruit types in the order also is thought to have had a high selective advantage in its evolution, because a variety of different forms would increase the chances of successful dispersal and establishment. In addition to the familiar edible types of fruits (e.g., apples and pears, cherries and plums, and strawberries), many species groups produce fruits with hooks and barbs that ensure their transport on animal's hair or on man's clothing from place to place.

More important than the foregoing, however, is the frequency of a form of asexual reproduction known as apomixis, a term often used loosely to include all forms of nonsexual reproduction. Some species in the order may reproduce exclusively by such nonsexual methods as runners (strawberries) or horizontal leafless stem structures called rhizomes (raspberries) and still retain their capacity, entirely or in part, to reproduce sexually by seed. Other species have lost all capacity for sexual reproduction. Obviously, apomictic reproduction confers considerable evolutionary advantage, for a species may achieve extensive

Medicinal
uses

Asexual
reproduction

distribution even in the absence of its principal pollinators or under conditions unfavourable to seed development and germination.

On the other hand, apomixis often produces such a multitude of forms that classification is more a matter of arbitrariness than a scientific attempt to express evolutionary relationships. In the rose and the apple subfamilies (Rosoideae and Maloideae), much of the taxonomic confusion, such as that concerning the genera *Rubus* and *Crataegus*, is the result of hybridization, polyploidy (having multiples of the basic number of chromosomes), and apomixis. Two sexual species, each of which may have a multiple set of the normal chromosome complement, can hybridize but produce largely sterile offspring. The latter, however, can become well established in nature, with well-developed geographic distributions, by either total or partial apomixis. At the same time, a doubling of the chromosome complement (polyploidy) may reestablish partial or full fertility. All these routes to survival of new forms appear to have operated during the evolutionary history of the rose order. Grafting and budding are man-made asexual means employed for the perpetuation of desirable varieties of apples, pears, peaches, and other related fruits.

Although knowledge of the cytology (the study of cells, especially of chromosomes) of the order is incomplete, much has been recorded about chromosome numbers in the family Rosaceae. The spirea subfamily (Spiraeoideae) has a basic chromosome number of 8 or 9, and it may be interpreted as more stable evolutionarily than some of the other subfamilies. The rose subfamily (Rosoideae), which includes the highly variable raspberry genus (*Rubus*), has at least three basic chromosome numbers, 7, 8, or 9. The apple subfamily (Maloideae), including the taxonomically confusing hawthorns (*Crataegus*), has a basic number of 17, and the plum group (subfamily Prunoideae) has 8 as its base number of chromosomes. The 17 chromosome pairs that are the basic number in the apple group have been explained by some researchers as being the result of hybridization and subsequent polyploidy between ancestral species of the spirea group (with its nine pairs of chromosomes) and the plum group (with its eight pairs).

Ecology. The ecological preferences of the Rosales order are diverse and wide-ranging. Altitudinally, species of herbs, shrubs, or small trees extend from sea level to Alpine meadows beyond the tree line. Many species are weedy,

occurring in association with man's activities, and some are clear indicators of soil sterility. Fruit-eating birds drop seeds or other propagula (*e.g.*, whole fruits or plant pieces that can grow to establish new plants) along fencerows or in hedgerows, so blackberries, hawthorns, and wild cherries are commonly found in such places. Members of the order are found in deserts, in the tropical rain forest, and in every intermediate situation.

Not infrequently the distribution of a species is determined by the chemical nature of the soil, for many species are able to succeed only on soils derived from limestone. The cultivated fruits of the order, for the most part, prefer well-drained situations, and, for that reason, much of the commercial production is in hilly or rolling countryside. Soil type is less important, for these fruit trees thrive on even heavy clay soils, but they must be well aerated and freely draining.

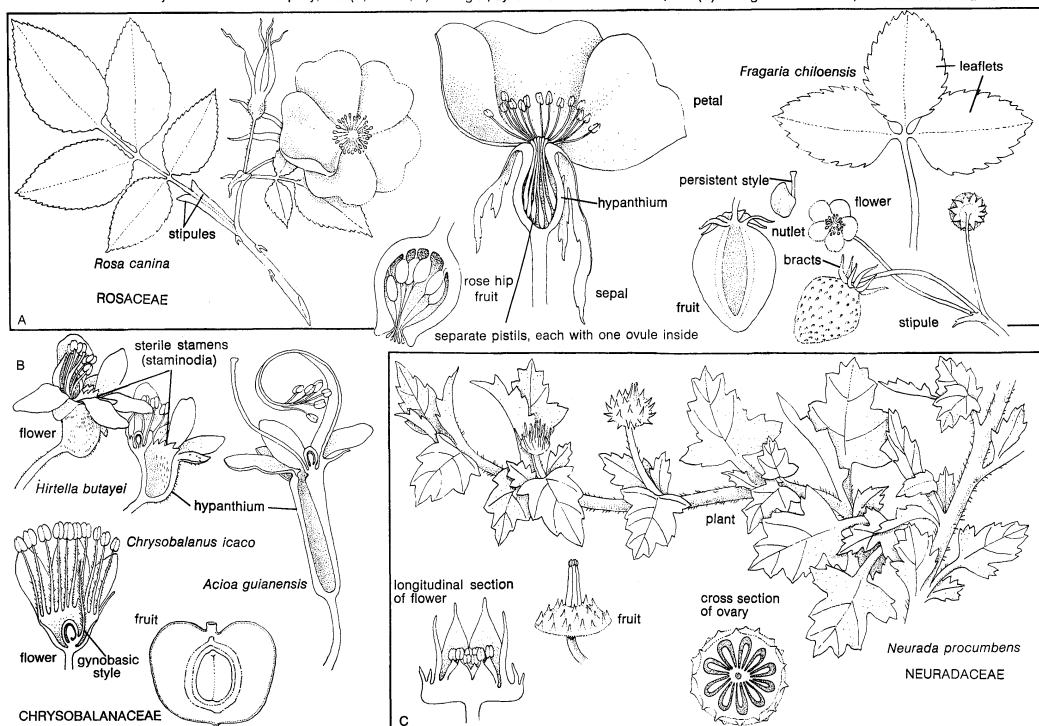

FORM AND FUNCTION

Vegetative characteristics. In habit the species of Rosales are about as diversified as possible, with every life form from small creeping herbs to giant hardwood trees. Many of the included groups have thorns and prickles, but this is scarcely a universal or even distinguishing characteristic. Much more typical is the alternating position of the leaves on the stems; only rarely do they occur opposite each other. The leaves are often compound (*i.e.*, with several leaflets to a common leafstalk), as in roses, strawberries, and cinquefoils, but the pome-fruited members such as apples and peaches have simple leaves. Stipules, small leaflike appendages at the base of the petiole (leafstalk), also are characteristic of the order. They sometimes fall very soon after expansion, or they are not obvious because they are often joined with the petiole, as in the roses.

Hairlets on various parts of the plants are usually one-celled and either glandular or, more commonly, not. The leaves sometimes bear nectaries (nectar-producing glands) on the petiole, on the blade surface, or on each tooth along the leaf margin. Crystals of calcium oxalate are found in the leaves of many species, either solitary or in clusters. The wood in species of the Northern Hemisphere has small, numerous vessels (water-conducting cells) that often have spirally thickened walls, simple perforations (*i.e.*, open-end walls joining the cells into tubes), and wood fibres that have many bordered pits (tiny openings

Vegetative and floral features of the three families in the order Rosales.

along the sides of the cells; the "borders" are structural complexities that distinguish this type of pit from "simple pits" found in many other plant groups).

On the basis of anatomy, only the plumlike species can be separated from the other groups of the rose family. The family Chrysobalanaceae, however, is quite distinct anatomically in numerous respects. The stomates (small pores in leaf surfaces) are of a type distinct from the rest of the order, and the leaf hairs are arachnoid (cobwebby) or even stellate (with radiating branches, starlike) or peltate (with a shield-shaped structure at the apex). Glands are often present at the base of the leaf in many species, and silica bodies (deposits of the glassy mineral silica) are found in leaf or young stem cells of many species. Wood vessels are large and occur as solitary elements lacking the spiral thickenings of the vessels in the rose family.

Reproductive
structures

Flower and fruit characteristics. Flowers of the rose order are almost always bisexual—that is, with stamens (male reproductive structures) and pistil (the female reproductive structure) in each flower. When this is not true, the male flowers occur on one plant and the female ones on another individual of that species (the dioecious condition). The flowers are regular (*i.e.*, radially symmetrical) in most genera, but several of the Chrysobalanaceae have irregular (bilaterally symmetrical) flower structure, either in the perianth (the collection of both sepals and petals) or in the reproductive parts. The flowers are borne singly or in a wide variety of inflorescence (flower-cluster) types, which are either determinate or indeterminate. Determinate inflorescences mature from the top downward; that is, the central or terminal flower blooms first, and, since this is located at the growing tip of the inflorescence, no further buds are produced. Indeterminate inflorescences mature from the bottom upward, and new buds are continually produced at the growing tip of the inflorescence.

Sepals and petals usually are present, but, in some species, one or both series are lacking. The perianth parts are usually joined with each other, in part, to form a cupular to elongate tubular structure called a floral cup or hypanthium, the wall of which may also involve the bases of adnate (fused, joined) stamen filaments. At the bottom of the cup there is often a ring of secretory or glandular tissue that produces nectar.

The stamens are commonly numerous, occurring in one to several whorls of five stamens each and arising from the inner surface or rim of the hypanthium. The filaments are free from each other except in several genera of the family Chrysobalanaceae, in which they are joined basally to varying degrees. In one genus the filaments are joined completely in a ribbonlike structure on one side of the flower.

The gynoecium (female structural complex—the pistil or collection of pistils) in this order is usually superior; that is, the sepals, petals, and stamens are attached below the base of the ovary. The large group of stone- or pome-fruited genera (apples, plums, pears), however, have a distinctly inferior ovary with the perianth and stamens arising above the compound, 2- to 5-parted gynoecium. The remainder of the genera have 2 to 10 carpels (structures comprising the ovary) in each superior gynoecium. The style, or styles when multiple, is terminal on the ovary or arises from its base. The erect or pendulous ovules (seed precursors) number 1 or more per carpel.

Fruits of the rose order are small and dry achenes (dry one-seeded structures that do not split open along definite lines) as in the strawberry and cinquefoil, follicles (dry structures that split open along one definite suture) as in spirea, pomes (fleshy fruits with cores) as in the apple and quince, drupes (fruits with stony pits) as in the plum and peach, or an aggregation of drupelets as in the blackberry and raspberry. The seeds have small embryos, and endosperm is usually lacking.

Biochemical features. Although concerted biochemical studies of the Rosales have not been undertaken, there are numerous data, some of which have special interest for taxonomists. A few examples may be instructive, but generalities at the level of the order are virtually impossible at present.

Certain amino acids occur with such widespread fre-

quency in stem tips as to be of little systematic (*i.e.*, relating to the classification of species) value. On the other hand, one of these (arginine) is the amino acid commonly present in the family Rosaceae. Elsewhere it makes only sporadic appearance. Similarly, certain fatty acids such as licanic acid are characteristic of some members of the family Chrysobalanaceae.

While relatively few sugar alcohols are found naturally, some are distinctive of major flowering-plant groups. Thus, sorbitol is infrequent generally but common among members of the rose family as a precursor of starch. It has been reported that leaves of certain Rosaceae, kept in the dark for a period to eliminate stored starch, will manufacture starch in the leaves when they are floated on a sorbitol solution.

Members of another class of compounds yield cyanide plus a simple sugar when they are broken down by enzyme action. These cyanogenetic materials are probably of systematic importance by virtue of their distribution, but the supporting data are incomplete. It is interesting to note, however, that these compounds are apparently almost totally restricted to the advanced vascular plants. Of those with cyanide-generating capabilities, the family Rosaceae has more species (150) than any other family. There may also be plant populations that produce cyanide within species that are otherwise not cyanogenetic. Still more significant is the distribution of this characteristic within the rose family: cyanogenesis is common among the pome-fruited species and the plum subfamily but is much less frequent in the rose and spirea subfamilies.

Cyanide
formation

Numerous groups of species of the rose family are dangerous because of the cyanide compounds contained in various parts of the plant. Mountain mahogany (species of *Cercocarpus*), evergreen, small-leaved shrubs of arid areas in the western United States, is browsed by animals, often with impunity, but at some sites the concentration of cyanide is high enough to be fatal to livestock. Similarly, but much more dangerous to livestock and to humans, several kinds of wild cherry, peach pits, and bitter almonds are poisonous. Ordinarily, grazing animals avoid such poisonous foliage as that of chokecherry (*Prunus virginiana*) and wild black cherry (*Prunus serotina*), but, either by accident or by elimination of other more desirable browse, animals are sometimes lost to cyanide poisoning from these plants. The cyanide is higher in wilted leaves and branch tips than it is in mature or dried leaves.

Some phenolic compounds also are distinctive of the family Rosaceae or of some of its subgroups. Isoflavones, for example, have been found only in the families Rosaceae and Leguminosae (also called Fabaceae, order Fabales), which is not surprising to phylogeneticists who consider the two families to be closely related.

EVOLUTION

Fossil record. As with most flowering-plant groups, fossil remains become increasingly common in the Tertiary Period (beginning about 65,000,000 years ago). Fossils are frequent in both European and North American formations of Eocene to Pleistocene age (*i.e.*, from about 54,000,000 to within the last 2,000,000 years). It is significant to note that fossilized parts have been found of plants readily assignable to all the subfamilies of the rose family and of the largely tropical family Chrysobalanaceae as well.

The genus *Spiraea* is known from fossils of its fruits, and there are leaf remains probably assignable to this group also. Ninebark (*Physocarpus*), a genus of modern-day shrubs, is represented in fossils of the mid-Tertiary. In the pome-fruited subfamily (Maloideae), seed remnants have been recognized of the hawthorn (*Crataegus*) and pear (*Pyrus*) genera. Leaf fossils are described for the quince (*Cydonia*), serviceberry (*Amelanchier*), and hawthorn. In the rose subfamily (Rosoideae), fruits of cinquefoil (*Potentilla*) and raspberry (*Rubus*) are known from the Pliocene Epoch (2,500,000 to 7,000,000 years ago) and Oligocene Epoch (26,000,000 to 38,000,000 years ago) of western Europe. The stone-fruited subfamily (Prunoideae) is represented by fossil fruits of both plum and peach (*Prunus*) in the Pliocene of Germany and France. The family

Chrysobalanaceae is represented by leaf fossils in the late Eocene flora of west central Oregon. This group, now largely tropical, was a part of a flowering-plant assemblage that unquestionably flourished in a tropical environment there, about 50,000,000 years ago.

Phylogeny. The fossil record characteristically is not very helpful either for relating the family to other families or the order to other orders. The speculations that follow are based more on comparative morphology and anatomy than they are on fossil evidence.

The order Rosales is considered to be one of the more primitive orders, derived from the Magnoliales through the modifications of one intermediate order, the Dilleniales. The genus *Spiraea* has sufficient similarities to the latter order and to the Saxifragales to indicate common ancestry. Likewise, the family Chrysobalanaceae is seen by many as the connecting link between the Rosales and the Fabales.

Within the order, the most primitive family is often considered to be the Chrysobalanaceae, with its superior ovary composed of a single carpel and the style arising from the ovary base. The family Rosaceae is probably even more basic, ranging as it does from having quite simple floral structures to very complex, from woody to herbaceous life forms, and with so many fruit types that give the family as a whole great selective advantage potentially over groups with less adaptive flexibility. The rose family consists of at least four subfamilies, which differ principally in the characters of their fruits. The family Neuradaceae probably is most nearly related to the rose family through the rose subfamily, but it is quite distinct in the wall structure of its pollen grains, as well as in the structure of its flower and fruit.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The features that distinguish the Rosales from related orders are several. Vegetatively, many species have compound or divided leaves that commonly are stipulate. The flower parts are usually in fives, arranged in concentric circles. Although the relationship among the floral organs varies from hypogyny (superior ovary) to epigyny (inferior ovary), the most characteristic condition is perigyny (half-inferior ovary), the sepals, petals, and stamens arising from the rim of a cupular to tubular hypanthium. The stamens are usually in many whorls, and the gynoecium consists of free to united pistils.

Alternate systems of classification. The classification presented in this article is a recent one that is relatively conservative in approach. Only 3 families are included, in contrast to as many as 17 families in older treatments. Likewise, the family Rosaceae has been divided by some authors into 6 separate families, which are treated in the classification above as 4 subfamilies. Although it represents perhaps the narrowest view taxonomically of what the order includes, it is thought to be more natural evolutionarily than more inclusive treatments.

The difficulty in extending the ordinal concept beyond these 3 families is that distinctiveness of the order is lost as family after family is added. This treatment is based on what appears to be a logical point of separation from related families. Some recent plant taxonomists include up to 19 families, some of which are subdivided by other workers into still other families. Solution of this situation may not be possible in a manner satisfactory to even the majority of botanists. Much of the present lack of agreement is based on the interpretation of abundant data of many kinds. Biochemical, paleobotanical, and anatomical researches perhaps hold greatest promise for further refinement of the order. (R.S.C.)

Fabales

Fabales is one of the three largest orders of flowering plants and is second only to the grass order (Poales) in economic importance. It includes a number of such familiar food products as beans, peanuts, and peas, as well as important sources of grazing food for animals, of which alfalfa and clover are the best known. In addition, most of the species are important elements of the natural ecosystem, in that they have the capacity, in conjunction with appropriate

Representative fruits of the order Fabales.

The characteristic fruit type, known as a legume, is the single character by which the order is best known and is the basis of the classical name of the order (Leguminales), still used by many authorities.

Drawing by M. Pahl based on (all except *Entada spicata*, *Millettia dielsiana*, *Erythrina rubrinervia*) J. Hutchinson, *Evolution and Phylogeny of Flowering Plants*

microorganisms, to convert biologically inert atmospheric nitrogen into nitrates, in which form it is readily metabolized by plants. While a few other plant orders possess species with this capacity, the Fabales order is responsible for the great mass of such biological recycling. Because of this factor, together with the high nutritive value of its grazing plants, the species are commonly employed in crop rotation practices.

Estimates suggest that the order is composed of approximately 20,000 species distributed among 800 or so genera. Except for the family Krameriaceae, which has been removed from the order by most recent workers, the group is exceedingly natural—i.e., all of its families are closely related. Thus, nearly all treatments have recognized the order Fabales as being divisible into three families (or sometimes subfamilies), Caesalpinaceae, Mimosaceae, and Fabaceae, and none has suggested that these families might be related to other groups more closely than they are to each other.

GENERAL FEATURES

The order, while worldwide in distribution, shows the greatest diversity of morphological types in the tropical and subtropical regions of the world. This is particularly true for the predominantly woody families, Caesalpinaceae and Mimosaceae. The former comprise the dominant tree

members of the savanna lands of tropical Africa, South America, and Asia; the latter family is especially abundant as small trees and shrubs in the drier subtropical regions of Africa, America, and Australia.

Crop
plants

Economic importance. In the more temperate regions of the world, the order is predominantly herbaceous, and most of the species belong to the large family Fabaceae. This family also contains the more important crop plants such as peanuts or groundnuts (*Arachis hypogaea*), chick-pea (*Cicer arietinum*), soybean (*Glycine max*), common lentil (*Lens esculenta*), alfalfa or lucerne (*Medicago sativa*), sweet clover (*Melilotus* species), mung bean (*Phaseolus aureus*), kidney beans (*Phaseolus vulgaris*), peas (*Pisum sativum*), clovers (*Trifolium* species), vetches (*Vicia* species), and cowpeas (*Vigna* species).

The families Caesalpiniaceae and Mimosaceae do not contain many food crops and are perhaps best known for their shade and ornamental species, such as the Judas tree or redbud (*Cercis* species), orchid tree (*Bauhinia divaricata*), and huisache (*Acacia farnesiana*), although some of the more rapid growing weedy species, for example, the white popinac (*Leucaena glauca*) and *Albizia* species, are widely used as green manure and fodder crops. *Acacia* species are widely used in the production of gum exudates and wood, especially in South Africa and Australia, where the species are known as wattle trees.

Diversity of structure. The order Fabales is a predominantly woody group, and most authorities believe that the more advanced herbaceous plant groups, characteristic of the temperate regions, evolved from such tropical, woody ancestors. Species of the order are abundant on all continents (except Antarctica), occurring as trees, shrubs, vines, delicate annuals, and sometimes, though rarely, as floating aquatic. An example of such an aquatic is *Neptunia oleracea*, a member of the family Mimosaceae, which is often tied to shallow lake bottoms in India so that it might be readily obtained for use as an edible vegetable. Bizarre species are especially abundant in the semidesert and savanna regions of western Australia; most of them belong to the tribe Podalyrieae of the family Fabaceae, and such oddities are presumably a reflection of the long isolation of that continent's flora from Asia.

Distinctive
character
of the fruit

The order Fabales is probably best known by its fruit. In fact, it is often referred to as the Leguminales order, because its fruit, a legume (often highly modified), is the most obvious single character by which the group is recognized. Technically speaking, a legume is typically a one-celled (chambered), two-valved seed pod with marginal placentation (ovule attachment), such as occurs in the common pea (*Pisum sativum*). The legume assumes a variety of forms, however, such as samaras, which are single-seeded, winged, indehiscent (not splitting open along definite seams) pods and loments (many-seeded, indehiscent pods, constricted between the seeds, which at maturity break off as separate reproductive units), and others. One of the more unusual legumes is that of the peanut (*Arachis hypogaea*), a fruit that matures underground. The peanut flower itself is produced above ground but as it ages it assumes a position close to the soil surface so the ovary can elongate and develop as a subterranean pod.

Seeds borne within the various legume types are also extremely variable, ranging from the size of a pinhead (in *Lotus* species) to that of a baseball (in *Mora excelsa*). Legume seeds are sometimes quite colourful; the *Abrus precatorius* and *Ormosia* species, for example, produce striking black and red seeds. These seeds have been used as currency by primitive people, and because of their usually hard seed coats they are commonly used in the production of beads and handbags, which are sold as tourist merchandise, especially in the more tropical regions. They may be quite poisonous if eaten, however, and for this reason such merchandise is often refused entry by government inspectors.

NATURAL HISTORY

The worldwide distribution and large size of the order is undoubtedly a reflection of its early dispersion throughout the tropics and later adaptation to the numerous adjacent, more temperate, habitats. Effective dispersal of the seeds

is assured by the large variety of seed pods found in the order and by the largely self-pollinated flowers found in the more advanced tribes of the family Fabaceae. Seed coats are generally quite hard and impermeable to water, which permits the seed to endure long storage periods in nature. In fact, seeds of this order from the genus *Cassia* have been known to germinate after having been in dry storage at ordinary room temperatures for 200 years. Upon fracture of the seed coats, however, germination is readily effected, for dormancy periods, often necessary for seed germination in other plants, are generally not found in legumes. Other reproductive specializations include cross-pollination, cleistogamy (self-pollination resulting from floral modifications that prevent the entry of other pollen—such as non-opening flowers), and vegetative (asexual) reproduction.

An interesting adaptation in a few tropical and subtropical species belonging to the families Mimosaceae and Caesalpiniaceae is that of myrmecophilism, in which vegetative specializations have been developed to accommodate ants. Special secretory glands on the leaves that ants use for feeding purposes and unusually large thorns on the stem in which they live are two such features.

The adaptive significance of such mutualism is debatable, but many authorities believe that in living off the excretory products of the plant, the ants readily provide protective measures to the plant by warding off potential leaf eaters such as grasshoppers, aphids, and perhaps even some of the larger browsing animals.

Pollen dispersal in outbreeders is largely provided by insects, especially bees, which have relatively heavy abdomens and easily cause pollination through landings made on the keel of the flower, a special structure found in the Fabaceae that encloses most of the reproductive organs. Other pollinators exist, however, and in at least one genus of the family Mimosaceae (*Parkia*), tropical fruit bats are the principal means assuring pollination.

FORM AND FUNCTION

Vegetative characteristics. The three families that make up the order Fabales are readily distinguished by their veg-

Floral and vegetative structures representing plants from the three families of the order Fabales.

Seed
dispersal

etative features. The family Mimosaceae possesses mostly twice-compound leaves, which have several leaflets arranged along either side of a central axis, the leaflets themselves being subdivided into a number of smaller units in a similar arrangement. The family Caesalpiniaceae has mostly once- or, less often, twice-compound leaves, and the family Fabaceae has once-compound leaves, these often reduced to a trifoliate (three leaflets) condition, as in the common clover, or modified with twining tendrils as in the sweet pea.

leaves
sensitive
to touch

Certain members of the order are especially interesting in that their leaves are sensitive to touch, temperature, and light changes. The tropical "sensitive plant" (*Mimosa pudica*) is widely grown in greenhouses for this effect. Touching the plant results in very rapid movements of the entire leaf or its component parts. Similar movements, but not so pronounced, occur in many other species of the order, particularly in the family Mimosaceae. For example, the so-called "mimosa" tree (*Albizia julibrissin*) folds its leaflets together at dusk, decreasing at least by half the amount of leaf surface exposed to the atmosphere. The adaptive significance of such movements is unknown, but the movement itself is caused by water pressure changes in specialized structures at the base of both the leafstalks (petioles) and leaflets.

Flower and fruit characteristics. The single floral feature most characteristic of the entire order is the presence of an hypanthium, a structure formed by the fusion at the base of sepals, petals, and stamens (male reproductive structures) to form a cup (often very small) about the base of the ovary. With the exception of this characteristic, the floral types are quite variable, with flowers ranging from regular (*i.e.*, actinomorphic, radially symmetrical) in the family Mimosaceae to highly irregular (*i.e.*, zygomorphic, bilaterally symmetrical) in the family Fabaceae. Flowers of the family Caesalpiniaceae are somewhat intermediate between these extremes, as regards symmetry.

Especially noteworthy are the floral modifications found in the family Fabaceae. The petals, which are uniformly five in nearly all of the 15,000 or more species, are characteristically modified into a so-called papilionaceous (butterfly-like) flower in which the uppermost petal (the banner) is usually quite enlarged and colourful, the two lateral petals are winglike structures (and are termed wings), and the two basal petals characteristically are united near their middle to form a boat-shaped structure called the keel.

arrange-
ment of
stamens

The stamens, usually 10 in number, are also highly modified in this family. They are joined into a single tubular structure (the stamens then being termed "monadelphous"), or more often into a set of nine united stamens that reside in the keel, plus a separate stamen that stands above the nine and just below the banner itself. The latter state is termed "diadelphous." At least two of the more primitive tribes (Sophoreae and Podalyrieae) of the family Fabaceae, however, possess free stamens and separate keel petals, as do many species belonging to the family Caesalpiniaceae.

Pollen grains in the order are quite distinctive and have proven of value in defining many of the tribal groupings in the several families. The fruiting structures within the order, while uniformly derived from a single carpel (or simple ovary), are variable in size, shape, and texture, ranging from the herbaceous coiled, hispid (rough or bristly) fruits, characteristic of bur clover (*Medicago hispida*), to the 2- to 3-foot- (60- to 90-centimetre-) long, woody pods of the genera *Cassia* and *Caesalpinia*.

Physiological features. Species belonging to the order Fabales are perhaps best known agronomically for their capacity to "fix" atmospheric nitrogen—*i.e.*, to convert it into a form that plants can utilize, usually the nitrate form. This is accomplished by symbiotic fixation, in which root nodules (swellings) are formed on the plant in reaction to infections by soil bacteria belonging to the genus *Rhizobium*. Root nodulation, while occurring in all three families, presumably does not occur in all species, the phenomenon being more common in the family Fabaceae and relatively less so in the families Mimosaceae and Caesalpiniaceae.

Biochemical features. The Fabales order is noteworthy for the large range and variety of secondary compounds found in its members' leaves and fruiting parts, such as flavonoids, alkaloids, terpenoids, non-protein amino acids, and others. Some of these, for example the amino acid canavanine, may comprise up to 5 percent of the dry weight of seeds. The interesting chemical compound rotenone, which is toxic to a number of organisms, is sufficiently abundant in the roots and stems of certain species belonging to the family Fabaceae that primitive peoples commonly used these plants to poison fish. More recently it has been shown that serious bone and neural diseases afflicting both man (*e.g.*, lathyrism) and livestock may be caused by the ingestion of unusually large amounts of certain free amino acids. In sheep, ingestion of large quantities of the amino acid mimosine, found in *Leucaena glauca* and some other species of the Mimosaceae family, apparently causes the cessation of the growth of hair or wool, and in certain cases the fleece itself has been observed to shed. A wide variety of alkaloids are found in the order, most of them restricted to the family Fabaceae, however. Some alkaloids are found in sufficient concentration in range plants to be quite poisonous to livestock, especially in species belonging to the large genus *Astragalus*. Species of *Astragalus* are commonly referred to as "locoweeds" by cattlemen in North America because, following excessive consumption of these plants, cattle seem to become unmanageable and "go crazy" or "loco."

Poisonous
plants

In spite of the toxic nature of many of the species, most of the plants are highly palatable and are especially nutritious because of the high concentration of vitamins and proteins in their young growing parts (*e.g.*, in alfalfa) and in the storage components in seeds (*e.g.*, beans and peas). The American Indians very early appreciated this and, along with corn, adopted the common bean (*Phaseolus* species) as one of their staple foods.

Except for the soybean and peanut, species of the order are not noted for the oil content of their seeds; most seeds contain only about 10 percent oil content by weight. Indeed, the fat content of many of the legumes used for food by humans is only between 1 and 2 percent. In general, legume seeds are usually highest in nutritive content in carbohydrates, followed by protein and fat.

An interesting biochemical component of the legume seed is phytohemagglutinin, a large protein molecule that is specific in its capacity to agglutinate certain human blood types. Approximately 60 percent of the several thousand seeds belonging to this order tested to date contain the compound.

Phytohemagglutinin is particularly abundant in the common bean and has been extracted in a relatively pure state on a commercial scale from species belonging to this genus. In addition to its agglutination properties, the compound has been of interest because of its other biological effects. It is toxic to rats, it inactivates some human tumor cells, and it has beneficial effects on aplastic anemia, the shortage of blood cells in man because of destruction of blood-forming tissues.

Chromosomal features. Chromosomal data have been assembled for a wide range of species in the order, including representatives from all three families and most of the tribes and subtribes. The chromosomes for any given genus are usually quite uniform, in both number and morphology (form); most of the genera possess a single base number. The incidence of polyploidy (multiples of the basic chromosome number), as contrasted with most plant families, is also relatively low. The family Mimosaceae, in general, has small chromosomes (1 to 3 microns, or about 1/25,000 to 3/25,000 inch in length), and most of the species possess haploid (*i.e.*, the base number, one-half the normal number of chromosomes in a typical body cell) numbers of 13 or 14. The family Caesalpiniaceae is quite variable as to chromosome size and structure, possessing genera with base numbers of 7 through 12—with the exception of 9; species with this haploid number are strangely absent. The Fabaceae is the most variable family, chromosomally. Woody tropical groups usually have relatively small chromosomes with haploid numbers of 10 and 11; the more temperate, herbaceous derivatives

Chromo-
some
size and
number

(for example, the genera *Vicia*, *Lathyrus*, and *Lotus*) have mostly larger chromosomes at lower haploid levels such as 6, 7, or 8. Although this purview is based upon only about 20 percent of the species in the family, surveys among genera are broad enough to suggest that additional sampling will not change the picture much.

EVOLUTION

Fossil record. There are abundant fossils of the Fabales order dating back to the Early Tertiary Period (Eocene Epoch, beginning about 54,000,000 years ago), most of which are similar to present-day woody genera such as *Gleditsia* (Caesalpiniaceae), *Prosopis* (Mimosaceae), and *Robinia* (Fabaceae). Thus, the order was presumably well developed on the several continents even earlier, probably in Cretaceous time (beginning 136,000,000 years ago). By then, the order's three families had already developed in essentially the same form as those represented today by living genera. Fossil materials do not exist that serve to link the order to other orders, consequently most phyletic treatments of the group are based almost entirely on comparative morphological and distributional data among living species.

Phylogeny. Most authorities consider the Fabales order to be related to the order Rosales. The two groups are similar in possessing mostly alternate leaves with stipules, perigynous flowers (*i.e.*, flowers with a partly enclosed ovary), and fruits derived from one or more separate carpels (in the Rosales the latter often fuse at maturity, as in the apple). Nearly all authorities also agree that the order has its origin in the tropical regions from woody ancestors, the herbaceous species being structurally reduced, but more highly evolved types, which arose independently in several phyletic lines, presumably in adapting to the more vigorous climatic conditions that developed in the temperate regions during Tertiary time. Within the order most workers reckon the family Caesalpiniaceae to be an ancestral group that gave rise to the more tropical and subtropical family Mimosaceae, on the one hand, and to the more temperate Fabaceae, on the other. The Mimosaceae and Fabaceae, while quite distinct, are inextricably linked through several genera belonging to the Caesalpiniaceae, such as *Swartzia*, *Amphimas*, and *Mora*.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The Fabales order has been treated classically as consisting of but a single family (traditionally named Leguminosae) of the large order Rosales. As such, the family was subdivided into four subfamilies, Mimosoideae, Caesalpinoideae, Papilionoideae (sometimes called Faboideae), and Kramerioideae. More recently the trend has been to remove the latter subfamily, consisting of but a single genus (*Krameria*), to the order Polygalales; the three remaining subfamilies are then treated at the familial level as members of the order Fabales. So constructed, the order can be distinguished from the closely related order Rosales by its (usually) solitary carpel, compound leaves, often more numerous, united stamens, and above all by its fruit.

Alternate systems of classification. Nearly all plant taxonomists recognize the order as an exceedingly natural one, and most would relate it to the order Rosales. Other orders recognized as being phylogenetically close to the Fabales are the Saxifragales and Cunoniales. Some authorities, however, prefer to treat the three families of Fabales as subfamilies belonging to but a single family within the much larger order Rosales. In such a treatment the Saxifragales and Cunoniales orders are usually accorded familial status. There would be little opposition to the recognition of the Mimosaceae and Fabaceae as distinct families if it were not for the transitional nature of many genera belonging to the Caesalpiniaceae—*i.e.*, they have characteristics similar to both families. Because of the transitional genera, however, some plant taxonomists believe the Caesalpiniaceae to be ancestral to these two groups. Most of the transitional genera, however, seem to link the Caesalpiniaceae to the Fabaceae, with the Mimosaceae standing somewhat more remote. It has been suggested that the Fabaceae, in part, has ancestors in more than one evolutionary line

(*i.e.*, the family is polyphyletic) and that at least some of the tribes have arisen from different phyletic lines within the Caesalpiniaceae.

Clearly there is much need of detailed morphological, cytological, and chemical study of the family Caesalpiniaceae, for it is poorly known and is represented in museums by relatively few collections and is generally neglected by cytologists and plant chemists. With more intensive study, especially in the area of chemosystematics (taxonomy systems based on chemical factors), it is likely that some of the tribes of the Caesalpiniaceae will be elevated to subfamily or family rank. In addition, considerable re-sorting of the genera among tribes of the Fabaceae seems likely, since at least some of them are believed to be classified on one or more technical characters of the fruit, which may or may not group together those genera with a common phyletic origin. (B.L.T.)

Nepenthales

The flowering plant order Nepenthales consists of two families, the Old World pitcher plants, or monkey cups (family Nepenthaceae), and the sundews and Venus's-flytrap (family Droseraceae). All of the approximately 180 species have leaves that are ingeniously adapted as pitfalls and traps to capture insects and other tiny animals, digest them, and absorb the nutrients.

The family Nepenthaceae contains the single but large pitcher-plant genus *Nepenthes*. Its approximately 80 species are found in wet tropical forests from Sri Lanka and Madagascar to New Guinea and northern Australia. All of the species capture insects by means of pitcher-shaped leaves that function as pitfalls. The prey is attracted to the

Classical
treatment
of
taxonomic
position

large showy leaves by nectar, and it slips from a treacherous lip into the pitcher-like hollow leaf, which in reality is a cistern of digestive liquid from which there is no escape.

The family Droseraceae contains species with leaves modified as real traps, active mechanisms that clamp shut or coil about victims lured by nectar secretions and delicate odours. The principal genus is *Drosera* (the sundew), with about 100 species, which together have a distribution in virtually all parts of the world. Three other genera each contain a single species. *Dionaea muscipula*, the Venus's-flytrap, is a narrowly distributed Atlantic North American endemic (a native species restricted to one region). *Drosophyllum lusitanicum* is an unusual sundew narrowly endemic to the Atlantic European area. *Aldrovanda vesiculosa* is a wide-ranging aquatic plant in the Old World.

GENERAL FEATURES

Size range and diversity of structure. The species of *Nepenthes* are quite uniform in general appearance and, by comparison with other known plants, stand clearly by themselves. The sizes and shapes of the pitchers are characteristic for each species, although there may be as many as three distinct pitcher forms in a single species. The pitchers are colourful and are often mistaken for flowers. The plant typically is a coarse vine that grows over vegetation, sometimes climbing to the crowns of 50- to 60-foot (15- to 18-metre) trees.

The Venus's-flytrap has jawlike leaf blades, which dominate the vegetative aspect of the plant and are capable of clamping shut with amazing speed when properly stimulated.

The commonest sundews are low, herbaceous (non-woody) plants consisting of a slender rhizome, or rootlike stem, crowned by a rosette of sticky leaves that snare insects. The small, often tiny leaves are densely covered with slender, sensitive tentacles capped by globular red glands that secrete a highly viscid, clear mucilage. The droplets of mucilage glisten in sunlight, giving the plant a dewy appearance. This explains the generic name *Drosera*, derived from the Greek word for "dewy," and the common name, sundew. Because the clear mucilage magnifies the red gland, the whole plant may appear bright red. Species of *Drosera* vary in height from a few inches (*D. rotundifolia*) to three or more feet (one metre or more; *D. gigantea*).

Drosophyllum lusitanicum is a shrubby plant up to 5 feet (1.5 metres) tall with linear leaves that remain attached to the plant after they die, forming skirtlike layers around the base of the stem. The leaves are covered with numerous stalked glands bearing large droplets of clear mucilage that give the plant a dewy appearance, thus the common name dewy pine. Although the glands cannot move as in *Drosera*, vast numbers of gnats and flies adhere to them, and the plant is sometimes called flycatcher.

Although widespread and unusual, the inconspicuous *Aldrovanda vesiculosa* is not well known except among the few botanists who specialize in carnivorous plants. *Aldrovanda* is a small freshwater plant that floats just below the surface of quiet waters, and its tiny trap leaves function as in the Venus's-flytrap (*Dionaea*) except that the lobes are not hinged. In the "set" position, these leaf traps suggest a widely opened clam or mussel. The whole plant, however, is only 4 to 6 inches (10 to 15 centimetres) long and barely an inch across, including the spreading leaves.

Distribution and abundance. The geographic range of the pitcher plants radiates from Borneo, particularly around Mt. Kinabalu in Sabah (East Malaysia), where the most striking species occur. Some 20 species have been reported from the island. About 12 species occur on the adjacent island of Sumatra; 8 to 10 species are found in the Philippines and in northern Australia. The extremely light seeds seem to be well adapted for wind dispersal, which may explain the distribution in radial manner from Borneo as the focal point. Many of the species, such as those in Madagascar and Sri Lanka, are relatively local endemics. *Nepenthes phyllamphora*, on the other hand, ranges from southeastern China to New Guinea and has close relatives in northern Australia. Several other species (*N. ampullaria*, *N. gracilis*, *N. rafflesiana*) are less widespread but relatively wide-ranging.

The 100 or more species of *Drosera* are distributed primarily in the Southern Hemisphere. Half of them are found in Australia and New Zealand, the centre of greatest diversity of the genus. Southern Africa is second as a centre of speciation. Only a few species occur in the north temperate zone, among them two circumboreal ones (*D. anglica* and *D. rotundifolia*) and one nearly circumboreal species (*D. intermedia*). Only these three species are found in Europe and Soviet Asia, although in temperate North America there are four additional well-marked species (*D. brevifolia*, *D. capillaris*, and *D. filiformis* of the southeastern states and *D. linearis* of the northern states and Canada).

Dionaea, the Venus's-flytrap, is endemic to the Atlantic Coastal Plain from Beaufort County, North Carolina, to the south bank of the South Santee River, Charleston County, South Carolina. Within this highly restricted range, the flytrap tends to occur in widely scattered colonies but may be abundant locally. *Drosophyllum* is native only to northern Morocco and southern Spain and Portugal. By contrast, *Aldrovanda* ranges from Atlantic Europe to India and Japan and south to Mozambique (East Africa) and Australia.

Economic importance. The pitcher plants, sundews, and especially the Venus's-flytrap have always been valued as objects of curiosity, but they have never accounted for more than an insignificant element of the horticultural trade. Otherwise, the order Nepenthales is of little or no economic importance except on a local basis.

NATURAL HISTORY

Life cycle. Except for some annual species of *Drosera*, the plants of this order are perennial (i.e., they grow for several years). In *Nepenthes* most species are caulescent (stemmed) and shrubby; in the Droseraceae the acaulescent (stemless) herbaceous habit predominates. Apart from a new crop of fine fibrous roots produced each year from the rhizome, few if any true roots are present. In some species of *Drosera*, the seedling has a short-lived taproot that functions while the earliest leaves are forming but never elongates. *Aldrovanda* is rootless and floating, and some species of *Nepenthes* are epiphytes, plants that grow upon the branches of other plants.

The stem is rudimentary or relatively short in most species of the Droseraceae, but in *Nepenthes* it may elongate considerably into a vine. The young *Nepenthes* stem is densely clothed with leaves, but the internodes (stem sections between leaf attachment points) lengthen with increasing age. When lying on the ground the stems of some species (e.g., *N. ampullaria*) may root abundantly at the nodes (points of leaf attachment) and produce dense clusters of leaves with reduced blades and richly coloured pitchers. Two or three types of pitchers may be formed on the same plant at different heights on the stem and seem to function like flowers in attracting insects. Some species of *Drosera* have climbing stems as in *Nepenthes*, and some form tubers (enlarged underground stem structures) by which they overwinter to produce new shoots the following season. The tuber-bearing species have no roots. In the common sundew (*D. rotundifolia*) the stem dies off behind as the plant grows, and in winter the rosette is reduced to a tight bud that may have no measurable stem or root; successively, a series of dead rosettes forms. *Aldrovanda* produces new shoots each season from a persistent terminal bud. The temperate perennial species of the Droseraceae all go through a period of winter dormancy.

The flowering period of *Nepenthes* in the wild, though extended and inconstant for many species, is mainly from March to September. Under cultivation in the Northern Hemisphere *Nepenthes* blooms from August to October. The inflorescences (flower clusters) attract clouds of insects to sip on the nectar secreted abundantly by the flowers, which are cross-pollinated by insects. The male flowers give off a fetid odour that probably attracts insects. After pollination the fruits, containing 100 to 500 seeds per capsule, mature in six to eight weeks.

The common sundew, which is representative of north temperate species of *Drosera*, sends up a slender, arching flower stalk in early summer or later. The flowers open

Distribution of the Venus's-flytrap

The sundew plants

Modes of
reproduction

one at a time in sunlight, for one morning each. They are bisexual and pollinate themselves after closing if cross-pollination has not taken place while they are open. The single flower stalk of the Venus's-flytrap is produced in late May, June, or early July. Each flower remains open about three days, and the ripe pollen is shed before the stigmas (pollen receptive surfaces of the female flower parts) are receptive. The seeds are shed as early as mid-July.

The seeds of *Nepenthes* germinate readily within five to six weeks after ripening in loose, moist habitats, such as humus or sphagnum moss. *Drosera* reproduces easily by seed, exhibits remarkable powers of vegetative regeneration, and in some species also reproduces prolifically by asexual means. Several species, including *D. pygmaea*, reproduce by brood bodies, or gemmae (small clusters of vegetative cells that break off and grow into new plants); in Australia, reproduction by tubers is common. The underground tubers are important as stored food and water reserves for the plant to use during the dormant season when the rosette leaves are not present. Some species (e.g., *D. rotundifolia*) have strong axillary buds (buds located in the angles between leafstalks and stems) that form secondary rosettes below the main one; as the stem decays, these are separated and propagate the plant. The formation of plantlets by adventitious budding, especially from the leaves but also from the roots and inflorescence, rivals seed reproduction in this genus.

In *Dionaea* seeds germinate immediately in the summer, and they are viable in nature only for a relatively short period of time. High humidity and loose organic matter on a sandy surface are required for germination. As in *Drosera*, regeneration from vegetative parts or the immature inflorescence is possible.

In *Nepenthes* hybridization, or cross-fertilization between different species, is common in cultivation and also takes place in the wild. All of the cultivated species have been hybridized, and the hybrids are highly fertile. As a result, many interesting artificial hybrids now exist in cultivation.

Carnivorous adaptations. Trapping mechanisms. The pitchers of *Nepenthes* are conspicuously supplied with glands that attract prey. Insects, particularly ants, are lured to the mouth of the pitcher by numerous nectar glands scattered over the stems and leaves, including the tendrils and the inner surface of the lid. An insect that successfully negotiates the peristome (corrugated lip of the pitcher) loses footing on the crumbly, waxy surface lining the upper half of the interior of the pitcher and drops into the pitcher. The surface of the digestive region in the lower part of the pitcher is crowded with more than 6,000 digestive glands per square centimetre.

Tentacle
movement
in the
sundew

All species of *Drosera* capture their prey by means of flexible tentacles on the upper surface of the leaf. As many as 400 tentacles have been counted on a leaf of the common sundew, which is about 0.4 inch (1 centimetre) in diameter. These tentacles really are stalked glands with globular heads that secrete a clear, sticky mucilage. When a midge, gnat, or mosquito lands on the leaf, the alluring mucilage becomes the first snare, smearing and smothering the insect. The struggling insect stimulates further secretion. Within minutes the inner tentacles bend over and gradually pin down the insect. Soon the outer tentacles, which become successively longer toward the edge of the leaf, also begin to curl inward. In a matter of minutes or hours, depending on the species and amount of stimulation, the insect is hopelessly engulfed by a web of sticky stalks. Bending and unbending of the tentacles are caused by differential rates of rapid growth. When the outer cells of the tentacles grow faster than the inner ones, incurving results. The tentacles straighten again when the inner cells grow faster than the outer ones. As a growth response, the action of the tentacles has limits; the bending and unbending can be repeated only about three times by any one tentacle. The action of the tentacles is slow compared to the trapping mechanism of the Venus's-flytrap, and the sundew can catch only small or very weak prey; flies and even ants are able to escape. After a few days to a week, digestion is completed, the leaf reopens, resetting the trap, and the remains of the previous victim fall off or are washed or blown away.

The trapping mechanism of *Drosophyllum* involves glandular tentacles like those of *Drosera*, but the tentacles do not move. The insect becomes caught among the copious sticky glands in much the same way as it might be stuck by flypaper.

In the Venus's-flytrap, *Dionaea*, the blade of the leaf consists of two lobes hinged to each other like the jaws of a steel trap and provided with spinelike teeth along the margins. On the face of the lobes are numerous nectar and digestive glands. The digestive glands, which secrete very actively when prey is captured, contain a red sap giving the entire surface a bright red and flowerlike appearance. In the middle of each lobe are three pressure-sensitive hairs that trigger trap closure when properly stimulated. Two or more stimuli are required to spring the trap, the number depending on the time intervals between the stimuli. Two stimuli are sufficient if the second comes not less than 1.5 seconds nor more than 20 seconds after the first. The same trigger hair may be struck twice, or two hairs may be struck once each. If the stimuli are spaced over a period of five to six hours, as many as 18 to 20 separate stimuli may be required. When stimulated, the trap springs shut with amazing speed, usually in about a half second at normal daytime temperatures. The minimum closing time recorded is 80 milliseconds, less than one-tenth of a second. If prey is captured, the clamping movement continues slowly until the surfaces of the lobes press tightly against the body and the marginal teeth enmesh. The more times the hairs are stimulated, the tighter the leaf closes; thus, a struggling insect inside the trap causes the trap to close more tightly. A fly caught one afternoon may still be struggling the next morning; but, in the meantime, the trap will have contracted so tightly that the fly's form shows through the trap lobes. If no insect is caught, or if the insect is tiny and is able to escape between the teeth, the leaf reopens in 5 to 10 hours. Otherwise the trap remains closed for 7 to 10 days or even longer. After having captured three or four victims, the trap has matured completely and dies.

In the aquatic *Aldrovanda* the trapping mechanism is similar to that of the Venus's-flytrap, although the trap is tiny by comparison. The number of stimuli required to trigger the trap depends on the age of the leaf. Small insects, larvae, copepods, and other tiny animals that spring the trap are locked into an ovate hollow formed when the two lobes snap together, a movement requiring only 1/50 of a second.

Digestive mechanisms. The pitchers of *Nepenthes* secrete a quantity of enzymatic fluid before opening, and after opening, secretion is stimulated greatly by the presence of animal victims. The fluid contains a weak acid in addition to proteinase, the main enzyme, which breaks down protein. Bacteria live in the mature pitchers and help to break down the animal compounds. Under high temperatures digestion is accomplished in two to eight hours. The nitrogenous end products are then absorbed through the walls of the pitcher.

Bacteria
and
enzymes in
digestive
fluid

When an insect becomes stuck on the leaf of a sundew and struggles to get free, the tentacles are stimulated to secrete a digestive enzyme that breaks down the proteins in the insect body. In *Drosophyllum*, enzyme secretion is continuous, and the digestive cycle does not have a well-marked beginning and end.

Most of the upper surface of the leaf in *Dionaea* (i.e., the inside of the trap) is covered with up to 50 sessile (stalkless) glands per square millimetre; the glands secrete a digestive fluid containing proteinase and formic acid after the trap has closed on an insect or other digestible victim. Digestion begins within 36 hours after trap closure and continues for about ten days.

Aldrovanda has glands lining the lobes of the trap that release digestive juices after the trap springs shut. The end products are absorbed by the plant, and the trap may reopen several times after feeding if the catches have been meagre.

Animals that exploit leaf traps. The pitched leaf of *Nepenthes* constitutes a special habitat with both wet and dry ecological niches, and certain insects and other small animals have adapted to these niches. They may exploit

the pitcher for food, shelter, or as a place to pass part of their life cycle. In some instances, the animal takes advantage of the trap by robbing the plant of its own victims; in other instances, the plant tissue itself is parasitized.

Adaptation to the pitcher-plant environment has become so specific in some cases that the animals have lost their ability to complete a life cycle elsewhere. Several species of spiders occur only in the pitchers of *Nepenthes*, in which they live in the mouth above the water level and prey on insects attracted to the pitchers. More than two dozen species of the insect order Diptera (flies) are known to occur exclusively in the aquatic environment of the pitchers; two-thirds of these species are mosquitoes.

Many animals have been recorded as accidental or occasional inhabitants of *Nepenthes* pitchers, especially in the creeping species (notably *N. ampullaria*), in which the pitchers stand half buried in the forest floor. These include protozoans, slime molds, desmids (a group of green algae), diatoms, rotatoria, oligochaetes (worms), crustaceans, larvae of various flies, and even an occasional tadpole. In Sabah, Malaysia, the small rodent *Tarsius spectrum* visits the pitchers of various species, perching on the margin to scoop out and devour the insects caught there.

A few animals are able to inhabit the sundews (*Drosera*). A moth larva of the family Noctuidae feeds on the glandless portions of the plant, and certain Australian bugs of the order Heteroptera (family Capsidae) move about the sticky leaves without apparent harm or difficulty, sucking the juices of ensnared victims. In Florida, the larva of the moth *Trichoptilus parvulus* (plume moth) has been discovered on the leaves of *Drosera capillaris*. It eats the stalked glands with their sticky secretion, the leaf blades, and even trapped dead insects.

Ecology. *Nepenthes* is a vinelike jungle plant (liana) that creeps over the ground or climbs on the trees of tropical swamp or rain forests. The genus ranges in altitude from sea level to 10,000 feet (3,000 metres), and only rarely does it grow in other than moist or very moist habitats. Around Mt. Kinabalu in Sabah, where the distribution of the group is centred, the species show a distinct zonation in their altitudinal distribution. Some species (e.g., *N. gracilis*) grow at low elevations on the hot humid plains; others (e.g., *N. ampullaria*) grow commonly at 2,000 to 2,300 feet (600 to 700 metres); still others (e.g., *N. rajah*) reach the 5,000- to 10,000-foot (1,500- to 3,000-metre) zone where clouds or rain are always present, and they are exposed almost continuously to a cool, dripping wet environment. No species of pitcher plants occur between the 10,000-foot level and the 13,700-foot (4,200-metre) summit of Mt. Kinabalu. At least one species inhabits wet savannas (grassland areas with scattered trees), where it climbs on shrubs; the genus is even known to occur on dry, sandy hillsides.

The species of the family Droseraceae typically inhabit damp heaths, bogs, swamps, wet savannas, or sandy shores, showing a marked preference for wet habitats with acid soil in which nitrogen and other nutrients are deficient or unavailable. The flycatcher (*Drosophyllum*) of the western Mediterranean region is an exception to the wet-habitat rule; this coarse, wiry sundew grows on dry, gravelly (quartz) hills, where, nevertheless, the soil is acidic.

In North America, the sundew (*Drosera*) is one of the first plants to invade newly disturbed habitats such as roadside ditches and abandoned logging trails. The bright red rosettes often cover the ground. Many of the species thrive best in habitats where sphagnum is growing. Several species of *Drosera* are often found in the same habitat. *Drosera anglica* and *D. rotundifolia* occupy swamps but always in the parts of the swamp most deficient in salts. Most *Drosera* species grow in poor soils. The soil of a pine forest, for example, contains some 27 times more nitrogen than a *Drosera* habitat. The sundew is among the earliest appearing inhabitants of raw peat surfaces, which are a nutrient-poor habitat. Too much calcium in the soil may be toxic to *Drosera* plants. The poor-soil generalization does not apply necessarily to all of the many species of *Drosera* in the Southern Hemisphere; in fact, at least one species of southern Australia (*D. whittakeri*) grows on wooded slopes among general vegetation.

Venus's-flytrap thrives in a habitat transitional between wet evergreen-shrub bog (pocosin) and dry sandy long-leaf-pine savanna on the Atlantic Coastal Plain of the United States. The plants tend to grow along the edges of wet depressions and pools, often in company with pitcher plants of the genus *Sarracenia*, sundews, and butterworts (*Pinguicula*). Occasional burning helps to maintain this limited pineland in the scrubby, semi-savanna condition. Thus fires, far from being the enemy of the flytrap, actually may be required for its continued existence.

Aldrovanda grows in shallow quiet water between the stems of such marsh plants as cattails (*Typha*), reeds (*Phragmites*), and wild rice (*Zizania*).

Carnivory, the adaptation for digesting animal prey, is the most important aspect of the ecology of the species in this order; it has enabled the plants to occupy otherwise unavailable niches.

FORM AND FUNCTION

The *Nepenthes* plant consists of a creeping rhizome from which arises a coarse, leafy stem that climbs over trees and other vegetation by means of its modified leaves, which may attain a length of 3 to 10 feet (1 to 3 metres). The expanded, tongue-shaped or round blade of the thick, glossy leaf narrows to a long tendril that twines around other plants and is always coiled except in the short upright or creeping species of the genus. The tendril has enormous strength and, in some species (e.g., *N. rafflesiana*), may support as much as 13 pounds (6 kilograms) of weight without breaking. The tendril finally becomes transformed at its tip into a pitcher that always is held upright and cannot function otherwise. The pitchers vary considerably in form even on the same plant; they may be tubular, cylindrical, urn-shaped, funnel-shaped, ovoid, goblet-shaped, or globose. In most species, but noticeably in the cylindrical ones, the upper one-third of the pitcher, corresponding to the inner waxy zone, is somewhat constricted. Pitchers range from the size of a thimble to that of a pint jar or larger (up to 20 inches, or 50 centimetres), but commonly they are 4 to 6 inches (10 to 15 centimetres) long. The colour usually varies, even on the same plant, from yellow green to dark green with all degrees of red marking, depending on age, light exposure, and soil conditions; sometimes, however, the pitchers are a uniform pale green or deep red. When red occurs on the rim (lip), it forms stripes. The rim of the pitcher is fluted, and the corrugations strengthen the lip and help to keep the mouth from collapsing. This corrugated structure, known as the peristome, is a conspicuous feature of nearly all species. An immobile lid (operculum), formed by an outgrowth of the leaf, may overhang the mouth and help to keep out rain, or it may be small, narrow, and turned back. The undersurface of the lid and the corrugations of the lip are supplied copiously with nectar glands except in a few species.

The small greenish or claret-coloured flowers of *Nepenthes* are borne in clusters at the tips of stems opposite leaves; as few as 15 to 20 and as many as several hundred flowers may be produced in one inflorescence. The flowers are noteworthy chiefly because they are unisexual, and the male and female flowers, unlike those of other carnivorous plants, are found on different plants (i.e., *Nepenthes* is dioecious).

Drosera species vary from a few inches to three or more feet in height. The smallest often are hidden among the mosses in a sphagnum bog. Among the North American species, which are herbaceous and stemless, there are three main leaf forms: oval or round (*D. rotundifolia*); spoon-, club-, or strap-shaped (*D. intermedia*); and threadlike or wirelike (*D. filiformis*). The leaves of the wide-ranging common sundew resemble tiny mittens or baseball catcher's gloves. The well-known sundews of the Northern Hemisphere usually produce 1 to 20 erect flowers on a single, leafless flower stalk that is 6 to 8 inches (15 to 20 centimetres) long or occasionally up to a foot (30 centimetres) or more long. The flower, measuring an inch (2.5 centimetres) or less across, is bisexual and regular (radially symmetrical); its five petals are white to pink or even deep red, the colour depending on the species. Some species of

Specialized structure of pitcher-plant leaves

Flowers of the sundew

Altitudinal distributions of pitcher plants

Drosera from the Southern Hemisphere bear their flowers on leafy stems.

The Venus's-flytrap has a single flowering scape (leafless stalk) up to a foot high. The 2 to 15 bisexual white flowers measure about 1 inch across and are similar to those of *Drosera*. The leaf is divided into a blade and a prominently winged petiole (stalk), narrowing at the base of the blade. The blade consists of two identical semi-circular lobes united along the middle by a thick midrib and standing at an angle of about 50° to each other; the lobes constitute the hinged trap. The outer margin of each lobe is provided with a comb of long bristles, about 13 in number, that interlock like fingers when the trap closes. The leaf is from 2 to 6 inches (5 to 15 centimetres) long and about 1 or 2 inches across. The plants are bright red when growing in strong sunlight, but green if in shade.

EVOLUTION

The fossil record of the order is extremely limited and does little to illuminate the evolutionary history. Speculations on the phylogenetic relationships, which have been based on comparative studies of the modern species of the order, have resulted in divergent views. Although there is no common view on the origin of carnivory among the flowering plants, authorities now agree that the carnivorous plants represent several more or less unrelated lines of evolution.

Phylogenists who accept the concept of the order Nepenthales as defined here, comprising the families Droseraceae and Nepenthaceae, believe that it probably evolved from the order Saxifragales. Most authorities now are convinced on the basis of floral morphology that the family Droseraceae is closely related to the Saxifragaceae, especially that part of the family sometimes segregated as the separate family Parnassiaceae.

Traditionally, the families Droseraceae and Nepenthaceae were thought, on the basis of leaf morphology, to form a natural group with the Sarraceniaceae (New World pitcher plants), because of the obvious vegetative transitions between the two pitcher-plant families (Sarraceniaceae and Nepenthaceae). Some authorities still hold to this view, choosing to place more weight on the evidence from leaf morphology than from floral morphology. At issue, primarily, is the evolutionary position of the Nepenthaceae, about which there is little agreement. The family Droseraceae clearly is more advanced than the Sarraceniaceae, and the two should not be placed in the same order (see *Sarraceniales* above). The members of the family Nepenthaceae are closely knit and clearly have evolved from a common ancestor. One line of phylogenetic reasoning places the Nepenthaceae in an order by itself that stands between the evolutionary positions of the Droseraceae and Sarraceniaceae but somewhat closer to the latter; another interpretation has placed Nepenthaceae in the order Aristolochiales (a group that includes the pitcher-like Dutchman's pipe). Evidence from pollen and ovule morphology, however, now indicates a close affinity between the Nepenthaceae and the Droseraceae and at the same time casts doubt on the supposed affinities of the Old World pitcher plants with the Aristolochiales or Sarraceniales.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The Nepenthales is distinguished from other orders chiefly by the characteristics of the distinctive insect-trapping leaves and, to a lesser extent, by features of the inflorescence and flower, particularly pollen features. The main characteristics for separating the two quite distinct families are the habit and size of plant; form and arrangement of leaves; presence of unisexual or bisexual flowers; presence or absence of differentiated petals; number of carpels (ovule-bearing segments of the pistil, or female structure); number, form, and fusion of styles (narrow, upper part of pistil); and number and fusion of stamens (male pollen-producing structures).

Alternate systems of classification. The classification presented in this article departs from the traditional one and places the Droseraceae and the Nepenthaceae in an order by themselves, apart from the Sarraceniales. Whatever the degree of their affinity may be, these two families

superficially do not show much morphological similarity. To the casual observer their chief similarity is functional—the carnivory of their leaves.

The many species of the family Nepenthaceae, despite their sometimes striking variation, are, by comparison with other plants, so morphologically homogeneous that they have always been placed in the single genus *Nepenthes*; the cohesiveness of the family never has been challenged seriously. The family Droseraceae, with several strikingly different types of traps, is by contrast a heterogeneous family of four vegetatively distinct genera, which, however, show a close affinity to each other on the basis of floral morphology. Some authorities have treated the bizarre Venus's-flytrap (*Dionaea muscipula*) as a separate, monotypic (single species) family, Dionaeaceae, although this view is defensible only if vegetative morphology is stressed at the expense of flower structure.

The question of the closeness of relationship between the Old World pitcher plants (family Nepenthaceae) and the New World pitcher plants (order Sarraceniales) will remain unresolved until more is known about the evolution of the pitcher leaves in *Nepenthes*, on the one hand, and *Heliamphora* (family Sarraceniaceae), on the other hand. New worldwide monographic studies are needed to determine the number of species in the large genera *Drosera* and *Nepenthes*. (S.G.S.)

Myrtales (myrtle order)

The myrtle order (Myrtales) consists of over 400 genera and nearly 10,000 species of flowering plants, and its representatives grow in a variety of habitats throughout the world. Members of the family Melastomataceae are particularly abundant in Brazil, where they form a characteristic component of the vegetation. In many parts of Australia, Myrtaceae is the most prominent plant family, with the genus *Eucalyptus* forming large forests. These two families are the largest in the order, and together they account for approximately three-quarters of the total genera and species.

GENERAL FEATURES

Predominance of the woody habit, either as shrubs or trees, is a feature of the order, and some members of the genus *Eucalyptus* are among the world's tallest trees. *E. regnans*, the mountain ash of Victoria and Tasmania, commonly attains a height of over 300 feet (90 metres), and an exceptional specimen was once measured at 370 feet (113 metres). Some herbaceous (nonwoody) species, however, occur in the families Lythraceae, Melastomataceae, and Onagraceae, while the family Trapaceae consists entirely of herbaceous annuals (plants entirely completing a life cycle in one growing season). In the Lythraceae family there is an association between habit and climate; in temperate regions the species are annual or perennial herbs, whereas in warmer areas they are often woody shrubs and, sometimes, trees. In the family Penaeaceae, which is confined to rather dry areas of southwestern and southern Africa, the plants are small shrubs of heathlike habit adapted to dry wasteland habitats. Diversity in size and habit is exhibited by members of the family Melastomataceae, which includes, as well as shrubs and trees, root climbers, epiphytes (plants that are not rooted in soil but live among the branches of trees), and herbaceous marsh and water plants. A similar range of variation is seen in the family Onagraceae which is found in the subtropics and temperate zones.

Distribution and abundance. Members of this order are to be found chiefly in the tropics and subtropics, but most families have some representatives in temperate regions. Apart from the families Oliniaceae and Penaeaceae, which are restricted to the southern half of Africa, all families are widely distributed either as native plants or, as in the families Punicaceae and Myrtaceae, as introduced species through extensive cultivation. The widest natural distribution is that of the Onagraceae family, which has its chief development in the temperate zones of the Americas, particularly in the western regions. Its largest genus, *Epilobium*, is composed of some 160 species and is cos-

Differing
opinions
on the
evolu-
tionary
position
of pitcher
plants

mopolitan except in the tropics. The family Lecythidaceae is found throughout the tropics, but the family Combretaceae, although mainly tropical, extends into the subtropics. The Lythraceae family has representatives in a variety of climatic zones, but it is most abundant in tropical America. The number of its species declines rapidly toward the temperate regions, and it is absent from the cold zones. *Lythrum salicaria* is one of the few plant species found in both Old and New Worlds, and its range covers Europe, through Asia to Japan, as well as North America and southeastern Australia. Melastomataceae, the largest family, is also mainly tropical, but its members extend into the subtropics and more temperate regions. About 2,000 of its species are native to the American continent. Two main centres of development of the family Myrtaceae are recognized; tropical America, for the berry-fruited members, and Australia, where the dry-fruited species predominate. The 600 species of *Eucalyptus* are distributed throughout Australia from the semi-arid regions to the coastal forests. The most widely spread genus is *Myrtus*, which grows in the warmer regions of both hemispheres; and the myrtle (*M. communis*) is either long naturalized in Europe or the only native *Myrtus* member in that continent. Mangrove species of the Sonneratiaceae and Rhizophoraceae families are found along tropical seacoasts, although the latter family is mainly Old World. *Rhizophora mangle* is the only native mangrove species in America, and it is restricted to peninsular Florida. The related family Anisophylleaceae is exclusively tropical, and the family Trapaceae is found from central and southern Europe to eastern Asia and from tropical to subtropical Africa.

Importance. Economically, the most important single genus is *Eucalyptus*, many of whose species are a valuable source of hardwoods. Because of their rapid growth rate, they are now grown widely throughout the temperate regions of the world as shade trees or in forestry plantations. In addition, oils with fever-controlling and germicidal properties, gums, and resins are extracted from their leaves and wood, while some species are of importance as a source of nectar and pollen for hive bees. Other members of the Myrtaceae family used for timber are *Metrosideros* and *Angophora*, and the pungent, medicinal cajuput oil is extracted from the paperbark tree, *Melaleuca leucadendron*. Two members of the Lythraceae family used as a source of good timber are the tulipwood tree of Brazil, *Physocalymma scaberrima*, and *Lagerstroemia flos-reginae* of eastern India, while *Terminalia* of the family Combretaceae and *Lecythis* and *Couroupita* of the Lecythidaceae family are also valuable timber trees. For underwater constructions such as piers and jetties, whole trunks of the mangrove *Rhizophora* are widely used because their tannin content inhibits attacks from marine wood-boring animals.

Although the order is not of great importance as a source of food, edible fruits are produced by some members of most families. The most widely known is probably the pomegranate (*Punica granatum*), which is now cultivated in the warmer regions of the world for its fruit and also as an ornamental shrub. In the Myrtaceae family the guava (*Psidium guajava*), strawberry guava (*P. cattleianum*), and many species of *Eugenia* are of local value, such as the Brazil cherry (*E. michelii*), the Surinam cherry (*E. uniflora*), the Otaheite apple (*E. malaccensis*), and the rose apple (*E. jambos*). The dried flower buds of *Syzygium aromaticum* are the cloves of spice commerce, and the powdered unripe fruit of *Pimenta dioica* is allspice. The water chestnut (*Trapa natans*) is eaten in China, and the fruits of *T. bispinosa* are the source of the singhara flour of northwestern India. Other edible fruits are found in the genus *Maietia* of the Melastomataceae family and in some species of *Fuchsia*, while in tropical Africa a butter-like substance, chiquito, is obtained from the fruits of *Combretum butyrosomum*. The family Lecythidaceae is notable for the Brazil nut (*Bertholletia excelsa*) and sapucaia nuts (*Lecythis*), for the oil extracted from the seeds of *Barringtonia*, and for the anchovy pear (*Grias cauliflora*), cultivated in the West Indies. The family Combretaceae supplies the Indian, or country, almond (*Terminalia catappa*) and the myrobalan nuts (*T. chebula*), but the only

edible products of the family Anisophylleaceae are the poga nuts (*Poga oleosa*).

Other products from members of this order are a red cosmetic dye from *Lawsonia inermis* and *Woodfordia floribunda* of the family Lythraceae, fibre for textiles from the soft bark of *Couratari* (family Lecythidaceae), colouring matter from some of the members of Melastomataceae family, and tannins for tanning hides from the bark and foliage of *Rhizophora* and *Terminalia*. Many species of the Lythraceae family are horticulturally important as shade trees or as garden plants, such as crape myrtle (*Lagerstroemia*), mignonette or henna tree (*Lawsonia*), loosestrife (*Lythrum*), and cigar flower (*Cuphea*).

Horticulturally important plants in the Myrtaceae family are *Eucalyptus*, myrtle (*Myrtus communis*), geraldton waxflower (*Chamaelaucium*), bottlebrush (*Callistemon*), and many others, including beautiful horticultural hybrids of *Leptospermum*. The family Melastomataceae provides the garden shrubs *Medinilla*, *Heterocentron*, and *Tibouchina* and the small vine *Schizocentron*, which is grown in hanging baskets. The herbaceous annuals or perennials of the Onagraceae family, such as those found in the genera *Oenothera*, *Clarkia*, and *Godetia*, as well as the shrubby *Fuchsia*, are familiar cultivated plants throughout the world.

NATURAL HISTORY

Life cycle. The flowers of most species have both male and female parts in the same flower (perfect, or bisexual, flowers), but those of the Sonneratiaceae, Anisophylleaceae, and Combretaceae families may have flowers of only one sex; structures of the opposite sex, though originally present, fail to mature in these cases. At the completion of meiosis (nuclear reduction division leading to gamete, or sex-cell, formation) in the anthers, the microspores remain joined together for a short time in tetrads, or clusters of four, before they separate as pollen grains. In the genus *Epilobium*, however, they remain together as permanent tetrads and are liberated as such when the anthers split open. In most members of the Onagraceae family, the pollen grains are connected by viscous threads that stick to a visiting insect; thus, hundreds of pollen grains are drawn out of the anther together. When mature, the pollen is usually two-celled; i.e., it consists of a large vegetative or pollen tube cell and a smaller generative cell. In the Lecythidaceae and Melastomataceae families, however, the generative cell has already divided to form the two male gametes, or sperm cells, when the anthers ripen and split. The pollen grains in these families are therefore three-celled, while in the Combretaceae family both two- and three-celled conditions are shown by different species.

Within the ovary are one or more future seeds, or ovules, each of which is provided with two seed coats, or integuments. In the centre of each ovule is the embryo sac, or female gametophyte, one of whose cells, the egg, develops into the embryo after it has been fertilized by a male gamete from a pollen grain.

In *Eucalyptus*, only relatively few of the ovules present in each ovary develop into seeds, and the majority are sterile because they lack embryo sacs. These are the ovulodes, which later shrivel and form the chaff that is shaken out of the mature capsule, together with the few viable seeds.

Pollination. Although normally the flowers open when mature, the opposite condition, of mature flowers remaining closed (cleistogamy), occurs in *Ammania* and *Rotala* of the family Lythraceae and in *Jussiaea acuminata*. The last mentioned plants grow near the Sahara in locales where the ground temperatures of 70°–80° C (158°–176° F) are too hot for insects, and there the mature flowers remain closed. Usually when mature flowers remain closed it implies self-pollination, but, in *Purpurella cleistoflora* of the family Melastomataceae, robber bumblebees effect cross-pollination when they force an entrance to the flowers in search of pollen. The normal condition, of mature flowers unfolding, however, does not necessarily mean that cross-pollination takes place, and the British *Epilobium* species form a series from the small-flowered, largely self-pollinated species to those with large, insect-pollinated

flowers. Pollination by wind occurs in some of the fuchsias and perhaps in *Eucalyptus*, but usually the transfer of pollen is accomplished by insects, chiefly bees or moths and butterflies. In certain species of the Lecythidaceae and Melastomataceae families, however, hummingbirds are the pollinators, and honey eaters are the pollinators in the larger flowered members of the Myrtaceae family. *Metrosideros excelsa* of New Zealand relies for its pollination on a forest bird, the tui, which migrates in early summer to the coast of the North Island in search of nectar. In Brazil, flowers of the genus *Feijoa* are visited regularly by small birds that eat the sweet, fleshy petals. The most complex cross-pollination mechanism in the order is that of *Lythrum salicaria*, which produces three forms of flowers on different plants. The stamens, pollen grains, styles, and stigmas likewise are of three different shapes, and only certain crosses are effective in seed production.

Postfertilization events. Following fertilization, nuclear endosperm, a special nourishing tissue for the developing plant embryo, is formed in the embryo sac. This tissue subsequently becomes cellular, except in the Melastomataceae family, where it is digested by the growing embryo while it is still in the free-nuclear condition. In all other families it is the cellular endosperm that is digested, and the mature seeds are nonendospermic. Extrusion of the endosperm through the broad micropyle opening of the ovule to form haustoria, special absorbing organs, is a feature of the family Rhizophoraceae, and these may play a supplementary role in the nutrition of the embryo. The genus *Trapa* is unique in the Myrtales order in that the primary endosperm nucleus degenerates, and so no endosperm is formed, but the lack of this source of nourishment for the embryo is compensated for by its formation of a haustorial suspensor, which invades the tissues of the ovule outside the embryo sac.

The embryo is dicotyledonous (*i.e.*, it has two cotyledons, or "seed leaves"), but in the Penaeaceae family the cotyledons are minute, and in the Anisophylleaceae family they are either very small or absent. In the Melastomataceae and Trapaceae families, one cotyledon is much smaller than the other and is sometimes reduced to a scale. Polyembryony, the presence of several embryos in each seed, has been reported in several families of the order and is very common in *Myrtus communis* and *Eugenia*. In *E. paniculata* up to 21 embryos have been found in a seed, and it is unusual for there to be fewer than two.

The fruit varies from dry to fleshy, these extremes often occurring within the same family. In the genus *Lecythis* (the monkey pot), the tissues giving rise to the stamens in the flower persist and enlarge to form a lid, which separates when the fruit is ripe, and in *Bertholletia excelsa* the hardened persistent sepals (green, leaflike structures next to the petals in a flower) form a plug that is later dislodged during seed germination, and the seedlings escape through the opening.

Vivipary is a feature of many of the mangroves; that is, the seed germinates while the fruit is still retained on the tree, and, following growth of the seed leaves, the root end of the embryo elongates and passes through the micropyle opening in the ovule and then through the ovary wall. In some instances it may reach three feet (one metre) in length before the seedling drops into the mud, where it establishes itself at once. In *Couroupita guianensis* and *Grias cauliflora* (family Lecythidaceae) and *Myrciaria* (family Myrtaceae) the flowers and, later, the fruits are borne directly on the old wood of the trunk. This is known as cauliflory, and in *Couroupita* the large, round, woody fruits attached to the trunk are responsible for the name cannonball tree.

Unusual responses to the environment. Those species of *Eucalyptus* that grow on poor soil in low-rainfall areas show a prominent development of the lignotuber, a woody rounded knot or lump surrounding the base of the tree trunk and usually partly or entirely underground. Such trees have a multistemmed type of growth and remain small, both in height and in stem diameter. A similar environmental response may be exhibited in medium- to high-rainfall localities in individuals growing on very shallow soil on the tops of ridges, while members of the same

species growing on deeper soil nearby show no lignotuber development and have normal growth. In the Onagraceae family, temporary adaptation to an oxygen-deficient environment is seen in the genus *Jussiaea*. When plants grow in water, air spaces develop in the tissues of the roots and submerged stems, and in *J. repens* some special spongy-tissued respiratory roots grow to the surface of the water. The same plants under ordinary dryland conditions do not exhibit these features.

Ecology. Certain members of the order are adapted to special ecological situations. For example, *Trapa* and some species of the Melastomataceae and Onagraceae families are aquatic or marsh plants, while the mangroves require habitats found only along tropical muddy seashores or estuaries. Both epiphytes and root climbers of the Melastomataceae family are confined to tropical forests, but the genus *Penaecia*, with its low, shrubby habit, is adapted to life in dry parts of southwestern and southern Africa. The fireweed *Epilobium angustifolium* is one of the first plants to appear after fire devastation or other disturbances, such as bulldozing, and it achieved fame by its rapid colonization of bomb sites in Great Britain during World War II.

FORM AND FUNCTION

No structural characters are common to all families of this order. Vegetatively, many of the plants are woody perennials and most bear opposite leaves, but variation both between and within the families is considerable, and the concept of the order is based on flower structures. Of these, the most important is the form of the receptacle, which forms a floral tube of varying length and degree of attachment to the wall of the ovary (female seed-bearing structure).

Representative plants from two families of the myrtle order.

Growth peculiarities are apparent in some members of the order. For example, the alternate adult leaves of *Eucalyptus* assume a vertical position by twisting of the petiole (leafstalk) during development, but this feature is not exhibited by those species that bear permanently juvenile foliage, in which the leaves are opposite instead of alternate. In the family Combretaceae, two types of leaf arrangement occur in one genus, *Quisqualis*. Alternate leaves are borne on the stem, but in the flowering shoots the leaves are opposite, and, in some climbing species, the petiole bases persist as hooks after the leaves have dropped. Probably the most unusual growth form is that exhibited by the mangroves of the Sonneratiaceae and Rhizophoraceae families, in which portions of some roots

The mangrove habit of growth

Early development of the seed

grow upward through the mud until they project some inches above low-tide level. These "breathing roots" bear small openings in their bark and act as aerating organs. Aerial prop roots are also a feature of most mangroves, and these persist, forming a tangled jungle, even after the main roots and stem bases of the trees have decayed. The genus *Terminalia* also possesses breathing roots, and loose internal cell tissue containing air spaces occurs in the submerged portions of the stems and roots of marsh-inhabiting species of the family Melastomataceae. *Trapa*, a floating annual, is supported by the inflated petioles of its floating leaves, while its submerged leaves are finely divided and resemble roots. An interesting association with ants is exhibited by some members of the Melastomataceae family, such as *Maietia* and *Tococa*. In these, saclike outgrowths are formed on the upper surfaces of the leaves and sometimes on the petioles, and they serve as shelters (*dormatia*) for ants, which enter them from the lower surface. The ants protect the flowers from all but the legitimate flower pollinators by swarming out of hiding at any unusual disturbance of the branch.

EVOLUTION

The fossil record has not contributed to an understanding of the origin of the Myrtales order, but its families, as now known, were probably all defined by Tertiary times (*i.e.*, by about 65,000,000 years ago). Theories advanced as to their evolution rest largely on deductions from comparative structural studies of living species and are, therefore, subjective. Most such schemes are based on details of floral structure. Accordingly, the perigyny-epigyny (*i.e.*, position of the flower petals and other flower parts relative to the ovary, being either "around" or "above" it) shown by the typical flower of the Myrtales order is seen as the expression of an evolutionary tendency initiated in the Saxifragales order. Because of its perigynous-epigynous flowers, the Saxifragaceae family of that order has been favoured by many as an ancestral family. It is considered by some authorities, on the other hand, that vegetative features are a more reliable guide to ancestry than those associated with reproduction (*i.e.*, the flower). On this basis, they recognize in flowering plants two independent but parallel lines of descent: the fundamentally woody families and the fundamentally herbaceous families. According to this concept, the families Lythraceae, Onagraceae, and Trapaceae in the Myrtales order may then be grouped into an order, the Lythrales, that can be thought to have arisen through the order Caryophyllales from the most primitive herbaceous flowering plants, and the remaining families can be traced ultimately from the most primitive woody flowering plants of the order Magnoliales.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The chief botanical feature of importance in classification in the Myrtales order is the nature of the floral tube (receptacle, or hypanthium), whose form ranges from the free tubular condition of varying lengths to partial or complete fusion with the ovary wall. This is the most important taxonomic character, and many taxonomists consider that its variation in expression between—and sometimes within—the component families represents an evolutionary sequence that reaches its final expression in epigynous flowers (*i.e.*, inferior-ovary flowers, those with flower parts appearing to arise at the top of the ovary rather than at its base). The number of component families in the Myrtales order varies in different classifications according to the authority. The form of the flower, the shape of the floral tube or receptacle, and the degree of its fusion with the ovary wall are characters of primary importance, but the number, arrangement, and points of origin of the stamens, as well as details of the female flower parts, are also taken into account. Vegetative features such as the form and arrangement of the leaves, the presence or absence of stipules (small, leaflike appendages at the bases of leaves), and the occurrence of internal phloem (an additional layer of special conducting cells inside the stem, in contrast with the usual presence of only one layer just beneath the bark) are of secondary taxonomic value.

Taxonomic problems. Earlier treatments of this order recognize 23 families in 4 suborders. The more recent view presented in this article, however, defines the order to include only 12 of the former families, and it recognizes the family Anisophylleaceae as a 13th independent, though closely related, family near the family Rhizophoraceae. The number of genera and species of each family also varies among authorities. (G.L.D.)

Rutales

The large flowering plant order Rutales consists of 12 families, about 324 genera, and about 4,000 species. Meliaceae is the largest family in the group with about 50 genera and 1,400 species. Some families, such as Aitoniaceae and Coriariaceae, among others, consist of only a single genus. The largest genera in the order are *Trichilia* (300 species, distributed in tropical America and Africa), *Aglaia* (about 300 species in China, Indo-Malaysia, and tropical Australia), *Fagara* (250 species in the tropics generally), *Dysoxylum* (200 species in Indo-Malaysia), and *Commiphora* (185 species in North Africa). Some genera, such as *Blepharocarya* (family Anacardiaceae), *Nymanina* (Aitoniaceae), *Toddalia* (Rutaceae), *Limonia* (Rutaceae), and others, are monotypic; *i.e.*, they consist of only a single species each.

Representative plants of three families of the order Rutales.

The order is possibly of greater importance as a source of hardwood timber than any other in the plant kingdom. It also includes some of the best known tropical and subtropical fruits—the cashew nut (*Anacardium occidentale*), one of the first West Indian fruit trees to be distributed throughout the tropical world by early Spanish and Portuguese adventurers, and the Indian mango (*Mangifera indica*), often called the queen of all tropical fruits; it

Criteria
used to
define
members
of the
order

has delightfully aromatic flesh. The mango has long been cultivated in the Indo-Malaysian regions and has recently been introduced into other parts of the world. The myrrh (*Balsamodendron*) and frankincense (*Boswellia carteri*) of biblical fame also belong to this order.

GENERAL FEATURES

Size range and diversity of structure. The order Rutales consists predominantly of woody shrubs and trees. Herbs are, as a rule, absent, although some are present in the families Rutaceae and Podoaceae. A few, such as the genera *Naregamia* and *Dictamnus*, are undershrubs. Rhizomatous (creeping) tuberous-rooted perennials are found in the family Podoaceae. The order has only a few climbers, but poison ivy (*Rhus toxicodendron* and *R. radicans*) is one well-known example. A great many beautiful forest trees, some of which are reckoned among the most elegant on Earth because of their feathery foliage and magnificent fruits, belong to this order. Several trees, such as *Camposperma auriculata*, *Mangifera lagenifera*, *Buchanania lucida*, and others, attain a height of 110 feet (33 metres). Trees like *Irvingia malayana* may even reach a magnificent height of 220 feet (67 metres). Many have buttresses, which may be thin and steep as in *Irvingia*, spreading as in *Pentaspadon*, or thick and prominent as in *Gluta*, *Parishia*, *Canarium*, and others. Several growth forms occur among the trees of the order. Many, such as *Mangifera lagenifera*, have a dense and almost hemispherical crown with a tall columnar trunk. *Dracantomelon mangiferum* has a conical crown when young, becoming dense and rounded at maturity. *Camposperma auriculata* has a flat-topped crown. There are several thorny trees in the family Rutaceae, among them the genera *Aegle*, *Citrus*, *Limonia*, and others. *Canarium* has aerial roots, especially on the side to which it leans. These roots may arise from a height above the ground of 13 feet (4 metres) or even more.

Distribution and abundance. The order Rutales is dominantly pantropical in distribution, with a few genera extending to temperate regions of both hemispheres. The chief centres of distribution are tropical America, South Africa, the Indo-Malaysia region, and northern Australia. Some genera show restricted distribution—e.g., *Kirkia* in tropical and southern Africa, *Nymania* in southern Africa, *Naregamia* on the west coast of India and in eastern Africa, *Cneorum* in the Mediterranean region and the Canary Islands, *Melosma* in California, and *Stylobasium* in southwest Australia.

Economic importance. The group is important in several respects. It includes many fruit trees, such as the Indian mango and cashew nut. The axis under the nut in the latter swells into a pearlike body that is also edible and is used for distilling wine. This false fruit, known as cashew apple, is fragrant. In many varieties of cashew apple the juice causes a slight irritation in the throat. Other varieties are known chiefly from tropical America, where the pulpy portion is extensively consumed. The shell of the cashew nut contains an irritant skin poison that produces blisters and dermatitis. The shell liquid is salvaged and used as a lubricant in electrical insulations in airplanes. The cashew kernel is generally removed and eaten after roasting the nut.

Mango is one of the earliest fruit trees known to mankind. The representation of this tree in the Buddhist *stūpas* bears testimony to its antiquity in India. The tree is inextricably connected with Indian life and religious ceremonies. Sanskrit literature is replete with delineations of its qualities. Every part of the tree, from root to the top, is used by man in one form or another. The fruit itself, in all stages of development, is used in India and neighbouring countries. Raw fruits are used as sources of tannin and other astringent products, for chutneys and in pickles, and for cool drinks. Beverages, syrups, marmalades, jams, jellies, and candies are made from the ripe fruits. The kernel, rich in carbohydrates, calcium, and fat, is used as a stock feed for pigs. When dried and ground into flour, it is used as food by people in some parts of Southeast Asia.

Pistachio nuts are obtained from *Pistacia vera* of the Mediterranean countries and west Asia. Lemons (*Citrus*

limon), oranges (*C. aurantium*), limes (*C. aurantiifolia*), and other citrus fruits are well known. Originally, *Citrus* was a fruit of the Orient, where it has been in cultivation for thousands of years. The oldest Oriental literature includes stories about *Citrus*. The United States is now a principal grower of the fruit. Citrus fruits are among the best sources of vitamin C.

Kumquat (*Fortunella*), hog plum (*Spondias*), and bael (*Aegle*) are some of the other common fruits of the Rutales order. *Lansium domesticum* is cultivated for its fruit, known as langsat or lansa, in the Malayan region. The fruits of *Canarium album* are eaten like olives. The brown pulp of wood apple (*Feronia limonia*) mixed with sugar is eaten after straining through a sieve to remove the seeds. Santol (*Sandoricum koetjape*) is a favourite fruit in the Philippines.

Timber from trees of the Rutales order is often excellent. Some of the well-known timber trees are mahogany (*Swietenia mahogani*) of tropical America and the West Indies, Guiana crab tree (*Carapa guianensis*), African cedar (*Khaya senegalensis*) of West Africa, Indian redwood (*Soyimida febrifuga*), Chittagong wood (*Chikrassia tabularis*) of the Indo-Burma region, toon (*Toona ciliata*) of India, satinwood (*Chloroxylon swietenia*) of the Indo-Malayan region, yellow wood (*Flindersia oxleyana*) of east Australia, and sneeze-wood, or cape mahogany (*Ptaeroxylon utile*). The important gaboon mahogany, or okoume of commerce (*Aucoumea klaineana*), is used for veneers and plywood. Sapele mahogany (*Entandrophragma*), Colorado wood (*Quebrachia lorentzii*), Spanish cedar (*Cedrela*), and African walnut (*Lovoa*), though less important, are known the world over. The best known timbers are typically reddish in colour, lustrous, easy to work, and unusually free of tendencies to warp under changing conditions of moisture and other atmospheric factors. Such characteristics make these woods eminently suited for cabinetmaking.

Tannin-yielding plants are known in the group—e.g., *Carapa* species (Indo-Malaysia), *Schinopsis* species (South America), *Coriaria myrtifolia* (Mediterranean).

Many barks are medicinal. The bark of *Guarea rusbyi*, known to pharmacologists as cocillana, has properties similar to those of ipecacuanha (i.e., *Cephaelis ipecacuanha*), the dried roots of which contain alkaloids such as emetine, cephaeline, and psychotrine. The tropical South American caspasia bark is obtained from *Galipea officinalis*. The extract of Surinam quassia wood (*Quassia amara*) is a tonic. Bitters are prepared from the bitter principles present in the barks of several species, such as cedron (*Simaba cedron*) of Central America, simaruba bark (*Simarouba amara*) of tropical America, and quassia wood (*Picrasma excelsa*) of the West Indies. The bitter fruits of *Brucea amarissima* are used in Malayan and Chinese medicines, particularly to treat dysentery. Among the medicinal plants are neem, or margosa (*Azadirachta indica*), and bael, both of India.

The art of lacquering had its origin in China centuries before the beginning of the Christian Era and reached its climax of development there during the time of the Ming rulers, AD 1368–1644. The lacquers used for this were obtained from the varnish tree (*Rhus vernicifera*). The exudate of this tree, a milky liquid, darkens and thickens rapidly on exposure to air. Lacquer, when applied as a varnish, affords remarkable protection, as it is unchanged by acids, alkalies, alcohol, or heat up to 160° F (70° C). *Melanorrhoea usitata* is the Burmese lacquer tree.

Members of the family Burseraceae have an abundance of fragrant balsams (aromatic substances that exude from plants spontaneously or by incision) and resins in their bark. Myrrh and frankincense, both in the family Burseraceae, contain the fragrant substances. Resins and balsams are oxidation products of various essential oils and are very complex and varied in their chemical constitution. The resins, secreted in definite passages or cavities, exude from the bark and harden into lumps on exposure to air. Tapping usually is necessary for commercial exploitation. Other important resins are the carana gum (from *Protium carana*) of South America and balm of Gilead (from *Commiphora opobalsamum*). *Bursera gummifera* is the turpentine tree, which furnishes the resin known as

Timber
character-
istics

Trees of
the order

Skin
poisons

Miscellaneous products from fruits, seeds, and leaves

American elemi, cachibou, or gomart. From the elephant tree (*Bursera*) of Mexico is obtained a copal (a type of resin), which is used as a cement and varnish. Chian turpentine is obtained from *Pistacia terebinthus*. *Amyris elemifera* gives African elemi. *Canarium commune* furnishes the resin Manila elemi, and its nuts are edible (Java almond). *C. strictum* of Kerala (India) is the source of black dammar. Fruits of *Canarium* are also valued for their kernels, which are processed to produce a cooking oil. Fat from the seeds of *Carapa* is used for making soap and as an illuminant. Rue (*Ruta graveolens*) is a narcotic and stimulant. Its leaves are used as a flavouring herb in Mediterranean regions, and oil of rue is also distilled from it. Leaves of *Murraya koenigii* are used for flavouring curries in Indo-Malayan regions. Dyes from the fruits of *Coriaria* have been used to prepare indelible inks. *Khaya*, *Feronia*, and other genera give gums that can be used in place of gum arabic. *Anacardium humile*, *A. occidentale*, and *A. nanum* provide cashew or acajou gum, which is not only a reasonably good adhesive but also contains a small amount of cashew oil, which acts as an insect repellent. *Pistacia lentiscus* of Greece furnishes mastic. Fruits of *Semecarpus anacardium* are known as marking nuts. The young fruits yield a black resin insoluble in water, and this is used as a marking ink in Southeast Asia.

A few, like the tree of heaven (*Ailanthus altissima*), Persian lilac (*Melia azedarach*), cork tree (*Phellodendron*), and orange jasmine (*Murraya*), are grown in parks and gardens. Orange flowers are used widely in perfumery in France. Because of the pleasantly fragrant aroma, citrus flowers are used throughout the world as decorations in special celebrations. Various kinds of citrus oils are extracted from the rinds (peel) of fruits. These oils develop in sacs or vesicles, which are ductless and without communication with surrounding cells or the exterior.

The fruits of Persian lilac are poisonous to rabbits, poultry, pigs, sheep, and cattle. *Dysoxylum angustifolium* has a preference for riversides, and, during fruiting season, the fruits often fall into the water, where they are eaten by fishes. The flesh of such fishes becomes poisonous to men and animals. The foliage and fruits of *Coriaria* are reported to be very poisonous, and the fruits are used as a dog poison in Mexico. The poison ivy of North America is either of two species, *Rhus toxicodendron* and *R. radicans*.

NATURAL HISTORY

Life cycle. Members of the order are perennials. The trees in the group play a dominant role in the formation of tropical forests. Many are quick growing and evergreen, as in *Camposperma auriculata*, *Buchanania lucida*, *Melanorrhoea wallichian*, and *Mangifera indica*, or deciduous, as in *Lannea*, *Juliania*, *Pentaspadon*, and *Rhus*.

Gluta is remarkable in having intensely violet young leaves. The young leaves of *Mangifera* may be brown, reddish brown, or violet. The leaves of *Camposperma macrophylla* wither red. The deciduous trees usually flower when leafless. Some trees, such as *Samadera indica* (Indo-Malayan), are reported to flower only once in three years. *Mangifera lagenifera* flowers only at intervals of many years, sometimes as long as 20 years.

The flowers are mostly suited for pollination by insects. The coloured corolla (petals) and sometimes stamens (male reproductive structures) render some flowers conspicuous. Fragrance makes others attractive. The disk (a fleshy structure inside the flower) secretes an abundance of easily accessible honey. Cross-pollination appears to be favoured by the protandry (*i.e.*, the maturing of the stamens before the female parts of the same flower) in many flowers. In rue (*Ruta*) the stamens rise in the centre of the flower, shed pollen successively, fall back, and wither. The stigma (part of the female reproductive structure) ripens only after all the stamens have fallen back. Some of the stamens, though fallen back, may not wither, and they often retain some pollen. If by chance no insect visitor comes, the unwithered stamens may rise up again and shed the pollen grains on the stigma, effecting self-pollination. Here is a remarkable instance in which seed setting is ensured by self-pollination if necessary, but cross-pollination is sought until the last possible moment. The usual

visitors are small flies and bees. Many species are also vegetatively propagated.

Ecology. Members of the family Rutaceae are adapted to various conditions. Some are xerophytes (adapted to dry habitats), frequently of heathlike habit (low dense shrubs)—*e.g.*, the South African *Diosma*. Some members have short shoots whose leaves are reduced to spines. Generally, the members of the order do not prefer open land. Many have a liking for riverside flood zones, as in the Malaysian *Aglaia salicifolia* and *Dysoxylum angustifolium*. Some species of *Aglaia* and *Amoora* grow in swamps. *Xylocarpus obovatus* and *Amoora cucullata* are found in mangrove forests. *Suriana maritima* is coastal in distribution. Plants of tidal stretches include *Gluta velutina*, but species of *Balsamodendron*, *Boswellia*, and others have a preference for dry hills. Mango does best where the climate has strongly marked seasons and rain is scarce at fruiting time. A shower at the time of flowering is inimical to the development of fruits.

FORM AND FUNCTION

Distinguishing characteristics. Members of the families Anacardiaceae, Julianiaceae, and Burseraceae have resinous bark. Leaves are generally alternately arranged along a stem and are only rarely opposite or whorled. The leaves are mostly pinnately compound (leaves with small leaflets along both sides of a central axis) and rarely simple. An interesting form of leaf is found in *Citrus*, in which the simple blade is separated from the wedge-shaped petiole (leafstalk) by a joint. Because this type of leaf occurs in genera with compound leaves, it is believed that this is a reduced form. Reduction goes still further in

Drawing by M. Pahl based on (Podaceae) J. Hutchinson, *Families of Flowering Plants*, the Clarendon Press, Oxford; (Coriariaceae) G.H.M. Lawrence, *Taxonomy of Vascular Plants*, The Macmillan Company

Representative flowers and fruits of seven families of the order Rutales.

Unusual leaf colours

Flowering
habits

Citrus, in which the first one or two leaves of an axillary bud (a bud located in an axil or upper angle between a stem and a branch or leaf) are reduced to spines. Leaves of *Chisocheton* (family Meliaceae) show continued growth at their tips. Members of the family Rutaceae have gland-dotted aromatic leaves. Stipules, small leaflike appendages at the base of petioles, are usually absent, and if present, obscure. In *Ailanthus* (family Simaroubaceae) abscission layers (zones of weakness) form at the base of the leaflets as well as in the petiole; the leaflets usually drop first.

The flowers may be single in the axils of leaves, as in *Naregamia*, or they may be arranged in racemes (spikelike flower clusters), cymose spikes (clusters that bloom from the top downward), or panicles (many-branched flower clusters). They may be bisexual or unisexual, and individual plants may be polygamous (bearing unisexual and bisexual flowers on the same plant). In *Juliania* not only are plants dioecious (*i.e.*, the male and female flowers are on separate plants), but the male flowers are in racemose panicles (panicles that bloom from the bottom upward), and females are crowded in an involucre (a cuplike whorl of green leaflike bracts). Generally, both calyx (sepals) and corolla (petals) are present, but in some the corolla may be lacking. In *Juliania*, which lacks petals, the male flowers have a three- to nine-lobed calyx; the females have none. The calyx in other members is generally three- to five-parted, as in the corolla. A conspicuous disk, which may be annular (ring-shaped), cushionlike, cuplike, or tubular, is present in most of the members.

Stamens are usually double the number of petals, but in some they are equal to the number of petals or sometimes indefinitely numerous. Filaments (the stalks of the stamens) are usually free, but in most of the members of the family Meliaceae the stamens are united into a tube at the tip of which are borne the anthers, on the inside. Some species in the family Rutaceae also have filaments united at the base. When the flowers are unisexual, stamens (sterile stamens) are usually present in the female flowers, and pistillodes (sterile pistils—female structures) in the male flowers; such is not the case in *Juliania*, however. Anthers, the saclike, pollen-producing parts of the stamens, are two locular (chambered) and open lengthwise. The gynoecium (female complex) may be composed of one to 20 carpels, structures of the ovary wall. It may be unilocular (*Coriaria*), multilocular at the base and unilocular above (several members of the family Meliaceae), multilocular throughout (some members of the family Rutaceae), or the carpels may be separate, as in *Ailanthus*, *Brucea*, *Samadera*, and others of the family Simaroubaceae. Styles, the upper parts of the pistil, may be three, as in the family Julianiaceae, or they may be united, as in some members of the families Rutaceae and Meliaceae. Each carpel has a single ovule (seed precursor) in some members of the families Anacardiaceae, Simaroubaceae, and others; two ovules, as in the family Burseraceae and some members of the Meliaceae; or several ovules, as in some of the Rutaceae. In the family Julianiaceae the funiculus, the stalk attaching the ovule to the ovary wall, or placenta, is unusual in being cuplike; and the nucellus, the central part of the ovule, is generally massive. An outgrowth from the base of the funiculus called the obturator is present in several genera. These obturators aid in conducting pollen tubes to the ovules. The genus *Rhus* is exceptional in that the pollen tube enters the ovule through the chalaza, the end of the ovule opposite from where the funiculus attaches, in a process known as chalazogamy.

Fruit
types
and their
develop-
ment

The fruit may be a drupe (stony-seeded—*e.g.*, *Mangifera*), a capsule (*Swietenia*), winged (*Ailanthus*), a berry (some *Burseraceae*), a berry with a woody rind (*Aegle*), or a hesperidium, a three-layered berrylike fruit derived from a multilocular ovary, as in the genus *Citrus*. In *Coriaria* the petals enlarge and protect the fruits. *Juliania* has fruits enclosed in enlarged involucre. In some the fruits develop from an ovary with only partially united carpels, as in *Dictamnus*, and the carpels become isolated in fruit and dehisce (open) along the ventral suture. *Citrus* has a smooth endocarp (inner layer of a fruit) or encloses a fleshy part consisting of juicy emergences from the inner walls of the many-chambered fruit that fills the cavity.

Cedrela, *Swietenia*, and others have winged seeds. The seeds may be with or without endosperm, the starchy nutrient tissue for the developing embryo. The embryo in the family Burseraceae is sometimes rolled (contortuplicate). Cotyledons (seed leaves) are usually fleshy. Some genera like *Zanthoxylum*, *Citrus*, and *Mangifera* have many embryos in the seed. The embryos may come from different parts of the ovule. Apomixis, the development of unfertilized seed, is known in *Citrus*.

Physical and biochemical characteristics. It is known that the genus *Canarium* synthesizes a large series of turpenes, naturally occurring hydrocarbons of great variety, an example being turpentine, which is a mixture of turpenes. The oil obtained from various *Canarium* species contains paracymol, an aromatic hydrocarbon widely distributed in the essential oils of flowering plants. Trees with resinous sap are usually irritating and poisonous. Notable among these are some species of *Mangifera*, *Holigarna*, and the rengas trees of Malaya. Because of the irritant sap, the wood of several species, though excellent, is seldom used because no method is known to remove the annoying agent. It is known that the poison in these is a volatile and aromatic substance that gradually disappears from the sap after it has been drawn. It is doubtful whether this poison has any effect on animals such as monkeys and squirrels, which are known to eat the fruits of these trees, and insects, which feed on the sap. The irritant present in cashew nut shells has been studied in detail and has been found to contain cardol, anacardol, and anacardic acid. *Coriaria* is one of the very few nonleguminous (leguminous plants belong to the family Fabaceae, order Fabales) plants that fix atmospheric nitrogen in root nodules.

EVOLUTION

The order Rurales appears to be fairly old, as is evidenced by the available fossil records. *Anacardites amissus*, *A. antiquus*, *Rhus membranacea*, and others are known from Cretaceous Period (beginning about 136,000,000 years ago) rocks. Tertiary (beginning about 65,000,000 years ago) deposits are abundant in fossils of *Rhus*, *Pistacia*, *Cedrela*, *Evodia*, *Ailanthus*, and *Bursera*. Some families, such as Simaroubaceae, are not known from deposits older than the Tertiary.

Certain lines of specialization can be traced within the group. These include changes from spiral arrangement of leaves to opposite arrangement; reduction from two whorls of perianth (sepals and petals considered together) to one whorl and from two whorls of stamens to one whorl; gradual adnation (fusion) and cohesion of stamens to form a staminal tube; changes from bisexuality to unisexuality; changes from apocarp (single, free carpels) to syncarp (fused carpels); reduction in the number of carpels from several-carpelled ovaries to single-carpelled ovaries; and reduction in the number of ovules from many to one for each carpel.

As presented here, the order is derived from the order Saxifragales. Affinities with the orders Sapindales and Dilleniales cannot, however, be ignored.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. There are several characters, combinations of which are used by taxonomists to set the limits of the order Rurales, that may be used to assess the relationships among the various families included within the group and to determine connections with other groups. The characters used are, chiefly, woody habit, presence or absence of oil glands in the leaves, presence or absence of resinous bark, presence of a conspicuous disk within the stamens, nature of the staminal whorl, nature of the ovary, number and attachment of the ovules in the ovary, number of styles, and features of the seed and embryo.

Alternate systems of classification. There is no unanimity of opinion among taxonomists with regard to the systematic positions of the families included in the order Rurales. While most of them agree that there is close relationship among the families Rutaceae, Meliaceae, Simaroubaceae, and Burseraceae, some treat the family Meliaceae in a separate order, Meliales. The above four families are placed in the order Geraniales in the majority

Evolu-
tionary
changesDoubtful
affinities
of some
families

of earlier classification systems. These families are included in the order Rutales by several important authorities who, however, also include other families not presented here. The families Julianiaceae, Coriaceae, Cneoraceae, and Anacardiaceae have been placed in other orders or have been elevated to ordinal status by themselves in several different classification schemes. To this list have been added Podoaceae, Stylobasiaceae, Aitoniaceae, and Kirkiaceae in the classification presented here. The affinities of Aitoniaceae, Kirkiaceae, and Coriaceae are, however, obscure. On anatomical grounds there is strong evidence for considering the families Rutaceae, Simaroubaceae, Meliaceae, Sapindaceae, Burseraceae, and Anacardiaceae as forming a natural group, with Rutaceae standing somewhat apart, showing the closest resemblance to the family Simaroubaceae. It has been stated that pollen grains in the families Anacardiaceae, Burseraceae, Meliaceae, Rutaceae, and Simaroubaceae show similarities. Totality of evidence indeed suggests that these families are related.

The genus *Blepharocarya* has been segregated from Anacardiaceae to an independent family Blepharocaryaceae by some authorities who feel that the female inflorescence (flower cluster) of *Blepharocarya* is apparently almost exactly homologous to the cupule (*i.e.*, the structure forming the cup in an acorn) of the family Fagaceae (oaks and beeches). The genus *Rhabdodendron* has been removed from the family Rutaceae and referred to the family Phytolaccaceae on anatomical grounds by some authorities. *Rhabdodendron* has also been raised to family status, and this view has been endorsed by many. Sometimes the genera *Suriana*, *Irvingia*, and *Picrodendron* of the family Simaroubaceae are treated as independent families, based on anatomical characters. *Irvingia* is sometimes placed in the family Ixonanthaceae (order Geraniales). It has been suggested that the tribes Melieae, Cedreleae, and Swietenaeae should be raised to the status of families. This is not supported by wood anatomy, palynology (pollen morphology), or floral anatomy. The family Podoaceae was included under the family Sapindaceae by some early workers and with Anacardiaceae by others. It has also been suggested that it could be raised to a family in its own right; this has been accepted by many authorities and is so presented here. Palynology supports such a contention. The genus *Kirkia* was formerly included in the family Simaroubaceae by early authorities. Sometimes it is referred to the family Ptaeroxylaceae, with which it has, however, fewer similarities than differences. (N.C.N.)

Sapindales

The plant order Sapindales consists of perhaps 2,300 species in 168 genera and 9 families. Although not a very large group compared to many other natural orders of flowering plants, the Sapindales attract much attention because most species are trees or shrubs, many of which are favoured ornamental, shade, or timber trees of both tropical and temperate regions. Several of the tropical trees produce fruits with distinctive flavours. Some of the widely disjunct distribution patterns possessed by several genera are of interest to biogeographers.

GENERAL FEATURES

Growth habit and size range. Centred around the largest family, Sapindaceae, the order is basically a tropical to warm-temperate group, relatively nonspecialized in habit of growth. Most members of the order are small- to moderate-sized trees, large shrubs, or woody climbers. There are no small annual herbs, desert succulents, or aquatic species. Even in the forests none has evolved into an epiphyte (plant that grows upon tree branches), a saprophyte (nongreen plant that absorbs nutrients from dead organic matter), or a parasite. The most specialized growth forms are rather strange, unbranched, palmlike trees (such as *Pseudima* and *Talisia*), woody climbers (*Paullinia*, *Serjania*, *Urvillea*, and *Sabia*), subshrubs or perennial herbs with woody basal parts (*Diplopeltis* and *Melanthus*), and one annual vine (*Cardiospermum halicacabum*, balloon vine).

The largest trees of the order are in the family Sapin-

Representative plants from the family Sapindaceae, the largest family of the order Sapindales.

Drawing by R. Findahl; from (Sapindus flowers) A. Engler, *Syllabus der Pflanzenfamilien*

daceae; they include *Schleichera oleosa* (to 200 feet, or 60 metres, in Myanmar [Burma]), *Pometia pinnata* (to 130–160 feet, or 40–50 metres, in the Malayan region), and *Tristiropsis canarioides* (to 145 feet, or 45 metres, in New Guinea).

Distribution. Although the family Sapindaceae is mostly distributed in the tropics and subtropics, it does have some temperate representatives. In temperate North America these include, among others: *Sapindus* (soapberries) with two species that extend north as far as Georgia, Missouri, Kansas, and Colorado; *Ungnadia speciosa* (Mexican buckeye) of Texas, New Mexico, and Mexico; the circumtropical *Dodonaea viscosa* (hopbush) reaching into Arizona and temperate Florida; and several members of the climbing, tropical genera *Cardiospermum*, *Serjania*, and *Urvillea*, all represented in Texas. The herbaceous vine *Cardiospermum halicacabum* (balloon vine), which presumably has escaped from cultivation, is occasionally found as far north as Missouri, Illinois, and New Jersey.

Other warm temperate areas of the world also have a few representatives of the family Sapindaceae. China, for example, has, among others, the decorative *Koelreuteria paniculata* (goldenrain tree) and *Xanthoceras sorbifolium*. Chile has several shrubs or small trees, as does the Republic of South Africa. Temperate Australia has numerous shrubby species of *Dodonaea* (varnish leaf), subshrubs or even prostrate herbs of *Diplopeltis*, and small trees of such genera as *Atalaya* and *Heterodendron*.

The order Sapindales presents many examples of the widely discontinuous patterns of distribution that are of interest to biogeographers. Among the more striking disjunctions are the following: (1) the essentially temperate North American-Eurasian (represented by the genera *Acer*, *Aesculus*, and *Staphylea*), (2) the largely tropical Asiatic-American (*Meliosma*, *Sapindus*, and *Turpinia*), (3) the tropical American-African-Madagascan (*Paullinia*), (4) the Mascarene Islands-Fiji-New Caledonia (*Cassinia*), (5) the African-Asian-Malaysian-New Guinea region (*Aphania*, *Filicium*, and *Ganophyllum*), and (6) the tropical African-Asian-Australian-American (*Allophylus*, *Cardiospermum*, and *Dodonaea*). On the other hand, many genera are restricted to single continents or portions thereof, archipelagos, or single islands.

continuous
distribu-
tion
patterns

Differing
opinions
on the
status
of some
groups

Economic importance. Because of the large number of trees, the principal economic importance of the order is for wood products. Undoubtedly the best known timber tree is *Acer saccharum* (sugar, hard, rock, or black maple), which has been described as the most valuable hardwood tree of North America. The figured wood (curly and bird's-eye maple) is valued for cabinet work; the plain wood for construction, flooring, interior finish, and furniture. The species also provides choice firewood and abundant maple syrup and sugar from the sap. The hard, strong, heavy, close-grained wood is often beautifully patterned. The sugar maple, too, is a splendid ornamental, shade, and street tree because of its thick, shapely crown and the bright yellows and reds of its autumnal coloration. Other American maples are of lesser importance as timber, paper pulp, sugar, and ornamental trees.

Next to the maples, the buckeyes probably have the most economic significance in temperate areas. The Balkan *Aesculus hippocastanum* (horse chestnut), the American *A. glabra* (Ohio buckeye), and *A. octandra* (yellow, or sweet, buckeye) have light, soft, tough, fine-grained wood; although once used for artificial limbs, splints, and various kinds of woodenware, the wood is now more important as a source of paper pulp. Selected varieties and hybrids of these species are frequently cultivated as ornamentals or as shade or street trees.

Economically valuable species of the order in the tropics belong mostly to the family Sapindaceae. Some of the larger tree species, such as *Pometia pinnata* of the Malaysian-New Guinea region and *Blighia sapida* (akee) of tropical Africa, are useful for their timber. *Pometia pinnata* has been described as one of the most important timber trees in New Guinea, where its wood is useful for general construction, furniture, mouldings, veneer, floors, interior finish, and boats. In tropical West Africa, *Blighia sapida* wood is used for furniture, boxes, oars, punting poles, and charcoal. It is light, hard, close-grained, durable, and apparently resistant to termites. In tropical America, none of the family is of more than local importance for timber or fuel because of scarcity or low resistance to decay. Some woods of this order are not durable if exposed to weather; they are not resistant to termites or borers, are somewhat saponiferous (*i.e.*, they produce a soapy lather), are cross-grained and hard to work, require very careful seasoning, and have heartwood difficult to impregnate with preservatives.

Orna-
mental
and shade
trees

As with the temperate maples, some species of the family Sapindaceae are much esteemed as ornamentals or shade trees. Among the more desirable of these are *Koeleruteria paniculata* (goldenrain tree), *Unghadia speciosa* (Mexican buckeye), *Blighia sapida* (akee), various species of *Sapindus* (soapberries), and *Dodonaea viscosa* (hobbrush, varnish leaf).

The plants of the family Sapindaceae are better known in the tropics for their fruit than for their wood. Most popular for the fleshy pulp or succulent seed coats are *Litchi chinensis* (litchi), *Nephelium lappaceum* (rambutan), *Euphoria longana* (longan), *Blighia sapida* (akee), *Melicoccus bijugus* (Spanish lime), and *Aphania senegalensis* (Senegal cherry).

Saponins—chemical substances that produce soapy lathers—are present in the fruits, seeds, and other tissues of many members of the family Sapindaceae; genera such as *Sapindus*, *Aphania*, and *Paullinia* are used in tropical countries as soap substitutes. Crushed materials from some species of *Paullinia*, *Serjania*, and related genera stupefy fish when thrown into pools or small streams. The seeds of the Brazilian *Paullinia cupana* (guarana) contain much caffeine, and the roasted seeds are used to prepare a stimulating beverage. The bark of *P. yoco* (yoco) is similarly used as a caffeine source.

NATURAL HISTORY

Pollination agents. Although little is known about pollination in the Sapindales, most species are thought to be pollinated by insects. This assumption is based on the usual presence of petals, the strong tendency toward bilateral symmetry in the flowers, and the presence in the flowers of a glandular nectar-secreting disk. The small size

of the flowers of the families Sapindaceae, Aceraceae, and Sabiaceae indicates small flies or bees as the pollinating insects. The larger flowers of *Aesculus*, often supplied with coloured honey guides, which are patterns on the flowers that indicate the location of nectar glands, are visited extensively by bumblebees. The white-flowered *A. parviflora* (bottlebrush buckeye) is probably pollinated by moths. The brilliant red flowers of *A. pavia* (firecracker plant; red, or scarlet, buckeye) and *Billia hippocastanum* closely match the colour and shape of known hummingbird flowers, and in the South African *Melanthus* (honey bush) the sturdy, dark purplish flowers with their abundance of nectar probably attract the nectar-eating sugarbirds and sunbirds.

The maples (*Acer*) demonstrate marked evolution toward wind pollination. Some species, which retain both petals and well-developed, ring-shaped, nectar-producing disks, are mainly visited by bees. Others, particularly the hard maples, retain the disk but have lost the petals. *Acer saccharinum* (silver maple) has lost both petals and disk, and its flowers form headlike yellow or reddish clusters; pollination may occur by both insects and wind. *Acer negundo* (box elder) has lost both petals and disk and is functionally and anatomically dioecious—the male and female flowers occur on separate plants. The male flowers produce an abundance of pollen in large anthers from densely clustered and pendulous flowers. The female flowers are in drooping clusters and have long, narrow stigmas. This is a characteristic group of features that points to complete reliance on wind pollination and to the highly specialized position of the species.

Dispersal. The wide variety of fruit types in the Sapindales indicates adaptations to an equally wide variety of dispersing agents. Among the kinds of fruits are capsules (in *Aesculus*, *Cupania*, *Dodonaea*, and *Melanthus*); drupes, which are fleshy fruits with a single-seeded, stony pit (*Exothea*, *Melicoccus*, and *Meliosma*); berries (*Allophylus*, *Aphania*, and *Hypelate*); and samaroid schizocarps, fruits that break up into winged segments (*Acer*, *Dipteronia*, and *Thouinia*). Possibly the most primitive fruit type is the simple, readily opening capsule containing seeds with fleshy outer seed coats (sarcotesta). During the evolution of the order this became reduced to the arillode, or partial sarcotesta. Later, through transference of function, the fleshiness of the seed was replaced by the fleshy pulp of the fruit, the fleshy, outer fruit wall (drupe), or the entirely fleshy fruit (berry). All these fruit types are especially attractive to birds, and some also attract small mammals. The fruits of several genera, including *Sapindus*, *Melicocca*, *Nephelium*, and *Xerospermum*, are thought to be dispersed by fruit-eating bats.

Throughout the order there is a rather marked evolution toward bladdery or winged fruits designed for transportation by wind. Because of their wide occurrence on oceanic islands and tropical shores, the polymorphic *Dodonaea viscosa* (hobbrush) and some *Sapindus* (soapberry) species are thought to be transported by ocean currents.

Ecology. Most species in the order are found in tropical or subtropical rain forests, mostly below elevations of 6,600 feet (2,000 metres). A few of the larger tree species, as *Pometia pinnata* in the Malaysian-New Guinea region, are important constituents of the canopy layer of lowland rain forest. Most members of the order, however, are smaller trees and thus are common members of the lower rain forest strata. In tropical Australia and in New Caledonia, they are frequent components of drier, more seasonal types of tropical forest and woodland. *Dodonaea viscosa* (hobbrush) is a common pioneer species not only on beaches and lava flows but also on landslides and other disturbed areas inland. *Jagera* also has rather weedy tendencies. *Meliosma*, *Billia*, and *Turpinia* are, in Mexico, frequent components of high-elevation oak forests. *Acer* and *Aesculus* are important components of the temperate deciduous forests, with *Acer saccharum* and *Aesculus octandra* often among the dominant trees of the richest deciduous forests of eastern North America.

FORM AND FUNCTION

Distinguishing vegetative characteristics. The order of Sapindales is overwhelmingly composed of woody plants,

Wind
pollination
in maples

Representative plants from three of the smaller families of the order Sapindales.

Drawing by R. Findahl based on G.H.M. Lawrence, *Taxonomy of Vascular Plants* (1951); The Macmillan Company

Leaves

mostly trees, large shrubs, or woody climbers. Small subshrubs and herbaceous vines are rare. Most species have compound leaves, usually pinnately divided (*i.e.*, with the leaflets of each compound leaf arranged along both sides of a central axis). The leaves are alternate on the branches and are without stipules, the small leaflike appendages at the base of leafstalks. Some genera, however, have simple or palmately divided leaves (compound leaves with leaflets radiating from one point) that are either alternate or opposite in arrangement on the branches and may have very small or large stipules attached to the leafstalks. Stomates, microscopic pores in the leaf surfaces, are mostly restricted to the lower surfaces of the leaves and are anomocytic (surrounded by ordinary epidermal cells). Most leaves have mucilage cells or secretory cells or sacs or both. The vascularization of the petiole (leafstalk) appears in cross section either as a circular strand or as a ring, sometimes dorsally flattened, of separate vascular bundles.

Flower and fruit characteristics. Throughout the order there is a strong tendency toward obligate crossbreeding through progressive decrease in bisexuality, culminating in dioecism, a condition in which there are species with male and female flowers borne on separate plants. Most species in the order appear to be polygamous—having bisexual and unisexual flowers on the same plant—thus presumably combining the advantages of maximum fertility through inbreeding with increased variability through outcrossing. Some species are polygamomonoecious—*i.e.*, with bisexual flowers and both male and female flowers on the same plant. Most are apparently polygamodioecious, with male and female plants each bearing a few bisexual flowers. Many structurally bisexual flowers, however, as in many maples, are functionally unisexual, for either the stamens (male organs) produce no fertile pollen or the stigmas (sticky pollen-receiving areas of the female flower parts) are not receptive. Even in species with functionally bisexual flowers, cross-pollination is assured through protogyny or protandry; *i.e.*, the female or the male organs, respectively, mature before the structures of the other sex in the same flower. Some species—*e.g.*, *Acer platanoides*, *A. spicatum*, and *A. saccharinum*—are self-sterile. Most unisexual flowers in the order have become that way

through abortion, in which either the male or the female structures fail to develop, for the flowers often retain rudimentary structures of the nonfunctional sex. Only a few species, such as *Acer negundo* (box elder), have unisexual flowers with usually no vestige at all of the organs of the other sex. Thus, though most species of the Sapindales have insured outbreeding by one technique or another, most have not achieved complete anatomical dioecism.

The anatomically bisexual flower is either radially or bilaterally symmetrical and is typically small, except in a few genera. The male flowers often have a nonfunctional pistil (the female structure consisting of stigma, style, and ovary), called a pistillode, and female flowers similarly have sterile stamens.

The fruit is basically a capsule that splits open between the partitions but is often modified into many other types, such as fleshy, berrylike, stony-pitted, or dry and bladderly or winged. In the seed, endosperm (the starchy nutrient tissue for the developing embryo) is usually absent or scanty, and the embryo is often curved, folded, or contorted.

Fruit characteristics

EVOLUTION

Fossil record. The fossil record, the many present-day relict endemics (species of restricted range that are remnants of an earlier widespread flora), and the widely disjunct distribution patterns, often relict, attest to the ancientness of this group. Because of the easily preserved and recognizable leaves, flowers, and fruits, the fossil record is rather good for *Acer*, *Dipteronia*, *Aesculus*, *Cupania*, *Cupaniopsis*, *Dodonaea*, and *Sapindus*, among other genera. Fossil evidence indicates that the distributions of these genera in former times exceeded their present ranges, especially in north temperate areas.

The earliest fossils attributed to this order, believed to represent early ancestors of the genus *Sapindus* (soapberries), are two species of the fossil genus *Sapindopsis* from late Lower Cretaceous time (the Cretaceous Period extended from 136,000,000 to 65,000,000 years ago) of Crook County, Wyoming. *Sapindophyllum* is also from Cretaceous deposits. *Sapindus oregonianus*, one of several early Tertiary Period (beginning 65,000,000 years ago) fossils of the modern genus, is known from the Miocene Epoch (26,000,000 to 7,000,000 years ago) of Idaho, Oregon, and Nevada and approaches most closely still-living Asiatic species. Two fossil *Cupania* species, resembling living South American species, are known from the Goshen and Chalk Bluff floras of the upper Eocene–lower Oligocene boundary (about 38,000,000 years ago) of central Oregon. Several species of the fossil *Cupanites* are represented by leaves and fruits in European Tertiary deposits and by leaves in the Eocene (54,000,000 to 38,000,000 years ago) of the southeastern United States. Tertiary leaves and fruits have been described from 15 fossil species of *Dodonaea* from western Europe, the southeastern United States, Colorado, California, Bolivia, and Brazil. *Dipteronia*, now restricted to China, was represented in western North America during the Tertiary by *D. insignis*.

The genus *Acer* has the most extensive Tertiary fossil record, consisting of fruits, inflorescences, and leaves, throughout the north temperate and boreal zones north to Iceland and Spitsbergen. The red maples, now restricted to Japan and eastern North America, were once found in Eurasia and North America north to Greenland. As late as Miocene time they were represented in Oregon by *A. chaneyi*; in northern Italy they were present until the Pliocene (7,000,000 to 2,500,000 years ago) and Quaternary Period (beginning 2,500,000 years ago). Other groups of maples, now absent from Europe, were present there in the Tertiary. Fossil species of *Aesculus* ranged farther north in the Tertiary in Europe, eastern Asia, and North America than they do today.

Phylogeny. Most authorities are convinced that the two groups of families here called the orders Sapindales and Rutales are closely related (see also *Rutales* above). Within the Sapindales, the family Sapindaceae is the large, varied, and central group. Very closely related to the Sapindaceae are the families Aceraceae, Hippocastanaceae, and the monotypic (single-species) relicts *Akania* and *Bretschneidera*. Less closely but still rather obviously related to this

family complex are the Asiatic-American family Sabiaceae (at least the *Meliosma* group) and the African family Melianthaceae.

CLASSIFICATION AND TAXONOMIC STATUS

Criteria
used to
determine
classifi-
cation

Distinguishing features. Within the order Sapindales, the families are usually distinguished from one another by combinations of characteristics or by the level or degree of advance along certain evolutionary trends. The classification of Sapindales used in this article includes the families Sapindaceae, Akaniaceae, Bretschneideraceae, Hippocastanaceae, Aceraceae, Sabiaceae, Melianthaceae, Greyiaceae, and Staphyleaceae. Regarded as especially critical in the group's classification have been placement and division of the leaves; presence, size, and position of stipules; kind of inflorescence; symmetry, size, and sexuality of the flowers; number and position of stamens; presence, shape, and position of the nectar-producing disk; number of locules (chambers) in the ovary; kind of fruit; abundance or absence of endosperm; and the alignment of the embryo.

Within the larger families, classification depends largely upon such characteristics as the number and position of ovules in each locule, habit of growth, presence of a terminal leaflet in compound leaves, shape and position of the disk, and number of fertile stamens.

Alternate systems of classification. The major problems related to the classification of the Sapindales are how to circumscribe the order and whether the order is distinct from or better treated as a suborder of the Rurales. The families included in the classification used in this article are those of a recent classification system. Other recent attempts at phylogenetic classification treat the order differently. One treatment, for example, includes 8 of the above families along with 10 others, primarily from the Rurales, and a few from the Rosales and Geraniales. The family Sabiaceae is placed in the order Ranunculales. Another recent treatment includes 7 of the above families in the suborder Sapindineae, coordinate with the suborders Rutineae and Juglandineae, in the order Rurales. The families Greyiaceae and Staphyleaceae are transferred to the order Rosales of that system. Several other classification systems also exist, and if any consensus can be drawn from recent classifications, it might be that 7 of the families are indeed closely related, *Bretschneidera* being perhaps too close to the family Sapindaceae for independent recognition as a family; that the sapindalean group is too close to the rutalean group to treat the two as separate orders; and that the families Greyiaceae and Staphyleaceae do not belong with the Sapindales but probably in the vicinity of the Saxifragaceae and Cunoniaceae.

General agreement in the treatment of the families described here must await more research and accumulation of data. Especially profitable areas of research not yet sufficiently investigated are paleobotany, leaf and stem anatomy, comparative biochemistry, embryology, palynological (pollen) fine structure, and the natural history of sexuality, pollination, and seed dispersal. Such important living relicts as *Akania* and *Bretschneidera* need definitive study; *Sabia*, *Greyia*, and some of the little-known genera of the family Staphyleaceae require monographic treatment. Whether the families Aceraceae and Hippocastanaceae are truly distinct on the family level from the Sapindaceae also needs careful examination. (R.F.Th.)

Geraniales (geranium order)

The Geraniales, or geranium order, is an order of flowering plants comprising 20 families that include approximately 143 genera and about 4,000 species. Half of the families contain 50 species or less, but the two largest families (Malpighiaceae and Oxalidaceae) each have about 900 species. These two large families have predominantly tropical distributions, although the Oxalidaceae has some temperate-region representatives. The families Geraniaceae and Balsaminaceae each have over 500 species with worldwide distributions. The remaining families are mostly tropical, and two (Dirachmaceae and Lepidobotryaceae) are monotypic (*i.e.*, they contain only one genus

and one species); the former is confined to the island of Socotra, where it appears to be very rare, and the latter to tropical Africa.

GENERAL FEATURES

Size range and diversity of habitat. With representatives in both the tropics and temperate regions, the order shows considerable variation in life form, from small annual herbs—nonwoody plants with short life cycles—to trees (*e.g.*, *Lepidobotrys*) of the tropical rain forest that have leathery leaves furnished with the drip tip (a sharp point at the end of the leaf) characteristic of this habitat. The families Zygophyllaceae, Nitrariaceae, and Peganaceae are adapted to dry or saline habitats and contain numerous desert or subdesert species. Certain genera of the family Zygophyllaceae, such as *Zygophyllum* and *Tetradiclis*, show adaptations to the environment in their succulent—thick, fleshy, water-storing—vegetative parts; these are sometimes coupled with an annual habit and abundant seed production. Several *Zygophyllum* species are characteristic of the desert regions of the Middle East and Central Asia, as well as Africa and Australia. *Tetradiclis*, which also grows in the Asian deserts, resembles some of the fleshy species of the family Chenopodiaceae (order Caryophyllales) encountered in the same regions and can easily be mistaken for them. The genus *Sarcocaulon* (South Africa) is the only species of the family Geraniaceae adapted to desert life, although many species of *Erodium* and *Monsonia* occur in desert regions. The species of *Nitraria*, conversely, are highly salt-tolerant, deep-rooted perennials. Spines or thorns frequently develop in desert plants, presumably as a protection against grazing; two genera of the Zygophyllaceae (*Fagonia* and *Plectrocarpa*) exhibit these features markedly.

A succulent form is sometimes found in plants growing in damp ground or, particularly, in shallow water; these species commonly have translucent stems, often much branched and either sprawling or supported by the stronger waterside vegetation among which they grow. The families Limnanthaceae and Balsaminaceae provide good examples of such plants.

Certain plants in disturbed ground exhibit a feature useful in aiding distribution by vegetative means—the production of bulbils (small buds, or bulbs) on the roots, in clusters at the stem base, or in the leaf axils (angles between the leafstalks and the plant stem). Each, if broken off, is capable of growing into a new plant. This feature occurs in several species of *Oxalis*, certain of which (*e.g.*, *O. corymbosa* and *O. latifolia*), although tropical in origin, have now spread widely by this means to become troublesome weeds of cultivated areas even in temperate regions.

Perhaps one of the most striking and obvious anatomical features in the order is that of the very characteristic single-celled plant hairs (trichomes) of the family Malpighiaceae—so widespread in the family that botanists frequently refer to these two-armed hairs as malpighian hairs when describing their presence in other families. They are very diverse in form, sometimes almost without a stalk below the branching point, sometimes with a more or less elongated stalk, with the branch arms spreading or ascending, and from nearly equal to very unequal in length. Sunken, cushion-shaped, or sometimes stalked glands also occur in this family.

Economic importance. The economic importance of the order is not great, with the exception of flax (*Linum usitatissimum*), the source of a valuable fibre that has been used by man since prehistoric times. It is grown in most temperate regions, especially in central and western Europe, not only for its fibre, from which linen is made, but also for its seed, the source of linseed oil.

A few timber trees occur in the order, the most famous being guaiacum wood (or lignum vitae), yielded by *Guaiacum officinale* (family Zygophyllaceae). The wood—very hard, durable, and heavy in weight—is used in shipbuilding and for mallets. The heartwood of *G. sanctum* produces a resin used for making small objects that require weight, hardness, and strength. *Bulnesia arborea* is Maracaibo lignum vitae, used just as is *Guaiacum*. Some species of the family Malpighiaceae are locally employed

Desert
adapta-
tions

Timber
sources

as timber sources, particularly *Ctenolophon parvifolium*, the durable wood of which is employed for house construction in Malaysia. The timber of *Klainedoxa gabonensis* is tough and hard-wearing. *Houmيريا balsamifera* is the source of a good timber, easily polished and used for furniture, house framing, and general carpentry. *Sacoglottis gabonensis*, from western Africa, produces an easy-to-work white wood.

Three species of *Balanites* are used locally. *B. aegyptiaca* seeds yield Betu oil, employed in soap manufacture. The wood is hard and used in Africa for clubs, plows, sticks, turnery, and general carpentry. *B. maughamii* yields a clear oil similar to olive oil, and *B. orbicularis* is the source of hanjigoad, a gum resin. *Irvingia gabonensis* (family Ixonanthaceae) is the wild mango (not to be confused with the true mango, *Mangifera indica*), the fruit of which is edible; the fat from the seeds yields dika bread and dika butter, staple foods in West Africa. The tough, hard wood has been used for street paving and in houses. The seeds of *I. oiveri* are the source of cay cay fat, used in candle manufacture.

Bulnesia sarmienti (family Zygophyllaceae), the source of guaiac wood oil, which has a roselike scent, is used in soaps and perfumery. Geranium oil for perfumery is obtained from *Pelargonium radula*, *P. odoratissimum*, *P. capitatum*, and other species of this genus.

A few plants of the order have been used medicinally. The root of *Hugonia mystax*, for example, has been used locally in India as a snakebite remedy and to reduce fever. *Linum catharticum* has laxative properties similar to those of senna (*Cassia*). *Geranium maculatum* is an American species known as alumroot from the styptic and astringent properties—ability to control bleeding and draw together soft tissues—of a liquid extract from the roots. The only species of widespread true medical significance, however,

is the coca, *Erythroxylum coca*. From this species the local anesthetic cocaine is prepared. The leaves of *E. coca*, the coca tree, act as a nerve stimulant, and tribal peoples of South America chew them so that they can perform feats of endurance without fatigue. The components of the leaves act on the gastric nerves, eliminating the sense of hunger and allowing the user to go for a long period without food. As with most stimulants, however, the use of coca is followed by depression. *Banisteriopsis caapi* (family Malpighiaceae) contains the hallucinogenic alkaloid harmine.

Use of
coca
leaves

The fruits of some *Malpighia* species (e.g., *M. puniceifolia*, the Barbados, or West Indian, cherry) are edible either fresh, as preserves, or as flavouring for jellies. The gooseberry-like fruits of *Averrhoa carambola* (family Oxalidaceae) are also edible, and those of *Nitraria* species are sometimes eaten. *Klainedoxa gabonensis* and *Desbordesia glaucescens* have edible seeds; those of the former are eaten fresh or roasted, and those of the latter are used in sauces. The outer layers of the fruit are edible in several *Humiria*, *Sacoglottis*, and *Vantanea* species; both fruit and seeds contain a fatty oil.

The families Geraniaceae and Tropaeolaceae produce many well-known decorative plants. The Geraniaceae contains not only handsome species of *Geranium* itself but also the cultivated varieties and hybrids (crosses between different species) of the genus *Pelargonium*, to which the well-known pot and bedding geraniums of gardeners belong. The garden nasturtium is *Tropaeolum majus*, and some others of this genus also appear in gardens—notably *T. peregrinum*, the canary creeper. Species of the family Tropaeolaceae contain a hot mustard oil similar to that found in certain members of the mustard family (Cruciferae), a fact that no doubt explains the name “nasturtium” as applied to the garden *Tropaeolum majus*—

Lawrence, Copyright 1951 by The Macmillan Company

Representative plants of five of the smaller families of the geranium order.

botanically, the genus *Nasturtium* is the watercress. Some herbaceous *Oxalis* species have been grown as ornamentals, as have one or two trees of the genus *Averrhoa*, also of the Oxalidaceae. The nuisance value of several weedy species of *Oxalis* that spread by means of readily detached bulbils is far greater than the aesthetic value of their relatives, however.

The dye Turkey red is prepared from the seeds of *Peganum harmala* (family Peganaceae), a common plant of arid regions in southwestern and Central Asia.

NATURAL HISTORY

Seed dispersal. Within the Geraniales, the family Geraniaceae is perhaps the most interesting from the point of view of seed dispersal; the genus *Erodium* (storksbill), particularly well represented in desert and subdesert areas, shows adaptation to this environment. The fruit is furnished with a long beak formed from the fused tissues of the styles, the narrow upper parts of the ovary segments, or carpels. The beak segments of all the carpels of each flower remain fused until the fruit is ripe. When the fruit ripens and dries, these segments spring apart and become spirally shaped; each seed-bearing carpel falls to the ground. With rain or increase in humidity, the beak segments absorb water and straighten, driving the carpels into the ground. In some species the inner surface of the beak segments have feathery hairs that aid in wind dispersal. In *Geranium* and some other genera, such as *Pelargonium*, the beak segments separate from the base and curl but remain attached at their tips. This abrupt dehiscence—splitting open—may either catapult the seeds away or leave them hanging by slender threads, from which they are easily dislodged.

Within the family Zygophyllaceae is the genus *Tribulus*, which derives its name from the Latin name of an instrument of warfare—the caltrop, a four-pronged device that served as a horse-crippling spike. The fruit of *Tribulus* is similarly formed; the carpels become hard and are heavily covered with sharp spines and bumps. They are picked up by grazing animals that disperse them to other parts of the arid regions. A further specialized form of distribution occurs in the genus *Impatiens* (family Balsaminaceae); the fleshy, five-valved capsule opens explosively. The valves remain attached at the base and apex when ripe but split along the joints, their elastic nature drawing base and apex together so that the seeds are shot, often for a considerable distance, through the spaces thus created between the valves. When the fruit is ripe, this explosive rupturing may

be set off by a very light brush with the fingers—hence the name of a well-known European species, *Impatiens noli-tangere*, or touch-me-not. A Himalayan species, *I. glandulifera*, has spread widely along waterways in Europe and in North America by this means in a comparatively short space of time. Explosive dehiscence—opening of seed-bearing fruits—also occurs occasionally in the family Oxalidaceae, in this case activated by the elastic separation of the aril, an appendage on the seed, from the seed coat. Wind-distributed samaras, winged one-seeded fruits, as in the maples, occur in the family Malpighiaceae. Otherwise, dehiscent dry capsules, schizocarps, berries, and drupes are prevalent, with distribution by birds in the last two cases. Some (e.g., *Vantanea* in the family Humiriaceae) are distributed by flowing water.

Pollination. Pollination is almost universally by insects—generally by bees, wasps, and flies, but also by beetles and butterflies. Some North American species of *Impatiens*, however, are pollinated by hummingbirds. In the family Linaceae, floral dimorphism, the existence of two forms of flowers, has long been known. At least 29 species of *Linum* have been shown to exhibit long- and short-styled flowers. (The style is the narrow, upper part of the ovary, bearing the pollen-receiving surface, or stigma.) Fertility is greatest when the long-styled form is fertilized with pollen from the short-styled form and vice versa. The long-styled form is almost self-sterile, but the short-styled form is not; when both kinds of pollen are put on one kind of stigma, only that from the opposite kind of flower is capable of fertilization. Several species self-fertilize in the absence of insects; the filaments bend inward, and the style branches spread with age.

In *Geranium* both self-sterility and self-fertility are known; it is well established that the more inconspicuous the flower, the more advanced the ability for selfing by movement of the styles and filaments, as in *Linum*. In the allied genus *Erodium*, the flowers may be radially symmetrical (regular or actinomorphic) or strongly bilaterally symmetrical (zygomorphic) in forms of the same species. Apparently, forms with regular flowers tend to be self-fertilizing, and those with zygomorphic flowers to be insect fertilized, the enlarged lower petals serving as a landing platform for visiting insects.

Flowers of the remaining large genus of the Geraniaceae, *Pelargonium*, are odorous at night and are visited by nocturnal insects. Such genera as *Tropaeolum* and *Impatiens* have bee-pollinated flowers with nectar secreted at the end of a spur formed by the sepals. The anthers shed their pollen shortly after the flowers open, the stigma of the same flower remaining immature. Insect visitors, dusted with pollen, transfer it to the mature stigmas of older flowers in which the anthers have fallen, thus ensuring cross-pollination. Insect-pollinated genera often have nectar guides in the form of dark blotches or streaks at the base of the petals. One member of the family Malpighiaceae, *Bunchosia gaudichaudii*, has bee-attracting glands on the outside of the calyx (sepals).

EVOLUTION

Fossil record. Fossils of the order are not of great quantity, and older records, such as those for *Balanites* and *Zygophyllum* from the Tertiary Period (about 65,000,000 to 2,500,000 years ago) of Europe, are considered suspect. About 12 or 13 fossil plant groups have been placed in the family Humiriaceae, and fruits of three different species of *Humiria* have been found in Tertiary deposits in South America. A fruit of a *Sacoglottis* has been found in Tertiary deposits in Germany. *Wetherellia* fossils occur abundantly as fruits in the London Clay (Eocene Epoch—38,000,000 to 54,000,000 years ago) at the Isle of Sheppey, Kent, as do those of *Decaplatyspermum*. Fossil remains of *Erodium* and *Geranium* have been recorded from Baltic amber, as well as fruiting pedicels (stalks) of *Oxalidites* and a *Linum* fruit. *Linum* seed has been found in the Russian Pliocene Epoch (about 7,000,000 to 2,500,000 years ago), and pollen of *Geranium* in the Miocene Epoch (26,000,000 to 7,000,000 years ago).

Phylogeny. The order Geraniales is considered to have its closest affinity with the order Rutales; indeed, the gen-

Hutchinson, *The Families of Flowering Plants*, The Clarendon Press, Oxford

eral relationship is so close that it is difficult to distinguish the two orders. It is also very difficult to plot phylogenetic (evolutionary) relationships between the families included within the order Geraniales. Both the Geraniales and the Rutales are among the many orders believed to have arisen from the order Saxifragales.

Within the Geraniales, the families Tropaeolaceae and Balsaminaceae, with their specialized floral structure, are probably the most advanced families. The Balsaminaceae presents certain problems, however. It differs from the Geraniaceae in anatomy and pollen structure, and the disposition of the ovules is similar to that found in the Sapindaceae (order Sapindales); some authorities have included it in that family. It has also been placed near the family Vochysiaceae in the order Polygalales—an opinion given some weight by the similarity in development of the embryo in *Impatiens* and *Polygala*. Overall resemblances with the remaining families in the order Geraniales, however, outweigh these contradictory features.

The tropical family Hugoniaceae is considered to be the most primitive in the order; from it the family Linaceae probably arose. The families Ixonanthaceae, Humiriaceae, and Erythroxylaceae may also be derivatives. The family Malpighiaceae, however, is close to the Erythroxylaceae and Nitrariaceae, and through the latter, a transitional family to the Zygophyllaceae.

Two families are of particular interest for the form of their pollen grains. Those of the Limnanthaceae are unique and serve to emphasize its isolated position. They appear to be asymmetrically bicolpate (*i.e.*, they have two unequal germination grooves or furrows). In the family Balsaminaceae the grains are very strongly flattened, with three or four germination furrows and a reticulate (netted, ridged) surface pattern. This strong compression clearly differentiates them from the Geraniaceae, with which they are most commonly allied, and all other families of the order. The closest resemblance is with *Jollydora* in the Connaraceae (order Connarales).

The order Geraniales is as diverse in anatomy as in pollen structure, particularly the family Linaceae and the small families that have been separated from it. Diversities within this group are so complex in pattern as to render difficult any phylogenetic interpretation based on anatomy. Similarly, anatomy provides no clues on the separation of the family Oxalidaceae or the Biebersteiniaceae from the Geraniaceae, all of which have the same basic vascular structure—the system of internal water- and food-conducting tubes, the vessels—and the same characteristic ring of thick-walled cells (sclerenchyma cells) in the pericycle, a layer of cells surrounding the central vascular cylinder in roots. This ring, however, is absent in other families that have been closely linked with the Geraniaceae, notably the Tropaeolaceae, Balsaminaceae, and Limnanthaceae. The family Balsaminaceae also differs from the Geraniaceae in the presence of raphide (needlelike crystals) sacs in the leaf and stem, which are sometimes visible as transparent dots. In addition, the vascular bundles in the leafstalks (petioles) are arranged in an arc, not a full ring.

The woods of the Zygophyllaceae are very specialized, showing this family to be a natural group. The family Balanitaceae differs from it in having high, wide wood rays; nevertheless, the general anatomy suggests affinity with the Zygophyllaceae rather than the family Simaroubaceae. The anatomy of the family Erythroxylaceae differs considerably from that of the Linaceae, with which it was formerly united by botanists. The wood structure in Malpighiaceae, more highly specialized than in the Linaceae, Humiriaceae, and Erythroxylaceae, differs also from that of the Zygophyllaceae.

Thus, relationships within the order follow a confusing pattern because so many anomalous members are included, and no clear phylogenetic conclusions are possible.

CLASSIFICATION AND TAXONOMIC STATUS

The geranium order is very heterogeneous, consisting of a number of families united by apparent general relationship rather than by a readily defined common group of characters. It is thus difficult to define by features that do not break down at some point or other.

Above the generic level, it seems unlikely that orthodox taxonomic methods based on external morphology will shed much more light on classification within the order or between the Geraniales and allied orders—particularly the Rutales, Sapindales, and Polygalales. In addition, many conclusions based on other plant disciplines, such as palynology and phytochemistry, are still founded on inadequate sampling of the families concerned, and more complete information may shed the necessary light, particularly if species showing primitive characters are first selected. At the generic level and below, taxonomic revisions of such large and troublesome genera as *Oxalis* and *Impatiens* are still much needed. (C.C.T.)

Cornales (dogwood order)

The Cornales, or dogwood order, of flowering plants encompasses 10 families, approximately 350 genera, and over 3,700 species. By far the largest family is the Umbelliferae or parsley family, also called the family Apiaceae, with about 275 genera and 2,850 species, about 80 percent of the species in the entire order; it is practically cosmopolitan in distribution but occurs chiefly in the north temperate regions. By contrast, the second largest family, the Araliaceae, is principally tropical. The family Cornaceae is mainly north temperate; the seven remaining smaller families are from North America or eastern Asia, mostly in warm or wet regions.

GENERAL FEATURES

Size range and diversity of structure. As befits an order with representatives scattered through both tropical and temperate regions, the members of the Cornales show considerable diversity in form. Most of the families are predominantly woody, principally consisting of shrubs but also with a fair representation of trees and a certain number of climbers, such as the ivy. Only the Umbelliferae

Representative plants from the two largest Cornales families.

contains any large representation of herbaceous (non-woody) species; even within this family, the variation in life forms is remarkable. At one extreme are low-growing, creeping species, such as the well-known marsh pennywort of Europe (*Hydrocotyle vulgaris*) and allied species in North America and elsewhere. At the other extreme are large tropical trees or bushes such as the African *Stegonotaenia araliacea*. Even in temperate regions gigantic species of the family Umbelliferae occur—notably the giant hogweed of the Caucasus (*Heracleum mantegazzianum*), which can cause photosensitization of the skin by sunlight so that painful blisters are formed when the skin is touched. Spine-bearing species are found in the genus *Eryngium*, some of which are grown as decorative plants because of their bright amethyst colour. No parasitic or saprophytic plants—those that obtain nourishment from living or dead organisms, respectively—occur in the order.

Members
of the
order used
as foods

Economic importance. Some members of the order are of widespread or local economic importance. Foodstuffs are important products of the family Umbelliferae, which yields such well-known vegetables as celery (*Apium graveolens*), carrots (*Daucus carota*), and parsnips (*Pastinaca sativa*), as well as the Andean root crop *Arracacia xanthorrhiza*. In various eastern Asiatic countries the young stems and leaves of several species of the Araliaceae are esteemed as vegetables. Plants of the family Umbelliferae also yield some well-known spices and flavourings, such as caraway seeds (*Carum carvi*). Some of these were used in biblical times; e.g., coriander (*Coriandrum sativum*), aniseed (*Pimpinella anisum*), and cumin (*Cuminum cyminum*). The last species is also employed in perfume manufacture. A few medicinal plants also occur in the order. Dill (*Anethum graveolens*), gum ammoniac (*Dorema ammoniacum*), and asafoetida (from several species of *Ferula*) are products of the family Umbelliferae. The bark of *Alangium salviifolium*, an emetic, has been used as an ipecac substitute, and that of one or two species of *Cornus* has been used as a quinine substitute. An interesting discovery has been that *Camptotheca acuminata* (family Nyssaceae) yields camptothecin, which is useful in the treatment of leukemia. Ginseng, *Panax schinseng* (family Araliaceae), one of the most famous Chinese drugs, is used to treat many diseases. North American ginseng is *P. quinquefolium*.

Many species of the Umbelliferae are poisonous, including the hemlock (*Conium maculatum*) used in ancient Greece as a means of capital punishment; hemlock water dropwort (*Oenanthe crocata*), which sometimes kills livestock; and cowbane (*Cicuta virosa*).

Tetrapanax papyrifera (family Araliaceae) is the source of the so-called rice paper of commerce, used for, among other things, surgical dressings and artists' watercolour papers. The wood of some species of this family is used as timber. The wood of *Dendropanax arboreum* is strong and is used locally in general carpentry. The wood of *Didymopanax* species is less durable; that of *Kalopanax pictus* is very easily worked, pliable, and resonant. For this reason it has been used in China to manufacture drums. It is also suitable for furniture, in which form it has been called Japanese ash. Both *Cornus florida* (flowering dogwood) and *C. nuttallii* (western flowering dogwood) produce a close-grained wood, heavy and strong, that is suitable for turnery, wheel hubs, and similar products. The one species of the genus *Curtisia* (also of the family Cornaceae), *C. faginea*, the assegai, or Cape Lance tree, yields a valuable, red-brown durable timber that is close-grained, produces a good finish, and is valued for making furniture. Two species of *Griselinia* (*G. littoralis* and *G. lucida*) also produce heavy timber, but that of *G. littoralis* is rather brittle. The close-grained, heavy wood of *Alangium salviifolium* has been used to a limited extent in India, and some *Nyssa* species give tough but nondurable whitewoods.

Several species of *Cornus*, such as *Cornus mas* and *C. florida*, are grown as decorative shrubs because of their attractive, white petallike involucre, leaflike structures positioned just below the true flowers. *Cornus mas* also produces the cornelian cherry, which is eaten fresh or as preserves and is used in the manufacture of *vin de*

cornouille, a wine. *Aucuba japonica* is a popular garden evergreen. Several genera of the family Araliaceae are grown as decorative plants, including the common ivy (*Hedera helix*), of which there are also attractive variegated forms. One or two species of *Garrya*, notably *G. elliptica*, are grown as garden evergreens, which are attractive because of their glossy, dark-green foliage and reddish-purple flower clusters. *Nyssa sylvatica*, which is known as the sour gum tree, produces beautiful foliage tints in the fall, and *N. ogeche* yields the ogeechee lime fruits; its flowers also serve as a valuable source for commercial honey production. One or two species of *Helwingia* are also occasionally seen in gardens.

NATURAL HISTORY

Seed dispersal. The Cornales is not among the more remarkable orders as far as seed dispersal is concerned, because most of the families produce drupes—stony-seeded fruits—or berries, and bird distribution is thus widespread. The fruit types, however, are of some interest. In some species of *Nyssa*, a genus mainly of swamp trees or shrubs, for example, the drupes may be distributed by water, but they do not germinate or establish seedlings while immersed. Seed distribution attains its greatest complexity with the family Umbelliferae. The characteristic fruit of this family is a dry compound fruit, known as a schizocarp, which splits down a septum, or wall, separating the adjacent segments of the fruit into two portions, called mericarps. These are at first anchored by a thin stalk (the carpophore), which usually divides to force the mericarps apart. In some genera the mericarps are strongly compressed and thin, with a broad, membranous wing for wind dispersal. In others, such as *Oenanthe*, the mericarps are frequently found in flood refuse and debris along riverbanks; a corky layer in the fruit presumably provides

Representative plants from the central family (Cornaceae) and two of the smaller families of the order Cornales.

the buoyancy necessary for distribution by water. In still others the surface of the mericarps is covered with hook- or grapple-shaped spines to facilitate distribution by attachment to animals. The efficiency of this last method is evidenced by the frequency with which an Australian species with grapple-shaped spines, *Daucus glochidiatus*, is found in European fields that have been fertilized with Australian wool refuse, or shoddy.

Pollination. Most families of the order produce species with a distinct nectar-secreting disk, and in correspondence with the exposed position of the nectar, pollination is usually accomplished by short-tongued insects, such as beetles, flies, wasps, and short-tongued bees. Higher bees visit plants that produce large quantities of concentrated nectar, such as are found in various genera of the family Umbelliferae.

Insects are attracted to members of the order by many-flowered open inflorescences (flower clusters) rather than by single, brightly coloured flowers. It has been suggested that the many tiny flowers of most species of the Umbelliferae, whose members have the greatest versatility of pollination mechanisms in the order, may appear to flicker to a passing insect. Some species of *Cornus* and certain genera of the family Umbelliferae, such as *Tordylium*, have much-enlarged petals in the outer rows of flowers. The central flower of the umbel (a name given to the inflorescence; typical of the Umbelliferae) of the carrot (*Daucus carota*) is often purple. The southwest Asian *Artedia squamata* has enlarged outer petals coupled with a purple tuft of hairs in the centre of the umbel. All these variations presumably attract insects. In some inconspicuous species of the Umbelliferae, such as *Hydrocotyle*, self-fertilization apparently occurs. Self-fertilization also takes place in more conspicuous genera, particularly those with crowded heads, such as *Eryngium* and *Sanicula*, in which the elongating styles (part of the female reproductive organ) arch outward to bury themselves in the pollen of the anthers (part of the male reproductive organ); but additional insect pollination is more typical of these genera.

The distribution of the flower sexes in the inflorescences (or umbels) of the family Umbelliferae is very complex. In all cases, however, the purpose is to ensure cross-pollination by having the female organs develop in the first flowers to open and by having a corresponding reduction in the development of ones that open later. Wind pollination in the order Cornales occurs only in the genus *Garrya*.

EVOLUTION AND PALEONTOLOGY

The fossil record. Fossil remains of woody families have been well investigated. *Nyssa* is one of the many genera generally considered to be remnants of a moist-climate forest belt that extended in the Tertiary Period (about 65,000,000 to 2,500,000 years ago) throughout almost all of the Northern Hemisphere. The distribution of *Nyssa* is characteristic of such persistent remnants of otherwise extinct floras—i.e., it is centred on North America and eastern Asia. Paleobotanical evidence indicates that *Nyssa* apparently persisted in Europe into the early part of the Pleistocene Epoch (beginning about 2,500,000 years ago), when glaciation finally destroyed it, thus creating its present disjunct areas of occurrence. Tertiary remains are frequently found for the families Cornaceae (especially *Cornus*), Nyssaceae (*Nyssa*), Araliaceae, Alangiaceae, Umbelliferae, and Mastixiaceae. Records from the Cretaceous Period (136,000,000 to 65,000,000 years ago) are based upon fragmentary material and are taxonomically suspect. The Tertiary records range across the entire Northern Hemisphere from North America through Europe and Siberia to Japan and from all Tertiary divisions from the Paleocene Epoch (beginning 65,000,000 years ago) to the Pliocene (ending 2,500,000 years ago) and include fruits, pollen, wood, and leaves. The genus *Nyssa* has been particularly well investigated. Its fruits, readily recognized because they have a characteristic germination valve, sometimes occur in great quantities and show considerable variation in form, as in the brown-coal deposits at Brandon, Vermont, and in those of Europe and Japan. It has been found that the number of well-defined species of *Nyssa* was at least as great in the past

as in recent times. The family Mastixiaceae, it appears, may have been considerably richer not only in species but also in genera—which may explain why the few members of this family today demonstrate such an interesting combination of features, some generally regarded as primitive and others considered more advanced.

As might be expected of generally delicate plants, Tertiary remains of members of the Umbelliferae are more scanty, consisting mostly of fruits identified with such recent genera as *Oenanthe*, *Eryngium*, and *Chaerophyllum*.

Phylogeny. The order Cornales is considered to have arisen from the order Saxifragales, one of the more primitive orders of the postulated central line of descent from the order Magnoliales. Definite links with the Saxifragales are indicated by morphological resemblances between genera that represent the more primitive members of the Cornales and some genera belonging to the Saxifragales—notably in the families Hydrangeaceae and Escalloniaceae, such as *Broussaisia* and *Polyosma*. It has also been demonstrated that the wood anatomy of the family Cornaceae (in its widest sense; i.e., including the Mastixiaceae, Toricelliaceae, and Helwingiaceae, here treated as separate families) closely resembles that of the wood of the family Hydrangeaceae of the Saxifragales—e.g., that of *Philadelphus*. The chief difference between these two representatives of allied orders—the families Cornaceae and Hydrangeaceae—is in the parenchyma, a type of tissue composed of simple, thin-walled, undifferentiated cells. In both families the parenchyma tissue tends to be scanty or even absent, but, when well defined, it is paratracheal (i.e., disposed around or close to the vessels) in the Hydrangeaceae and apotracheal (not associated with the vessels) in all genera of the family Cornaceae with the exception of *Aucuba*.

There has been considerable phylogenetic speculation; yet, within certain limits, the authors of most general systems of classification have been in relatively good agreement. In addition to the order Saxifragales, the orders Sapindales, Rutales, Celastrales, and Rhamnales have received considerable support as close allies of the Cornales. All of them, including the Cornales, have progressively simplified flowers, the formation of an inferior or enclosed ovary, a tendency toward the production of flowers whose basic parts occur in sets of four, the formation of a nectar-producing disk surrounding the ovary, and a reduction in the number of ovules. The cumulative effect of this evidence is impressive, but it is probably also true that the many common characters indicate a common line of descent for all of the orders rather than lines of descent from one to the other; the most likely candidate as a common ancestor remains the order Saxifragales.

Within the order, most authorities agree that the Cornaceae is the basic and most primitive family and that the family Nyssaceae is derived from it. The remaining smaller families show distinct affinities with these two and, in some cases, also show links with the family Araliaceae.

As in many other plant orders, pollen morphology—form and structure of the pollen—has been of great assistance in the Cornales in helping to establish associations or divisions within the group. Pollen morphology has also provided evidence against unsatisfactory classification systems. The position of the family Alangiaceae, for example, has long been in doubt, and it has usually been compared with the Combretaceae. Evidence from pollen is against this association, however. On the other hand, the pollen grains of *Alangium chinense* show some similarity to those of certain genera of the family Nyssaceae (*Nyssa*, *Campylothea*) and of Cornaceae, thus associating a disputed link with an undisputed one (i.e., that between Cornaceae and Nyssaceae). Evidence from pollen confirms the separation of *Davidia* as a family distinct from the Nyssaceae and *Toricellia* and *Mastixia* as genera not belonging to the Cornaceae. In the last two cases, however, the evidence is less conclusive, since the family Cornaceae is diverse with respect to pollen morphology. Further investigation along this and other lines of research may lead to the permanent isolation of additional families from the Cornaceae to accommodate such genera as *Aucuba* and *Kaliphora*. The distinctiveness of the family Garryaceae is no longer

classifica-
tion

debated. The occurrence of pollen types of a more or less similar nature between Cornaceae and Garryaceae, and Garryaceae and certain Araliaceae provides a further confirmatory link within the order, as does the occurrence of common pollen types between the families Araliaceae and some members of the Umbelliferae.

With regard to relationships with other orders, pollen studies tend to confirm that the close association of the Cornales to the family Caprifoliaceae (order Dipsacales), specifically to the genera *Viburnum* and *Sambucus*, postulated by several authorities, may be well founded. Below the family rank, further studies with pollen work will probably confirm other types of evidence that several natural sections occur within the genus *Cornus*.

CLASSIFICATION AND TAXONOMIC STATUS

As far as the broad outline of the classification is concerned, the evidence for the unity of this order is impressive, and it is one of the few orders that has been given attention by many disciplines. Opinions differ as to whether the family Araliaceae should be separated as an independent order (Araliales) from the Cornales in the strict sense, largely because of the differing weight of evidence given by the study of anatomy, external morphology, and other evidence.

There is much need for further serological (study of plant proteins by means of effects similar to immune reactions in animals) and comparative biochemical studies on common species and groups of species in the order and particularly for general study in the developing countries of more obscure and atypical species, which, although largely ignored because they are of no economic value, often hold the key to plant relationships. (C.C.T.)

Celastrales

The Celastrales is a moderately sized order of flowering plants composed of 12 families containing about 147 genera and 2,000 species. The 4 major families (Celastraceae, the staff-tree family; Aquifoliaceae, the holly family; Hippocrateaceae, the Hippocratea family; and Icacinaceae, the Icacinaceae family) contain well over 90 percent of the total genera and species. The holly family, the best known in the order, is widely cultivated and economically important as an ornamental.

GENERAL FEATURES

Distribution, size range, and diversity of structure. The families of the order Celastrales are primarily tropical and subtropical; only the Celastraceae and the Aquifoliaceae occur to any degree in the temperate zones. The larger families have a broad distribution in their climatic range; the smaller have relatively limited ranges.

Most members of the order are either trees or shrubs; a few occur as herbs. The family Hippocrateaceae is somewhat unusual within the order in that it is composed primarily of woody vines, but shrubs and slender trees also occur within this family. Members of the family Celastraceae often are characterized by a scandent mode of growth—climbing or twining in other vegetation without the aid of tendrils. *Celastrus scandens*, the American bittersweet, is a familiar native shrub of the northeastern United States that exhibits this mode of growth, often reaching with long whiplike shoots to the tops of tall trees. The family Stackhousiaceae is unique within the order because all of its members are herbs. The leaves are consistently simple throughout the order and can be either alternate or opposite in arrangement. The flowers are usually perfect (both sexes in one flower) but are sometimes unisexual. They typically have only one cycle of stamens alternating with the petals and frequently a nectar-producing disk inside or outside the whorl of stamens. Several types of fruits occur within the order, but they all characteristically have only one or two ovules per locule (compartment within the fruit).

Economic importance. The economic importance of this order can be attributed primarily to one genus in the family Aquifoliaceae—the genus *Ilex*, which is composed of species of the well-known holly. The use of the

holly plant dates back many centuries. European pagans brought holly sprays into their homes, offering them to the fairy people of the forests as refuges from the harsh winter weather. During the Saturnalia, the Roman winter festival, branches of holly were exchanged as tokens of friendship. The earliest Roman Christians apparently used holly as a decoration at the Christmas season. Despite its past and present association with holy seasons, however, the root of the term holly is *holen* (*holegn*), an old English word meaning holly; holly has no etymological connection with the word holy.

Holly now is grown commercially to supply the considerable demand for its use as Christmas decorations. The red berries and shiny green foliage make it an ideal decoration, and, as it is an evergreen, it possesses excellent lasting qualities after it is cut. Hollies are also cultivated extensively as ornamentals, and numerous horticultural varieties have been bred. The attributes that give this group such ornamental appeal include hardiness, long life, beauty of form and colour, considerable variation in berry colour (there are red-, black-, and yellow-berried varieties), and variation in leaf form. In addition, hollies can be adapted to a wide range of uses—as accent trees, driveway plantings, hedges, foundation plantings, bonsai, topiary, and even as ground covers.

Holly also has other important economic values. It has been used for centuries as a hot drink, in the same manner as tea. Spanish explorers in 1542 commented on the use of yaupon holly (*Ilex vomitoria*) as a ceremonial and medicinal drink of the coastal Indians of the southeastern United States. In South America, particularly in Brazil, Paraguay, and Argentina, a drink called *yerba maté* enjoys a wide popularity; it is made from a native holly, *Ilex paraguariensis*. The best *yerba maté* is made from wild trees, although they are also cultivated for this purpose. The leaves are dried, ideally first in the sun and then over wood fires, after which they are steeped in hot water as in tea making. The active ingredient is the stimulant caffeine, whose content in the leaves approximates that of tea leaves.

The wood of holly, particularly that of the American holly (*Ilex opaca*), is also of some commercial importance. Small ornamental objects, inlay, and extremely fine furniture are made of its wood. The honey of holly has an extremely delicate flavour.

Although hollies are the commercially dominant group in the order Celastrales, several other plants also have economic value. A few members of the family Icacinaceae are raised domestically as garden ornamentals. In the family Celastraceae, the American and the oriental bittersweet are grown as ornamentals and are noted for their brightly coloured fruits. Several other members of the Celastraceae are also grown as ornamentals, particularly *Euonymus* species. In the Soviet Union two species of this genus, *E. verrucosus* and *E. europaeus*, are cultivated as sources of gutta-percha, a resinous, rubberlike substance that is used principally as an electric insulator and in temporary fillings for teeth.

NATURAL HISTORY

Specialized reproductive systems. The order Celastrales does not possess any unique feature that clearly delineates it from other orders; rather, it is classified on the basis of a number of unifying morphological characters. There are, however, within some families in the order, two particularly relevant features. The first is the frequent occurrence of a nectar-producing disk of tissue either to the inside or to the outside of the whorl of stamens (male reproductive structures) in the flower. This disk, which is a reduced whorl of stamens, serves to attract pollinators.

The second feature is the presence of polyembryony (more than one embryo in a seed) in some members of the family Celastraceae, especially in the genus *Euonymus* and in *Celastrus scandens* (American bittersweet). The polyembryony is a somatic type—the extra embryos developing from vegetative cells rather than from sex cells—known as adventitious polyembryony, in which the adventive, or extra, embryo originates from the inner integument, or covering, of the egg-containing body (ovule). A relatively

Place of holly plants in history

Multiple embryos in seeds

Representative plants from three of the largest families of the order Celastrales.

Drawing by M. Moran

uncommon phenomenon, polyembryony most frequently occurs in species of plants that are native to warm temperate or tropical climates. Further research may well reveal other examples of polyembryony within the order.

Beyond a general adaption to tropical and subtropical climates, the order Celastrales possesses no unusual ecological characteristics and no particular adaptations to special habitats or modes of life. A few families within the order, however, have some interesting ecological characteristics. The family Celastraceae often shows a scandent mode of growth, enabling shrubby plants to attain a considerable height by climbing and twining up neighbouring trees. The family Hippocrateaceae often includes woody vines that can also reach considerable heights. Three families exhibit an adaptation to xerophytic (hot and dry, often arid) conditions: the Stackhousiaceae to a limited degree, the Geissolomataceae, and the Salvadoraceae. Species of the family Salvadoraceae are often adapted to very salty coastal regions; such habitats require considerable morphological and physiological modifications for survival.

EVOLUTION

Fossil record. Three families—the Aquifoliaceae, the Celastraceae, and the Icacinaceae—are reasonably well documented in the fossil record. The Wilcox flora of the early part of the Eocene Epoch (38,000,000 to 54,000,000 years ago), found in about 130 localities in the southeastern United States, has many records of the Celastraceae, as does the Paleocene (54,000,000 to 65,000,000 years ago) flora of northeastern France. The London Clay flora, also Eocene, has members of the Icacinaceae, and the Aquifoliaceae and Celastraceae are well recorded in the boreal (northern) flora of the Tertiary (beginning 65,000,000 years ago) and in the excellent amber fossils of the late Eocene Baltic flora.

The genus *Celastrus*, in the family Celastraceae, is of particular interest because fossil members are well represented in many localities. In strata from the Cretaceous (about 125,000,000 years ago) fossil records from such disparate places as the northeastern region of China, Greenland, and Alaska have been found. The majority of records for this genus are from the central European floras of the Eocene and Miocene (7,000,000 to 26,000,000 years ago), from the Wilcox flora localities, and from the western United States.

Phylogeny. The phylogenetic (evolutionary) relationships of this order are not clear. The fossil record has not yet yielded much definitive information, and there is disagreement among the leading authorities; according to

one of them, the order Celastrales is thought to be closely related to the Saxifragales—apparently derived from the common ancestors of some families within that order. The orders Oleales, Santalales, and Elaeagnales appear to share a common origin with the Celastrales; they are also particularly closely associated with three Celastrales families: Icacinaceae, Aquifoliaceae, and Salvadoraceae.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The families have several common features: simple leaves; stamens alternating with the petals, with the exception of the Corynocarpaceae, a family of somewhat doubtful affinities; and usually one to two ovules in a locule. In addition, the nectar-producing disk is an important diagnostic character for seven of the families—the Celastraceae, Hippocrateaceae, Siphonodontaceae, Goupiaceae, Corynocarpaceae, Aextoxicaceae, and occasionally the Icacinaceae. The absence of the disk separates the Aquifoliaceae from the families most closely related to it. If the disk is present, its position inside or outside the whorl of stamens is of importance in further delineating families. Among the major criteria for delineating families within the order are: the presence or absence of stipules (leaflike appendages at the bases of leafstalks); the type of inflorescence, or arrangement of flowers; the presence of the lianoid, or climbing, habit; the polygamodioecious state (male and female flowers on different plants but with a few flowers of the opposite sex or a few bisexual flowers on all plants at flowering time); the structure of the gynoecium (female parts); the curvature of the ovule; and seed characteristics.

Taxonomic problems. Many taxonomic questions are yet to be resolved in this order. Some present-day taxonomists would consider various other families to be part of the Celastrales and would exclude some that are discussed here. Most authorities agree, however, that there is a solid core of distinct families that definitely belong in the Celastrales: Aquifoliaceae, Icacinaceae, Celastraceae, and Hippocrateaceae. The Geissolomataceae, Stackhousiaceae, Salvadoraceae, and Siphonodontaceae are accepted to a lesser degree as being definite members of the order, but some taxonomists would place them elsewhere. The members of the family Phellineaceae clearly belong in the Celastrales, but the one genus of the family (*Phelline*) often is considered as part of the Aquifoliaceae and not as comprising a separate family. The remaining three small families of the order—Goupiaceae, Aextoxicaceae, and Corynocarpaceae—generally are considered to have rather unclear relationships. The family Aextoxicaceae has a

Presence of the nectar-producing disk

particularly uncertain position, but it does exhibit the following characteristics of the order: simple leaves, a nectar-secreting disk, and two ovules per locule. The placement of these families in the Celastrales can be contested on the basis of present knowledge, but the problem cannot be resolved until more information is gathered both about these families and about the groups to which they appear to have affinities.

(E.C.Du.)

Rhamnales (buckthorn order)

The Rhamnales, or buckthorn order, is an order of flowering plants containing about 1,550 species in 3 families. General interest in this group rests primarily on the cultivated grape and the fruits known as jujubes. Both products have been consumed since prehistoric times in the Mediterranean countries. Tradition has it that Jesus' crown of thorns was fashioned from jujube twigs.

Bitropical
distribu-
tion

Scientific interest in the group is especially piqued by the number of genera (but no species) native to both Old World and New World tropics or subtropics. This kind of distribution is by no means rare, but the Rhamnaceae (buckthorn) and Vitaceae (grape) families are among the dozen families of flowering plants with the highest proportion of genera to be found in both tropical regions. Distributions such as these have yet to be satisfactorily explained, but at least they seem to give some evidence of great antiquity, perhaps 150,000,000 years or more according to some writers. It has been conjectured that such families probably arose before Cretaceous times (*i.e.*, more than 136,000,000 years ago), but there is no fossil evidence either to support or to undermine this opinion. In contrast to the Rhamnaceae and Vitaceae families, which are widely distributed in temperate and tropical regions, the Leeaceae family, comprising a single genus of about 100 species, is restricted to tropical areas from southern Asia to Africa.

GENERAL FEATURES

Size range and diversity of structure. Trees, shrubs, and woody vines predominate in the buckthorn order, herbaceous plants being extremely rare. Climbing plants are common. Perhaps the most bizarre forms encountered are the nearly leafless shrubs of *Colletia paradoxa* (Rhamnaceae family) of South America, whose short, opposite green twigs are modified to thick, laterally flattened thorns; this species is widely planted as a curiosity. The one notable tendency in the Rhamnaceae family is that of xeromorphism, meaning adaptation to a dry climate, which encompasses a syndrome of adaptations including reduced size of leaves, crowding of leaves, shortening of some branch axes, thorniness or spininess, and a low, shrubby, intricately branched habit. In the Vitaceae family the most notable tendency is that toward trailing and twining, in general a vinelike habit. There are no true aquatics, epiphytes, or parasites in the order.

Economic importance. Two important members of the buckthorn order that furnish edible products are the grape and the jujube. The grape (genus *Vitis*, family Vitaceae) has been a source of fresh and dried fruit and has been used in wine making in Mediterranean lands since prehistoric times. The jujubes (genus *Ziziphus*, family Rhamnaceae), spiny shrubs that abound in arid areas from the Mediterranean region eastward, also furnish fresh and dried fruit, and their culture probably dates as far back as that of grape culture. Other species furnishing edible products include *Hovenia dulcis* (Rhamnaceae), widely grown in China and neighbouring countries. The fruits of species of *Sageretia* (Rhamnaceae) are eaten fresh in parts of India and China. The leaves of *Sageretia thea* furnish a substitute for tea in southern China.

Green and yellow dyes are obtained from the fruits of various Old World species of *Rhamnus* (Rhamnaceae).

Two species of *Rhamnus* furnish the famous "Chinese green" or lokao dye, which is the only natural plant dye giving a green colour in cotton.

Laxatives are obtained from the berries and bark of species of *Rhamnus*, including the famous cascara sagrada from the North American *Rhamnus purshiana*.

The fruits of *Colubrina asiatica* (Rhamnaceae) of tropical shores and of the Mexican *Ziziphus amole* are used as soap.

Ornamental plants, other than shade trees, are rare in this order, owing to the usually small size and scattering of the flowers. But a number of species of the North and Central American genus *Ceanothus* (Rhamnaceae) are cultivated for their showy flower clusters and are sometimes called "wild lilac" or "French lilac." The Virginia creeper (*Parthenocissus quinquefolia*, family Vitaceae) is widely planted as a wall and ground cover.

A number of kinds of plants from the Rhamnaceae family furnish useful timber. Perhaps the most important economically is the tropical African *Maesopsis eminii*, which is now widely planted in Indonesia and Malaya as well as Africa; the lumber is used in building houses and boats. The wood of the genus *Ziziphus* is often hard and dense. Among the Old World species the wood of *Ziziphus mauritiana* is used for houses and for furniture; that of *Z. spina-christi* and of *Z. jujuba* for cabinetmaking; of *Z. xylopyra* and *Z. mucronata* for making wagons, agricultural implements, etc. Two Jamaican species, *Z. sarcomphalus* and *Z. chloroxylon* yield good wood, the former for construction and the latter a hard, heavy, elastic wood excellent for all purposes. The wood of *Hovenia dulcis* is valuable for furniture and musical instruments. *Pomaderris apetala* of southern Australia is especially used in cooperage. Some West Indian species have such dense, strong wood that it is often called "ironwood" in the trade—for example, *Reynosa latifolia* and *Krugiodendron ferreum*; the latter, air-dried, has a specific gravity of about 1.42 and is, thus, one of the densest woods known. The wood of *Colubrina arborescens* is used in the West Indies; that of the related *Colubrina oppositifolia* is so dense and durable that it was used as money by the ancient Hawaiians. *Rhamnus cathartica* and *R. frangula* of Europe furnish limited quantities of high-quality wood for various small objects, lathework, and furniture, as do *Berchemia zeyheri* of Africa and the North American *Condalia hookeri*.

Wood
products

NATURAL HISTORY

Little is known of the natural history of the Rhamnales order. Of the few species that have been intensively studied in culture, it can only be said that their vital success seems to be related, at least in part, to a lack of specialization. Seed germination is rarely checked, but in those species widely cultivated it seems to be prompt and easily achieved. Seed dispersal is usually by means of animals attracted to the fruits, although some genera have winged fruits adapted to wind dispersal. Reproduction is primarily by sexual means, although root sprouting is not uncommon. Pollination, in spite of the drabness and small size of the flowers, is accomplished by insects, which apparently are attracted to the nectar of the flowers. Extraordinarily little is known of the identity of the pollinators. Various small wasps, flies, bugs, bees, beetles, butterflies, and moths have been observed to visit the flowers of various species of the Rhamnaceae and Vitaceae families, but the extent to which any one species accomplishes pollination is unknown. In contrast to the situation in some groups, birds, ants, bats, and wind and water currents apparently are never involved in the pollination process in the buckthorn order. Special soil characteristics or other environmental requirements, such as a dependency upon fires, have not been found in the Rhamnales order. In fact, the members of the order are apparently so diverse as to their habitat requirements or at least their preferences that no cogent generalization is possible on this subject, though it can be said that, on the average, tropical forested areas are favoured. Many members of the order occur in forests and many in low forests or scrubby vegetation or desertic scrub. Few occur in grasslands. Certain spiny jujubes abound in some desertic and semidesertic scrub formations in the Old and New Worlds, but apparently nowhere does any member of the buckthorn order so dominate the vegetation that species of other groups are essentially excluded. While each species of the order seems to have a narrower range of habitat tolerances and preferences, the

Wide
range of
habitats

order, as a whole, ranges from exceedingly arid areas to rain forests and from sea level to elevations and latitudes near the perpetual snow line. Perhaps the most specialized habitat requirements are exhibited by *Colubrina asiatica*, which is restricted to tropical beaches. The seeds of this species are known to float unharmed in seawater for long intervals, and this apparently accounts for its dispersal to numerous islands scattered in a vast expanse of the Pacific Ocean.

Representative plant structures of the order Rhamnales.

FORM AND FUNCTION

Members of the buckthorn order share the distinction that the stamens, which are the male flower parts that produce the pollen, are exactly as numerous as the flower petals and, even more important, are attached opposite (just toward the floral axis from) the petal attachments. The number and placement of stamens as found in the buckthorn order, known as *obstemony*, is a relatively rare condition among flowering plants. This is another reason for the considerable botanical interest in these plants. In most groups in which the stamens are just as numerous as the petals, they are attached alternate to the petals—*i.e.*, nearly between them. Other characteristics that these plants share include a disk (a ring-shaped structure of several distinct masses of tissue) that is located toward the central axis from the stamen attachments (intrastaminal) and usually produces nectar. The ovules (immature seeds) are anatropous (*i.e.*, the micropyle or depression through which the pollen tube bearing the male sexual cells enters for fertilization is at the same end of the ovule as the stalk by which the ovule is attached), bitegmic (the micropyle is defined by a double flange of seed-wall tissue), and erect (they are attached at the bottom of the seed cavities of the ovary). Each of the cavities of the ovary has only one or two ovules.

EVOLUTION

Fossil record. Numerous fossil leaf impressions and a lesser number of fossil woods, fruits, and seeds have been referred to this order. The oldest such remains are from Cretaceous Period beds (about 100,000,000 years old), but the most numerous are from younger beds, especially those of the Miocene and Pliocene Epochs (about 10,000,000 to 20,000,000 years old). Unfortunately, there is no single character or set of characters of the foliage that, beyond a shadow of a doubt, distinguishes leaves of this order from those of some other orders. None of the leaves has been found in organic connection with flowers or fruits. Thus, the assignments of fossils to the Rhamnaceae or Vitaceae families range in probability of correctness from high to infinitesimal. In general, the oldest fossils are of the most dubious identity, but even some of the most recent fossils

are not certainly referred to the Rhamnales order. Numerous Cretaceous and early Tertiary leaf impressions (about 30,000,000 to 100,000,000 years old) previously referred to the genus *Ziziphus* have more recently been referred to *Cercidiphyllum*, which is not a close relative of the Rhamnales order. This illustrates the pitfalls of hasty assignment of fossil leaf impressions to modern kinds of plants. Fossils that are assignable to this order with a higher degree of probability have been found in Oligocene or younger beds (about 30,000,000 years old or less). By Miocene times (about 20,000,000 years ago), apparently both the Rhamnaceae and the Vitaceae families were large and diverse. This seems to indicate a much greater antiquity for both families, but it is impossible to trace them further back through the fossil record with any certainty. Evaluation and correlation of the fossil wood, fossil pollen, and fossil leaf evidence is not yet in a sufficiently advanced state to permit the presentation of a coherent evolutionary story.

Phylogeny. The idea that the buckthorns and the grapes are closely related dates at least as far back as 1671 and continues to be accepted by present-day botanists. The gathering consensus that the buckthorn and grape families have an especially close affinity by now amounts to a botanical article of faith. There have been important but relatively few dissenters. The placing together of the buckthorn and grape families (the latter including the genus *Leea* as a subfamily) as the narrowly construed order Rhamnales dates from 1892. Previously, these families had been associated at the ordinal level with families now placed variously in the Celastrales, Sapindales, Rurales, and Cornales orders. The assumption implicit in the close modern taxonomic placement of the families Rhamnaceae, Vitaceae, and Leeaceae is that they represent the products of a single ancestral population that was not the same as those from which plants of neighbouring taxonomic groups arose, though it may in turn, further back in time, have sprung from a population from which plants of neighbouring taxonomic groups also arose. This is thought by many to be a reasonable assumption, and, if it is accepted, then the relationships of such presumably closely related groups as the Sapindales and Celastrales orders can only be described as collateral to the Rhamnales order.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The following characters are especially useful to delineate groups within the order: the degree of lobing of the leaves; the presence or absence of a floral cup; the degree of bud closure by the calyx (sepals) or corolla (petals); the number of ovules per ovary cavity and the dorsal, lateral, or ventral placement of the raphe (a ridge along the ovule); the formation of the micropyle either by the inner or outer integument; the nature of the fruit, and, especially, whether the endocarp is soft or indurated; and the relative size of the embryo to the seed.

Taxonomic problems. The internal coherence and assumed origin from a single ancestral population of each of the three families circumscribed in the classification system in this article is unquestioned. Also, most authorities consider the Vitaceae and Leeaceae families to be naturally and closely associated, although it has been recently suggested that the family Leeaceae has as much in common with the Rhamnaceae family as it has with the Vitaceae family. The Leeaceae family, however, is probably a specialized derivative of the Vitaceae.

The internal coherence of the Rhamnales order as a whole, however, is not such as to convince all taxonomists that their close association at the ordinal level and their segregation from other orders such as Sapindales are required. Nor will the careful phylogenist find it necessary to postulate a common origin short of that which is common to various other orders such as Sapindales, Rurales, etc. Erect ovules and tricolpate pollen (pollen with three equidistant germinal grooves) are scarcely rare in such other orders, and *obstemony* could easily have arisen in two or more diplostemonous ancestors (*i.e.*, ancestors with two series of stamens, one series opposite, and one series alternate with, the petals).

The true measure of the interrelatedness of Rhamnaceae,

Relation
of the
buckthorn
and grape
families

Vitaceae, and Leeaceae families and the various groups with which they have been associated in the last 200 years is perhaps indicated by the gathering consensus that all these plants were derived ultimately from plants similar to some of the more primitive members of the Rosidae subclass. The character combinations by which families of the loosely coherent Celastrales, Sapindales, and Rutales orders are distinguished from one another are often of about the same magnitude and diversity as those which distinguish the Rhamnaceae family from the Vitaceae and from the Leeaceae families.

In fact, the suggestion is not at all farfetched that the ancestors of the Rhamnaceae may be found in the vicinity of the Rosales order, whereas those of the suborder Vitineae (including Vitaceae and Leeaceae families) may be found, as suggested by some authorities, in the neighbourhood of the ancestors of the Sapindales and Celastrales orders, that is to say, near Saxifragales order.

If this suggestion is accepted as having greater probability of correctness than the widespread assumption of a rather approximate common ancestry of the families here included in the Rhamnales order, then the taxonomic action indicated is the dismemberment of the traditional Rhamnales group. The Rhamnaceae family would then be referred to the Rosales order, and the suborder Vitineae either to the Saxifragales or to the Sapindales or, more likely, placed near these two orders as a distinct order, Vitales. (M.C.J.)

Oleales (olive order)

The Oleales, or olive order, is a small order of flowering plants containing a single family, the Oleaceae. The woody plants comprising this group are distributed throughout the world, except in the Arctic. Although they are found in many different habitats, only rarely are they the dominant plants.

GENERAL FEATURES

Diversity and distribution. A number of plants in this order are of economic or aesthetic importance—for example, the olive (*Olea europaea*) is the source of olives and olive oil; the ashes (genus *Fraxinus*) are noted for their hardwood timber; and many genera are famous for their horticultural merit—e.g., *Syringa* (lilacs), *Jasminum* (jasmynes), *Ligustrum* (privets), *Forsythia*, and *Osmanthus*. Most members are trees or shrubs, but a number, such as most jasmynes, are woody climbers. The tropical and warm-temperate species are evergreen; those from the colder north temperate zone are deciduous. Certain genera are found in both Eurasia and North America (e.g., *Fraxinus*), others are scattered throughout the tropics (e.g., *Linociera*). The largest genus, *Jasminum*, is confined to the Old World; any species growing wild in the Americas today have escaped from cultivation. The genus *Menodora* has an unusual disjunct distribution (found in widely separated regions without apparent connections) and is found in North America, South America, and South Africa. This distribution is also remarkable in that one species, *M. heterophylla*, is native to both South America and South Africa.

Economic importance. The most important economic product is the olive, the fruit of *Olea europaea*. This tree, particularly characteristic of the Mediterranean region and of very ancient origin, appears to have no truly wild progenitors, and, although the cultivated olive can seed itself, the offspring fail to produce the same large fruits. The olive probably arose at the dawn of agriculture, perhaps in the area of the Fertile Crescent in the Middle East. Very closely related plants with small, generally inedible fruits are found over a large part of the Old World—in southwest Asia; in eastern Africa as far south as South Africa, including the highest mountains of the Sahara; on Madeira Island in the North Atlantic; and in the drier areas of the Sino-Himalayan region. Today the olive is widely grown as a commercial crop in every country with a Mediterranean-like climate.

Although several members of the order Oleales are well known in horticulture, the most famous is the lilac, with

its colourful, sweetly scented blossoms. More than 400 cultivars of the European lilac, *Syringa vulgaris*, with colours ranging from lilac, purple, red, and pink to white and with single or double flowers, have been developed. Lilacs have been grown in gardens for centuries. The Persian lilac, *S. persica*, was one of the first plants introduced to Europe from the East; other Asiatic species have been introduced more recently.

NATURAL HISTORY

Members of this order are generally characteristic of woodlands, woodland margins, and forests of various types. Their ecological amplitude is not particularly great, and no members are especially adapted to desert conditions, salty soils, or the Arctic climate. Some species of *Fraxinus*, the ashes; of *Olea*, the olives; and of *Menodora* grow in dry climates, but not in true desert.

Pollination and diversity of flowers. Pollination is usually carried out by insects; many types are involved, and no particular specialization exists between the flowers and their pollinators. Nectar is usually produced within and at the base of the petals, and where these form a tube, it is more or less concealed. This ensures that in obtaining nectar the insect pushes down beyond the stamens (male pollen-producing structures) and stigma (the female pollen-receiving structure), touching both. A wide variety of insects visit flowers within this order, including bees, beetles of various kinds, and several different flies.

The most common flower colour in the order is white, although lilacs occur in a range of colours, and in *Forsythia*, *Menodora*, and a few species of *Jasminum* the flowers are yellow. In many genera in which the individual flowers are not very large, their conspicuousness to pollinating insects is increased by aggregation into fairly compact inflorescences (flower clusters) and by the production of a strong scent. In fact, the family Oleaceae, especially lilacs, jasmynes, and *Osmanthus*, is noted for its sweetly fragrant flowers. The name *Osmanthus* means “fragrance flower,” and this genus is particularly prized in China and Japan, where the dried flowers are used to scent certain Oriental teas, as are those of a few species of *Jasminum*. *J. sambac*, whose native provenance is uncertain but is probably India or Southeast Asia, is cultivated throughout the tropics and has been for many centuries. Its flowers are often used in making necklaces, or leis; and in Hawaii, where it is not native, it is especially grown for this purpose. *J. grandiflorum*, commonly called Spanish or Catalonian jasmine, has long been prized for its scent and cultivated in Spain and in southern France, where it is grown commercially for the extraction of oil of jasmine.

Other genera in the order are also noted for their fragrance, and even the privets (species of *Ligustrum*) have a strong, sweet odour. It is probable that some of the heavily scented, white-flowered members are pollinated at night. The pollinating insects of *Jasminum*, the fused petals of which form a longish tube, probably are night-flying moths with a long proboscis, a tubular sucking organ with the mouth at the tip.

In a few species of *Fraxinus*, such as the manna or flowering ash, *F. ornus*, which is native to the Mediterranean region, the flowers have small, white, strap-shaped petals and produce nectar. (The name manna ash refers to an edible sugary material exuded from the cut stem of the tree and at one time used in medicine.) Most species of *Fraxinus*, however, like the majority of forest trees in temperate regions, are wind-pollinated. The flowers of the white ash (*F. americana*), many other American species, and the common European ash (*F. excelsior*) possess no petals; quantities of pollen are blown by the wind, and the sexes of flowers on individual trees are often separate.

The chance of cross-pollination is increased by the development of unisexual flowers in several genera. The American genus *Forestiera*, like many ashes, has unisexual flowers without petals. In other genera, such as *Osmanthus*, the flowers of individual trees are often functionally unisexual because either the small ovary or the stamens are nonfunctional. In *Forsythia*, *Abeliophyllum*, and *Jasminum* the flowers of individual plants have either short styles (the narrow upper end of the ovary, with the stigma

Scent and colour

Origin of the cultivated olive

at its top), with the stigma below the level of the stamens, or long ones, with the stamens borne below the stigma. Seed normally develops only if pollen is transferred from a long-styled to a short-styled flower or vice versa. The plants in fact are self-sterile, and cross-pollination is essential.

Seed dispersal. Seed dispersal in a number of genera is aided by wind. The whole fruit is winged in *Fontanesia*, *Abeliophyllum*, and the ashes, in which the fruit is traditionally known as a "key." Individual seeds are somewhat flattened in *Forsythia*, *Syringa*, and the tropical genus *Schrebera* so that, after being shed from the capsule, each has a greater chance of being blown away from the immediate vicinity of the parent plant. In most members of the family (e.g., olive, most privets, and jasmines), however, the fruit is fleshy, generally dark purple or black, and has a hard, stony seed. In the natural state these fruits are consumed by birds, which helps to disperse the plant species.

FORM AND FUNCTION

Vegetative characteristics. A vegetative feature common to almost every member of the order is that of opposite leaves; a few species of *Jasminum* are the only exceptions. In many genera the leaves are pinnately compound—i.e., with numerous small leaflets arranged on both sides of a central axis, the whole constituting a single leaf. Examples include most species of *Fraxinus*, many jasmines, two lilacs (*S. laciniata* and *S. pinnatifolia*), and some species of *Schrebera*. In *Forsythia suspensa* the leaves are trifoliate (three leaflets) on some shoots, especially those growing rapidly, or single-bladed, as in the other forsythias. The groups of genera closely related to the olive have simple leaves, often thick and leathery, and in some species of *Osmanthus* the leaves are holly-like and prickly.

Representative plants of two genera in the order Oleales.

Anatomically the family is fairly uniform in its characteristics. Typically the water-conducting cells of the wood are small, and accordingly, the wood of the olive, with its fine and close grain, is prized for carving and turnery. The timbers of most species of *Olea* and their close relatives are very durable—even when used out-of-doors—and their hardness is often reflected in their native names—e.g., black ironwood for *Olea capensis* of South Africa, and devilwood for *Osmanthus americanus* of southeastern United States. Ash timber, from species of *Fraxinus*, has a worldwide reputation for toughness and resilience and is used for purposes where these characteristics are required—e.g., in tool handles, hockey sticks, and frames for tennis rackets.

Floral characteristics. Generally speaking, flower structure throughout the family is very uniform, with four sepals, four petals, two stamens, and two fused carpels forming a single superior (i.e., positioned above the other flower parts) ovary. The four petals (in *Jasminum* there may be seven, eight, or nine) are generally joined at the base to a greater or lesser extent to form a tube. Most species of *Fraxinus*, however, have no petals; nor do the four native olives of New Zealand (*Nestegis* species), the American genus *Forestiera*, and one of two Asiatic species of *Olea*. In *Chionanthus*, the fringe-tree, the long, strap-shaped petals form a very short tube at the base. Superficially similar flowers are found in the relatives of *Fraxinus ornus*; in *Linociera* the petals, split to the base, are held together in pairs by the base of stalks of the two stamens.

Although two is the characteristic stamen number, there are a few exceptions. *Nestegis* species, four of which are from New Zealand and one, *N. sandwicensis*, from Hawaii, often bear four stamens (occasionally up to six), as does the Malesian *Osmanthus scortechinii*. The ovary is much more constant in its characters, producing only one or, at most, two mature seeds in a fleshy olivelike fruit, in a winged "key" as in *Fraxinus*, or in a dehiscent (splitting-open) capsule as in the lilacs. In *Forsythia* the capsule may contain several seeds.

The pollen produced by members of the order is more or less similar in structure and of a rather nonspecialized type. The grains are ellipsoid with three (or four) longitudinal furrows and a finely reticulate surface. The minor differences in pollen structure among the various genera help confirm that the members form a natural group. Pollen grains somewhat similar in appearance are found, however, in several other families, including, for example, certain members of the family Celastraceae (order Celastrales).

EVOLUTION

Fossil record. The order Oleales is relatively poorly known from fossils. The oldest one recognized as belonging to the order is a leaf impression identified as *Fraxinus* from the early Cretaceous beds of Greenland (of about 80,000,000 years ago). Similarly, a leaf identified as *Fraxinus* is recorded from the Upper Cretaceous in the United States (about 65,000,000 years ago). Numerous fruits and leaf impressions, many bearing a very close resemblance to present-day species, have been found in later beds throughout north temperate regions, through to the Pliocene (7,000,000 years ago), and in even more recent deposits.

Other fossil members of the Oleales are first known from a fruit named *Olea headonensis* from the early Paleocene to Oligocene deposits in Britain (65,000,000 to 38,000,000 years ago) and one called *Oleaecarpium germanicum* from the upper Oligocene of Europe (about 30,000,000 years ago). Good leaf impressions of *Olea* dating from 20,000,000 to 12,000,000 years ago have been found in south and central Europe and North America. Leaves said to represent *Notelaea*, a present-day Australian genus, have also been found in the same regions, but in this case the generic identification is not so certain. A fruit identified with the tropical genus *Nathusia* (now known as *Schrebera*)—several living species occur in Africa, one in South America, and one in Asia—and called *N. rugosa* has been found in European deposits from the middle to upper Oligocene (30,000,000 to 26,000,000 years ago). tropical genus, *Jasminum*, has been recorded from fruits found in The Netherlands dating from 7,000,000 years ago in the lower Pliocene.

Phylogeny. The order Oleales contains the single, somewhat isolated family Oleaceae. A relationship has been suggested to certain families in the order Celastrales, such as the holly family, Aquifoliaceae, the Salvadoraceae, and the Icacinaceae, and it has also been suggested that these groups probably share a common ancestor in the order Saxifragales. There is little unanimity among botanists, however, as to how the family Oleaceae should be classified. It has been variously given ordinal status, sometimes alone or with the small family Salvadoraceae; classed within the order Gentianales; and sometimes placed in a restricted part of the Gentianales that is separated and called the order Loganiales. Most recently it has been placed within a modified order Scrophulariales. Because in most genera the petals are joined into a tube and the ovary is always two-parted, the family Oleaceae has usually been included in orders in which there is always a corolla (the collection of petals) of united petals and often in that group of families that have in the past been loosely called the "Bicarpellatae." It seems most probable, however, that the order Celastrales or its progenitors were the group from which the family Oleaceae arose.

The family Oleaceae seems to consist of two main groups of genera: those placed in the subfamily Jasminoideae and those in the subfamily Oleoideae. A study of the chromosome numbers of different genera confirms the affinity of various genera otherwise grouped on morphological characters. *Forsythia* and *Abeliophyllum* (which has been called white forsythia) are unique in that both possess 28 chromosomes in their vegetative cells; in a recent classification the two genera have been placed in the subfamily Jasminoideae along with *Jasminum* and *Menodora*, which have 26 and 22 chromosomes respectively. They are perhaps best treated separately, however, as the two pairs of genera bear little resemblance to each other.

Within the subfamily Oleoideae the genus *Fraxinus*, which, because the best known species lack petals, has traditionally been classified alone or with *Fontanesia* (because of the latter's winged fruits), is probably quite closely related to the many genera that produce olivelike fruits. The genus *Syringa* (lilacs) and the genus *Ligustrum* (privets) also belong in this subfamily and are closely related, despite their dissimilar fruits.

The small genus *Nyctanthes* (best known from *N. arbor-tristis*, a tree sacred to the Hindus), native to India, together with the related monotypic (having a single species) *Dimetra* of Thailand, has been variously classified in the family Oleaceae or in the family Verbenaceae (order Lamiales). Traditionally it belongs to the former and is possibly, if distantly, related to *Jasminum* or *Schrebera*; various anatomical and morphological characteristics suggest, however, that they should be treated as a subfamily within the family Verbenaceae.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The family Oleaceae is most easily recognized by a combination of characters: it has a woody habit with opposite leaves; flowers consisting of four sepals and petals (usually united), two stamens, and a united ovary of two chambers. There are exceptions, however, to most of these individual features.

The characters used to classify the genera within the family are the presence or absence of the petals and whether they are united to form a tube, however short, or free, and whether the petals overlap in the bud (imbricate) or are arranged with their edges touching (valvate). The type of fruit has also been important, whether it is a fleshy olive-like drupe (a stony-seeded fruit), a capsule that splits open to release dry seeds, or a winged samara (or key) as in the ashes. The fruit type, however, is no sure guide to relationships, nor is the absence of petals; *Nestegis*, for example, generally has no petals but is related to the petaloid genera *Olea*, *Osmanthus*, and *Notelaea*. The wild olive of Hawaii (*Nestegis sandwicensis*), however, has petals in its flowers. Similarly, although most species of *Fraxinus* have no petals, those related to *F. ornus* have well-developed

ones. Most ashes, such as the common European ash, *F. excelsior*, have flowers reduced to complete simplicity, for there are no sepals either, and because the sexes are often separated in different inflorescences or on different individual trees, the flowers consist only of a single, naked ovary or a pair of stamens. Many of these, however, are crowded together in branching inflorescences. There seems no doubt that this simplicity results from reduction and does not reflect primitiveness.

Taxonomic problems. The Oleaceae comprise a natural family, despite the number of individual exceptions to characteristic features, such as the lack of petals in some members and the occasional occurrence of alternately arranged leaves. Moreover, its classification in an isolated position is probably correct, for relationships with other families and orders are not clear. New information from the traditional study of morphology or anatomy that might help to elucidate these relationships is unlikely, but the rapidly developing fields of palynology (the study of pollen grains) and chemotaxonomy (the study of biochemical characters in relation to taxonomy) may well provide valuable new evidence.

Within the family the relationships of certain genera are uncertain. The subfamily Jasminoideae, as at present constituted, appears to be a rather heterogeneous assemblage containing the genera *Jasminum*, *Forsythia*, *Fontanesia*, *Schrebera*, and *Myxopyrum*. It is doubtful whether these genera are really more closely related to one another than to others now placed in the second subfamily, the Oleoideae. Here, however, the correct delineation of the genera themselves is often the problem. Should *Olea* be split into two or three separate genera (e.g., into *Steganthus* and *Tetrapilus*) as has been proposed, and within the genus *Osmanthus*, should the sections *Leiolea* and *Siphosmanthus* be raised to generic rank? As with problems at interordinal and interfamilial levels, new and significant morphological data are unlikely to be forthcoming. Chromosomal information seems of no assistance in this subfamily, but modern developments in biochemistry may eventually be of value.

Perhaps the outstanding problem at the species level concerns the relationships and origin of the cultivated olive. *Olea europaea* is not known in the wild, and, although closely related plants exist in many tropical and warm temperate parts of the Old World, it is uncertain whether the domesticated olive was developed from them and, if so, how it was done. Chemotaxonomic studies together with breeding and cultural experiments—growing species and plants from different provenances side by side and crossing them—might provide decisive information, but because the olive is a relatively slow growing tree such investigation could be undertaken only on a long-term basis. (P.S.G.)

Santalales (sandalwood order)

The Santalales, or sandalwood order of flowering plants, consists chiefly of members that are either partially or entirely parasitic on other plants. The order is of interest from several points of view. For example, the true sandalwood (*Santalum album*) and some of its near relatives play an important role in the practices of various religious groups in the Orient. The oil distilled from its wood continues to be of commercial importance and is used as a body ointment and a constituent of many soaps and perfumes. The European mistletoe (*Viscum album*) is thought to have had special ritual significance in Druidical ceremonies and lives in folklore today, its special status as the Christmas mistletoe having come from Anglo-Saxon times. *Phoradendron serotinum*, somewhat similar to its European counterpart, is an acceptable substitute in North America.

GENERAL FEATURES

The order contains trees up to 60 feet (18 metres) high and many shrubs and perennials, but no shorter lived annuals or biennials. The smallest member of the order is the dwarf mistletoe (*Arceuthobium minutissimum*), one of the smallest of all vascular plants, its flowering stems

Structural
variation
among
close
relatives

extending from the host plant for no more than about $\frac{1}{8}$ inch (3 millimetres).

Distribution and abundance. The great majority of species in the order are tropical and subtropical, but a number of genera, especially in the families Santalaceae and Loranthaceae, have temperate representatives. There are no truly Arctic species, although *Geocaulon* (Santalaceae) occurs north to the shores of Hudson Bay and to north of Inuvik in Canada. Of the mistletoe genera only *Arceuthobium* of the Northern Hemisphere is present in both the Old and New Worlds. In other large families in the order, such as the following, geographic distribution is more limited: Erythralaceae (Southeast Asia); Cardiotpteridaceae (Indo-Malayan); Dipentodontaceae (Southeast Asia); Medusandraceae (tropical West Africa); Myzodendraceae (southern tip of South America); and Cynomoriaceae (Mediterranean). Many of the parasitic forms are restricted in occurrence, but some of the smaller species may be extremely abundant and widespread, as in *Arceuthobium*, *Phoradendron*, and *Comandra*.

Importance. The economic importance of the order focusses on the sale of mistletoe, the use of sandalwood products, and the destructive effects of various parasitic mistletoes.

Mistletoe branches are gathered in rural areas of many central and western European countries and shipped to larger cities, to reach the market during the week before Christmas. In North America most of the commercially important mistletoe is harvested in Texas, New Mexico, and Oklahoma.

The use of sandalwood products is varied and goes back to the dawn of history. Sandalwood was known as long ago as 1700 BC (Egypt), and its use in the Far East is probably older. It is used as a ceremonial burning material during religious rites (especially burials) of Hindus, Buddhists, Parsis, and Muslims in Southeast Asia. The wood is also of excellent quality for wood carvings. The famous sandalwood oil is slowly distilled from the wood, that of older roots being especially high in oil content. Used for centuries as a body ointment, it has more recently been found to be extremely useful in fixing such delicate and quickly vanishing fragrances as jasmine. Both the United States and France import significant amounts of sandalwood oil from Australia and India, respectively, for use in the manufacture of perfumes and soaps. Because of the high cost of sandalwood, various substitutes are offered locally, some from closely related members of the families Santalaceae or Olacaceae in the sandalwood order (as in the Australian *Eucarya spicata* and the Indian genus *Ximenia*); others from quite unrelated families of other orders (as in *Erythroxylum* of the family Erythroxylaceae in India and the Venezuelan genus *Amyris* in the family Rutaceae). The best sandalwood oil is derived from the wood of *Santalum album*, a tree extensively planted in Southeast Asia. The most important industry is centred in the Indian state of Mysore, where it has been a state monopoly for many years. In Hawaii, the rise of King Kamehameha in the 19th century has been credited to the income from local sandalwood, which was exported to the Orient.

Although the great majority of species in the sandalwood order are parasitic upon other vascular plants, only the mistletoes cause serious damage to economically important plants. Primitive agricultural practices in many tropical areas frequently take little account of the occasionally very great populations of mistletoes on cacao, rubber, citrus, and many other trees, especially fruit. The genera *Dendrophoe* in the Indian region and *Struthanthus* in tropical America can be especially bothersome. *Viscum album*, the Christmas season mistletoe, deforms ornamental trees in many European countries, thus decreasing their value. The dwarf mistletoes, *Arceuthobium americanum*, *A. douglasii*, *A. campylopodum*, and *A. vaginatum*, are among the most serious forest pathogens (causes of diseases) in western North America because they attack most of the conifers in the region to varying degrees. Numerous *Phoradendron* species in the United States are also important pathogens of several trees, including walnut, oak, and some conifers.

NATURAL HISTORY

Predominance of parasitism. By far the most interesting evolutionary development in the order is the phenomenon of parasitism. More than half of the species in the order are parasitic, including all known members of the following families: Santalaceae, Loranthaceae, Viscaceae, Eremolepidaceae, Myzodendraceae, Cynomoriaceae, and Balanophoraceae. In addition, the genera *Cansjera* (Opiliaceae), *Olex*, *Ptychopetalum*, and *Ximenia* (Olacaceae) are known to be parasitic.

The most obvious evidence of parasitism lies in the occurrence of the haustorium, a specialized absorbing organ that penetrates into living host tissues and functions to transfer various materials from the host into the parasite.

In certain advanced species an extensive invasion of host tissues takes place. The intrusive organ becomes fragmented and branches out through the softer tissues of the host. This development is especially noteworthy in most members of the family Viscaceae, and probably in the genus *Phacellaria* (Santalaceae). In certain species of dwarf mistletoe (*Arceuthobium*) parasitic on conifers, a threadlike system develops internally and may reach into the growing point of the host. The host tree responds to such an all-pervasive parasite attack by developing a striking abnormal bushy growth at its top, known as a witches' broom.

Witches'
broom

The degree to which the parasitic species is dependent on the host is poorly understood but is probably high for most species, even obligatory under natural conditions. Chlorophyll is present in all species except those of the families Cynomoriaceae and Balanophoraceae, which are completely dependent on parasitism for nutrition. Studies with radioactive isotopes indicate that the more reduced forms, such as *Arceuthobium*, have a greater dependence on the host compared with greener and more leafy parasites such as *Phoradendron*.

Dispersal. In the treelike or shrubby species of the order, the nutlike or drupelike fruits are probably spread by birds or other animals. It has been known since Roman times, however, that a rather special relationship exists between mistletoes and birds. The fleshy, one-seeded berries of mistletoes are eaten by a great variety of birds. The extremely viscous seeds pass through the digestive tract unharmed and, when voided on a suitable object, will sometimes germinate and become established on a new host tree. Outside the mistletoe families, *Phacellaria*, and possibly some other santalacean, tree-inhabiting genera have evolved a similar dependence upon bird dispersal. In most mistletoes, the degree of dependence on this partnership is complete.

Several mistletoes, however, are not dependent upon birds. The Australian treelike mistletoe *Nuytsia floribunda* has winged, dry nuts, which hold no interest for birds. The minute fruits of the family Myzodendraceae bear long, hairy structures that attach themselves to leaves and branches of the host tree. These seeds are probably wind dispersed. In the dwarf mistletoe genus *Arceuthobium* (Viscaceae), the fruit is explosive, and the sticky bullet-shaped seed may travel up to 50 feet (15 metres) with astonishing velocity (initially, 80 feet, or 24 metres, per second) before adhering to a new host branch.

FORM AND FUNCTION

Vegetative characters. One of the most remarkable vegetative characters of the sandalwood order is the haustorium, a specialized absorbing organ that attaches to other plants and provides a means by which the parasite obtains water and nutrients from the victimized host plant. The typical young haustorium is a small bell-like or even clamplike organ, which attaches by its lower surface to a suitable host. From the central tissues of the anatomically complex haustorium a small intrusive, wedgelike organ grows out toward and into the host tissues, where it undergoes further development. The mature haustorial organ is characterized by a partial fusion of the xylem, or water conducting tissues, of host and parasite. The bell-like shape of the original haustorium soon disappears during expansion of the host-parasite contact zone. The size of the haustorium ranges from about 0.04 inch (1 millimetre) in

sandal-
wood oil

most species up to 1 foot (30 centimetres) in diameter in the exceptionally large, mature *Psittacanthus* haustorium. The *rosas de palo*, or *flores de palo*, sold as curiosities in Mexico, consist of the abnormally developed wood of the host tree where these large haustoria were once attached.

Few generalizations can be made about other vegetative characters. Nearly all species have simple leaves lacking stipules, and only a few bear surface hairs on the leaves or stems. In many parasites of the order, including, among others, all members of the family Balanophoraceae, leaves are reduced to scalelike organs. Even among species with well-developed leaves, including the temperate-climate woody species, the evergreen habit predominates and leaf fall in autumn is rare.

Flower and fruit characters. The flower may have both petals and sepals as in any typical flower, or, as is common in many members of the order, one or both of these sets of flower structures may be entirely lacking. The male parts of the flower, the stamens, usually occur in numbers equalling the number of petals and are positioned directly opposite the lobes of the petals rather than between adjacent ones. The female structure, the ovary, is positioned in the flower embedded in tissues below the region where the petals and sepals are attached, or it may be positioned higher up in such a way that the sepals and petals are located at its base. The first condition, termed inferior ovary, is the type that predominates in the order. Inside the ovary, two to several ovules, or developing seeds, are present. Sometimes these ovules lack the tissues that are destined to become seed coats in later development.

Floral characteristics in representative families of the sandalwood order.

Variations in fruit

The fruit ranges from rather large nuts in many members of the Olacaceae family to exceedingly minute fruits in the Balanophoraceae family. Almost invariably, the seed is solitary and contains special nutrient tissue, the endosperm. Especially in the parasitic groups a trend toward reduction of seed coats and embryos is evident, resulting in a propagative unit that in some groups is different from a typical seed. In most mistletoes a portion of the ovary wall supplies the viscous layer of this "seed."

Evolution and paleontology. There is no significant fossil record for the order Santalales, and evolutionary considerations must therefore be based upon contemporary members.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The order Santalales as defined by most authorities consists of an apparently unnatural (*i.e.*, unrelated by descent from a common ancestor) association of the Santalales core families (Aptandraceae, Eremolepidaceae, Lorantheae [in the broad sense], Lorantheae [in the restricted sense], Myzodendraceae, Octoknemaceae, Olacaceae, Opiliaceae, Santalaceae, Schoepfiaceae, and Viscaceae) with various other small families, the number and assortment of which depend upon the authority consulted. For this reason, it is virtually impossible to describe meaningful characteristics held in common by all members of the order. In the restricted conception of the order the primitive olacacean complex (families Olacaceae, Opiliaceae, Schoepfiaceae) plus the families Lorantheae and Santalaceae predominantly contains species with bisexual flowers; all other derived (*i.e.*, related by descent from primitive complex) families have unisexual flowers only (families Viscaceae, Myzodendraceae, Eremolepidaceae). Leaves are without stipules and are simple in all core families. In more advanced parasites, the leaves are often reduced to small scales. Ovules are few, frequently only one or two, and their attachment to the ovary tends to be on a central column unsupported except at its base. Seeds of nearly all have nutritive tissues called endosperm for the use of the developing young plant at germination.

Taxonomic problems. The extremely variable composition of this order and the apparently unnatural assemblage of families, even in many recently proposed systems, makes an acceptable grouping of families by relationship impossible.

The order Santalales, in the broad sense, is clearly a miscellaneous collection of families many of which are of uncertain affinity. Following detailed analysis, some of these families may eventually be placed in different orders related to but outside the order Santalales. Others (Cynomoriaceae, Balanophoraceae) seem to be included mainly because of their parasitism and extreme reduction and are not likely to remain in the vicinity of Santalales. Other parasitic families (Hydnoraceae, Rafflesiaceae) were at one time placed in the order for similar reasons. When stripped to families of undoubted relationship there remain in the order five to nine families, depending on taxonomic judgment. The olacacean complex (families Olacaceae and Opiliaceae, including Aptandraceae and Schoepfiaceae) is very inadequately known. Nearly all authors agree that other families in the order are traceable to Olacaceae-like ancestors, although the exact lineages are not completely agreed upon. The more common concept visualizes a descent of all mistletoe-like plants (Lorantheae, Viscaceae, Myzodendraceae, Eremolepidaceae) from Olacaceae, via Santalaceae. This particular evolutionary pathway has logical obstacles, except for Viscaceae. Separate evolutionary lines from the olacacean complex to each of Eremolepidaceae, Myzodendraceae, Santalaceae, and Lorantheae are perhaps a more accurate concept of descent. Viscaceae as a separate family might be derived from ancestral members of the Santalaceae family. (J.Ku.)

Polemoniales

This order of flowering plants, consisting of 8 families and more than 4,000 species, includes some of the most handsome and favoured of garden and wild flowers. European and American gardens sparkle in spring and summer with the colours of *Phlox*, *Polemonium* (Jacob's ladder or Greek valerian), *Ipomoea* (morning glory), *Myosotis* (forget-me-not), and *Phacelia*. Woodlands, glades, mountains, and deserts, particularly in North America, are often brilliantly coloured with their petals. Many other species, however, are often considered weeds, and a few justly deserve that appellation. Most members of the order are annual, biennial, or perennial herbs, many of which are delicate and ephemeral desert inhabitants. Several others, however, are woody trees, shrubs, or vines of great duration, but because of their limited size, number, and distribution they are not important timber producers. Two families of the order are unusual in consisting of nonphotosynthetic parasites.

GENERAL FEATURES

Economic importance. On the whole, the order is of minor economic importance. The one species of major importance as a food plant is the sweet potato, *Ipomoea batatas* (family Convolvulaceae). The nutritious tuberous roots of the plant have been an important food source since prehistoric time. Utilization is now worldwide, but long before European man began to eat the plant its use was well established in South America and in the Pacific Islands. The fact that it was well known as a crop plant in two isolated geographic areas before botanists began to study it presented an interesting dilemma for students of the origin of cultivated plants. Was it originally American or Polynesian? Even though the sweet potato is not known as a wild plant, its apparent close wild relatives are found in South America. This, and other compelling reasons, led most botanists to the conclusion that the cultivated plant originated in South America and was transported at an early time to such diverse regions as New Zealand, Hawaii, and Easter Island. The mode of transport and the migration route of the sweet potato to these remote regions are matters not yet resolved.

Other members of the family Convolvulaceae (morning glories) have aroused recent interest because their seeds contain significant quantities of the hallucinogenic chemical substances lysergic acid amide and isolysergic acid amide, which are similar to the drug LSD. This psychotomimetic attribute was known to the Aztecs, and certain Mexican Indians still use the seeds for divinatory purposes. Species of the genera *Ipomoea* and *Rivea* possess significant quantities of the drugs, the different species varying in their potency. The natural quantitative variation in the drug content of the seeds leads to public-health problems among illicit drug users because it is difficult to determine the drug content of a seed before it is eaten. Serious psychic effects and even death have resulted from uncontrolled use of the seeds. Since many *Ipomoea* species are common weeds, it is unlikely that legislation would be effective in controlling the use of morning glory seeds for psychotomimetic purposes.

Use of members of the order for aesthetic purposes as garden ornamentals is another economic application of these plants. Compared with the cash value of sweet potatoes, the commercial value of these plants as ornamentals is not very great, but the annual spring perusal of seed catalogs is a much richer experience because of the inclusion of members of the families Convolvulaceae, Polemoniaceae, Hydrophyllaceae, and Boraginaceae. Species of the genus *Dichondra* (Convolvulaceae) have unique value as turf plants in tropical and subtropical regions. They are tough, low-growing, small-leaved, small-flowered plants that grow appressed to the ground, qualities that enable them to compete successfully with grasses. They are superior to grasses in one respect—they need little or no mowing. A vigorous stand of *Dichondra* provides one of the most beautiful lawns possible.

Size range and diversity of structure. As treated here, the eight families of the order Polemoniales can be grouped into two categories. The three small families, Cuscutaceae, Lennoaceae, and Hoplestigmataceae, are sufficiently distinct individually that each will be discussed separately. The five larger families, Polemoniaceae, Convolvulaceae, Hydrophyllaceae, Boraginaceae, and Loasaceae, however, show a similar range of variation so that one family may serve as a model to portray the whole group of five. The family Polemoniaceae is ideally suited for this, since it is large enough to illustrate most of the variation encountered in the other families, yet small enough to have undergone critical study.

Growth forms. The form of members of the family Polemoniaceae and the entire order includes a great range of morphological (structural) diversity. Large shrubs and small trees grow in the Andes in South America. In North America, the nearest approach to this growth habit is seen in some Mexican plants, but most others are at best low shrubs or woody-based perennial herbs. The latter constitute a significant part of the family in western North America. Large herbaceous perennials with extensive underground stems are another important growth form in

the family. There are other plants that may be weakly perennial but that tend for the most part to be biennials. Such plants often attain large size. By far the largest number of species in the family are annuals. Some tend to grow for many months when conditions are favourable, but many others are desert annuals, whose growth is rapid and usually complete in just a few weeks. Some annual members of the family are extreme dwarfs that flower while seemingly mere seedlings. Some of the latter rarely produce true foliage leaves but exist on the produce of their cotyledons ("seed leaves"), photosynthetic stems, and floral bracts.

Stems. Stem growth varies from extensive in the trees and shrubs to very little in desert annuals. The patterns of stem growth include underground rhizomes (rootlike stems), thickened woody crowns, typically branched aerial stems, and vines.

Leaves. Leaf form is similarly varied, ranging from pinnately (lateral leaflets arranged along a central axis, featherlike) or palmately (all leaflets radiate from a common point) compound to simple needles and from large to nearly lacking. In a few cases, the tips of compound leaves grow out into tendrils, which provide support in the climbing vines. The general outline of the leaf includes those that are broadly elliptical or lance-shaped, those that are elongate but narrow, and small needles or scales. Leaf margins may be lobed, toothed, or smooth. Veins may be extensive, branched, and prominent or so poorly developed as to be nearly lacking in some leaves. Leaves are often clothed with a hairy covering that may often consist of cobwebby, prickly, or glandular plant hairs. In most members of the family the leaf arrangement is alternate along the stem but in two genera it tends to be opposite.

Flowers and fruits. Flowers of the order Polemoniales are usually disposed in clusters in which the first flower to bloom is the apical one; thus, they are cymose. The cluster may be loose or, in a few cases, a compact head. Some species have clusters consisting of hundreds of flowers whose period of bloom may last many days. Others have only a few flowers per inflorescence (flower cluster), and a few species have a solitary flower at each branch tip. In these, the flowers are either very large, or, if smaller, the plant is so compact that it may literally be covered with flowers—each flower solitary at the end of a crowded branch. The flowers of the order Polemoniales are highly varied in structure, form, size, and colour; however, they share a basic plan, consisting of hypogyny (sepals, petals, and stamens attaching at the base of the ovary), five united sepals, and five united petals, to which the filaments of the five stamens are fused; they generally have three carpels (ovary wall structures) united into a three-locular (chambered) compound pistil (female structure). Nectar, produced by special glands at the base of the pistil, often collects in the corolla base. The sepals vary in shape from a large saucer-shaped structure to a constricted tube. The tissue along the midrib of each sepal tends to be green and dense, but the tissue between the lobes is thin and membranous. The membrane may be flat, corrugated, or prominently ridged. In some genera, the calyx (all sepals considered together) enlarges bladderlike in fruit, whereas in other cases the membranes are ruptured as the enclosed fruit enlarges. The most striking variation in flowers is seen in the petals or corolla. Usually the corolla is radially symmetrical, but in some genera it tends to be bilabiate (two-lipped). In other aspects of form it may be described as rotate (round, wheel-like), campanulate (bell-shaped), tubular, funnellform, or salverform (trumpet-shaped). The individual corolla lobes may be rounded, truncate, pointed, or erose (with eroded margins, as if gnawed). In size the corolla may be minute or up to several centimetres long or broad. Colours vary from white to yellow through orange, pink, red, mauve, or blue. The flowers may be uniform or multicoloured, often with conspicuous spots or streaks arranged in definite patterns. Stamens (male reproductive organs) likewise vary. They may be large or small, set deeply within the flower, variously disposed upon the petals, set at the orifice of the corolla, or strongly exserted (extended beyond the opening of the corolla tube). are typically protandrous; *i.e.*, the stamens mature before the stigma (tip of the female organ, where pollen is deposited) is receptive to pollen. The pistil and resulting fruit may bear one seed, a few seeds, or many seeds. Generally, the mature fruit is a dry capsule that is often dehiscent (capable of splitting along definite lines) into three parts. The stigma, as is the case with the stamens, may be set deeply within the flower or long exserted. The seeds vary in size, weight, colour, markings, and in the presence or absence of a mucilaginous coat, and they may have a broad wing, especially in the tropical woody species. Pollen grains, elaborately sculptured, show variations that may exceed the variations in other features of the plants.

Other variations. The previous examples, taken mostly from the family Polemoniaceae, reflect some of the basic features of the order as a whole. There are, however, some outstanding specializations found in other families that deserve additional mention. In the matter of floral biology, the family Boraginaceae shows heterostyly. This is the condition of the flower in which members of a species population differ in the length of the stigma relative to the length of the stamens. Most often encountered is the distylous condition, wherein the style is very short and the anthers stand near the throat of the corolla (a condition known as thrum form), or the styles are elongate, with the stigma standing in the throat of the corolla and the anthers disposed in the base of the flower (pin form). This is an arrangement that enhances crossing because pollen from a thrum plant normally leads to fertilization in a pin flower, and pollen from pin leads to fertilization in thrum. In regard to seed dispersal, many unusual modifications

related to dispersal by fur-bearing animals are found in the Boraginaceae. In most members of the family the two-carpellary ovary divides into four nutlets at maturity—the fruit wall of each nutlet tightly embracing a single seed. The outer surfaces of the nutlets bear hooks, barbs, bristles, and similar structures that adhere to fur. The family Loasaceae, which is usually not placed in this order, differs in having an inferior ovary (*i.e.*, the sepals, petals, and stamens appear to attach at the upper end of the ovary, their basal portions enclosing it). Along with certain members of the families Boraginaceae and Hydrophyllaceae, they usually have harsh, often stinging, trichomes (plant hairs).

NATURAL HISTORY

Pollination. Variation in floral features within the order is matched by variation in pollination mechanisms. The range of pollinators known in the order includes bees, hummingbirds, flies, beetles, butterflies, moths, and bats. Many species are self-pollinated. Floral structure is closely correlated with mode of pollination, and the order exhibits nearly all the floral modifications associated with such a diversity of pollinators.

Dispersal. Seed-dispersal mechanisms in the Polemoniales order are varied but not nearly so diversified as the pollination mechanisms. In nearly all species the fruit is a dehiscent capsule, the rupturing of which allows a slow sifting of seeds from it, or else an explosive split scatters the seeds forcibly. In a few cases the fruit does not split and it (and its seed or seeds) is dispersed as a unit. Once liberated from the capsule, the seeds may simply fall to the ground immediately about the parent plant, but those with explosive capsules may eject the seeds three feet (one metre) or more. In both of these cases the seeds are subject to being carried about by animals, wind, water, or other agents. The tropical members of the order with winged seeds may be dispersed great distances by strong winds. A peculiar adaptation of many annual species is the development of a mucilaginous layer on the outside of the seed coat. When wet, this layer may increase in thickness to the diameter of the seed itself and is very sticky. These sticky seeds may be eaten, especially by birds, and may, by chance, stick to their feet or beaks and thus be carried great distances. Some North American species are represented by disjunct (widely separated) populations in South America, and it is reasoned that they may have been established there by transport on migratory birds. This must be thought of as the extreme form of dispersal, and most movement is probably the result of fitful small jumps repeated over thousands of generations.

Physiology. The physiological diversity in the family is evident from the ecologically diverse habitats occupied by some populations. The perennials of Arctic or Alpine regions are adjusted to short, cold growing seasons and long dormant seasons. In contrast, some tropical species may grow the year around, with only slight variations in growth brought on by fluctuations in available moisture. Seasonal adjustment is very evident in the perennial plants of eastern North America, where a succession of species develop and flower, starting in the early spring, through summer, and, finally, to a species whose last flowers are killed by the first autumnal frost. The desert annuals have perhaps the most rigorously programmed physiological systems. Their seeds germinate only when certain minimal moisture and temperature requirements have been satisfied. Then they grow rapidly to flowering and fruiting before the onset of the next drought period. Most populations vary in their requirements for germination, so that not all seeds germinate every year. Many seeds, in fact, may remain dormant for several years before germination occurs. This variation ensures that some seeds will always be available in the event of a crop failure caused by the extreme rigours of the fluctuating desert environment.

Parasitism. Two families in the order, Cuscutaceae and Lennoaceae, consist of totally parasitic plants. With the exception of certain species of *Cuscuta* (dodder or love vine), they are rarely observed. The dodders are thought to be closely related to, and derived from, the twining members of the family Convolvulaceae. In *Convolvulus* the advantage of twining seems to be purely mechanical,

Life cycle of desert annuals

whereas in the nearly leafless and achlorophyllous (*i.e.*, without chlorophyll—nonphotosynthetic) *Cuscuta*, twining brings the stem of the parasite into intimate contact with the host plant, where specialized organs (haustoria) penetrate the nutritive as well as the water-conducting tissues of the host, withdrawing sustaining substances. Dodder plants flower and produce an abundance of seeds with ample reserve food in the endosperm (starchy nutrient tissues). Typically, the seeds germinate in soil, producing first a club-shaped rootlike structure and later a wiry stem that may establish a new parasitic relationship with a suitable host. Soon the root dies, leaving only the haustorial connections established between parasite and host. Since dodder plants are lacking in the usual photosynthetic machinery, they die unless a satisfactory parasitic union is established. Seedlings, however, may live for several weeks and grow many centimetres before their successful establishment or their starvation occurs.

The family Lennoaceae shows no obvious resemblance to *Cuscuta* in its general morphology or mode of parasitism. Usually only the flowering portion of the plant emerges from the sandy soil where it grows, but an extensive underground root system is present. This system apparently ramifies randomly until host root systems are encountered. When a root of the parasite approaches a host root, a haustorial type of root system develops that penetrates into, and absorbs from, an appropriate host root. The mechanisms of lateral rather than vertical root growth and the sensing of an appropriate host plant are unresolved questions regarding the physiology of these plants.

EVOLUTION

There is very little fossil evidence that would be helpful in understanding the relationships of the order. The few fossils known are isolated organs scattered geographically and stratigraphically. Consequently, phylogenetic relationships must be deduced by comparing modern species.

It is conceded by phylogenists that the order Polemoniales is an advanced plant group. Its high level of specialization is evident in the flowers, fruits, vegetative morphology, and physiological adaptations. Because of its advanced state, however, it is difficult to deduce a group ancestral to the order and to demark clear lines of relationship within the order. These are problems common among many flowering plant orders. Taxonomic groups referred to as Polemoniales, or that have included all or most of the families appearing here, range in size from 3 families to 26 families. The 8 families here constituting the order bear a relationship to the order Gentianales, especially in several floral and anatomical characters. It is difficult, however, to conceive of one of these living orders as having been derived from the other. The 2 orders could better be thought of as having been derived from a common ancestor. Some of the more primitive members of the groups within—or closely related to—the orders Rosales and Dilleniales, such as the family Pittosporaceae, have been suggested as possible ancestors from which both the orders Gentianales and Polemoniales arose.

The lines of relationship within the order are also obscure, since most of the families show parallel specializations. It seems, therefore, unrealistic to attempt a sequential arrangement of the families Convolvulaceae, Polemoniaceae, Boraginaceae, Hydrophyllaceae, and Loasaceae, when surely none exists. On the other hand, the family Cuscutaceae seems clearly to be a parasitic derivative of the family Convolvulaceae, whereas the families Hoplestigmataceae and Lennoaceae show a strong similarity to either or both of the families Boraginaceae and Hydrophyllaceae.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The families of the Polemoniales order are delimited primarily on the basis of flower and fruit characters, their vegetative, chemical, and ecological considerations being of secondary importance. Most families have gynoeceia (female apparatus—stigma, style, and ovary) of 2 carpels, but the family Lennoaceae is exceptional in having 6 to 14 carpels, the family Polemoniaceae regularly has 3, and the family Loasaceae may

have as many as 5. In the latter family the ovary is inferior, but in the rest of the order the ovary is superior. The petal number (or lobes of the corolla) is mostly 5 in the order, but the family Loasaceae often has from 4 to 10, and the family Hoplestigmataceae has from 11 to 14. Occasional individuals or even some unusual species may have either 4 or 6 petals in other families. In the families Hydrophyllaceae and Boraginaceae the petals often bear appendages or crests. Nearly all members of the order have 5 stamens per flower, but the family Loasaceae often has many, and the Hoplestigmataceae family has from 20 to 30 stamens. The tendency in the Boraginaceae for the fruit to ripen as four-dividing nutlets is unique to that family within this order, as is the gynobasic style (that is, the style arises from the base of the four-parted ovary). Vegetatively, the Hydrophyllaceae, Boraginaceae, and Loasaceae families often possess harsh epidermal trichomes, or plant hairs, that, in some species, have stinging capability. Woodiness is lacking only in the parasites, the families Lennoaceae and Cuscutaceae. Both species of the family Hoplestigmataceae are trees. In the remaining five families, trees and shrubs or woody vines occur, along with herbaceous species.

The classification of Polemoniales that is presented in this article (Polemoniaceae, Convolvulaceae, Cuscutaceae, Hydrophyllaceae, Boraginaceae, Lennoaceae, Hoplestigmataceae, and Loasaceae) includes only a small portion of the families usually treated together as an order in most former classification systems, along with 3 families of doubtful affinity. On practical and theoretical grounds, the 5 families listed first are difficult to separate from the remainder of the approximately 26 families of those systems. The other 3 families (Lennoaceae, Hoplestigmataceae, Loasaceae) have rarely been included with them. They do bear some relationship to the families Boraginaceae and Hydrophyllaceae, however, so they may rest about as comfortably in the Polemoniales as they would in other orders.

Alternate systems of classification. The families grouped here as the order Polemoniales have been treated in a variety of contexts in different systems. Most systems, however, include the families Convolvulaceae, Cuscutaceae, Polemoniaceae, Hydrophyllaceae, and Boraginaceae in the same order, whether it is designated Polemoniales, Tubiflorae, Solanales, or by some other name. In addition, several families such as Solanaceae, Nolanaceae, Verbenaceae, Scrophulariaceae, and other families with tubular corollas and superior ovaries are often included in an ordinal group along with more typical Polemoniales. The family Lennoaceae has sometimes been placed in the order Ericales, but its relationship to the Hydrophyllaceae and Boraginaceae families now seems firmly established. The arrangement presented here deviates most from other proposed systems in the inclusion of the families Hoplestigmataceae and Loasaceae. That the relationship of the first is uncertain is clearly exemplified by its inclusion in the orders Lamiales, Violales, Bixales, and Ebenales by various authorities. Similarly, the family Loasaceae has been placed in the orders Cistales, Violales, and Loasales by different workers. It seems particularly out of place in the Polemoniales because of its inferior ovary, separate petals, and multiple stamens; however, its resemblance to the families Hydrophyllaceae and Boraginaceae in characters of indument (covering of plant hairs), seed, embryo, and endosperm is considered adequate to permit its placement in the Polemoniales order as defined here.

These variations in treatment of the families are the result of inadequate data and also disparate opinions about the value of certain characters in phylogenetic taxonomy. Until more data are available, particularly additions of critical material to the fossil record, concepts of the primitive condition of angiosperms (flowering plants) will have to remain theoretical. In view of the variations in thought on this subject, there is certain to be a continuing disparity in the evaluation of the evolutionary significance of plant characters and their utilization in the construction of classifications purporting to be phylogenetic (that is, reflecting actual evolutionary relationships).

(D.M.Sm.)

Relationships to other plant orders

Uncertain status of some families

Scrophulariales

Economically, the Scrophulariales order of flowering plants is prominent for the many ornamentals it contains; for important food plants (e.g., potato, tomato); for well-known drugs (atropine, scopolamine, digitalis); for certain agriculturally significant parasitic weeds (broomrapes, witchweeds); and for tobacco. The order contains 18 families, about 870 genera, and about 11,800 species. In variety of form and colour, some flowers of the order rival the orchids.

GENERAL FEATURES

Members of the order Scrophulariales occur on most of the landmasses of the Earth, with the exception of Antarctica. About two-thirds of the species are found in the tropics, one-third in temperate regions. About 50 species occur in the Arctic; of these, only a few species of lousewort (*Pedicularis*) reach the most northern lands.

Life span
categories

In life span, members of the order range from short-lived desert herbs to long-lived tropical trees. Many are annuals—i.e., plants that complete a life cycle from seed to seed in a single growing season and withstand unfavourable seasons in seed form. A few are biennials, plants that produce flowers and fruit the second year and then die. Most, however, are perennials, plants that live several years and withstand adverse seasons by means of underground parts (e.g., the herbaceous perennials) or by means of long-lived above ground parts (e.g., woody perennials). Of the perennials, most are polycarpic (i.e., they come into flower year after year). A few are monocarpic and live for several years—15 to 20 in certain cases (e.g., *Boea*)—before flowering and then die after flowering once.

Size range and diversity of structure. The plants range in size from the diminutive aquatic bladderwort, *Utricularia olivacea*, one of the smallest in bulk of all flowering plants, with threadlike stems to about 4 inches (10 centimetres) in length with a very few minute leaves, to large trees, of which the largest may be the guayacan (*Tabebuia guayacan*), which reaches about 165 feet (50 metres) in height and 6.5 feet (2 metres) in trunk diameter.

Flower size is also diverse. The smallest flowers are perhaps those of the aquatic *Micranthemum umbrosum*, about 0.06 inch (1.5 millimetres) in length. The largest are those of the tree daturas (*Datura*) and the related *Methysticodendron amesianum*, whose trumpet-shaped flowers grow to about 11 inches (28 centimetres) long and 4 to 5 inches (10 to 13 centimetres) wide.

Fruits of the order range from the minute globose capsules of *Micranthemum*, less than $\frac{1}{16}$ inch long (about 1 millimetre), to the elongated pods of the midnight horror, or Indian trumpet flower (*Oroxylum indicum*), 2 to 4 feet (60 to 120 centimetres) long but only about 3 inches (8 centimetres) wide, and the sausage-shaped fruits of the sausage tree (*Kigelia pinnata*), which attain 3 feet (90 centimetres) in length and sometimes exceed 15 pounds (7 kilograms) in weight.

About two-thirds of the species in the order are herbaceous—i.e., nonwoody. Most of the woody species are shrubs. There are few woody vines except in the bignonia family (Bignoniaceae). Trees are few, and most, except for some in the bignonia family, are small (40 feet [12 metres] or less in height).

Especially well known among the aquatic plants of the order are the bladderworts (*Utricularia*), which are among the few “carnivorous” plants and the only ones that capture their prey underwater. Most bladderworts produce, on their leaves, small, pear-shaped bladders provided with a trap door. These bladders trap tiny animals, such as protozoans, crustaceans, worms, and even newly hatched fish. Within the bladders, the animals are digested, but whether this occurs by bacterial action or through the action of enzymes secreted by the plant is not certain. Nitrogenous end-products of the digestion are presumably absorbed by cells in the walls of the bladder and provide a nutritional supplement to the plant.

Parasitic
species

Parasitic species are known in 14 families of flowering plants. Two of these families, the broomrape family (Orobanchaceae) and the figwort family (Scrophulari-

aceae), are in the order Scrophulariales and contain all of the world's agriculturally important root parasites—i.e., their roots are attached to the roots of their hosts by means of haustoria (“suckers”). Plants of the broomrape family are holoparasitic; i.e., because they lack chlorophyll and are unable to carry on photosynthesis, they depend entirely upon their host for organic food materials. The broomrapes (*Orobanche*) are serious pests on various crop plants—tobacco, tomato, eggplant, hemp, and sunflowers—and on various fodder plants. *Aeginetia* attacks sugarcane in Asia. In the Philippines, sugarcane is parasitized also by *Christisonia*.

In the figwort family, parasitism is known in 26 genera. Among these, all degrees of parasitism exist, ranging from holoparasitism (*Harveya*, *Hyobanche*) to semiparasitism—in which the parasite, being green, can carry on photosynthesis but relies in greater or lesser degree upon the host for at least water and minerals. The most important of the parasites in the figwort family are the semiparasitic witchweeds (*Striga*, *Alectra*), which attack many grasses, including corn, sugarcane, rice, and sorghum, and certain broad-leaved plants, including peanuts, soybeans, and tobacco. An Old World native, the mealie witchweed (*Striga asiatica*) has appeared in the United States, where, starting in 1956, it was reported on corn in the Carolinas. Other well-known parasitic members of the figwort family are Indian paintbrushes (*Castilleja*), gerardias (*Agalinis*, *Aureolaria*), eyebrights (*Euphrasia*), bartsia (*Bartsia*), and yellow rattles (*Rhinanthus*), all semiparasitic.

All members of the broomrape family, so far as is known, and the witchweeds of the figwort family produce seeds that germinate only when close to a host root. They are stimulated to do so by substances secreted by the root. The emerging root of the parasite grows toward the host root and eventually may establish a haustorial union.

Epiphytes, plants that grow upon other plants for support, are infrequent in the order except in the family Gesneriaceae, which also includes species that grow on rocks. Many of these plants have tubers (thickened storage stems, such as potatoes) that function apparently as water-storage organs.

Economic importance. Ornamentals. Ornamental herbaceous plants (annuals, biennials, and perennials), shrubs, trees, and vines are well represented in the order Scrophulariales. Among the best known herbaceous garden and greenhouse plants are flowering tobacco (*Nicotiana*), datura (*Datura*), butterfly flower (*Schizanthus*), petunia (*Petunia*), apple of Peru (*Nicandra*), salpiglossis (*Salpiglossis*), calceolaria (*Calceolaria*), veronica (*Veronica*), mullein (*Verbascum*), beard tongue (*Penstemon*), foxglove (*Digitalis*), snapdragon (*Antirrhinum*), torenia (*Torenia*), monkey flower (*Mimulus*), nemesia (*Nemesia*), African violet (*Saintpaulia*), gloxinia (*Sinningia*), and bear's-breech (*Acanthus*).

Ornamental shrubs of the order include matrimony vine (*Lycium*), *Cestrum*, angel's-trumpet (*Datura*), *Hebe*, *Leucophyllum*, Cape fuchsia (*Phygelius*), desert willow (*Chilopsis*), caricature plant (*Graptophyllum*), and shrimp plant (*Beleperone*).

Members of the Scrophulariales are among the showiest of tropical ornamental trees. Among them are the jacaranda (*Jacaranda mimosifolia*), widely used as a street tree for its blue flowers and lovely foliage; the white-flowered Indian cork tree (*Millingtonia hortensia*), once described as the handsomest of India's flowering trees; the African tulip tree (*Spathodea campanulata*), with scarlet flowers; and the New World trumpet trees (*Tabebuia*), with white, pink, lavender, purple, red, or yellow flowers. In temperate regions the catalpas (*Catalpa*), with their white flowers and large leaves, and the princess tree (*Paulownia tomentosa*), with blue flowers, are well known.

Both herbaceous and woody vines are frequent in the order. Some rank with the world's most beautiful flowering vines, including sky flower (*Thunbergia grandiflora*), with an abundance of sky-blue flowers; cat's-claw vine (*Doxantha unguis-cati*), golden yellow; flame vine (*Pyrostegia venusta*), orange; golden chalice (*Solandra maxima*), yellow; and Costa Rican nightshade (*Solanum wendlandii*), lilac blue and yellow. Woody vines are especially com-

Ornamen-
tal tree
species

mon in the bignonia family. Most of the vines in the order Scrophulariales are tropical, but in the United States the native cross vine (*Bignonia capreolata*) and trumpet creeper (*Campsis radicans*) are well known. Vines in the order support themselves by several means: by prickles on the stem (*Lycium*) or spines on the leaves (*Solanum*); by tendrils (*Bignonia*); by aerial clinging roots (*Campsis*); or simply by leaning on other plants.

Food plants. Food plants of the order include potato, tomato, eggplant, capsicum pepper, and sesame. The most important, and a basic food for millions of humans, is the potato (*Solanum tuberosum*). A potato is a tuber—i.e., a swollen portion of an underground stem. The potato was introduced into Europe from South America in the late 1500s and into the United States in the early 1620s. By the 19th century it had become a staple crop the world over, except in tropical lowlands.

The tomato (*Lycopersicon esculentum*), another New World contribution, was brought to southern Europe in the early 1500s and utilized there long before other Europeans accepted it. Once considered to be poisonous and grown as a curiosity or an ornamental, by the end of the 19th century it had become a major vegetable crop.

The eggplant (*Solanum melongena*), native to India, is grown throughout warm regions for its purple, white, or yellow fruits, which are used as vegetables. The name eggplant refers to the egglike appearance of the fruits of certain white-fruited varieties, which were the first ones known to northern Europeans.

Spice and
oil species

The only spice produced by a member of the order Scrophulariales is capsicum, or red pepper, derived from fruits of the genus *Capsicum*, native to tropical America. The many varieties differ in size, shape, colour, and pungency of the fruits. The fruits of some are used as a spice (e.g., tabasco and paprika); those of others, the sweet, or green, peppers, are used as food.

Cultivated for its edible, oil-rich seeds since antiquity, the sesame plant (*Sesamum orientale*), native to the Old World, is now grown in many warm regions. The oil is used largely in cooking; the seeds, in confections and as a garnish on baked goods.

Drug and narcotic plants. The order contains only a few drug plants, but they are important. In the potato family are the belladonna plant (*Atropa belladonna*), source of belladonna; henbane (*Hyoscyamus niger*), source of hyoscyamus; and jimsonweed (*Datura stramonium*), source of stramonium. Atropine, extracted from belladonna, and scopolamine, extracted from hyoscyamus, are much used in medicine. In the figwort family, the foxglove (*Digitalis purpurea*) is a source of digitalis.

Several members of the order have narcotic properties. These plants are members of the potato family. Best known are species of *Datura*, including jimsonweed and the tree daturas. Also narcotic is a relative of the tree daturas, *Methysticodendron amesianum*, unknown outside of one mountain valley in Colombia until the 1940s. The Aborigines of Australia utilized pituri, leaves of shrubs of the genus *Duboisia*, as a narcotic.

Tobacco, made from the cured leaves of *Nicotiana tabacum* (and to a much lesser extent, *N. rustica*), belongs to the potato family and is the world's most important material used for smoking. The tobacco plant, native to tropical America, is widely grown in temperate and tropical regions.

The order contains a number of poisonous plants. Among the best known are the jimsonweeds (*Datura*), belladonna (*Atropa*), henbane (*Hyoscyamus*), tobaccos (*Nicotiana*), nightshades (*Solanum*), and foxglove (*Digitalis*). Even tomato and potato leaves are dangerous if fed to animals. Potato tubers that are turning green also contain poisons.

NATURAL HISTORY

Pollination. Pollination mechanisms in the order are varied. In addition to normally opening (chasmogamous) flowers, a few species regularly produce cleistogamous flowers—i.e., flowers that never open but nonetheless develop viable seeds because they are self-pollinated in the bud. Such flowers characteristically are smaller and somewhat different in structure from chasmogamous flowers of

the same species. In most members of the order Scrophulariales, the flowers open normally and then depend upon various agents for pollination. None is known to rely on water. A few species are wind-pollinated—e.g., the plantains (*Plantago*), some of which are considered a cause of hayfever because they shed considerable pollen. Most members of the order rely on animals for pollination, especially insects, including bees, flies, moths, and butterflies. Some are pollinated by hummingbirds. A few are pollinated by bats; outstanding among these are the sausage tree (*Kigelia pinnata*) and the midnight horror (*Oroxylum indicum*).

Insect
pollination

Seed dispersal. The range of seed-dispersal mechanisms is great. In the family Acanthaceae seeds are thrown for short distances by the sudden—"explosive"—opening of the seed capsule. Most other plants of the order, however, rely upon external agents, such as wind, water, or animals, for dispersal. Those that are wind-dispersed may have dustlike seeds or seeds with wings or netlike coats that increase their buoyancy. Those that are spread by water include some beach plants (*Nolana*), whose seeds owe their dispersal to sea drift. The seeds of animal-dispersed species are carried on or in animals. Small-seeded water plants are dispersed in the mud clinging to the feet of waterfowl. Fruits of species of the sesamum family (Pedaliaceae) and the family Martyniaceae may hook onto the feet and legs of grazing animals. Seeds of many species are eaten by birds and mammals and are voided undigested in the feces. Dispersal in this way is especially important for species that produce juicy, brightly coloured berries (e.g., the nightshade, *Solanum dulcamara*). Seeds of a few members of the family Scrophulariaceae (e.g., *Veronica*, *Melampyrum*, *Pedicularis*) are dispersed by ants, which seek the seeds for food. A portion of the seed, the "elaiosome," is white, oily, and edible. Such seeds are not only

Drawing by M. Pahl

Some representative members of the family Scrophulariaceae, the largest family in the order Scrophulariales.

dispersed by the ants but can be planted by them as well—the ants carry them underground.

FORM AND FUNCTION

Vegetative characteristics. The leaves of most members of the order are simple. In few species—e.g., in some louseworts (*Pedicularis*) and in tomato—they are pinnately compound (i.e., each leaf has smaller leaflets arranged along both sides of a central axis). Leaf arrangement on the stem varies, being alternate, opposite, or, rarely, whorled or in rosettes. In certain members, the mature plant possesses but one leaf, up to 30 inches (76 centimetres) long and 22 inches (56 centimetres) wide, which has developed from growth of one of the two cotyledons, or “seed leaves”; the other cotyledon aborts early. This single-leaf condition is seen in several genera of the family Gesneriaceae (e.g., *Streptocarpus*) in which the flowers develop on the leaf, at the base and on the midrib. Other related species may produce a rosette of three or more leaves, the largest of which has developed from the one cotyledon.

The sesamum family and martynia family possess unique glandular (“mucilage”) hairs, which secrete a mucilage responsible for the sticky feel of these plants.

Floral and fruiting characteristics. In arrangement of the flowers—i.e., in the inflorescence type—the plants of the order are exceedingly diverse. The flowers of some are solitary and are borne in the axils of leaves, the upper angles between the stem and the leafstalks, as in the monkey flowers (*Mimulus*). Other solitary flowers are borne on long leafless stalks (scapes) that arise from a rosette of leaves, as in African violets (*Saintpaulia*) and butterworts (*Pinguicula*). In the majority, however, the flowers are grouped into clusters of various kinds.

Flowers. The flowers are almost always complete; i.e., they have sepals (leafy parts), petals, stamens (male reproductive structures), and carpels (simple ovaries or segments of a compound ovary—the ovary and its upper portions, the style and stigma, form the female reproductive unit called the pistil). Flowers of the family Hydrostachyaceae, however, have either only one stamen or one pistil. In most members of the order the flowers are perfect (bisexual); i.e., they contain both stamens and carpels. Imperfect (unisexual) flowers occur in the family Hydrostachyaceae and in *Littorella* of the plantain family (Plantaginaceae). The plants with imperfect flowers may be monoecious (flowers of both sexes occur on each plant—e.g., *Littorella*) or dioecious (flowers of one sex only occur on each plant—e.g., *Hydrostachys*). Flowers of the order Scrophulariales are generally irregular in shape, sometimes strikingly so. In plantains (*Plantago*), in many members of the potato family (Solanaceae), and in some members of the family Gesneriaceae, however, regular, or radially symmetrical, flowers occur. Most members of the order are hypogynous; i.e., the flowers have superior ovaries. In such flowers, the sepals, petals, and stamens originate at a position at the base of the ovary. The families Trapellaceae, Columelliaceae, and some members of the Gesneriaceae, however, are epigynous; i.e., the flowers have inferior ovaries—the ovaries are enclosed within the basal portions of the other flower parts, which appear to arise at the upper end of the ovary. The calyx, or collection of sepals, is regular to highly irregular. Typically it is composed of five free to variously united sepals. In some species, suppression of one or more sepals may occur, as in many veronicas (*Veronica*), in which the upper sepal is absent. In bladderworts (*Utricularia*), the calyx is strongly two lipped, the upper lip being formed from the union of three sepals and the lower lip from the union of two sepals; the whole suggests a calyx of only two parts. In the plantain family there are only four sepals.

The corolla (the collection of petals) is regular in the plantain family, nolana family (Nolanaceae), many species of the potato family, and in a few species of the gesneria family; in the rest of the order it is irregular, sometimes highly so. Typically it is composed of five united petals. The union ranges from incomplete—only at the base, so that the five-petalled condition is evident—to complete—so that the five-petalled condition is obscure. The corolla,

when composed of completely fused petals, is more or less trumpet- or funnel-shaped as in jimsonweed (*Datura*). In some of the highly irregular flowers of the order, the five-petalled condition is also obscure. The lowermost petals may, as in some linarias (*Linaria*) and in all bladderworts, bear a backwardly projecting spur. In many species the corolla is more or less two lipped; the upper lip is composed of two petals, the lower of three. The lips may be the same size, or one or the other may be larger, sometimes markedly so. An upward bulge, the palate, in the central portion of the lower lip may be pronounced in some species, such as the snapdragon (*Antirrhinum majus*), in which it closes the corolla throat. In some species (e.g., *Veronica*) the corolla appears to be composed of four petals; in these, however, the upper “petal” is really two completely united petals. The plantains have only four petals.

Inflorescence types

Representative plants from two of the large families of the order Scrophulariales.

In some members of the order, the full complement of five stamens is present, as in many species of the family Solanaceae. Typically, however, one or more stamens is missing. Species having four stamens (an upper pair and a lower pair) lack only the uppermost stamen. Other species lack the uppermost stamen and, in addition, either the upper or the lower pair; thus they have only two stamens. Any of the “lost” stamens may be represented by a staminode, or sterile stamen, borne in place of a normal stamen but not producing pollen. A staminode may range, depending on the species, from a minute projection on the inner surface of the corolla to an elongated filament-like structure equal in size and conspicuousness to the normal stamens. Throughout the order the stamens are epipetalous; i.e., their filaments are united with the petals. The union ranges from slight to considerably over one-half the length of the stamen. The stamens are alternate with the lobes of the corolla; i.e., they are attached be-

Corolla structure and form

tween the petals. In some highly irregular flowers, the alternate arrangement is difficult to see. The anthers (in which pollen develops) of all members of the order are tetrasporangiate; *i.e.*, they have four pollen sacs. Pollen grains are shed singly except in the family Hydrostachyaceae, in which they remain in groups of four. Pollen morphology (form and structure) is exceedingly diverse. One family of the order, the acanthus family, is alleged to show a wider range of pollen morphological features than does any other plant family.

Female
flower
parts

The carpels of the order Scrophulariales are united into a compound gynoecium, or female structure. In the family Nolanaceae, there are five carpels. In other members of the order, almost without exception, there are two. The locule, or ovary chamber, number is usually two; the most notable exceptions are the one-locular broomrape family (Orobanchaceae) and gesneria family. In most species of the order, placentation, or ovule attachment, is axile—*i.e.*, along the central axis of the ovary. In some, however, notably the broomrape family and the gesneria family, it is parietal—to the ovary walls. The bladderwort family is characterized by free-central placentation, in which the ovules are borne on a central stalk that is attached only at one end of the ovary. In the family Globulariaceae, the solitary ovule is pendulous from the apex of the locule. In *Littorella* of the plantain family, the ovule arises from the base of the locule. In most members of the order, the septum partitioning the ovary into two chambers is horizontal. In the potato family, in contrast, the septum is oblique; its plane is about 45° from the horizontal.

Depending on the species, the ovule number may range from 1 to about 70,000 (in *Aeginetia*) per ovary. The ovules have one integument (covering) and are mostly anatropous (inverted and straight with the micropyle, or opening in the integument, next to the hilum, or point of attachment) or hemianatropous (similar to anatropous, but less pronounced). Less often the ovules are campylotropous (curved with the base and apex nearly together) or amphitropous (half-inverted and straight, the hilum lateral).

Fruits and seeds. Most Scrophulariales species are characterized by a capsular fruit. The capsule may open by splits or pores in its wall; in some species, the capsule top comes off like a lid. Another fruit type of the order is a berry, well illustrated by the tomato. Fruits of the nolana family typically consist of one ring of five sections or two or three such rings, one on top of another. Each section contains one to seven seeds and separates from the others at maturity.

Although most Scrophulariales species produce several to many seeds per fruit, a few produce only one (*Globularia*, *Littorella*). Perhaps the record for seed production in the order goes to *Boschniakia rossica* (broomrape family), an average plant of which is said to mature more than 333,000 seeds. In size, the seeds of the order range from those of some members of the bignonia family, which may be several inches long, though thin and light, to the dustlike seeds of broomrapes (*Orobanche*), which are about 1/80 of an inch (about 0.3 millimetre) long.

EVOLUTION

Families of the order Scrophulariales are poorly represented in the fossil record and do not appear until the Tertiary Period (beginning about 65,000,000 years ago). These families, known from remains of leaves, pollen, fruits, and seeds, are the potato, figwort, bignonia, and acanthus families.

Relationships. The order Scrophulariales is closely related to the order Polemoniales and shares with it a common origin from the order Gentianales.

Within the order, the figwort, bignonia, sesamum, martynia, gesneria, broomrape, bladderwort, and acanthus families are clearly related to each other. The boundaries between some families are not clearly defined and thus are subject to individual interpretation.

The relationships of several families in the order are controversial; for example, the family Columelliaceae is variously considered to belong in the Scrophulariales or in the order Rosales. The family Buddlejaceae is sometimes

placed in the order Gentianales. The families Solanaceae and Nolanaceae are thought by some to belong in the order Polemoniales. These differences of opinion have not yet been settled; the answers to them depend on individual—and varying—interpretations.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The order Scrophulariales comprises somewhat more than 50 percent of the families included in the order Tubiflorae of older systems. Major characteristics helpful for delineating the families within the order include: symmetry of the flowers; carpel number; locule number; ovary position; placentation type; fruit type; presence or absence of endosperm; parasitic or nonparasitic habit; and collateral or bicollateral vascular bundles.

Alternate systems of classification. The families included in the order Tubiflorae of older taxonomic systems have been variously grouped, the groupings depending upon the characteristics emphasized. Some authorities recognize one large order. Others group the families of the Tubiflorae into three to seven smaller orders, of which the order Scrophulariales, as presented here, is one of three. The evidence is not overwhelmingly in favour of any of these views. It is largely a matter of personal preference how these families are divided into orders if the large group Tubiflorae is considered too unwieldy as a single order.

Because phylogenists subdivide the old group Tubiflorae differently, it is difficult to find the equivalent of the Scrophulariales, as presented here, among the orders recognized by other authorities. In older classification systems there is simply no order comparable to it. It is most closely equivalent to the suborder Solanineae of the order Tubiflorae, but it differs mainly by the inclusion of the plantain family and the myoporaceae family. A major distinctive feature of the order Scrophulariales, as presented here, is the inclusion of the potato family, which most other phylogenists place in an order separate from the figwort family and its allies. Thus the order Scrophulariales as defined here is not the same grouping of families as the order of that name as recognized by many other authorities. The classification presented here is a recent one of wide acceptance with as much claim to authoritativeness as other widely known systems. (J.W.Th.)

Lamiales

The order Lamiales includes four families of flowering plants: Verbenaceae (verbena family); Lamiaceae, sometimes called Labiatae (mint family); Phrymaceae (*Phryma*, or lopseed, family); and Callitrichaceae (water-starwort family). The family Lamiaceae, with more than 3,500 species, is the largest and is among the 10 largest families of flowering plants.

GENERAL FEATURES

Size range and diversity of structure. The order Lamiales shows a considerable diversity in size and habit, ranging from the slender, weak-stemmed aquatic and semiaquatic herbs of the Callitrichaceae to large trees of tropical forests in some genera of the Verbenaceae.

Of the many trees in the family Verbenaceae, the best known is teak (*Tectona grandis*), which ranges in height from 80 to 150 feet (20 to 50 metres) and has large leaves 18 to 24 inches (45 to 60 centimetres) long. Several genera of the family are entirely shrubby, a few are woody climbers, and others are annual or perennial herbs, small nonwoody plants that either complete their development and die within a single growth season (overwintering by means of seeds), or that live and produce seed from year to year (surviving winter or dry seasons by means of underground parts). Plants in the family Lamiaceae are mostly annual or perennial herbs, less often shrubs. Trees are rare and of small stature, generally not more than about 30 feet (9 metres) tall.

Distribution and abundance. The closely related families Verbenaceae and Lamiaceae, when considered together, form one of the large natural alliances of flowering plants, worldwide in distribution. The Verbenaceae tends to be

The teak
tree

Contro-
versial
position
of some
families

tropical and to occur in low-lying regions, in contrast to the Lamiaceae, which is predominantly temperate to subtropical and more often occurs in mountain or foothill regions.

The family Verbenaceae, with about 100 genera and 2,600 species, has its greatest concentration of genera and species in the warm parts of South America, Africa, and Madagascar. Lesser concentrations occur in continental Asia, Japan, and the islands of the Indian Ocean and the Pacific Ocean. The smallest concentrations are found in Europe, Asia Minor, and North America. In the family Lamiaceae, which has about 160 genera and 3,500 species, the primary centre of concentration is in the Old World from the Canary Islands to the Himalayas, with secondary outlying centres in Ethiopia, Madagascar, the Cape region of southern Africa, southern India, Sri Lanka (Ceylon), the Malaysian region, southern Australia, and Hawaii. In the New World a second principal centre of concentration lies in the mountain region extending from central Mexico southward to Bolivia and central Argentina; secondary centres include the northern plateau of Mexico, southwestern and southeastern United States, the highlands of Brazil and Guyana, the Caribbean region, and Chile.

Phryma leptostachya, the single species of the family Phrymaceae, has a distribution discontinuous between eastern North America and eastern Asia, a distributional phenomenon common to many plants and one that illustrates the floristic relationships between these two regions. This pattern is seen in such woody genera as *Magnolia* (order Magnoliales), *Hamamelis* (Hamamelidales), and *Wisteria* (Fabales) but not in any other member of the Lamiales. In *Callitriche*, the single genus of the family Callitrichaceae, there are 25 or more species which occur around the world, always associated with water.

Economic importance. The families Verbenaceae and Lamiaceae are of considerable economic importance, particularly the Lamiaceae.

From the Verbenaceae are obtained several useful wood products and some beautiful garden plants. Teak (from *Tectona grandis*), one of the most valuable of all known timbers, is native to India and Myanmar (Burma) but is also cultivated for its timber in the Asiatic tropics. Other useful timbers are obtained from the genera *Vitex*, *Citharexylum*, *Peronema*, and *Premna*. The family Lamiaceae is an important source of oils, which are used in the manufacture of perfumes, deodorants, and toilet preparations and as flavourings for foods and beverages. Perfume oils are obtained commercially from basil (*Ocimum*), lavender (*Lavandula*), marjoram (*Origanum*), rosemary (*Rosmarinus*), thyme (*Thymus*), and sage (*Salvia*). Horehound (*Marrubium vulgare*) yields an essential oil used medicinally. Spices and flavouring oils are obtained from spearmint (*Mentha spicata*), peppermint (*Mentha piperata*), and balm, or melissa (*Melissa officinalis*). Spices are obtained from sage (*Salvia officinalis*); savory (*Satureja hortensis*); origanum, or European oregano (*Origanum vulgare*); thyme (*Thymus vulgaris*); dittany of Crete (*Amaracus dictamnus*); sweet marjoram (*Majorana hortensis*); and basil (*Ocimum basilicum*).

Both the Lamiaceae and the Verbenaceae have many attractive ornamental plants. In the Lamiaceae most of the plants used as seasoning herbs are also used as garden ornamentals. Border and bedding plants come from several herbaceous (nonwoody) genera with brightly coloured and showy flowers, such as *Monarda*, *Mentha*, *Colquhounia*, *Phlomis*, *Physostegia*, and *Lavandula*. The shellflower (*Molucella laevis*) with large, saucerlike green calyxes (sepals—the outer series of petallike, usually green, structures in a flower) is popular for flower arrangements. *Coleus*, which has brightly coloured leaves, is one of the most popular houseplants. Shrubby ornamentals in the family Verbenaceae include the Chinese hat plant (*Holmskioldia sanguinea*), pigeonberry (*Duranta erecta*), the beauty-berries (*Callicarpa* species), the glory-bowers (*Clerodendrum*), the chaste tree (*Vitex agnus-castus*), lemon verbena (*Aloysia triphylla*), and the lantanas (*Lantana camara* and *L. montevidensis*).

Several of the mangroves of the genus *Avicennia* (Verbenaceae) have astringent bark that is used for tanning.

There are a few edible plants in the Verbenaceae and the Lamiaceae. The beauty-berry (*Callicarpa americana*) of the southeastern United States has juicy, slightly aromatic, sweet, fleshy fruits that are sometimes eaten. Several species of *Stachys* and *Lycopus*, in the eastern United States, and *Coleus esculentus*, of southern Africa, have tuberous roots that are used as root vegetables. The seeds of chia (*Salvia columbariae*), one of the sages widespread in the dry parts of the western United States, were once used extensively as food by the Indians. Members of both families have been used for various medicinal purposes. Bugleweed (*Ajuga reptans*) of the Lamiaceae, for example, has been used in treatment of bleeding of the lungs and as a safe and mild narcotic.

NATURAL HISTORY

Life cycle. *Pollination and seed dispersal.* Most of the Lamiales have brightly coloured, often bilaterally symmetrical flowers, which usually occur in showy clusters. These flowers are pollinated by insects and birds. Flowers with short corolla tubes are usually pollinated by bees; those with longer tubes, by butterflies and moths. The lobes of the corolla serve as a landing place or platform for the insect visitor, but in bird-pollinated flowers a platform is not usually present.

Pollination in the family Callitrichaceae takes place either on the surface of the water or in the water.

The unisexual flowers of *Callitriche* are of necessity cross-pollinated, but cross-pollination is the rule in the order. The families with bisexual flowers are adapted to cross-pollination through the agency of insects and birds. In addition, there are several floral devices that further ensure cross-pollination. One is a time difference in the maturation of the stamens and stigmas. Flowers of the families Lamiaceae and Verbenaceae are largely protandrous; that is, the anthers (pollen sacs) mature earlier than the stigmas on a particular flower. This differential maturation time is sometimes accompanied by a change in position of the stamens, relative to the stigmas, during the life of the flower. In the large genus *Clerodendrum* (Verbenaceae), for example, the long stamens and style are at first parallel to each other; then the style bends down, away from the stamens, as the anthers open. Following this the stamens curve downward, and the style returns to its original position before the stigmas become receptive to pollen.

In some genera of the Lamiaceae, there is a change from the bisexual condition to one in which there are two kinds of plants, some bisexual, others only female. This is called gynodioecy and occurs in *Origanum*, *Salvia*, *Mentha*, *Glechoma*, and *Ziziphora*. Sometimes, when this occurs, the plants with the female flowers are smaller than those with bisexual flowers. In a few instances size and sexual differences have not been recognized, and the two forms of one species have been described as separate species.

Fruits and seeds of the Lamiales show little diversity in structure in relation to their dispersal. The calyxes (sepals), except in *Callitriche*, remain attached much longer than in most flowers, usually enclose the fruits or seeds, and act as the vehicle for disseminating them.

Vivipary. *Avicennia*, a mangrove, is one of the remarkable genera of the Verbenaceae. It is a small genus of about 14 species found in coastal mud flats, tidal estuaries, or salt marshes of tropical or subtropical Africa, Asia, Australia, the Philippines, and North and South America. In these restricted habitats it occurs with *Rhizophora* and *Bruguiera* (family Rhizophoraceae) and *Sonneratia* (Sonneratiaceae) to form the vegetation type called mangrove forest. Mangrove plants are all similar in appearance, having prop roots or sucker shoots, and their seedlings are viviparous—that is, they germinate while still attached to the parent plant. In *Avicennia*, the seedling, when ready to be released from the parent plant, has a protruding rudimentary root and shoot that enable it to become embedded as soon as it falls into the mud. Vivipary is regarded as an adaptation to a saline environment. While growing on the parent plant, the seedlings store chloride, and their cell sap contains a very high salt content. Later, when the seedlings fall, they are able, because of their internal salt content, to take up water from the salty mud.

tal plants

Root adaptations to obtain oxygen

Ecology. Some members of the Lamiales are adapted to specialized growth requirements. One of the most outstanding of these is seen in plants of the genus *Avicennia*. These plants have long cablelike roots that run horizontally through the mud and send up numerous erect suckers, or pneumatophores, the ends of which stand above the surface of the water and supply the underground roots with needed oxygen.

In the South American genus *Junellia* (Verbenaceae) are plants adapted to dry conditions that occur at high elevations from 10,000 to 14,000 feet (3,000 to 4,000 metres) in the Andes mountains and others adapted to dry desert regions of lower elevations. In the family Lamiaceae a number of species of *Scutellaria*, *Pogogyne*, *Stachys*, *Lycopus*, and *Mentha* grow in wet marshy ground. Several species of *Salvia*, which occur in the arid southwestern United States, are hard-leaved evergreen shrubs that are resistant to long dry spells.

FORM AND FUNCTION

Vegetative characteristics. Members of the order Lamiales characteristically have opposite or whorled evergreen leaves. Square stems, which are popularly associated with the Lamiaceae, are lacking in some members of the family, particularly those with a shrubby habit. Square stems also occur in a few herbaceous members of the family Verbenaceae. The leaf blades of many of the Lamiaceae and the Verbenaceae and the single species of the Phrymaceae are entire—smooth margined—but in others the margins show all possible variations from smooth to variously toothed or cut; occasionally they are lobed. Compound leaves are uncommon. In some members of the family Lamiaceae, the stems, leaves, and inflorescences (flower clusters) are more or less hairy, sometimes with glandular hairs that secrete an aroma characteristic of the particular plant. In addition, there are frequently oil-secreting glands on the surfaces of the leaves and flowers. Except for the well-known lemon verbena (*Aloysia triphylla*; also called *Lippia citriodora*), scented foliage in the Verbenaceae is rare.

The family Callitrichaceae, well adapted to an aquatic or semi-aquatic habitat, is characterized by extreme reduction in its vegetative parts. The delicate and slender stem, which is either supported by water or lies prostrate, consists of a much-reduced vascular bundle and pith composed—in cross section—of only two or three cells.

Flower and fruit characteristics. The plants of the order Lamiales, with the exception of the family Callitrichaceae, have attractive, often brightly coloured flowers. Usually, the flowers are not individually large but instead are generally clustered in various showy and often conspicuous inflorescences. These are usually racemes—flower clusters with a central axis and short side branches bearing flowers that mature from the bottom of the cluster upward—or whorls, and they have bracts (leaflike appendages below flowers) that are occasionally colourful or enlarged. The flowers are almost always bisexual (that is, structures of both sexes are found in one flower), with the basic parts—sepals and petals—five in number and more or less irregular or zygomorphic (bilaterally symmetrical). It is usually the corolla, the collection of petals, that is brightly coloured, mostly in shades of red or blue; white and yellow are rare. The calyx, or collection of sepals, is mostly tubular and five-parted or two-lipped at the apex and is usually green, smaller, and less conspicuous than the corolla. The corolla consists of a tube (the basal part) and a limb (the terminal showy part). The tube may be short or long in relation to the limb and is usually straight with parallel sides; it is rarely pouched. The limb shows variation in shape and size. It may be divided into five more or less irregular parts or into two unequal parts to form a two-lipped corolla. The five-parted corolla is more often seen in the family Verbenaceae, and the two-lipped one is typical of the Lamiaceae. The flowers in the family Phrymaceae have a tubular calyx and a two-lipped corolla. There may be four stamens (male pollen-producing structures), usually in two pairs of unequal length; however, two or, more rarely, five stamens are also possible. They are attached to the inner side of the corolla tube and are

Representative members of the order Lamiales.

Drawing by M. Pahl; from A. Engler and K. Prantl, *Die Natürlichen Pflanzenfamilien*, 2nd ed., vol. 19c (1931); Duncker & Humblot

contained within or sometimes extended beyond it. The ovary is superior; that is, it is located above the point where the sepals, petals, and stamens arise. It is composed of two carpels—simple ovaries or segments of a compound ovary—that usually appear to be four because of the division of each into two parts. Within each carpel are two ovules, seed precursors, which are usually erect but with the micropyles, tiny openings through which fertilization takes place, directed downward. The single style, the narrow upper part of the compound ovary or pistil, may or may not extend beyond the end of the corolla tube along with the stamens. The stigmatic surface, the pollen-receiving portion of the style tip, usually matures after the pollen is shed from the stamens of the same flower. The fruit in the family Lamiaceae usually consists of two to four hard, dry, one-seeded nutlets. Sometimes, in the Verbenaceae, the fruit is a drupe, a stone-seeded fleshy fruit, which breaks up into one-seeded pyrenes, nutletlike fruit segments.

The tiny flowers of *Callitriche* are lacking in showy parts—i.e., sepals and petals—and are as much reduced as a flower can be and still function. They consist of only their essential organs, each flower having but one stamen and one pistil (female complex with stigma, style, and ovary). Each flower is solitary in a leaf axil—the upper angle between a leafstalk and the plant stem or branch—and is usually subtended by a pair of tiny, delicate bracts. Both staminate (male) and pistillate (female) flowers are on the same plant, so that the plants are monoecious, a condition not found elsewhere in the order Lamiales. The ovary of the female flower is two-celled and two-lobed; each cell is further divided into two parts as in the Lamiaceae and the Verbenaceae, but unlike them there are two separate styles. The small solitary fruits break up into four tiny one-seeded nutlets.

Aquatic plants

EVOLUTION

Fossil record. Fossil records show occasional occurrences of modern genera of both Lamiaceae and Verbenaceae. Perhaps the earliest record is that of *Vitex pentadactyla* (Verbenaceae) in the Cretaceous Period (65,000,000 to 136,000,000 years ago) of Bohemia. Nutlets of *Hancea* (Lamiaceae), a genus that now occurs in eastern Asia, have been found of a few present-day species. *Verbena officinalis*, now widespread in Europe, has been found in deposits of the Pliocene Epoch (2,500,000 to 7,000,000 years ago) of Belgium.

The fossil record, although small, indicates that some modern genera have been in existence since the Cretaceous and early Tertiary and suggests that during these times groups similar to those of the present day were being differentiated.

Phylogeny. The meagre fossil record is of no help in explaining relationships of the Lamiales to closely related families in other orders. Nor does it explain relationships among the families within the order. The characters most generally useful for establishing relationships among the flowering plants are in the flowers and fruits, and these are seldom found in the fossil record. As a result, the living members of these groups must provide the clues to relationships. In their floral structures, for example, the plants of the order Lamiales are considered to be among the most highly evolved groups of dicotyledons, the group of flowering plants with two "seed leaves" and net-veined leaves.

The similarity between the families Lamiaceae and Verbenaceae has been evident for many years. The four-lobed ovary and gynobasic style—a style arising from near the base of the ovary—of the Lamiaceae separate it from the Verbenaceae in which the entire, rarely shallow, four-lobed ovary has a terminal style. Several genera of the Verbenaceae, however, have a nearly gynobasic style partially sunk between the four shallow lobes of the ovary. This and other intergrading characters make it difficult to separate all the members of one family from the other, but at the same time it emphasizes the closeness of the relationship between the two families.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. In the classification used in this article, of the four families constituting the Lamiales (*i.e.*, Callitrichaceae, Phrymaceae, Verbenaceae, and Lamiaceae), the Callitrichaceae is the most easily distinguished by its greatly reduced vegetative and floral structure. The Phrymaceae is distinguished from the Lamiaceae and the Verbenaceae by its single-celled ovary.

The most useful characters for distinguishing the large and closely related Lamiaceae and Verbenaceae are the ovary and fruit structure, type of inflorescence, and, to a lesser extent, habit. The four-lobed ovary and gynobasic style of the Lamiaceae contrasts with the nonlobed ovary and terminal style of the Verbenaceae.

In its inflorescence types, the family Verbenaceae shows greater diversity than the Lamiaceae, with racemes, spikes, and compound cymes, complex-branched clusters that mature from the apex downward. The Lamiaceae infrequently has racemes and frequently has whorled clusters, which may be separated or crowded. In fact, the latter inflorescence occurs widely enough in the family to be considered characteristic of it.

In the Verbenaceae the woody habit predominates, but in the Lamiaceae the plants are mostly herbaceous and, less often, somewhat shrubby.

The descriptions of the four families presented in this article are generalized to include most of their genera. In the large families there may be exceptions. Thus, the Lamiaceae is said to be bisexual, yet the family includes at least one genus, *Iboza*, with male and female flowers on separate plants and other genera with separate female flowers besides the bisexual ones. Exceptions to the characteristic two-lipped flowers are seen in *Ajuga* and *Teucrium* in which the upper lip of the corolla is lacking. In the Verbenaceae are several genera so unlike most of the family that from time to time they have been placed in separate families. One of these is *Avicennia*, which some

botanists place in its own family, the Avicenniaceae, on the basis of its ovary structure.

Alternate systems of classification. The family Callitrichaceae with its tiny unisexual flowers may seem out of place in the Lamiales. Because of its flowers it has been placed from time to time with other families that are largely unisexual and without flower petals, such as the Haloragaceae or the Euphorbiaceae. Recent embryological studies of the ovule, however, have shown features that are characteristic of the Verbenaceae, which tends to place the Callitrichaceae with the Lamiales. Placing it in this order might still be questioned, however, since its well-developed endosperm and separate styles are not generally found in the Lamiales.

The families of the Lamiales were formerly placed in the large order Tubiflorae. This order contained about 20 families with bisexual flowers having tubular corollas. In their floral structures these families are among the highly evolved groups of dicotyledons. (E.McC.)

Campanulales (bellflower order)

Campanulales is the formal name of the bellflower order of flowering plants. The order derives its name from the diminutive of the Latin *campana*, which means "bell," referring to the bell-shaped flowers of a number of species of the family Campanulaceae. The order includes seven families with a total of about 2,000 species. The largest and most attractive family, Campanulaceae, with about 900 species belonging to 40 genera, has received the most attention from botanists; yet the classification of the family, as well as of the order, is not quite satisfactory, and many problems remain to be solved.

The main reasons for interest in the group are purely scientific, but much attention has also been paid to the great domestic importance of the large number of ornamentals in the group. Some genera—notably the best known one, *Campanula*—are very interesting with respect to problems of evolution; others show highly remarkable morphological characteristics and anatomical peculiarities. The geographic distribution of a number of groups (notably the genus *Donatia*) shows that a close affinity exists between the floras of New Zealand and South America.

GENERAL FEATURES

Most species are herbs, but shrubs and even trees up to 30 feet (9 metres) high (*e.g.*, *Clermontia*) are also present in the order. *Campanula vidalii*, which originates from the Azores, has the growth habit of a shrubby *Sempervivum*; *i.e.*, it is adapted to dry environments and has fleshy leaves. Some giant *Lobelia* species, which may reach a height of 20 feet (6 metres), are characteristic of African alpine vegetation zones. They occur at altitudes between 6,500 and 14,100 feet (1,950 and 4,300 metres).

The distribution of the family Campanulaceae is worldwide, but most species occur in mountainous areas of temperate regions in both hemispheres. The family Lobeliaceae inhabits tropical regions and many temperate areas of the Southern Hemisphere, with some species also distributed in temperate regions of the Northern Hemisphere. The representatives of the other families are mainly Australian. Some members of the Lobeliaceae that inhabit islands (notably the Hawaiian Islands) have a treelike or shrubby habit.

The order Campanulales is generally of slight economic importance, although one exception is the large number of ornamentals in the family Campanulaceae, particularly the genera *Wahlenbergia*, *Campanula*, and *Phyteuma*, and in the family Lobeliaceae, the genera *Lobelia* and *Downingia*.

Some members of the order, however, have a certain importance as medicinal plants. The roots of *Platycodon grandiflorum* (family Campanulaceae), known as *kikyo*-root, are used in China as expectorants and anti-asthmatics. The blue-flowering wild specimens, especially, contain large quantities of the active substance, platycodin (= *kikyo* saponin). *Scaevola koenigii* (family Goodeniaceae), a characteristic plant of the tropical beach jungle, furnishes a kind of rice paper, made by squeezing its pith flat. The fruits of *Canarina campanula*, *Clermontia*

ance

macrocarpa, and *Centropogon surinamensis* (all belonging to the family Campanulaceae) are locally eaten. *Lobelia inflata*, native to the eastern and central regions of the United States and Canada, is of medicinal importance. The plants are usually short-lived annuals with an inflated capsule. They were used by the North American Indians as an emetic and because of their tobacco-like taste were called Indian tobacco. Also known under the name Herba Lobeliae, these plants are characterized by an unusually high content of closely related alkaloids, which are derivatives of piperidine, especially of n-methyl-piperidine. The alkaloids are thought to occur only in the milky juice of the laticiferous vessels, a system of latex-bearing ducts in the stems and leaves. The best known and most active of them is lobeline, a substance characterized by its stimulating effect on respiration. Because of this property, lobeline is used to enhance the activity of certain centres of the central nervous system in cases of asphyxia in newborn infants. The action of lobeline also resembles that of nicotine to a certain extent and is sometimes used as a remedy for nicotine addiction. Other species of *Lobelia* also contain lobeline, especially representatives of the subgenus *Tupa*, such as *Lobelia tupa* and *Lobelia excelsa*, which occur in South America.

NATURAL HISTORY

The flower. The natural history of the flowers of the family Campanulaceae is of interest, and the flowers of *Campanula* are the best known in this respect. They are provided with a nectar-secreting disk situated at the base of the style, the narrow upper part of the ovary. In most cases the disk is covered by the triangular bases of the male sex organs, or stamens, which fit closely together. The size of the flowers, their frequently blue colour, and their drooping position indicate that they are well adapted to the visit of bees. There are, however, many other insect visitors such as flies, butterflies, and moths. In nearly all species of Campanulaceae the flowers are protandrous, which means that within an individual flower the mature pollen is always presented for dissemination before the female pollen-receiving structures, or stigmas, of the flower are receptive. The pollen is usually shed in the bud, in which the long, pollen-filled anthers form a column around the end of the style, whose stigmas are closed up against one another. The style is densely covered with short, stiff hairs, which hold the pollen after it has been shed by the anthers. After the opening of the flower bud, the anthers wither quickly, and for some time the style acts as a pollen presenter to insects. Insects trying to get at the nectar contact the hairs of the style and carry away the pollen. The pollen-collecting hairs, each of which is formed from a single epidermal (surface) cell, invaginate at this stage into the style, which may possibly be caused by extraction of water. This implies that after some hours the style becomes denuded.

After a time the stigmas separate and expand. Usually this expansion occurs the second day after the opening of the flower, which signifies that the mature female stage has begun. The stigmas are receptive to pollen by the time they are spread. On the third or fourth day the stigmas curl back so far that they touch any pollen that may still be present on the style, thus effecting self-pollination. Self-pollination, followed by self-fertilization, does not seem to be very common, although there are self-fertile species, such as *Campanula colorata* and *C. canescens* of the Himalaya region, whose flowers may be cleistogamous—i.e., they remain closed at maturity—and some populations of *Campanula rotundifolia*. In most species, however, if the pollen of a certain flower is transferred to its own receptive stigmas or those of another flower of the same plant, no fertilization is effected. The final conclusion is that in most *Campanula* species a considerable amount of outbreeding occurs.

In the genus *Phyteuma* the flowers are grouped together in dense heads. The tips of the long and very thin petals cohere and form a kind of tube within which the anthers are held. The style pushes up through this tube and drives the pollen gradually out at the end where it is exposed to insects. In the final stage the style itself emerges, the

tion
mecha-
nism in
Phyteuma

Representative vegetative and floral structures of three of the smaller families of the order Campanulales.

Drawing by M. Moran after Baillon from Die natürlichen Pflanzenfamilien

stigmas expand, and the petals separate and fall back.

In the family Lobeliaceae, the pollen-collecting hairs often take more or less the form of a ring, concentrated on the stigmatic branches. The anther walls and the closed stigmatic branches together form a structure that encloses the pollen. Agitation of the hairs on the top of the anthers causes the pollen grains to shake out. It is assumed that the pollen grains are no longer viable after the opening of the stigmatic branches. Some plants of the family Lobeliaceae are visited by birds for nectar. This is especially true for some species of *Clermontia*. So well adapted are both bird and flower that the birds' bills (e.g., those of the Hawaiian honeycreepers) match the curvature of the tubular flowers.

The flowers of the family Goodeniaceae are also protandrous. In *Leschenaultia formosa*, for example, before the flower opens, the pollen is shed into a membranous cup surrounding the stigma. Insects rub against this cup and carry the pollen away with them, thus pollinating other flowers. The same process is also carried out in other species.

The flowers of the family Stylidiaceae are also protandrous. The characteristic connection of the anthers and style again indicates that insect pollination is necessary. In all cases in this family, however, the pollen is presented to visiting insects while still contained within the anther lobes.

Ecology. The order Campanulales is distributed throughout the world, and its members grow in very different habitats, ranging in elevation from sea level to 13,000 feet (3,900 metres). For that reason it is impossible

to give a survey of all the ecological diversity encountered in the order, but there are some general trends.

In the largest genus of the order, *Campanula*, the species show a great ecological diversity. Many, such as *C. cochleariifolia* and *C. medium*, grow on calcareous (lime-containing) soils, but some, such as *C. excisa*, avoid such soils. Some species prefer woods (*C. latifolia* and *C. trachelium*), others light woodland in more or less shady places (*C. persicifolia*), but the majority prefer sunny habitats. The Portuguese species *Campanula loeflingii* prefers sandy soils, whereas the North American *Campanula aparinoides* occurs in marshes, swamps, and bogs. Sometimes closely related species are very different in their ecological requirements: the alpine species pair *C. elatinoidea* and *C. elatines* present a clear example; the first prefers dolomite, the second avoids it and all other calcareous soils as well. Most *Campanula* species, however, prefer calcareous soils.

It is remarkable that some species, such as *Campanula xylocarpa* of Czechoslovakia, which grows in rocky habitats on limestone and dolomite, never colonizes humus soils in natural habitats, even though plants growing on vertical rock walls often disseminate seeds there.

In the other large genus, *Lobelia*, many species grow in moist habitats such as ditches, marshes, and along streams. Some North American species, however, can tolerate much drier conditions; populations of *L. spicata* or *L. syphilitica*, for example, are sometimes found in open fields but mainly in areas where the soil is saturated with water.

Giant lobelias

Another very interesting group of the genus *Lobelia* consists of the giant forms, which are a characteristic element of the lower alpine and alpine mountainous regions of East Africa. They are characterized by tall, unbranched stems; numerous narrow leaves; terminal racemose (spike-like) flower clusters; large blue or purple flowers; and large anthers, the three upper ones at the top, the two others bearded. Species of the same group occur not only in East Africa but also in the West Indies, Brazil, and India. Five series of giant *Lobelia* species are distinguishable, conforming largely to altitudinal and precipitation zones.

In spite of the tree-like habit of the giant lobelias, the stems remain largely herbaceous (nonwoody). All giant species flower only once during their lifespan. The group is thought to have evolved from some annual forest species with a branched habit and lax inflorescence (flower cluster). *Lobelia longisepala* and other species of its group are regarded as a relic of the ancestral forest forms from which the giant lobelias evolved. The dense inflorescence, the unbranched stem, and the thick, hairy leaves characteristic of the alpine species are explained as adaptations to the higher altitude and severe climate.

Seed dispersal. Knowledge concerning the seed dispersal of the various species of the order is rather limited. Usually the seeds are small. The fruits are generally capsules (only exceptionally drupes—stony-seeded fruits), and they open in various ways. The seeds are not adapted to wind dissemination and usually fall to the ground close to the mother plant. In some species, however, such as *Campanula rotundifolia*, the wind may carry the seeds up to crevices, cliffs, or walls, in which they lodge.

Wind-assisted release of seeds

In the genus *Campanula* the species have capsules that open laterally. The capsules have apical pores or basal valves. Species with apical capsule pores have erect fruits, whereas those with basal valves have pendent fruits. This implies that, from the biological point of view, the pores and valves are always situated at the top position. For that reason, the seeds are shed only if the stems are moved by the wind, thus enabling the seeds to spread over some distance. In the group including the genera *Campanula*, *Legousia*, *Phyteuma*, and *Adenophora* the fruits open laterally, whereas in the genera *Wahlenbergia*, *Jasione*, and *Lightfootia* the capsules open apically. In these genera the seeds are not adapted to wind dissemination, but the wind promotes the spread to a limited extent by moving the capsule-bearing stems.

The fruits of *Scaevola* (family Goodeniaceae) are stony-pitted fruits (drupes), their outer layers being more or less fleshy, the stone very hard, woody, or sometimes corky. Dispersal in most species is effected by fruit-eating birds.

In the seashore species *Scaevola sericea* and *Scaevola plumieri*, however, the fruits float very well in seawater and retain their viability for some time. This means of dispersal accounts for their large area of distribution.

FORM AND FUNCTION

Distinguishing anatomical characteristics. One of the most distinguishing anatomical characteristics of the families Campanulaceae and Lobeliaceae is the presence of laticiferous vessels, a system of ducts carrying latex and characterized by cross walls at intervals along their length. They are distributed throughout the plants. In the stems they are usually localized in the outermost portion of the vascular system (the phloem region). These laticiferous vessels are absent in the other families of the order. The family Goodeniaceae differs from the Campanulaceae and Lobeliaceae in the more complex anatomy of the cambial tissue—the region of cell division contributing to stem thickness. In the family Styliaceae growth in stem thickness is a result of the formation of new vascular bundles outside the primary cylinder, a situation also observed in some woody representatives of the flowering plant class Liliopsida, or monocotyledons (e.g., *Dracaena*, *Yucca*). The cell walls of some species of the Campanulaceae and Goodeniaceae are silicified.

With the exception of some shrubby species, most Campanulales plants are perennial herbs, surviving from year to year, but there are also some short-lived annual species that overwinter in seed form. Both of these types usually have a repeatedly branched stem. The biennial species, those that fruit and die in the second year, often have

Representative plants and floral structures of the two largest families in the order Campanulales.

fleshy roots and a basal rosette of leaves. The leaves are always simple and lack stipules, which are small appendages at the base of the leafstalk. The leaves of the different species vary considerably in shape, from grasslike in the family Stylidiaceae to rather large in some *Campanula* species. Sometimes the basal leaves are different in form and size from those of the upper stem.

The flowers of the family Campanulaceae are sometimes solitary in the upper angles between leafstalks and the plant stem (the leaf axils) but are usually arranged in inflorescences of various shapes, including spikes, heads, and racemes, which all have a top flower. In the family Lobeliaceae the axis of the inflorescence may be branched, but the top flower is usually lacking. In both the Campanulaceae and Lobeliaceae solitary terminal flowers are sometimes found, which are thought to represent the last flower of a reduced inflorescence. The other families exhibit a variety of inflorescences ranging from solitary in Goodeniaceae to dense heads in Brunoniaceae, closely resembling those of the family Asteraceae (order Asterales).

The flowers are radially symmetrical or bilaterally symmetrical and consist in principle of five sepals, five petals, five stamens, and five carpels (ovary segments), the number of locules, or ovary chambers, varying. The number of sepals, however, may vary from three in some species of *Wahlenbergia* to six in *Canarina* or eight in *Michauxia*.

The corolla, or collection of petals, is bell-shaped in many species (e.g., *Campanula*, *Adenophora*, *Platycodon*, and others), but in others it is deeply divided (e.g., in *Phyteuma*, *Jasione*, and *Michauxia*). In *Phyteuma* the corolla lobes are united at the top, but in the genus *Lobelia* the corolla is split down one side. The family Lobeliaceae has irregular corollas, but Campanulaceae has regular ones. The lips of the corolla are reversed (resupinate) in *Lobelia* by a twisting of the flower stalk. In the family Goodeniaceae the corolla is bilaterally symmetrical and usually two-lipped, whereas the irregular corolla of the family Stylidiaceae usually consists of four petals of equal size, the fifth being much smaller (*Stylidium*, *Levenhookia*). The number of stamens is usually five in the families Campanulaceae (except for some species of *Wahlenbergia*, which have three), Lobeliaceae (in which three stamens are usually longer than the other two), Goodeniaceae, Sphenocleaceae, and Brunoniaceae. The stamens number only two or three in the family Donatiaceae, however, and finally only two in the Stylidiaceae, in which they are united with the style to form a structure known as the gynostemium. The anthers are free or variously closely associated, but not fused, as in *Symphyandra* and *Jasione* (Campanulaceae) or even joined as in the Lobeliaceae. The bases of the stamen filaments are triangular and form a dome-shaped chamber over the nectar-producing disk that surrounds the ovary. This disk may be very large and glandlike in the genus *Adenophora* (Campanulaceae).

The fruits of the family Campanulaceae are usually capsules that open by apical or lateral pores or valves. In some genera (e.g., *Canarina*) the fruits are berries.

The same is the case in the family Lobeliaceae, in which the majority of the species have capsular fruits but some (*Pratia*, *Clermontia*) have drupaceous ones. The number of locules, or ovary chambers, varies, sometimes within the same genus (e.g., three or five in *Campanula*) but is very often three in the family Campanulaceae. In the other families of the order the number of locules is often less than three. In all families there are usually numerous ovules in the ovaries. As a rule the ovules are inverted, or anatropous, and have only one integument. The endosperm formation, the development of starchy nutrient tissue for the embryo, is cellular in all families.

Some chemical characteristics. The families of the Campanulales are of little economic importance, and only a few chemical investigations have been carried out. There is some information with regard to saponins, polyphenols, latex, and carbohydrates. In many species of the Campanulaceae the occurrence of inulin has been demonstrated. This substance has been used as a test for kidney function. Fructan A and fructan B are common, not only in the perennial species but also in the annual ones. These compounds are also found in the family Asteraceae (or-

der Asterales), but usually they are lacking in the annual species. The accumulation of the fructans tends to corroborate the opinion that the families Campanulaceae and Asteraceae are related. Polyfructans are also present in the Lobeliaceae, but at least some members of this family differ from the Campanulaceae in the presence of alkaloids. This is an argument for separating the Campanulaceae and Lobeliaceae, which are usually united in one family.

EVOLUTION

Some authorities are of the opinion that the orders Campanulales and Polemoniales are probably derived from the Gentianales. Others, however, derive the Campanulales from the order Rubiales. Chemical and morphological characters suggest that the order Campanulales is a rather natural one, but fossil evidence is lacking, and most opinions remain speculative.

On the basis of cytological, taxonomical, geographical, and geological data, some authorities believe that the principle genera of the family Goodeniaceae arose in the early Tertiary Period (about 60,000,000 years ago) in Australia, the present-day species originating subsequent to the formation of distinct eastern and western floristic regions in Australia.

In the family Campanulaceae the genus *Campanula* has been most extensively studied with regard to the number of chromosomes per cell, and such studies strongly suggest that the evolution of its species ran along two separate and independent lines. A few isolated species differ in form and structure rather markedly from the other species of the genus, and it is thought by some authorities that some of them should be transferred to a number of smaller, usually monotypic (single-species) genera. *Campanula vidalli* of the Azores, for example, should be placed in the genus *Azorina*, and the North American species *Campanula americana* should be placed in the monotypic genus *Campanulastrum*. At present the genus *Campanula* contains other groups of species that are only remotely related to each other, and some of its species and species groups are undoubtedly closely related to the genera *Adenophora* and *Symphyandra*. In the eastern Mediterranean Basin and in the Caucasus the genus *Campanula* shows the greatest morphological and cytological diversity. It is thought that the genus probably originated in that area.

Studies of the North American species of the family Lobeliaceae indicate that there are four lines of speciation in that group. The earliest populations of *Lobelia* in eastern North America are thought to have been established in Tertiary times or before.

CLASSIFICATION AND TAXONOMIC STATUS

Three orders, Campanulales, Calycerales, and Asterales, are often considered as separate but closely related plant groups. Many authorities, however, regard the last two orders as families (Calyceraceae and Asteraceae or Compositae), which they place in the order Campanulales. The family Calyceraceae, however, differs from the Campanulaceae in having an undivided style and a one-locular ovary that contains only one pendulous ovule. There are some arguments in favour of placing the Asteraceae in the Campanulales order, however. The accumulation of fructans and the occurrence of derivatives of caffeic acid and triterpene saponins is a characteristic shared by both the families Campanulaceae and Asteraceae. Also, the position of the anthers, which are frequently in contact with each other in the Campanulaceae, and the usually inferior ovary are characteristics shared by both groups. Finally the septate laticiferous vessels of the subfamily Cichorioideae of the Asteraceae and of the family Campanulaceae point in the direction of a close affinity.

The position of the family Lobeliaceae is a much disputed one. The dominant genus of the Campanulaceae, *Campanula*, and the dominant one of the Lobeliaceae, *Lobelia*, differ considerably from each other, but there are so many intermediate genera that the differences become less significant as these intermediates are considered. On the other hand, as far as is known, the family Campanulaceae seems to lack alkaloids and has a much more pronounced accumulation of caffeic acid.

Absence of fossil evidence

Disagreements over placement of the Lobeliaceae

Floral characteristics

The family Sphenocleaceae is often united with the Campanulaceae, but it is sometimes regarded as related to the Phytolaccaceae. The pollen grains resemble those of the family Lobeliaceae, however. Combined cytological and phytochemical studies must be undertaken in order to obtain a better insight with regard to the position of this family. The same holds true for the family Donatiaceae, which is placed by some authorities near the family Saxifragaceae. This, however, does not seem justified in view of the presence of inulin, a character that the Donatiaceae share with the other families of Campanulales. Moreover, the pollen grains of the Donatiaceae are slightly similar to those of *Cyphia* (Lobeliaceae), whereas the grains in the family Saxifragaceae (*Brexia* and other genera) are different. The only resemblance between the families Donatiaceae and Styliaceae is the habit of *Donatia* and the species of the genus *Phyllachne*, but otherwise these families seem to be very different. There is much agreement in the various systems with regard to the inclusion of both Styliaceae and Goodeniaceae in the order. Only the family Brunoniaceae is treated in different ways by various authors. Earlier botanists accepted the genus *Brunonia* as constituting a separate subfamily of the Goodeniaceae. It has been raised to family rank by most recent workers, both on the basis of morphological characters and on palynological (pollen) and cytological (chromosome count) evidence. (T.W.J.G.)

Asterales

The order Asterales consists of a single large family of flowering plants called the Asteraceae, also known as Compositae. The Asteraceae family is one of the largest families of flowering plants. The exact number of species is not known, but an estimated 15,000 to 20,000 species are believed to exist. The only other family with a comparable number of species is the orchid family, Orchidaceae. Asterales is the order for the subclass Asteridae in the class Magnoliopsida (dicotyledons) of the division Magnoliophyta (angiosperms, or flowering plants). The order includes many familiar garden ornamentals, such as asters, chrysanthemums, dahlias, daisies, marigolds, sunflowers, and zinnias. Some other members of the group, such as dandelions, ragweeds, and thistles, are familiar weeds. Lettuce and safflower are examples of economically important members of the Asterales order.

GENERAL FEATURES

The most obvious and outstanding general feature of the Asterales is that the flowers are characteristically grouped into compact inflorescences (heads) that superficially resemble individual flowers. The name Compositae refers to this feature; what appear to be individual flowers are actually composite flowers. Each such head is ordinarily subtended by a usually green involucre of small modified leaves (bracts), which bear the same relation to the flower head that the green sepals do to an individual flower in other families. Furthermore, in more than half the members of the order, the flowers in the outermost row or rows of the head have a modified, mainly flat and elongate corolla (the collection of petals) that more or less resembles an individual petal of most other flowers. The "petals" of a daisy or sunflower are actually these outermost flowers of the head. Various members of the order may produce anywhere from one to more than several hundred of these composite-flowered heads.

Several other families or individual genera of flowering plants have the flowers grouped in heads more or less resembling those of the Asterales, but they lack the other features that characterize the order, and most of them especially lack the complex pollen-presentation mechanism (see below *The flower*).

Structural diversity and distribution. Members of the Asterales order are diverse in habit and habitat. They are most characteristically herbs that grow in sunny places in temperate to subtropical regions, but they are not restricted to those areas. Few of them are large trees, and only a few are adapted to life in undisturbed moist tropical forests, but otherwise they are ubiquitous. They

are trees, shrubs, herbs, or woody or herbaceous vines. The herbs are annual, biennial, or perennial, with or without an active cambium (a zone of growth contributing to stem thickness). Some of them are megaphytes (coarse, simple, or sparsely branched shrubs with thick, soft, almost herbaceous stems). Many of the perennial herbs have long, creeping rhizomes (underground rootlike stems) from which large colonies (clones) can develop by vegetative multiplication; others are taprooted or fibrous-rooted from a caudex (stem base) or a short rhizome. The leaves are simple or occasionally compound, and their arrangement along the stem may be opposite, alternate, or less commonly whorled; not infrequently they are opposite toward the base of the stem and alternate above. Species occur from the Arctic to the Antarctic and from above the timberline to the ocean shores. In addition to the more ordinary habitats, some of them are adapted to growth in sand dunes; others to cliff crevices; others to talus slopes; others to seleniferous, gypsiferous, or alkaline soils; and others to fields or disturbed sites around human habitations. A few species are aquatic.

The greatest centres of diversity in the order are the dry highlands of Mexico, where the primitive Heliantheae is especially well represented, and the Mediterranean-Near East region. South Africa is an important secondary centre of diversity. In most temperate regions more than 10 percent of the species of angiosperms belong to the Asterales. In tropical regions the percentage is smaller, but the numbers are still significant.

Economic importance. The greatest economic importance of the Asterales order lies in the use of many of its members as garden ornamentals. Species and garden hybrids of *Aster*, *Bellis* (English daisy), *Callistephus* (China aster), *Chrysanthemum*, *Cosmos*, *Dahlia*, *Helianthus* (sunflower), *Rudbeckia* (coneflower, black-eyed Susan), *Tagetes* (marigold), and *Zinnia* are well-known garden favourites. *Achillea* (yarrow), *Ageratum*, *Anaphalis* (pearly everlasting), *Anthemis*, *Artemisia*, *Calendula*, *Centaurea*, *Echinops* (globe thistle), *Erigeron* (daisy), *Eupatorium*, *Gaillardia* (blanketflower), *Helichrysum* (strawflower, everlasting), *Liatris*, *Ratibida* (coneflower), *Santolina*, and *Stokesia* are also familiar in gardens. The florists' cineraria, a popular wintertime pot flower, is *Senecio cruentus*, originally from the Canary Islands.

The most important food plant in the Asterales is lettuce, *Lactuca sativa*, a European cultigen. Second in importance is the common sunflower, *Helianthus annuus*, a native of the United States. Sunflower seeds are excellent poultry food, and a light-golden oil made from them is used in cooking and in the manufacture of margarine, soap, paint, and varnish. Oil cake is fed to livestock, and the whole plant is used as ensilage. Flowers of the safflower, *Carthamus tinctorius*, are the source of red and yellow dyes, and the seeds produce an edible oil that is also used in soap, paint, and varnish. Several other members of the order, including the artichoke (*Cynara scolymus*) and the Jerusalem artichoke (*Helianthus tuberosus*), are of minor importance as food plants.

Pyrethrum, an insecticide that does not produce the environmental problems associated with DDT and other synthetic products, is obtained from the flowers of several species of *Chrysanthemum*, particularly *C. cinerariaefolium*. Extracts from several species of *Artemisia*, notably *A. cina* from the Middle East, have been much used to expel intestinal worms, thus the common name wormwood applied to this genus. *Artemisia absinthium* is the source of a poisonous oil used to give the liqueur absinthe its distinctive character.

A few other members of the order have minor economic uses, and several of them have excited interest as a possible source of rubber. Guayule (*Parthenium argentatum*) and the Russian dandelion (*Taraxacum koksaghyz*) are two species that have been studied in this regard, but neither is economically profitable when other sources of rubber are available.

The ragweeds (*Ambrosia*), dandelions (*Taraxacum*), and thistles (*Carduus*, *Cirsium*, and *Onopordum*) are the most troublesome weeds in the Asterales order. Among the wind-pollinated weeds, *Ambrosia artemisiifolia* (common

ragweed) and *Ambrosia trifida* (giant ragweed) are two of the most important plant species causing the allergic reaction known as hay fever.

NATURAL HISTORY

Pollination. Pollination is effected by diverse agents, most commonly various sorts of insects. The individual flowers of most species are relatively small, and the nectar within the corolla tube is thus readily available to most insect visitors. The pollen itself is freely exposed on the surface of the head, and such heads are likely to be visited by diverse kinds of insects. A considerable minority of members of the order are wind pollinated; these generally have small and inconspicuous flower heads.

Some species are pollinated by both wind and insects. *Solidago speciosa*, one of the common goldenrods of the eastern United States, for example, produces a considerable amount of airborne pollen in addition to attracting insect visitors. The goldenrods, like the ragweeds, generally flower in late summer and fall; and because they are common and conspicuous when the ragweeds are pollinating, they have often been blamed for the allergies that are actually caused primarily by the ragweed.

A relatively few species are regularly self-pollinated; the genus *Psilocarphus* provides an example of this method. Bird pollination is also uncommon, but the tropical American genus *Mutisia* is bird pollinated.

Various genera and individual species of the order are known to be reproduced by apomixis, the setting of seed without fertilization, either completely or in addition to normal sexual means. The genus *Antennaria* (pussytoes), well known in the Northern Hemisphere, is dioecious

(male and female heads on separate plants), and some of the species are represented in large parts of their range only by pistillate (female) plants. In this genus, normal sexual reproduction produces equal numbers of staminate and pistillate plants, but apomictic reproduction yields only pistillate plants. Among the members of the Asterales order, as in other orders, apomixis is often associated with polyploidy (the presence of three or more complete sets of chromosomes in every cell) and a past history of hybridization.

Seed dispersal. The fruit of the Asterales is an achene; *i.e.*, it is dry, contains only one seed, and does not open at maturity. The apparent seeds of the sunflower, for example, are actually achenes. The hull is the achenial wall, and the proper seed coat surrounding the embryo is thin and insignificant. In speaking of seed dispersal of the Asterales, it should be realized that it is actually the achenes, each containing a seed, that are dispersed.

The seeds of many Asterales species are distributed by wind, having fluffy or parachute-like structures that provide buoyancy. In others, such as *Coreopsis* (tickseed), the achene is thin and flat, and the surface area is increased by the presence of an even thinner expanded margin (wing). Some have barbed structures or are provided with hooks or spines, as in cocklebur (*Xanthium strumarium*) or burdock (*Arctium* species), that engage man or animals as means of transport. Other means of seed dispersal are less common. The achenes of species that grow in wet places may be carried in mud on the feet of migrating waterfowl; those of some streamside species have minute air cavities in the wall and are buoyant, achieving dispersal by floating until they become waterlogged. In *Centaurea* and some related genera, the achenes are attractive to ants, which carry them about and feed upon special parts of the wall. The achenes of some field weeds have been widely distributed by becoming mixed with the seeds of cultivated crops. Many other members of the order have no obvious means of seed dispersal.

FORM AND FUNCTION

The flower. The flowers of the Asterales are sym-petalous; *i.e.*, the petals are joined together by their margins, forming a tubular or mainly strap-shaped corolla that often has apical teeth representing the petal tips. The flowers are also epigynous; *i.e.*, the other floral parts are attached to the top of the ovary rather than beneath it. These two features occur individually in various other groups of flowering plants, but their occurrence in combination is much more limited.

The calyx (collection of sepals) of the Asterales is so highly modified, in contrast to that of other orders, that it is given a different name, the pappus. The pappus consists of one to usually several or many dry scales, awns (small pointed processes), or capillary (hairlike) bristles; in some, the scales may be joined by their margins to form a crownlike ring at the summit of the ovary. In only a few genera (*e.g.*, *Marshallia*) of the primitive tribe Heliantheae does the calyx consist of five regularly placed scales that are obviously homologous with sepals. Often the pappus is completely wanting. When the pappus consists of numerous capillary bristles, as in the common dandelion (*Taraxacum officinale*), it facilitates wind distribution of the achenes. In some other genera, such as *Bidens* (beggar ticks), the pappus awns are barbed, permitting them to stick in fur or clothing, and some achenes are thus transported by animals. In many other genera, especially those with the pappus of scales or a crown, the function of the pappus is obscure.

The pollen-presentation mechanism of the Asterales is especially characteristic, being shared only by the orders Campanulales and Calycerales and a few genera of the family Rubiaceae, in the order Gentianales. The stamens (male reproductive structures) are generally joined together by their anthers (pollen producing region of stamen) to form a tube; the stamens open toward the centre by lengthwise slits, releasing the pollen into the tube. The style (part of the female structure) grows up through the tube, pushing the pollen out ahead of it. The style usually has two branches that separate after it has grown up

Floral structures of the Asterales.

through the anther tube. The stigmatic surfaces (pollen receiving regions) are usually arranged in lines along the inner margins of these branches, well back from the sterile tips (appendages), which are the structures that push out the pollen. The stigmatic lines later become exposed to the air, when the style branches spread apart.

The pistil (female structure) is composed of two carpels, united to form a compound ovary with a terminal style. There is usually a nectar-producing region (nectary) in the form of a minute ring surrounding the style atop the ovary. The ovary has only one locule (seed cavity), with a single ovule arising from the base. The fact that the ovule is basal provides the best single distinction of the Asterales from the related order Calycerales, which also has involucre heads with a similar pollen-presentation mechanism but which has the ovule pendulous from the top of the ovary.

As in most flowering plants, the ovule is anatropous; *i.e.*, it is curved back on itself so that the micropyle (the apical opening) is alongside the funiculus (the stalk). As in other members of the subclass Asteridae, the ovule has a single, rather thick integument (outer covering layer, the forerunner of the seed coat) rather than the double integument found in so many other orders. The seed has no endosperm; its reserve food is stored largely in the two cotyledons (seed leaves) of the embryo.

The inflorescence. The secondary inflorescence of the Asterales (*i.e.*, the arrangement of the flower heads) is typically cymose (determinate). The terminal head blooms first, followed by the terminal heads of the main branches. After that the sequence is less clear, not infrequently being mixed, with both cymose and racemose (indeterminate) components. Only rarely, and then clearly as a derived condition, is the secondary inflorescence racemose throughout, with the lowest heads blooming first and the terminal ones last.

The sequence of flowering within the individual heads, on the other hand is always racemose (indeterminate,

centripetal). The outer flowers bloom first, and there is a progressive spiral of flowering thence to the centre of the head. The head is in essence a compact shoot, with spiral (alternate-leaved) phyllotaxy. The involucre bracts are more or less modified leaves, and very often they are green and leafy in texture. Sometimes the flowers in the outermost row of the head are borne in the axils (angles) of involucre bracts, sometimes not.

In many members of the order, especially the relatively primitive tribe Heliantheae, the common receptacle (the short stem tip, on which all the flowers of the head are borne) is also provided with bracts, to which the individual flowers are axillary. The receptacle is said to be chaffy when these bracts are present and naked (or sometimes bristly) when they are not. Sometimes the receptacle is chaffy only toward the margin or only toward the centre. In some genera (notably of the tribe Cynareae) the receptacle is bristly; *i.e.*, it is set with bristles that are difficult to interpret in terms of bracts, although that may be their evolutionary origin.

Flowering head types. Individual heads of most members of the Asterales order are said to be ligulate, radiate, discoid, or disciform, according to the kinds of flowers they contain. The simplest type is the discoid head, with all the flowers having a regular, tubular corolla, the generally four or five apical teeth representing the tips of the petals. This kind of flower is called a disk flower. Ordinarily the flowers in a discoid head are all perfect (with reproductive parts of both sexes) and fertile. In a comparison of the flower head to the individual flowers of other kinds of plants, the discoid head lacks the marginal, petal-like flowers. Thistles and ageratum are examples of Asterales species with discoid heads.

The radiate head has disk flowers in the centre, surrounded by one or more marginal rows of another kind of flower, the ray flower. The corolla of ray flowers is very irregular. It is tubular at the base but prolonged on the outer side into a generally flat projection, the ray, or

Inflorescence types in the order Asterales.

ligule. These rays are the petallike parts, in a comparison of the flower head to an ordinary flower. The ray in radiate heads represents only three lobes of the corolla; often there are two or three minute apical teeth. The other two corolla teeth (those toward the centre of the head) are much reduced or, often, wanting.

The details of size and structure of ray flowers in a radiate head vary, but the position of the ray flowers with respect to the disk flowers is absolutely constant. The disk flowers are always central and the ray flowers marginal. Ray flowers in radiate heads are never perfect (bisexual). Instead they are pistillate (with female reproductive parts only) or neutral (with a vestigial, nonfunctional ovary and no style). Disk flowers in a radiate head are usually perfect, but sometimes they are functionally staminate, with a normal pollen presentation mechanism but without a viable ovary.

Occasional mutant forms of species that normally have radiate heads have most or all of the disk flowers more or less transformed into ray flowers, with only a few (or no) normal disk flowers in the centre. These "double-flowered" forms do not survive long in nature, but they are valued and perpetuated horticulturally because of their more showy flower heads. The "daisy-flowered" chrysanthemums, with only a single marginal row of ray flowers, have the normal type of radiate head, but the more commonly cultivated kinds of mums are double flowered. The garden dahlia is another member of the Asterales order that is cultivated in both normal and double-flowered types, with the double-flowered ones being more frequent. China asters, marigolds, and zinnias are also commonly cultivated in double-flowered forms.

The disciform head is a special derivative of the radiate type. It resembles the discoid head in lacking the marginal rays, but the outer flowers are pistillate, with a tubular, rayless corolla. The corollas of these marginal pistillate flowers are generally very slender, in comparison to the normal disk corollas, and they do not have the four or five well-defined teeth of the disk corollas. *Artemisia stelleriana*, one of several plants called dusty miller, has disciform heads, as do plants of the genus *Gnaphalium* (cudweed). Some species, such as *Erigeron compositus*, show a complete series of transitions from the radiate to the disciform type of head, the ray part of the marginal corollas varying from elongate to short to very short to lacking.

Radiate, discoid, and disciform heads occur in various tribes of the Asteraceae family. The ligulate head, on the contrary, is almost entirely restricted to one tribe, the Lactuceae (Cichorieae), and is found in all members of that tribe. Ligulate heads consist entirely of one kind of flower, the ligulate flower. Ligulate flowers superficially resemble the ray flowers of radiate heads in having the corolla tubular at the base and prolonged on the outer side into a flat, strap-shaped ligule. They differ from ray flowers in being ordinarily perfect (with functional stamens as well as a pistil) and especially in the structure of the ligule itself, which consists of all five lobes of the corolla and generally shows five terminal teeth. The dandelion is a familiar plant with ligulate heads. The term ligulate flower is often loosely used to cover both ray flowers and the type here described as ligulate. It is helpful, however, to have separate terms for these two kinds of ligule-bearing flowers, and no other terms for them are in general botanical use.

Still another kind of flower is found nearly throughout another tribe, the Mutisieae. This tribe is largely tropical, and only one of its genera, *Gerbera*, is familiar in cultivation in temperate regions. Most members of the Mutisieae have some or all of the corollas bilabiate (two-lipped), with a large, three-lobed (sometimes four-lobed) outer lip and a smaller, two-lobed (or one-lobed) inner lip. These bilabiate flowers may be either pistillate or perfect. When pistillate, they are always external to any perfect flowers that may be present in the head. Often they are much like ordinary ray flowers, except that there are two small teeth at the top of the corolla tube, opposite the ligule. The Mutisieae tribe shows every degree of transition from the typical disk flower to the typical ray flower and the typical ligulate flower.

Disk corollas in the Asterales generally have an unusual

sort of vascular system, scarcely found outside the order. There are as many longitudinal veins as corolla lobes, typically five, but the veins are directed to the sinuses of the corolla rather than to the teeth. At the sinus each vein forks, one fork following along the margin of each corolla tooth and meeting the vein from the other side of the tooth at the tip. Ray flowers and ligulate flowers are similar, but some of the larger rays have more numerous veins, and many of the smaller ones have reduced or no veins.

Numbers of flowers. A curious feature about the flower heads of the Asterales is the frequency with which the number of ray flowers (and sometimes also involucral bracts) reflects the Fibonacci series, a mathematical series that proceeds 1, 1, 2, 3, 5, 8, 13, 21, 34, . . . , with each succeeding number being the sum of the two previous ones. Fibonacci numbers also appear in efforts to explain the arrangement of leaves on a stem (phyllotaxy) in angiosperms in general. The appearance of Fibonacci numbers as absolute numbers in heads of the Asterales is thought to reflect the fact that the flower head is a compact shoot. Given the existence of normal phyllotaxy on this shoot, it is easier to produce a symmetrical arrangement with 5, 8, 13, or 21 rays than with other numbers such as 7, 9, 11, 19, etc. Heads with 13 rays, for example, probably have a 5/13 phyllotaxy (5 turns around the stem to pass through 13 leaf bases, before the next leaf is directly above the first one). Given the same phyllotaxy, a head with 14 rays would have the 14th ray on top of the first one, and one with only 12 rays would have a gap in the series.

These Fibonacci numbers, when they appear, often represent tendencies rather than fixed numbers, especially when the number is 13 or more. Five-rayed or 8-rayed heads may be very constant, with few or no examples of other numbers; but it is not uncommon to see within one local population (or on one plant) a range of 10 to 16, with 13 as the high point of the curve of distribution. Sometimes there is even a bimodal curve, with high points on adjacent Fibonacci numbers, such as 13 and 21, or 21 and 34.

EVOLUTION

Fossil record. The fossil record of the Asterales is not especially useful in helping to understand the evolutionary history of the group. The floral structures that would permit identification of the order on critical technical features are rarely fossilized, and with few exceptions fossils can be referred to the group only by a close resemblance to modern species or genera. A fossil (*Palaeanthus problematicus*) from the Upper Cretaceous Period (about 75,000,000 years ago) in New Jersey is more or less suggestive of a sunflower head, but it could equally well be any of several other things, and its status as a member of the Asterales order is dubious at best. The oldest generally accepted fossil representatives of the order are some dandelion-like achenes of Oligocene age (about 30,000,000 years ago). There is also a recently discovered fossil from the Oligocene-Miocene boundary region (26,000,000 years ago) in Montana that looks very much like a head of the modern genus *Viguiera* (tribe Heliantheae) and has been so interpreted in the literature. The order is poorly represented in Miocene (about 13,000,000 years ago) and even Pliocene (about 5,000,000 years ago) deposits, not becoming abundant until the Pleistocene (beginning about 2,500,000 years ago), but this situation doubtless reflects the difficulty of identification rather than a real absence of the group.

Phylogeny. Phylogenetic speculations in the absence of a useful fossil record are hazardous, but there is a fair degree of agreement among students of the Asterales (synantherologists) about the evolutionary trends within the order. The interpretation necessarily depends mainly on comparison of living members of the group, in the light of generally accepted principles of angiosperm evolution. Present evidence leads taxonomists to believe that the currently accepted broad-scale organization and evolutionary concepts concerning the Asterales order are probably correct, but some major uncertainties remain. In the following discussion, as elsewhere in this article, the terms primitive and advanced refer to phylogenetically anterior, or

Fibonacci numbers in composite flower heads

"Double-flowered" plants

primary (*i.e.*, early appearance in a group), as opposed to subsequent, or secondary, status and imply nothing at all about the adaptive significance of the features in question.

It is generally believed that the ancestral prototype of the Asterales was woody, perhaps a small tree. Some of the woody members of the group (*e.g.*, the sagebrush, *Artemisia tridentata*) are clearly only secondarily woody, deriving from herbaceous ancestors within the order, but many more or less woody Mexican species of Heliantheae are considered to be primitively woody. Many of the temperate zone herbs in the order, such as the common sunflower, develop a considerable amount of wood, but the stem does not persist from one year to the next.

It is believed that opposite leaves are primitive in the Asterales and alternate or whorled leaves derived. Numerous transitional forms from opposite to alternate leaves occur in the Heliantheae, a tribe considered on a syndrome of features to be relatively primitive within the order. Many of the Heliantheae have the lower leaves opposite and the upper ones alternate. It is thought that a progressive phyletic change from opposite to alternate phyllotaxy began in the flower heads and spread progressively farther down the stem until all the leaves were alternate.

Resin
and latex
systems

The presence of a well-developed resin system (a system of ducts or intercellular spaces lined with specialized cells that secrete resin, a sticky organic substance insoluble in water) in the vegetative parts is considered to be a primitive feature in the Asterales. Reduction and loss of the resin system proceed from the top downward. Presence of a latex system, on the other hand, is secondary, and its phyletic development proceeds from the top downward. Elaboration of the latex system is usually associated with reduction of the resin system, but the two systems are anatomically and genetically independent. A few genera and species have both the latex and the resin system.

Since each head represents a complete inflorescence, it is assumed that primitive members of the order had relatively few heads, each with relatively numerous flowers. The cymose secondary inflorescence (the arrangement among the heads) is also primitive.

Synanthrologists are agreed that aggregation and reduction in the inflorescence have been pervasive trends within the order. The culmination of these trends is the production of composite composites, such as in *Echinops* (tribe Cynareae) and *Lagascea* (tribe Heliantheae), which have numerous one-flowered, individually involucre heads aggregated into a secondary head with its own secondary involucre.

Another assumption based on the premise that the flower head is a complete inflorescence is that the involucre primitively consisted of several series of green, more or less leaflike bracts. Involucres with dry, nongreen bracts, or with the bracts in only a single series, are thus considered as derived rather than primitive. The situation is not perfectly simple and straightforward, however. It is not always easy to distinguish the outer involucre bracts from the uppermost leaves of the peduncle (flower stalk), and in diverse species in various tribes the involucre has evidently been augmented by modification of these uppermost peduncular leaves into bractlike structures.

The presence of chaff on the receptacle is uniformly considered to be a primitive character in the order and its absence to reflect a loss. Only one tribe, Heliantheae, has more representatives with the receptacle chaffy than with it naked.

The discoid head, with the flowers all tubular, has traditionally been considered the primitive type within the family, but this concept is now held to be too simplistic. Scattered throughout the several usually radiate-headed tribes (Heliantheae, Astereae, Anthemideae, Arctotideae, Inuleae, Senecioneae, and Calenduleae) are special subtribes, genera, species, infraspecific taxa (varieties, races, etc., within a species), and individuals with discoid heads. Among the radiate tribes the absence of rays represents a loss, and the discoid head is phylogenetically secondary. The consistently discoid tribes Cynareae, Eupatorieae, and Vernonieae are more difficult to explain as secondarily discoid, but neither is there any reason to suppose that they are primitive in other respects.

There is no doubt that the ray flower is, phylogenetically, a modification of the disk flower, but its time of appearance during the evolutionary development of the order is not known. If, as is thought by some, it occurred in pre-Asterean ancestors and was transmitted to the earliest members of the Asterales order as a normal feature of the group, then the discoid tribes have lost their rays, and all discoidy in the order is secondary. On the other hand, if the change took place in the ancestors of the Heliantheae tribe, after this group had already diverged from the ancestors of the present discoid tribes, then discoidy is primary in the discoid tribes and secondary only in the radiate tribes.

The Mutisieae tribe is a special case. It shows all transitional stages in the development of ray flowers from disk flowers, and the changes evidently occurred within the tribe rather than in remote pre-Asterean ancestors. The Mutisieae are advanced in other features, however, notably the caudate ("tailed") anthers, and the radiate tribes could not have evolved from them. Evolution of rays in the Mutisieae shows how it may have happened elsewhere in the order, but it is not the direct source of the rays in other tribes.

Synanthrologists consider fertile disk flowers to be more primitive than functionally staminate ones. Similarly, pistillate, fertile ray flowers are considered to be more primitive than ray flowers that are sterile but that still have a style; the neutral ray, lacking even a style, is still further advanced.

Yellow floral pigments have been considered to be primitive in the Asterales, and anthocyanic pigments, which produce blue to red colourings in flowers and other plant parts, to be derived. This hypothesis has been extended to suggest that the sequence is from carotenoids (yellow to red pigments) to anthoxanthins (yellow to scarlet flavonoid pigments, visually similar to the carotenoids) to anthocyanins (blue to purple or crimson flavonoid pigments). Thus the major chemical change, from carotenoids to flavonoids, occurs without much influence on the actual flower colour, and the major change in flower colour reflects a very minor chemical change.

The restriction of the stigmatic surfaces to parts of the style well back from the tip is part of the pollen presentation mechanism syndrome. The condition of the Heliantheae tribe, in which the stigmatic lines are often not well differentiated from the nonstigmatic part of the style branches, is considered to be primitive in this regard. Both ray flowers and ligulate flowers generally have well-defined stigmatic lines extending all the way to the tip of the style branches, which are without a sterile appendage. This condition is thought by some to argue for the evolution of both of these floral types very early in the evolutionary history of the order, before the style tips were sterilized.

The Asterales, like the angiosperms in general, are so beset with parallel evolution (*i.e.*, the independent appearance of similar structures in related groups) that it is often difficult to distinguish independently evolved similarities from those inherited from a common ancestor. There is, in fact, no sharp line between these two conceptually different types of similarity, and close parallelism among phyletic lines from closely related ancestors is very common indeed. Before all the members of an admittedly natural group can be traced back to a common ancestry, it is likely that the path will lead outside the confines of the group. These considerations apply with especial force to the genera and tribes of the Asterales. A genus that combined all the primitive features found in various genera of the tribe Astereae would probably have to be referred to the tribe Heliantheae. The Astereae, like the other tribes, probably evolved as a set of closely related genera undergoing similar sorts of evolutionary changes, rather than by diversification from a single genus that had all the characteristic features of the tribe.

For the reasons noted above, there may never have been an original member of the Asterales, primitive in all respects within the order but possessing all the essential features of the group. Nevertheless, it is conceptually useful to consider what such a plant might have been like and from what other group it might have originated.

Evolutionary
appearance of the
ray flower

Description of proposed Asterales ancestor

The hypothetical ancestral prototype of the Asterales, subject to the limitations noted in the preceding paragraph, may be considered to have been a small to medium-sized tree, probably in or near the dry highlands of Mexico. It had a well-developed resin system and opposite, simple, exstipulate leaves with anomocytic stomates (lacking specialized supporting cells around the guard cells). It had relatively few heads, terminal to the branches and more or less cymosely arranged. Each head had more or less numerous yellow flowers, collectively subtended by an involucre of several series of herbaceous bracts. The head may have been radiate or less probably discoid. The rays, if it had them, were pistillate and fertile. The receptacle was chaffy, with each bract subtending a flower. The flowers were arranged in a close spiral, blooming from the outside of the spiral toward the centre. The flowers were epigynous (*i.e.*, the floral parts attached to the top of the ovary), and the disk flowers were perfect. The pappus consisted of five scales. The disk-corollas were regular and of five lobes, with the midveins to the teeth and lateral veins to the sinuses well developed. The anthers were joined into a tube, into which the pollen was released; they did not have a sterile tail. The style grew up through the anther tube, pushing out the pollen, and there was no sharp differentiation of the style branches into stigmatic lines and sterile appendages. The ovary was of two carpels, with a single basal ovule.

No presently existing genus combines all of these features, but more of them are found together in the Heliantheae than in the other tribes, and if such a plant did exist it would probably be referred to that tribe. The Heliantheae tribe is thus generally considered to be the most primitive tribe in the order. The Astereae, Anthemideae, Arctotideae, Inuleae, and Senecioneae tribes are generally considered to be derived directly from the Heliantheae, and the Calenduleae tribe is thought to be a specialized derivative of Senecioneae. These several tribes collectively constitute the radiate tribes.

The phyletic position of the discoid tribes (Cynareae, Eupatorieae, and Vernonieae) is less certain, but the Arctotideae do provide a sort of link to the Cynareae, suggesting that this latter tribe, at least, may also be derived eventually from the Heliantheae tribe. The Mutisieae tribe is thought to be allied to the Cynareae, and it also provides a tenuous link to the Lactuceae, the most isolated and distinctive tribe of the order.

Looking backward for possible ancestors to the Asterales, it is found that the families Rubiaceae (order Gentianales) and Caprifoliaceae (order Dipsacales) come the nearest to providing the required features. Many authorities have thought that these two families are themselves closely related. Some of the other members of the Dipsacales order, such as the family Dipsacaceae, have often been compared to the Asterales; but they are already too advanced to serve as possible ancestors, being herbaceous and having a terminal rather than a basal ovule.

In the past, the Asteraceae family was often included in the order Campanulales, but that order is basically herbaceous and alternate leaved and thus can scarcely be ancestral to the Asterales. The small order Calycerales, which has involucre heads much like those of the Asterales, is also excluded by being herbaceous and alternate leaved. The Calycerales order, furthermore, has a terminal ovule. The Campanulales and Calycerales do have a pollen-presentation mechanism similar to that of the Asterales, and this is probably the main reason that the Asteraceae family has often been associated with the order Campanulales; but a similar mechanism is also present in some members of the Rubiaceae family.

A comprehensive interpretation of the evolutionary origin and diversification of the Asterales order in terms of adaptation and survival value is difficult and has never been seriously attempted. The flower head obviously acts as a single large flower, with the ray flowers serving the function of petals to make the flowers conspicuous and attractive to a wide range of insects. The pollen-presentation mechanism, which makes the pollen available to all kinds of pollinators, fits well into such a scheme. The pappus in many genera is clearly adapted to seed dispersal. On the

other hand, the repeated reduction and loss of both the ray flowers and the pappus are more difficult to account for, although presumably there could be a series of different explanations for the different examples. The functional significance of both the resin system and the latex system is obscure. There is no obvious value in the change from opposite to alternate leaves, nor in the frequent reduction and aggregation of the flower heads to form clusters of small heads. Indeed, there would seem to be some wastage of energy in composite composites such as *Lagascea* and *Echinops*, which continue to produce apparently useless individual involucre around the one-flowered heads that make up the compound head.

CLASSIFICATION AND TAXONOMIC STATUS

The most widely accepted arrangement of the species of the Asteraceae family into genera and tribes dates essentially from the work of George Bentham, in 1873. Many new genera and species have been described since that time, and the limits of many genera have had to be reconsidered, but botanists still turn to his treatment for an overall view of the family and for information on the characteristics and limits of genera that have not been recently revised. Bentham recognized 13 tribes. One of these, the Helenieae, is now submerged by many students of the family in the tribe Heliantheae, but the others are still generally accepted, with only minor modifications.

Although the order Asterales is morphologically (structurally) and ecologically very diverse, it is absolutely sharply defined. There is not a single species about which there is any doubt as to its inclusion in or exclusion from the order. Botanists dealing casually with the order have often been so impressed by its diversity that many have suggested it must be an artificial rather than a natural group, but serious students, both past and present, are agreed that it is highly natural.

The great majority of species of Asterales could be included in a single genus if the standards of sharpness of distinction that are useful in some other families were rigorously applied. Only the tribe Lactuceae (Cichorieae) stands somewhat apart from the others, and it is connected to the rest by the tribe Mutisieae. In practice botanists have found it necessary, in order to have any mental organization at all, to recognize genera and tribes in the Asterales that are imperfectly defined and are connected by transitional members. The tribes more nearly represent syndromes of correlated tendencies than morphologically definable groups. Each of three tribes (Eupatorieae, Senecioneae, Vernonieae) is dominated by a single very large genus, with which most of the other genera are associated as satellites. A number of the smaller genera may prove to be misplaced, and there is need for a careful reconsideration of generic and subtribal groupings throughout the family, especially in the Heliantheae.

(A.Cr.)

Alismales (water-plantain order)

The Alismales, or water-plantain order, is a group of flowering plants belonging to the monocots and containing three families of aquatic plants that grow in fresh water, either entirely submerged or partly exposed to the air. Although widely distributed, this group of plants is small in both number of species (about 100 in 18 genera) and population. They are of little economic value but hold considerable botanical interest through their relationships with the environment and with other aquatic plants. In their role as temperate-climate and tropical weeds, they are important factors in conservation, navigation, irrigation, and fisheries.

GENERAL FEATURES

Economic importance. Their nutritional status in the present-day world is insignificant, but the underground storage organs are swollen with food reserves, and this carbohydrate source was once utilized by North American Indians and others. In the Orient, rhizomes (underground stem structures) of *Sagittaria* have been eaten both cooked and fresh, and it is reported that Eskimos still make bread

Functional significance of evolutionary adaptations

from dried and powdered rhizomes of *Butomus*. In Java, juvenile plants of *Limncharis flava* are highly esteemed as a vegetable, and this species, together with *Sagittaria trifolia*, is also collected and used as fertilizer and for cattle and pig fodder in tropical Africa, India, and Southeast Asia. Although these plants have no medicinal importance today, in medieval times some species were considered important and were featured in early herbals.

Many plants of the Alismales are decorative in form and have been used as ornamental models; *Sagittaria trifolia*, for example, appears as a motif in Japanese religious metalwork of the 16th century. Ornamental species are cultivated in formal pools, and *Sagittaria* and *Butomus* occur frequently in landscaped water gardens. Tropical species are much used in tropical-fish aquariums to both aesthetic and biological advantage.

Size range and diversity of structure. There is some variation in size among species, which range from 2 to 60 inches (5 to 150 centimetres) in height, but none attains the extreme dimensions common in many plant orders. Members of all three families of the order are rather uniform anatomically. Surface hairs, for example, are absent in the order except for the large, simple, and branched ones on the undersurfaces of *Echinodorus macrophyllus* leaves. Stomata (small air pores) are present in the leaves of all species of the order except *Wiesneria schweinfurthii*. They usually occur in greater numbers on the upper surfaces of the leaves—markedly so in *Hydrocleys*, in which the upper side of the leaf is exposed to air and the lower side is submerged.

Arrange-
ment of
vascular
tissues

In all families there are species with massive leafstalks, which may be triangular, horseshoe-shaped, circular, or elliptical in cross section. Internal tissues are largely filled with air spaces, which occupy 80 percent of the total plant volume. Vascular tissue is universally present, although the xylem, the water-conducting tissue, is primitive and may be nearly absent in submerged species. The phloem, or food-conducting component, is more marked. The number of vascular bundles in any plant organ can be correlated with its size and degree of elaboration. In the Alismales order they are not randomly scattered, in contrast to the condition prevailing in most monocots, except in the flower stems of *Butomus* and *Limnophyton*. The most frequent arrangement is in arcs or circles. In every species, the first-formed xylem (protoxylem) disintegrates, forming conspicuous canals. Conducting elements in all parts of the plant except the root consist of tracheids, long, thin-walled cells that are primitive in type. Protoxylem tracheids may have ringlike or spiral cell-wall thickening, but later formed elements, called metaxylem, may have more complex wall sculpturing. The true vessel, a more advanced type of conducting cell, is confined to the root, where it is constantly present.

In the families Alismaceae and Limncharitaceae, metaxylem elements of the leaf are arranged in a crescent-shaped arc surrounding the protoxylem canal, with phloem similarly disposed around the metaxylem. The vascular strand is V-, U-, or C-shaped in section, open to the inside facing the main axis of the plant. In the genus *Butomus*, the metaxylem is inverted, enclosing the oval phloem group, with the V-arms facing outward.

Mechanical tissue is reduced in all members of the order, and there is a lack of cell-wall thickening in conducting tissue. Secretory canals exuding a type of latex are frequent in aerial parts of members of the Alismaceae and Limncharitaceae families but are not present in *Butomus*. Crystals and tannin occur in the cells of *Butomus* and some members of the Alismaceae but are not found in the Limncharitaceae.

Some species show more than one form of leaf structure. Stomata, for example, are absent from submerged strap-shaped leaves of *Sagittaria sagittifolia* but are present in floating leaves, less frequently in the aerial arrow-shaped leaf. Surface cells also differ in shape.

Root structure shows little variation among members of the order except in minor details such as number of vascular strands, and in general architecture it resembles that of other monocots and water plants. The outer layers contain many air spaces.

Typical plants and structures of the water-plantain order.

Drawing by M. Moran

Comparing different organs of the plant, *Hydrocleys* is structurally more homogeneous than other genera, probably because all its parts are submerged. Leafstalk, flower stem, and runners are similar in shape and diameter and are almost identical in organization of their tissues, differing only in number and distribution of vascular bundles. In other genera the histology of different plant organs is more varied.

Distribution and abundance. The order is broadly distributed throughout temperate and tropical regions and includes many widespread and familiar water plants. All three families are small in size, and one (Butomaceae) has only a single species. Populations are small and are frequently included in mixed communities. Common genera with larger numbers of species are widely spread; e.g., *Alisma*, *Sagittaria*, and *Echinodorus*. *Sagittaria* and *Butomus*, less frequently found, are more local in distribution than *Alisma*. *Butomus*, native to England, where it is reasonably common, has been introduced in North America. *Alisma plantago-aquatica*, the water plantain, which gives its name to the family and order, is the most abundant member of the group.

As with other water plants, those of the Alismales order have a great geographical range and at the same time a high frequency of species confined to a particular region only, mostly in the tropics.

Botanical importance. Although commercially unimportant, the external and internal form and type of leaf of the Alismales order have been studied intensively from the earliest days of botanical research. This ancient group, with its key position in the taxonomic system, is significant in speculations about the relationships between the two major groups of flowering plants (monocots and dicots) and their past origin. The Alismales order forms a link in the evolutionary chain between them. Since the order is restricted to water habitats, its status is heightened in con-

Geograph-
ical range

cepts that stress aquatic ancestry of the monocots and their hypothetical origin from aquatic dicots or predecessors.

NATURAL HISTORY

Reproduction is both sexual and vegetative. The latter method is more variable in mechanism and possibly of greater significance in multiplication.

Sexual reproduction. In the reproductive phase, vascular water plants betray their land-based ancestry. The form and structure of their vegetative organs are modified in relation to their aquatic habitat, but the reproductive organs are remarkably similar to those of related land plants in both general organization and microscopic structure. The flowers are adapted to aerial life and are pollinated by insects or wind.

There is evidence that ability to reproduce is related to age, a minimum juvenile period elapsing before flowering takes place. In genera such as *Sagittaria*, with more than one type of leaf, flowers are typically associated with adult aerial foliage. In contrast, *Alisma gramineum* can flower when possessing only submerged foliage.

Inflorescences (flower clusters) arise from the junctions of stem and leaves, and vegetative growth of the axis is resumed by subsequent development of other lateral buds. Aerial flowers are mainly bisexual and are borne on erect or floating axes in whorls. The petals, though small, are significant and attractive, and the species of most genera are pollinated mainly by flies, with beetles and snails possibly playing a minor role.

The fruit develops aerially. In the Alismaceae family the separate female structures develop into a head of dry, one-seeded fruits. In the Butomaceae family the fruit is primitive, consisting of a cluster of pods that split open when mature.

Seeds of many species have a prolonged dormancy. In the single-seeded indehiscent achenes (dry, one-seeded fruits that do not split open along definite seams), the embryo is protected by a hard seed coat that is thick and tight fitting. Some fruits retain their viability even after being frozen in ice and mud for some weeks. The ovary walls of *Alisma* fruits contain large intercellular spaces providing buoyancy for water dispersal. Seeds of *Sagittaria* have lateral wings containing air-space tissue. These seeds float in water, and the period of flotation may last several days to two months. In *Baldellia* the fruits sink immediately, but the young seedlings rise to the surface and float for several weeks before rooting.

Asexual, or vegetative, reproduction. Aquatic plants resort to vegetative reproduction more frequently than land plants, although methods of propagation are fairly universal. The uniform environment and abundance of carbon dioxide and water encourage leaf development and sustain vegetative growth. Vegetative reproduction is facilitated by fragmentation of the plant body followed by regeneration from any small part bearing a bud.

Multiplication by means of modified stems such as rhizomes, stolons, and runners is widespread in temperate species. These specialized organs also serve the purpose of sustaining plants during adverse conditions. In hot climates vegetative growth may be more continuous. Vegetative parts that can grow into new plants may be transported by water or animals, further contributing to the distribution of a species.

There are many instances of pseudovivipary, wherein asexual reproductive units replace some or all of the normal sexual flowers in the inflorescence. This method is common in the family Alismaceae, in which the inflorescence may set seed above water but bear young plantlets when submerged.

In many genera there is an abbreviated axis from which arises the crown of leaves. This rootstock becomes swollen with starch grains and serves as a storage organ during the resting period when foliage dies down. Many plants with underground stems reproduce vegetatively and spread horizontally by means of runners at the soil-surface level or by similar underground stems. These become erect at intervals to form new plants with adventitious roots. Later, intermediate parts may disintegrate and the secondary plants become independent.

Species of *Sagittaria* remain alive during adverse seasons by the production of special terminal tubers behind the apical bud. These structures are one to two inches (two to five centimetres) long and may be brightly coloured blue and yellow. They remain dormant during the winter but sprout into a new plant the following spring.

Vegetative reproduction is of the utmost importance in the maintenance and spread of some species. In all three families of this order it is correlated with aquatic existence, and this perhaps accounts for its success and frequency in comparison with sexual reproduction, which is not adapted to aquatic conditions.

Ecology. Members of these families, together with other species, participate in water-habitat plant succession but do not play a particularly dominant role at any stage. Plants with largely immersed shoots, such as *Sagittaria* and *Alisma*, mostly occur in silted waters just beyond or replacing reed swamp and in fairly shallow water. Both belong to a mixed aquatic community, and *Alisma* is a ready colonizer of fresh ponds, though not necessarily always present in the succession. *Sagittaria* occurs frequently in rivers with moderate current and may dominate submerged communities in its strap-leaved form. It may act as pioneer for the reed-swamp community and is frequent in the upper Thames and River Cam in England. *Alisma* also participates in reed swamp and, together with *Sagittaria* and *Butomus*, can form a shoreline reed swamp in muddy rivers that are subject to flooding.

Temperature is a factor of great uniformity in an aquatic environment and may partly explain the vast geographical range and latitudinal extension of some species. The requirement for water itself is perhaps the most restrictive factor in the occurrence of these plants.

FORM AND FUNCTION

Flower characteristics. Flower structure of the Alismales order includes several features held to be relatively unspecialized. Male and female structures are found in the same flower. The flower parts arise at the base of the ovary. The ovaries are separate, and there is an absence of fusion in other floral parts. The Alismaceae family shows a trend from crowded or spirally arranged female structures to a single whorl. The families of the order are considered to be advanced in having whorled flower parts in two circles of three petals and three sepals. *Sagittaria* shows an interesting tendency toward unisexual flowers that are male in the upper and female in the lower parts of the flower cluster. Flowers are aerial, borne erect on floating axes, and are similar to those of land plants in structure. Members of the family Alismaceae have nectar-producing structures between the flower parts.

Vegetative characteristics. The plants are nonwoody and persist through more than one growing season (*i.e.*, they are perennial). They are characterized by a structural uniformity that adapts them to an aquatic existence. Variations in leaf form and shape are associated with the degree of immersion in water, and some species have leaves of two or more forms. In many others it is possible to discern a gradation in leaf shape along the plant.

Butomus (Butomaceae) has a broad, horizontally creeping, underground stem with thick, fibrous roots from which arise tall leaves in two vertical series. Leaves are linear, erect, and triangular in section but are not differentiated into a separate leaf and blade. The leaf base is broadly sheathing (*i.e.*, it wraps around the stem), and the tip may be slightly flattened. The whole leaf is morphologically equivalent to the petiole (leafstalk) of other genera and is thus a phyllode (a flattened leafstalk that functions as a leaf blade).

Limncharis (Limncharitaceae) consists of a short rootstock with fine basal roots. The leafy shoot is erect and partly emergent. Leaves are massive and grow out of the water with the blade and upper stalk aerial. The sturdy stalk is three-angled, and the blade is inclined to the upright, varying in shape from broadly oval to elongated lance-shaped.

Hydrocleys (Limncharitaceae) is a floating form with runners producing small plantlets at intervals. The leaf is submerged. Long, rounded leafstalks float sinuously,

Typical
habitats

Seed
dispersal

Leaf
variation
with water
depth

and the flattened leaf blades rest horizontally near or on the water surface with their upper faces exposed to the atmosphere.

In the Alismaceae family the main plant axis is similar throughout, with crowded, sheathing leaf bases arranged in two ranks. Leaf type and shape vary according to locality and depth of water, and there may be two or more forms of leaf, together with intermediates, on a single plant. Leaves of *Sagittaria* show the greatest degree of elaboration in the family. The leaf blade develops paired and pointed lateral lobes, giving rise to the typical arrow-head shape. Submerged leaves may be linear, transparent, and floating. All leaves have the parallel venation typical of the monocots.

EVOLUTION

It has been suggested that the dicotyledon group that gave rise to monocotyledons must have had many features in common with the plants of the Alismales order. The Nymphaeales order is such a group and itself was probably derived from some ancient, vesselless stock of the Magnoliales order. Nymphaeales plants are aquatics without vessels and show tendencies towards cotyledon (seed-leaf) fusion. It is certainly feasible that an ancient stock of plants resembling the modern Nymphaeales order gave rise to the Alismales order.

Monocots are considered to be of aquatic ancestry, later evolving land forms that in turn secondarily gave rise to groups that have returned to the water. The Alismales order shows a progressive adaptation to an aquatic habitat, and the closely allied order Hydrocharitales has marine as well as freshwater species.

One of the fundamental differences between the two great groups of flowering plants, the monocots and dicots, is the difference in leaf-vein arrangement between them. The Alismales order is important in being positioned, in an evolutionary sense, near the bottom of the monocot sequence, and some of its members show leaf structure that can be viewed as showing the evolution of the parallel-veined monocot leaf from the dicot leafstalk. This interpretation is well supported by *Sagittaria*, which shows all the transitional stages between a normal leaf with blade and stalk and a linear leaf with parallel veins, all the stages being present within a single population. The occurrence of the various forms appears to depend on the water depth at which each is located. There is evidence that when present and developed, the parallel-veined leaf blade is derived from the secondarily expanded tip of the stalk, which becomes flattened and expanded through the evolutionary series. Thus, in this interpretation, the monocot and dicot leaf blades are not homologous.

Phylogenetic trends within the order are difficult to discern because they are masked by characters that are more readily correlated with ecological factors. *Butomus* has shorter and wider vessel elements in its roots than members of the Limncharitaceae family, suggesting that the latter family is more primitive. With respect to the xylem water-conducting elements, dimensions, and many other characters, the Alismaceae family appears to be close to and more advanced than the Limncharitaceae family. The Butomaceae family seems to have diverged from the other two families or some common ancestor of all three, becoming more specialized. There are indications of possible affinities with the Scheuchzeriaceae family of the order Potamogetonales (also known as Najadales).

Individuals of the Alismales order, in common with other water plants with soft, vegetative organs, have rarely been preserved in fossil deposits. In the absence of woody parts, usually only resistant hard fruits, seeds, or pollen grains remain, the identification of which is uncertain.

CLASSIFICATION AND TAXONOMIC STATUS

These groups convey an overall impression of unity in form, structure, and habit. Within the families, the genera and species are distinguished by minor characters not always immediately apparent to the untrained eye. Some authorities isolate the Butomales and Alismales as the first two orders of the monocot sequence. In the Butomales order of those systems are two families, the Butomaceae and

Hydrocharitaceae. Other taxonomists afford order status to the latter family as the Hydrocharitales, near to and derived from the Alismales order. The Hydrocharitaceae family can be separated from the three families of the Alismales order by its inferior ovary (located below the other flower parts), although there is support for the idea that the family may have descended from ancestors similar to the Butomaceae family.

The inclusion of the Limncharitaceae family together with *Butomus* in one family, the Butomaceae, as is sometimes done, is not supported by the evidence. In the past, genera belonging to all three families have been combined under the Alismaceae family. It is clear now, however, that there is a great weight of anatomical, morphological, palynological (analysis of pollen types), embryological, and biochemical characters all splitting *Butomus* from the genera that can be included in the Limncharitaceae family. This last group exhibits closer affinities with the family Alismaceae, *Limncharis* with its large elaborate leaves particularly resembling *Alisma* and *Sagittaria*, whereas the submerged and reduced leaves of *Hydrocleys* are in some respects more reminiscent of members of the Hydrocharitaceae family. (M.Y.S.)

Liliales (lily order)

The order Liliales is a vast assemblage of plants whose flowers usually have three petals and three sepals—the sepals usually resembling the petals in shape and colour—and whose leaves are generally linear or strap-shaped with the veins running parallel. These characteristics—along with one leaf in the embryo—are common to most monocotyledonous plants. Within this large order, exemplified by the lily, are more than 400 genera and 8,000 species, including erect perennial herbs, climbers, shrubs, and a few trees. The group contains many common garden plants and vegetables, such as lily, hyacinth, narcissus, amaryllis, asparagus, onion, and yam. Other economically important members include the agaves, fibre crop plants; *Colchicum*, from which the drug colchicine is extracted; and *Smilax*, from which the flavouring sarsaparilla is derived.

Contemporary authorities recognize from 5 to 20 families in the Liliales, an indication of the lack of consensus among botanists as to what constitutes the order. In the *Annotated classification* (see above), 20 families are recognized, according to a recent classification scheme; the validity of this outlook is critically appraised in the section *Alternate systems of classification* below.

GENERAL FEATURES

Diversity. Species of the Liliales are usually perennial herbs, with fleshy stems arising from various kinds of underground stems. Herbaceous climbers are found in the yam family (Dioscoreaceae) and in the families Alstroemeriaceae and Alliaceae. Climbing shrubs are known from the families Smilacaceae and Petermanniaceae. The order also contains succulents such as the *Aloe* and *Agave* species. Agaves include some of the largest members of the Liliales: the flower stalk of the so-called century plants (several *Agave* species) may attain 20 feet (6 metres) in height. *Yucca* and *Dracaena* species are often woody and treelike, such as the Joshua tree (*Yucca brevifolia*) and the dragon tree (*Dracaena draco*).

Aquatic Liliales are rare. They include erect or floating herbs in the family Pontederiaceae, particularly in *Pontederia* species and the water hyacinth (*Eichhornia crassipes*), and rarely in the Amaryllidaceae, notably *Crinum thaianum*, native to Thailand.

Distribution. The lily order is cosmopolitan in distribution, although most of its members are found in temperate and subtropical regions. The extreme range is as far north as northern Greenland (*Tofieldia coccinea*) and as far south as the southern tip of South America and New Zealand (*Luzuriaga marginata*). In numbers of species and individuals the order is best represented in southern Africa, North America, western Asia, and Australia.

Among the widest in distribution are the families Liliaceae, Amaryllidaceae, and Pontederiaceae. The lily family is worldwide in distribution but is most abundant in tem-

perate and subtropical regions. The amaryllis family ranges from southern Africa to Asia and the Western Hemisphere; and the family Pontederiaceae, common in tropical fresh waters, ranges as far north as southern Canada.

Importance. The lily order is notable for species producing food and other useful products, on the one hand, and its many showy cultivated ornamental plants, on the other.

Edible products. Among food crops, the outstanding ones are onion (*Allium cepa*), garlic (*A. sativum*), leek (*A. porrum*), chive (*A. schoenoprasum*), rakkyo, or ch'iao (*A. chinense*), and Chinese chive (*A. tuberosum*). The most important of these is the onion, the others being grown mostly for local consumption or in limited quantities.

Other edible crops of the lily order are asparagus (*Asparagus officinalis*), of the family Liliaceae, and various species of *Dioscorea*, of the family Dioscoreaceae, of which white yam (*D. alata*), negro yam (*D. cayennensis*), and cush-cush, or yampi (*D. trifolia*), are considered among the best. Used locally as important starchy food crops throughout the tropics, they are twining plants that produce tubers rich in starch and containing poisonous alkaloids; the latter are easily destroyed by boiling.

Elephant's-foot, or Hottentot bread (*Testudinaria elephantipes*), of the family Dioscoreaceae, produces a very large edible rhizome (underground stem structure) used as a food locally in Africa. Black bryony, or black bindweed (*Tamus communis*), a perennial vine of the family Dioscoreaceae, is occasionally cultivated and consumed as a vegetable from southern and western Europe to Kurdistan in Asia. The roots are also used medicinally. Another source of starch is Otaheite arrowroot, from *Tacca pinnatifida*, the pia plant, of the family Taccaceae. It is used locally in the South Sea islands as food. Starch from the tuberous roots of *Alstroemeria* species, of the family Alstroemeriaceae, is used locally as a food by the Andean Indians of South America.

Sarsaparilla, the flavouring extract, is obtained from the dried roots of several species of *Smilax* native to South America. The elongated berries of species of *Gethyllis* and *Apodolirion*, of the Amaryllidaceae, known as *kukumakrankas*, are collected and consumed locally in South Africa. In China and elsewhere, the buds of daylilies (*Hemerocallis* species) are harvested and used as a vegetable.

Industrial products. The 300 species of *Agave*, ranging from the United States to tropical South America, and the related 30 species of *Furcraea* provide important commercial fibres, obtained by processing the leaves. Sisal hemp is obtained from *Agave sisalana*, native to Yucatán; henequen from *Agave fourcroydes*, Mexico; Mauritius hemp or flax from *Furcraea gigantea*, the tropics; and Ceylon bowstring hemp, from *Sansevieria zeylanica*, Sri Lanka.

Many other *Agave* species are cultivated or harvested from native stands mostly for local fibre needs or for fermented beverages. Several species are used in making pulque, the national drink of Mexico; the alcoholic liquor mescal is distilled from pulque.

The water hyacinth, with its bladderlike leaf bases, has been recommended as a source of cellulose for papermaking and other uses.

Dracaena cinnibari, a tree native to the island of Socotra, in the Indian Ocean, is the source of a red resin called dragon's blood, or Socotra resin, which is used in varnishes and also as an astringent and to stop hemorrhage. *Dracaena draco*, a tree native to the Canary Islands, is the source of a red resin, also known as dragon's blood, which is used in the varnish industry, for pigment in papermaking, and in medicine.

Drug products. Drug products include many crude drugs used locally. Aloe juice, obtained from various *Aloe* species, is used as a purgative. The flowers of lily of the valley (*Convallaria majalis*) are used as a cardiac tonic in place of digitalis; squill, from the bulbs of *Urginea scilla*, is, among other things, a cardiac stimulant. White hellebore (*Veratrum album*), *min-mun-tung*, from the tubers of *Ophiopogon japonicus*, and China root, from the dried rhizomes of *Smilax china*, have been used medicinally in China since ancient times. The seeds and corms of the

meadow saffron (*Colchicum autumnale*) are used to treat gout. The active chemical is the alkaloid colchicine, which is one of the most efficient chemicals yet discovered for causing the doubling of chromosomes in cells; it has played an important role in plant and animal science since 1937.

Ornamental plants. The lily order is outstanding for its many ornamental plants, cultivated from most of the 20 families; the more important ones, however, are found in the following families: Liliaceae (e.g., tulip, hyacinth, crocus, lily, daylily, aloe); Amaryllidaceae (e.g., *Amaryllis*, *Narcissus*, *Lycoris*); and Agavaceae (e.g., *Agave*, *Yucca*, *Hosta*, *Dracaena*, *Cordyline*, *Sansevieria*).

In The Netherlands there is a considerable export business based on certain bulbous and cormous plants of the Liliales. In the United States, particularly in Oregon, lily (*Lilium*) breeding for the domestic and export trade has developed into a considerable industry. Locally, the growing of plants of the lily order is active in season, particularly the forcing and marketing of lilies, tulips, hyacinths, narcissus, amaryllis, and others for holidays.

NATURAL HISTORY

The life cycle of members of the Liliales is similar to that of other monocotyledonous plants (plants with one seed leaf). Pollination is usually by insects or by other small animals, but cleistogamy, a condition in which self-fertilization takes place within unopened flowers, occurs in the genera *Heteranthera* and *Hydrothrix*, of the Pontederiaceae.

Food and water storage. One of the outstanding features of a large number of the Liliales is the manner in which they have adapted to the seasonal peculiarities in different parts of the world. The most primitive Liliales are usually herbaceous perennials having short rhizomes with fibrous roots; they are adapted to humid climates. Organs for moisture and food storage have been evolved to carry the plant over unfavourable periods when growth is inhibited by dry or cold weather. These include creeping rhizomes, specialized thickened stems on or just below the ground surface, as in daylilies (*Hemerocallis*) and lily of the valley (*Convallaria*); bulbs, as in *Lilium*, *Allium*, and *Amaryllis*; corms, swollen bases of the stem, as in *Brodiaea*, *Milla*, and *Tecophilaea*; tubers, short underground stems, as in *Gloriosa*; and tuberous roots with buds at the stem end, as in *Alstroemeria* and *Dioscorea*.

In the agaves and aloes, the problem of surviving in a dry desert climate has been successfully solved by the evolution of tough, thick succulent leaves and a tough, thick stem for food and moisture storage. The American *Agave* species, family Agavaceae, have assumed the outward shape, within limits, of the thick succulent-leaved African *Aloe* and allied genera of the family Liliaceae. It is interesting to note that the related genera, *Hosta*, native to humid parts of China and Japan, and *Polianthes* (tuberose), native to Trinidad and humid Mexico, have not developed the succulent habit.

Extreme drought resistance is exhibited by such amaryllids as *Leucocoryne*, native to the extremely dry Atacama Desert of Chile, where scant rainfalls occur years apart. When limited rains do occur after prolonged droughts, the bulbs, dormant for years, quickly sprout, come into flower, and produce seed. Another interesting adaptation to an arid climate is found in certain species of *Vellozia*, in which the upper parts of the stems are covered with fibrous sheaths of the leaves, and the lower parts with a covering of aerial roots inches deep. When water falls on the aerial roots, it disappears as if into a sponge. The plant is thus able to supply itself with moisture in the form of dew and occasional light rainfall as well as from moisture condensed on the aerial roots.

Reproductive adaptations. In many species of the Amaryllidaceae, the seeds soon lose their viability, but some, such as *Chlidanthus boliviensis* and *C. fragrans*, which grow in dry mountain habitats, retain their germinating power over a period of years. *Amaryllis petiolata*, native to the forests on the riverbanks in southern South America, produces no viable seeds but has evolved a novel means of dispersal. The parent bulb produces many small, nearly round bulblets on the bulb scales. They remain

Representative plants from three major families of the order Liliales.

Drawing by M. Moran

Apogamous reproduction

dormant almost a year. During the spring floods they are carried long distances.

Apogamy, a form of parthenogenesis (reproduction in which seeds are developed without fertilization), occurs in such genera of the Amaryllidaceae as *Habranthus* and *Zephyranthes*. Copious seed production by such means has allowed certain species of these genera to spread over very large areas of Texas and northern Mexico.

Vivipary, in the sense of bulblets sprouting from buds in a flower cluster (inflorescence) almost to the total exclusion of the regular florets in the inflorescence, is found in some *Allium* species. European wild garlic (*Allium vineale*) by such means has been naturalized as a noxious weed over wide areas in North America and elsewhere. Protandry, the maturing of the stamens before the pistil, is found to a slight degree in many Alliaceae and Amaryllidaceae and to an extreme degree in *Alstroemeria* species, of the family Alstroemeriaceae, in which the stamens mature and shed their pollen before the pistil begins to enlarge and mature. These processes favour cross-pollination.

Miscellaneous adaptations. The Pontederiaceae are adapted for life in an aquatic habitat. In *Eichhornia crassipes*, for instance, the swollen petioles enable the plant to float; and floating has led to very wide distribution of this species. In species of the family Smilacaceae, the prickly shrubs and climbers are protected to some extent against animals. Seeds of many species in the order Liliales are winged, enabling them to be carried by the wind.

FORM AND FUNCTION

The rootstock varies from creeping rhizomes, bulbs, corms, and tubers, all of which are modifications of the stem, to thickened storage roots with buds at the stem end. The plants are usually perennials, very rarely annuals, rang-

ing from herbs to shrubs and climbers or very rarely to types with a woody stem that is branched and treelike. The leaves are usually linear or strap-shaped, with longitudinal veins; rarely, the leaves are broader, and with stalk (petiole), with longitudinal veins separated by netted venation. Latex-bearing vessels (laticifers) are present in the Alliaceae.

The flower varies from small and in loose clusters to large, solitary, and showy, with the showy perianth (petals and sepals collectively) usually six-parted, rarely three-parted or less; the perianth segments are similar and are sometimes united below into a tube. Occasionally there is a floral structure called the paraperigone, consisting of inward extensions of the lower part of the perianth tube; or scales or bristles may be present at the base of the filaments. The stamens usually number six, rarely three or less; each stamen consists of an anther—in which pollen is produced—and a filament, or stalk. The filaments may be variously modified, united into a tube below or into a conspicuous staminal cup. The pistil—usually one to a flower—consists of a three-parted ovary formed of three greatly modified leaves (carpels) and a stalk (style) capped by a pollen-receptive tip (stigma). Pollination is accomplished by small animals, including birds, insects, and arachnids. Fertilization—the union of a sperm cell and the egg cell—follows pollination. Most of the Liliales depend on cross-pollination, and thus fertilization follows flower opening; rarely are the flowers cleistogamous, a condition in which there is fertilization without opening of the flowers. The fruit is usually a dry, three-parted (rarely a one-celled) capsule, sometimes a fleshy berry, very rarely a nut; the seeds are sometimes winged.

Floral variations

EVOLUTION

In the absence of a fossil record, any estimate of the evolutionary relationships must be based on the characteristics of the living species. The evolutionary course within the Liliales, as well as in the superorder Liliales, which includes several other orders as well, is only partly understood; enough is known, however, so that the general evolutionary course may be described to a limited extent on the basis of gross morphology, chromosomal complement, anatomy, and biochemistry.

Morphological evidence. The general evolutionary course of some prominent morphological features in the Liliales is listed in Table 2.

Table 2: Evolutionary Course in the Liliales

organ	original form	evolved form
Stem	stem with taproot and fibrous secondary roots	rhizome, bulb, corm, tuber, or storage root with buds at the stem end
	herbaceous	shrubby or climbing, rarely woody, rarely treelike and branched
Leaves	linear, with longitudinal veins (originally evolved from petiolate leaves)	secondary petiolate leaves, with longitudinal veins, and reticulate veins between
Flower	perianth segments six, free	perianth segments three or fewer; perianth segments united below into a tube, with six or three segments above
	perianth tubular	perianth tubular with accessory structure (paraperigone)
	carpels free	carpels partially or fully united
	ovary three-parted	ovary with single compartment or two
	ovary superior	ovary inferior
	stigma three-parted	stigma three-lobed, capitate, or pointed
	stamens six, free	functional stamens four or fewer, filaments modified in various ways

Chromosomal evidence. Evidence from the chromosomal makeup of the cells has helped to solve difficult problems in phylogeny. The basic chromosome set, with a few large and many small chromosomes, in the *Yucca-Agave* group is very stable. The chromosome complement in *Hosta* is similar, on which basis it has been suggested that *Hosta* be recognized as the type of a separate tribe,

Hosteae, to be placed next to the tribe Yuccae (*Yucca* and its allies) in the family Agavaceae. The evolutionary course is irreversible, and the chances that such a unique chromosome complement originated a second time are remote. The suggestion is therefore valid, indicating that these two tribes originated from the same ancestral stock. The difference in gross morphology can be attributed to differences in habitat: *Hosta* evolved in humid parts of China and Japan; *Yucca* and its allies in the arid parts of southwestern North America. Later, apparently, a few species of *Yucca* spread to the more humid southern United States and the West Indies, but only after leathery leaves and other characters had evolved in the arid climate.

The presence of laticifers in the Alliaceae indicates the distinctness of this family and its presumed early evolutionary divergence from the rest of the Liliales.

Biochemical evidence. Biochemistry and other scientific disciplines have yielded evidence that suggests relationships among the flowering plants. On the basis of the presence of one substance—saponin—the Liliales may be divided into two groups:

1. Families in which the plants usually contain saponin compounds, including the Liliaceae and its allies, Xanthorrhoeaceae, Alphyllanthaceae, Philesiaceae, Smilacaceae, and Asparagaceae; the Dioscoreaceae and its allies, Stemonaceae, and Taccaceae; the Agavaceae; and the Alliaceae.

2. Families in which the plants lack saponins, including the Pontederiaceae and its ally Philydraceae; and the Amaryllidaceae and its allies, Alstroemeriaceae, Haemodoraceae, Hypoxidaceae, and Velloziaceae.

Chelidonic acid is present in many families of the Liliales. Alkaloids are present in a number of families, including the Amaryllidaceae. Thus, this group is singled out as a very distinct entity. Alkaloids have also been reported for *Dioscorea* species, *Tacca chantrieri*, and *Stemona* species. Colchicine has been extracted from *Colchicum*, *Meren-dera*, and *Gloriosa* species of the Liliaceae. The occurrence of these and other distinct biochemical compounds in Liliales suggests the potential value of this approach in solving outstanding phylogenetic problems.

Most authorities on the monocotyledons place the order Liliales in a central position from which other orders have arisen. A hypothetical, now extinct, group with nutritive tissue (endosperm) in the seeds, two-celled pollen grains, and separate or partially united carpels and numerous stamens presumably gave rise to three main lines.

The Liliales, Iridales, Zingiberales, and Orchidales are derived directly from the Liliales ancestral stock. The order Iridales is probably derived from the subfamily Melanthioideae of the Liliaceae. The order Zingiberales was probably derived directly from the Liliales and is claimed to have much in common with the Amaryllidaceae and the subfamily Asphodeloideae of the Liliaceae. The order Orchidales shows closest connections with the family Hypoxidaceae of the Liliales, especially the genera *Hypoxis* and *Curculigo*. The connecting link between these and the Orchidaceae is the most primitive subfamily of the Orchidaceae, the Apostasioidae. The Liliales stock may have given rise to two additional superorders, the Juncanae and Commelinanae.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. In the past, the position of the ovary with respect to the perianth was considered very important in distinguishing groups within the Liliales, but it is no longer considered as reliable in delimiting larger groups. Currently, the number of chromosomes, the presence of such internal features as laticifers (vessels bearing latex), and the presence of chemical compounds such as saponins and alkaloids are considered of greater significance in grouping of families within the Liliales.

Alternate systems of classification. The classification presented above is the product of several contemporary botanists, prominent among them being A. Cronquist, an American, and A. Takhtajan, a Soviet citizen. It is the nature of a taxonomic system that it can be improved, and, as new data are amassed, it is expected that changes will be made in the disposition of the families.

The interrelationships of the families listed above are determined to a considerable extent on the basis of gross morphology, as offered by earlier workers (see in the *Bibliography* the works of Engler and Prantl, Hutchinson, and others). This approach has yielded important results but is now being enlarged by data from other disciplines, including (1) chromosome number and morphology, such as the presence of a unique and stable basic chromosome complement in the Agavaceae, (2) evidence from anatomy, such as the presence of laticifers in the Alliaceae, and (3) evidence from biochemistry, such as the presence or absence of saponins, alkaloids, and other compounds.

In view of these data, the 20 families listed above may be accommodated as follows (see also in the *Bibliography* the works of Traub, Sterling and Huang, and others): the families Tecophilaeaceae and Cyanastraceae have been placed under the new order Tecophilaeales, which is transferred to the subclass Iridae, leaving 18 families—plus 2 new families under the new order Alliales—again making 20 families to be accommodated under subclasses Liliidae (saponin-containing) and Amaryllidae (saponin-free).

Subclass Liliidae

Order Liliales, laticifers absent, chromosomes not of *Yucca-Agave* type; families Liliaceae, Xanthorrhoeaceae, Alphyllanthaceae, Philesiaceae, Smilacaceae, and Asparagaceae. Order Dioscoreales, laticifers absent, unique alkaloids present; families Stemonaceae, Discoraceae, and Taccaceae. Order Agavales, laticifers absent, unique and stable basic chromosome complement of *Yucca-Agave* type present; family Agavaceae. Order Alliales, laticifers present, and unique alliaceous scent usually present; families Hesperocallaceae, Milulaceae, and Alliaceae.

Subclass Amaryllidae

Order Pontederiales; families Pontederiaceae and Philydraceae. Order Amaryllidales; families Amaryllidaceae (unique alkaloids present), Alstroemeriaceae, Haemodoraceae, Hypoxidaceae, and Velloziaceae.

(H.P.Tr.)

Iridales (iris order)

The flowering plant order Iridales is composed of 4 families: the Iridaceae with 58 genera and about 1,500 species, the Burmanniaceae with 16 genera and about 130 species, the Corsiaceae with 2 genera and 10 species, and the Geosiridaceae with 1 genus and species.

The order derives its name from the iris family, Iridaceae, which is of economic importance for its ornamentals. Many species are known for their commercial and medicinal uses. The families Burmanniaceae, Corsiaceae, and Geosiridaceae are primarily of academic interest.

GENERAL FEATURES

Size range and distribution. The order Iridales is mostly composed of herbaceous annuals—short-lived, nonwoody plants or long-lived perennials that inhabit the tropics, subtropics, and temperate zones of the world. A few South African genera (*Aristea*, *Klattia*, and *Witsenia*) of the family Iridaceae are shrubs. The genus *Geosiris* is interesting from a distributional viewpoint because it is restricted to Madagascar.

Utility and economic importance. Horticulturists have for many years cultured and bred members of the Iridaceae, particularly the genera *Iris* and *Gladiolus*. Numerous hybrids and cultivated varieties exist, and newcomers appear almost every year. The hybrids and varieties, with the many different shades of their falls and standards—the outer and inner members of the perianth, corresponding to sepals and petals, respectively—have become so popular that many of the less showy nonhybrid species are ignored by all but professional botanists.

The iris varieties are generally categorized as bearded (referring to a hairy region on the upper surface of the falls), beardless, and bulbous forms. The bearded forms are either tall or dwarf. Examples of the beardless form include the Japanese *Iris kaempferi* and the Siberian *I. sibirica*. The Dutch, Spanish, and English varieties are bulbous, and the so-called German iris is a tall, bearded form.

Iris and *Gladiolus* have become the flowers of specialists, and national societies sponsor periodical exhibitions of the flowers in some Western countries.

Other plants of the family Iridaceae that are popular among gardeners are the genera *Antholyza*, *Belamcanda*, *Crocus*, *Freesia*, *Ixia*, *Moraea*, *Nemastylis*, *Neomaria*, *Romulea*, *Sisyrinchium*, *Tigridia*, and *Tritonia* (*Montbretia*), among others.

The dried rhizomes—horizontal, creeping, rootlike stems—of *Iris florentina*, *I. pallida*, and *I. germanica* have a sweet odour that is associated with volatile and nonvolatile oils. The dried material is orrisroot, which is widely used commercially; for example, it is utilized in the manufacture of perfumes, powders, soaps, and dentifrices. Orris oil is used in flavouring candies, soft drinks, and gelatine desserts; however, because it apparently contains allergy-causing components, its use for these purposes has been discouraged. Orris also possesses mild medicinal properties and is used in the treatment of disorders such as bronchitis and dropsy and those involving the liver. In the form of a powder or in poultices, it is applied to sores.

The stigmas, feathery extensions of the female flower parts, of *Crocus sativus*, the saffron of commerce, yield a yellow dye. Saffron, which is valued for its flavouring and colouring properties, is used to colour butter, cheese, confections, and medicines. It is used as a remedy for catarrhal affections (inflammation of mucous membranes) of children, for melancholia (mental depression), and to treat enlargement of the liver. It is a nerve sedative and also promotes menstrual discharge. Bulbs of the saffron crocus are toxic to animals, and overdoses of the stigmas are narcotic.

Belamcanda chinensis, the leopard lily, is a remedy for tonsillitis in Chinese medical practice. It is also used to treat chest and liver complaints. The leaves of *Iris germanica* contain ascorbic acid (vitamin C); they are also used to treat frozen feet.

The leaves of *Iris kumaonensis* and *I. ensata* are used as animal feed. Those of the latter, the plants of which are reported to be fibrous, are also used for thatching, matting, and basketwork.

Starchy corms—bulblike stem structures—and rhizomes of some members of the iris family are edible. On the other hand, fatal cases of iris poisoning of cattle have been reported from Canada. The rootstocks of the blue flag, *Iris versicolor*, contain a poisonous irritating substance (iridin) that affects the digestive organs and gastrointestinal tract. Poisoning is, however, rare, as the rootstocks are seldom eaten in large quantities. Some allergic individuals suffer skin rashes as a result of handling certain irises.

Poisonous
substances

NATURAL HISTORY

Life cycle. The order Iridales (except for the family Iridaceae) and the order Triuridales are saprophytes, plants that obtain their food from dead organic matter rather than by photosynthesis. In addition, they are mycotrophic, which means that their roots are in close association (mycorrhizal association) with the mycelia (filamentous bodies) of a fungus that generally helps the plant to absorb nutrients and receives some benefit from the plant in return. The plants, in keeping with their saprophytic and mycotrophic modes of nutrition, have reduced scalelike leaves and an undifferentiated embryo contained in a very small seed. These are also features of the orchid order, the most highly evolved group of petaloid monocotyledons—plants with one seed leaf and parallel-veined leaves whose flowers have sepals that are showy and look like petals (see *Orchidales*).

The family Iridaceae is autotrophic—it produces its own food by photosynthesis—and exploits the growth habits characteristic of the families Liliaceae and Amaryllidaceae, in which the underground food-storage parts are rhizomes, corms, or bulbs. The roots have a velamen, a thick corky epidermis or covering, as in the Liliaceae, the Amaryllidaceae, and the Orchidaceae. Members of the iris family propagate vegetatively, although they also reproduce by seeds. In many species, germination of the seed is slow and irregular; the seeds of some species also require a moist-chilling treatment prior to planting.

The saprophytic and mycotrophic families Burmanniaceae, Corsiaceae, and Geosiridaceae grow in the shade of forests and require a fungal symbiont-partner at an

early stage in development. Only in some species of the Burmanniaceae that grow in open situations are the leaves green and capable of photosynthesis.

Most flowers of the order are brightly coloured and are generally pollinated by insects. Interesting pollination adaptations that impede self-pollination and ensure cross-pollination are present in the Iridaceae. The shape of a flower, for example, bears a close relation to its insect visitor. Pollination in *Freesia refracta* and in some species of *Gladiolus* is by the moth. The flower is adapted to the flight of the moth, which hovers while its tongue probes to the base of the floral tube. Pollen deposited on the moth during the process is transferred to another flower on the next visit. The flowers of *Lapeyrouisia* have a long floral tube and are adapted to pollination by a long-tongued fly. The blue-flag beetle makes many punctures in the nectary of *Iris versicolor*, and the nectar that flows out attracts many other insects, especially flies, which may provide pollination services.

Insect
pollination

The pollination mechanism in *Iris pseudacorus* (water flag) is unique. The flowers are pollinated by a hover fly or a bumblebee. When the flowers open, the styles, the upper parts of the female pistils, stand about 0.4 inch (1 centimetre) above the falls (the outer members of the perianth, corresponding to sepals), facilitating pollination by the bee alone. As the flower ages, the petallike styles gradually come to lie close to the falls, thereby leaving a narrow passage insufficient for the bee. The fly pollinates such flowers.

Members of the Iridaceae are susceptible to diseases and pests. *Septoria gladioli*, a fungus, attacks the leaves and the corms, causing hard rot; i.e., the corms wrinkle and harden. The leaves of many *Iris* species are subject to leaf-spot and rust diseases that are caused by the fungi *Didymellina macrospora* and *Puccinia iridis*. *Fusarium* wilt is another fungus-caused disease resulting in the yellowing of leaf sheaths. Bacterial soft rot caused by *Erwinia caratovora* is a foul-smelling rot of the rhizome; it is spread by the iris borer. Small gladiolus thrips suck the juice from leaf sheaths and flower buds. Most of these diseases and pests are, however, easily controlled by conventional methods.

Ecology. The three mycotrophic families usually grow under the shade of tropical and subtropical rain forests, and most favour acid soils. The family Iridaceae is composed of tropical and temperate plants. Its species prefer sunny habitats and also grow in temperate deserts and alkaline soils. The evolution of the cormous and the bulbous habits has enabled the members of the iris family to grow in some of the most arid regions of the world. Areas in the Mediterranean region in which forests have been destroyed are rapidly colonized by the sunny habitat genera of the family—e.g., *Iris* and *Crocus*. The water flag, *Iris pseudacorus*, forms part of the swamp flora along waterways and is characteristic of sedge-reed zones and boggy poolsides.

Members of the Iridaceae are prone to hybridization, which enables them to become established in different ecological habitats. This appears to have contributed to their wide distribution and evolution.

The minute size of the seeds of the mycotrophic families affords wide dispersal by wind. The need for the specific fungal symbiont on which the plants are physiologically dependent, however, has resulted in a comparatively limited geographical range for the members of these families.

Hybridization
as an aid in
habitat
exploitation

FORM AND FUNCTION

Vegetative and floral characteristics. Plants of the order Iridales are caulescent or acaulescent—stemmed or stemless—herbs with radical (basal) or distichous (in two vertical rows), parallel-veined leaves.

The flowers are mostly bisexual (both sexes in one flower) and radially or bilaterally symmetrical; they have a petaloid perianth—the sepals and petals look alike or are both showy and petallike (that is, generally united at the base). There are three (less commonly, six) stamens (male pollen-producing structures) that are attached to the upper surface of the tepals (the showy petallike sepals and petals when considered together, as in this case, in which

the attachment may be with the sepals or petals or with both when the stamens are six in number). The anthers, or pollen-bearing parts of the stamen, are two-celled; the pollen grains are mostly binucleate. The ovary in most species is inferior—i.e., enclosed within the basal portions of the sepals and petals; it is three-celled, and the ovule attachment is axile or along the central axis. In some species the ovary is one-celled, in which the ovule attachment is parietal (to the inner ovary walls). The fruit is a capsule.

Physiological and biochemical features. Many species in the order respond to environmental factors; for example, high intensities of light are necessary for well-developed flowers in *Gladiolus*. Temperature has an effect on the flowering of the Wedgwood iris; at extremely high or low temperatures no flower formation occurs. It is possible to make the irises bloom year round by lifting the bulbs prematurely and storing them at a controlled temperature.

The opening and closing of the flowers of the crocuses are dependent on temperature. This is because of the differential growth rate of certain inner cells of the tepals according to temperature. *Crocus* is sensitive to even as small a change as 0.5° C (0.9° F).

Among the known chemical components of the family Iridaceae, the glycosides (sugar-containing compounds), resinoids (gummy substances insoluble in water), anthocyanins (reddish or purplish pigments), flavonoids (base compounds of certain yellow pigments), volatile and non-volatile oils, and seed fats rich in linoleic acid are worthy of note. The blue flag *Iris versicolor* contains the resinoid iridin (which should not be confused with the glycoside, also called iridin, found in *I. florentina*). The floral pigments are mostly anthocyanins. Coumarin glycosides (compounds with a vanilla-like odour sometimes used in flavourings) are present in some species—e.g., *I. wattii*.

Chemical similarities among related species is of diagnostic value in the genus *Iris*. The species in the *pogoniris* and *evansia* sections of the genus, for example, do not contain leuco-anthocyanins or flavonols (organic compounds containing the ring-structured molecule phenol); in those of the *sibirica* and *californica* groups, however, both the compounds are consistently present. Species of the subsection *spuria* have only leuco-anthocyanins. It is of interest that the two isoflavones, iridin and tectoridin, that are found in species of the *pogoniris* and *evansia* groups, respectively, have not yet been found in any other plant.

EVOLUTION

In earlier classification systems, the family Iridaceae was considered to be derived from the Amaryllidaceae, a view

chiefly based on the common character of the inferior ovary. The importance given to the position of the ovary has been questioned, however, and, even though the Tasmanian genus *Isophysis* has a superior ovary, it has been transferred from the family Liliaceae (order Liliales) to the Iridaceae; the genus therefore is iridaceous in all respects except the superior ovary. Furthermore, it is now widely believed that, although the families Amaryllidaceae and Iridaceae are similar, they have evolved separately from the Liliaceae.

The tiny seeds with an undifferentiated embryo and mycotrophy are features that the family Burmanniaceae shares with the orchids. The two families are closely allied, and the orchids, in older classification systems, are considered to be derived from the Burmanniaceae. Current phyletic appraisals, however, have resulted in the shifting of the Burmanniaceae from the orchid order to the order Iridales, or, in some classification systems, to the order Liliales.

Evidence based upon variations in the development of the stomatal complex (i.e., the stomates, the microscopic pores in the leaves, and the cells near them) among the monocotyledons is valuable in considerations of phylogeny. All the studied plant groups of the order have a stomatal complex with two guard cells (the cells that control the size of the stomate opening) and no subsidiaries (cells that surround the guard cells). This type is regarded to have arisen only once in the evolutionary history of the monocotyledons. Furthermore, the plant groups with this type of stomatal complex usually are closely related. Floral features are thought to have developed along one or, at most, only a few related and parallel lines of increasing specialization, starting with the more primitive order Liliales. According to recent authorities the families of the iris order are derived from the family Liliaceae. Furthermore, the Burmanniaceae and the Corsiaceae are now considered to represent a parallel evolutionary line with the orchids.

Relation to
iris order

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The most important distinguishing features that are useful in delimiting the families of the iris order include the growth habit of the plants, the nature of the leaves, the symmetry of the flowers, the arrangement of the sepals in the bud, the number and position of the stamens, and the number and structure of the seeds.

Alternate systems of classification. The classification adopted in this article is a recent one; however, the inclu-

Representative plants and structures from three of the four families of the iris order.

sion of autotrophic and mycotrophic families in the iris order is a situation about which there is no unanimity of opinion among botanists at present.

In an older classification system, the family Burmanniaceae and the family Orchidaceae were placed together in a single order, the Microspermae. The genus *Geosiris* was removed from the Iridaceae and included in the Burmanniaceae. The family Iridaceae of that system then formed a suborder, Iridineae, under the order Liliiflorae.

Eventually each of the three tribes of the family Burmanniaceae (Euburmanniaceae, Thismieae, and Corsieae) was raised to the rank of a family. A new order was proposed for them—the Burmanniales. The family Iridaceae was also elevated to the level of an order representing a distinct group.

Other authorities included the tribes Euburmanniaceae and the Thismieae in a newly circumscribed family, Burmanniaceae, and treated the tribe Corsieae as a separate family, Corsiaceae. The genus *Geosiris* was also raised to the rank of a family.

All four families are now placed in the order Liliiflorae of one widely accepted classification system. The Burmanniaceae and the Corsiaceae are included in the suborder Burmanniineae of that system, and the Iridaceae and the Geosiridaceae are placed in the suborder Iridineae. A different, also widely accepted classification system places the Iridaceae in the order Liliales and the three mycotrophic families in the order Orchidales. In the scheme adopted here, the four families compose the order Iridales.

The above taxonomic and phylogenetic controversies result, at least in part, from the nonavailability of allegedly primitive and critical genera and species for morphological study. Studies in the vegetative and floral anatomy, embryology, and cytology (structure and function at the cellular level) of the various groups of the order are necessary for detailed phyletic and taxonomic appraisals. (R.M.P.)

Zingiberales

Zingiberales (formerly known as Scitamineae) is an order of monocotyledonous flowering plants. The order includes 8 families, 89 genera, and about 1,800 species. Plants of the order are abundant and conspicuous throughout the wet tropics, and some are also found in the seasonally dry tropics. They are herbaceous perennials in the sense that most of them have little or no woody tissue, but the plants and their leaves are, in many cases, very large; and in the wet tropics they are evergreen. Because their stems lack the power of secondary growth in thickness, their possible growth habits are restricted, but within these limits they are remarkably varied. The family Musaceae provides the cultivated bananas and Manila hemp (*Musa textilis*). All species of the family Zingiberaceae are more or less aromatic, and the family provides several kinds of spices, among them ginger, turmeric, and cardamom; some species also have medicinal uses. The family Marantaceae includes arrowroot, a source of fine starch; and the allied family Cannaceae, to a more limited extent, provides edible rhizomes (rootlike stem structures). Though many species of all families have other minor uses (e.g., flower buds and leaf sheaths for food, leaves for wrapping food and for thatching, etc.), the remainder are chiefly notable for the decorative character of their leaves and flowers, and many are cultivated for this reason. The only genus, however, in which considerable breeding for production of fine decorative varieties has been attempted is *Canna*. In recent years work on banana breeding in the West Indies has resulted in a great extension of knowledge of the wild species of *Musa*, which have been used, or studied for possible use, in the breeding program. The only plants of the order that are hardy in north temperate regions are species of *Roscoea* (Zingiberaceae) from the Himalayas.

GENERAL FEATURES

Size range and diversity of structure. The largest plants of the order are the traveller's tree (*Ravenala madagascariensis*), which has a woody trunk about 30 feet (9 metres) or more tall and a fan-shaped array of 20 or more leaves 13 to 16 feet (4 to 5 metres) long, and the gigantic

Musa ingens of New Guinea with its false trunk about 30 feet (9 metres) tall. *Musa* are actually herbaceous, non-woody plants whose rolled leaf bases and sheaths form what looks like an aerial stem. The smallest Zingiberales are the lowly herbs of *Kaempferia* (Zingiberaceae) and some members of the family Marantaceae that raise their upward facing leaves only a few centimetres above ground. The leaves of *Musa* and *Canna* spread in all directions from the stem, but most other genera have them in two ranks; variety in appearance is caused by close or wide spacing of the leaves, size of leaf blades, short or long leafstalks, vein patterns, and (especially in Marantaceae) colour variegation of leaves. The inflorescence (flower cluster) is always terminal on an erect stem, but sometimes these stems are very short and are separate from the leafy ones. Flower clusters are located in the axils (the angle between two organs) of the main inflorescence bracts and vary from very compact to spreading with well-spaced flowers. In many species the cluster is reduced to a single flower. Similarly, the size of flowers and the relative size of their parts show great differences as between the various families, though all have the same basic pattern. The pattern is further complicated by a reduction of the basic number of six stamens (the male parts of the flower) and the replacement of some of them by petallike staminodes (sterile stamens). At the extremes are the large and spectacular blossoms of the bird-of-paradise flower (*Strelitzia*) with two erect much-modified petals and only one stamen missing, and the very small flowers of some Marantaceae species, which have staminodes of four different shapes and only half a functional stamen. *Maranta* flowers are thus asymmetric, and as if to compensate for this lack of symmetry, they are produced in pairs, each flower a mirror image of the other.

Distribution and abundance. Though the order is represented by conspicuous plants throughout the tropics, the distribution of the constituent families is diverse. Probably the woody members of the order (in the family Strelitziaceae) are the oldest in an evolutionary sense, and they have a curiously discontinuous distribution. The family is thought formerly to have contained more species than at present and was probably more widely distributed. Two of the genera (*Ravenala* in Madagascar and *Phenakospermum* in South America) have each only one species; the third genus, *Strelitzia*, has five species in southern Africa. Musaceae species are confined, as wild plants, to the Old World tropics, with a centre of distribution in the region of Myanmar (Burma), Thailand, and Malaya, but cultivated bananas have been carried by man to all parts of the tropics and some subtropical regions. The only genus of Musaceae in Africa (*Ensete*) has no part in the production of edible bananas but provides food in Ethiopia from its leaf sheaths. The family Heliconiaceae mainly occurs in tropical America, but there is one variable species in the western Pacific (New Guinea to the Samoa Islands), some forms of which have been widely cultivated for decorative purposes. Zingiberaceae, the largest family in number of species, is found throughout the tropics but is predominantly Asian; the related family Costaceae, also worldwide tropical, is most numerous in America. Marantaceae, the second family in order of size, is most diversified in the New World but also occurs in the Old (the American species have been better studied and are the only ones in cultivation). The family Cannaceae is confined to the Americas. The family Lowiaceae consists of six little-known species in the forests of Malaya and Sarawak; its short-lived, foul-smelling flowers are orchidlike but have five stamens. The family Zingiberaceae is still very imperfectly known, and many species have been described only from imperfect dried specimens; over much of its range this family needs a new study based on living material for a better understanding of generic concepts, which are still confused.

NATURAL HISTORY

Growth habits. With the exception of the genus *Ensete*, all plants of the order have the same basic growth habit, but this is disguised by differences in foliage and the presence of varying development of rhizomes. Each erect

(Left) Floral structures of two families and (right) growth habits in the order Zingiberales.

In the right-hand figure a diagrammatic interpretation of the evolution of the various growth habits is shown by the stem structures (not to scale). The arrows indicate the direction of evolution according to the concept that woody plants were primitive in the order.

(A) *Phenakospermum*, with a short woody stem and terminal inflorescence. New stems occur at the ends of rhizome elements. (B) *Ravenala*, with tall, woody stem and lateral inflorescence. New stems appear as suckers near the parent stem. (C) *Musa*, with stem consisting of a large, fleshy corm bearing a terminal inflorescence and suckers. (D) *Ensete*, with growth habit as in *Musa* but lacking suckers. (E) The nonwoody rhizomatous habit of *Zingiber*, of the family Zingiberaceae, and most other members of the order.

Drawing by M. Pahl based on (Musaceae) Curtis's Botanical Magazine (1898), (*Zingiber ortensii*) R.E. Holttum, *Plant Life in Malaya* (1953); Longman Group Ltd., (*Ravenala madagascariensis*, *Musa paradisiaca*) A.B. Rendle, *The Classification of Flowering Plants* (1967); Cambridge University Press, (A-E) Evolution (1962)

Limited manner of growth

leafy stem is of limited growth because it has no power of increasing in thickness; the main root is similarly limited, but many additional roots are produced from basal stem nodes (the "joints" of the stem). New growth comes from a bud in the axil of a basal leaf, and this new growth has to start horizontally to become clear of the parent stem. If its end turns up close to the parent stem, the new shoot is called a sucker; if horizontal growth is extended, it is called a rhizome or stolon. In either case the horizontal part and the base of the new erect stem bear new roots at the nodes; thus every new leafy stem has its own new complement of roots. The first erect shoot of a seedling is usually small, successive ones becoming larger until the mature size is reached, after which the pattern is repeated indefinitely, the rhizomatous species at least being potentially immortal; how long individual plants live in nature is, however, unknown. This kind of growth is called sympodial; a horizontal rhizome may ultimately appear continuous, but it is built up from a series of elements, each of which grows upward at its tip. *Musa* and *Ravenala* plants produce suckers that grow up close to the parent stem; some species of the family Zingiberaceae have quite long rhizome elements, and the leafy shoots are far apart. This sympodial growth is common to most monocotyledons, though often it is more modified than in the order Zingiberales.

Ecology. The majority of species are shade plants of the rain forest of evergreen tropical regions, though some grow mainly on forest margins or in clearings or on riverbanks. Within a single genus (e.g., *Musa*, *Costus*) some species may grow only in shade while others grow in more open places. In Malaya many members of the family Zingiberaceae that have tall leafy stems produce their flowers on separate, short, sheath-covered stems that arise from buds on the rhizome; the flowers are protected by overlapping

bracts, the whole inflorescence often being shaped like a pinecone. In species having long rhizome elements the inflorescence may appear some distance from the nearest leafy stem. In the genus *Achasma* the inflorescence shoots are so short that they do not emerge from the ground and all that can be seen is a circlet of flowers with bright red labella (prominent petallike structures) radiating outward, the flower tubes and ovaries being below ground level. Fruits ripen below ground and the seeds are thought to be dispersed by wild pigs or other animals. The leafy shoots may be 10 to 16 feet (3 to 5 metres) tall, so that the leaves are high in the air, even though the flowers are partially buried in the ground. In the genus *Hornstedtia* the inflorescences are wholly just above ground level, with firm empty outer bracts forming a spindle-shaped structure out of the top of which the flowers emerge, one or two at a time. In one Malayan *Hornstedtia*, however, the whole rhizome is raised 20 inches (50 centimetres) or more above the ground by thick red stilt-roots so that the flowers are also raised. In nearly all such inflorescences the overlapping bracts (leaflike structures attached just below an individual flower, or below a flower-bearing branch of the inflorescence) hold water in which flower buds and, later, fruits develop. Alternatively, moisture may be provided by the rotting of main bracts (e.g., in some species of *Amomum*) so that fruits develop in a mass of black putrescence maintained in a wet state by frequent rains. In species that flower at the top of leafy stems, the main inflorescence bracts are often small or lacking and the flowers are fully exposed. The inflorescence develops inside the tube of overlapping leaf sheaths and appears at the top of the plant with flowers fully formed; the leaf sheaths thus take over the protective function of the main bracts. All members of the family Zingiberaceae have brightly coloured flowers and slender flower tubes full of nectar,

Water-storing structures

and they are probably mostly pollinated by butterflies. Flowers are, in all cases, short-lived, often lasting only a few hours.

The small flowers of Marantaceae, usually white, have a curious mechanism that is little understood but is doubtless connected with pollination by small insects. The style develops an internal tension but is held straight by the hooded staminode; when the latter is touched, the style escapes and instantly bends so that the stigma (the sticky pollen receiving surface) faces downward. Pollen is deposited from the ripe stamen on the style below the stigma before the flower opens and may be removed by a visiting insect, but self-pollination is impossible.

Musa flowers are individually not conspicuous but the large main bracts are so; the bracts curl back in turn to expose the flowers they have protected while in bud. *Musa* species (including cultivated bananas) with pendulous inflorescences and dull purplish bracts have flowers with a rank odour and copious nectar; they open at night and are visited by bats. An important character of the cultivated bananas is that fruits develop without pollination; and if pollinated by bats (as they often are) they do not form seeds. Other species of *Musa* have erect inflorescences and brightly coloured bracts; such appear to be bird-pollinated, though the flowers are also visited by bees for pollen. The large flowers of *Strelitzia* are thought to be bird-pollinated.

The curious genus *Orchidantha* consists of rather small plants found in Malayan forests. One species has quite large flowers with dull purplish sepals and creamy white labellum, both as long as 5 inches (12 centimetres). The flowers have a strong unpleasant odour and probably attract flies, but no observations on pollination have been made and few fruits have been found. The ovary (female flower part) has a long solid neck to which the other parts of the flower are attached.

The species of the order that occur in seasonal parts of the tropics are adapted to withstand drought. Some of them (e.g., *Kaempferia*, *Curcuma*, and *Zingiber* species) lose their leafy parts and survive the dry season as underground rhizomes. Some *Curcuma* and *Kaempferia* species also produce tuberous roots, which act as an additional store of food and water. Many such plants produce their inflorescences in the latter part of the dry season before the new leafy shoots appear. An African species of *Costus* produces downward-growing rhizome branches that function as tubers (underground storage organs) and do not end in leaf shoots. *Ravenala* plants grow in open places in Madagascar but are evergreen; they may be helped to withstand dry seasons by the water they produce and store (not rain water) in their closed sheathing leaf bases, about a litre in each. *Phenakospermum* is a swamp plant.

Epiphytes (plants that are not rooted in soil but grow upon the branches of other plants or in other aerial locations) in the wet tropics, like plants of seasonally dry climates, need to have some method of withstanding drought, because their roots are exposed. The few species of Zingiberaceae that grow epiphytically (at least two species of *Hedychium* in Malaya) have thick fleshy roots not unlike the tubers of some *Kaempferia* species, but their function is probably storage of water rather than food. The plants are evergreen and do not grow in places exposed to strong sun and wind.

FORM AND FUNCTION

Vegetative characters. Leaves normally consist of a broad blade with a conspicuous midrib and a stalk that grades into a long sheathing base, but leaves at the base of a new shoot consist of sheaths only. One of the common characters of all members of this apparently diverse order is the arrangement of tissues seen in a cross section of a leafstalk. This arrangement typically includes prominent arcs of vascular bundles and air canals. Each new leaf grows up inside the sheath of the preceding one. In this position its blade has to be tightly rolled, one half being rolled inward, the other being rolled entirely outside the inner one; this is another peculiar character common to all members of the order. As a consequence, the halves of a fully expanded leaf are often slightly unequal, or the base of the blade is asymmetric. There are also other anatomi-

cal characters common to all members of the order, as well as some peculiar to each family. Each leaf in the family Marantaceae, for example, has a peculiar firm specialized tissue called a pulvinus at the junction of the blade with the midrib or stalk; this consists of elongate cells arranged obliquely to the surface, and it serves to fix the angle between blade and stalk. In the family Cannaceae, which on other grounds also shows relationship to Marantaceae, there are similar cells on the lower surface only.

In almost all members of the order, the long leaf sheaths overlap, so that the true stem bearing them is not exposed. The stem is slender and lacks firm tissues, the leaf sheaths (inner ones very long) providing the necessary rigidity. In consequence, the only fully exposed stems occur where the flowering stalk projects above the false stem of leaf sheaths. Exceptions to this rule are found in the genera *Costus* and *Canna* and in some species of the family Marantaceae. Plants of *Donax* (Marantaceae) in Malaya have one stem section 7 to 10 feet (2 to 3 metres) or more tall from the ground to the first bladed leaf; these slender, firm structures are much used locally for mat making and basketmaking and are known by the Malay name *bembans*.

Inflorescence. The inflorescence terminates the growth of a stem in most members of the order. The exceptions are the axillary inflorescences of *Ravenala* and some *Strelitzia* species and those of the family Zingiberaceae in which the leafy shoots bear no inflorescence. The basic inflorescence type consists of an erect axis bearing main bracts (specialized leaves, unlike the regular leaves, located immediately below a flower or flower cluster), in the axil of each of which is a monochasial cyme (a flower cluster whose first flower is located at the end of the axillary shoot attached to the main axis of the plant, the second flower arising in the axil of a bract located on this shoot below the first flower, the third flower similarly arising below the second, and so on for many additional flowers). In some cases there may be branch inflorescences, each like the top of the main one, in the axils of lower main bracts. This arrangement can produce a great variety of different floral displays. The main bracts may be large or small, absent (some Zingiberaceae) or reduced to one (*Strelitzia reginae*), closely overlapping or widely spaced, green or brightly coloured. Some species are cultivated because of their decorative bracts (*Heliconia* and species of *Nicolaia* known as torch gingers). The cyme within each main bract may be very condensed so that its branching is hardly detectable, or it may be reduced to a single flower; in other cases (*Alpinia* and *Globba* in the family Zingiberaceae) the cyme is extended and its branching conspicuous. In *Musa* the flowers are functionally unisexual (the stamens, although present in the female flowers, lack pollen), and the cyme within each main bract lacks all minor bracts, but a careful study of the sequence of development of flower buds shows that the arrangement is cymose (i.e., the terminal flower matures first). The terminal part of the inflorescence, usually pendulous, bears only male flowers, in which ovaries and stigmas are reduced and nonfunctional; this male inflorescence tip is cut off and often cooked for food.

Flowers and fruits. Zingiberales flowers have three sepals (calyx), three petals (corolla), up to six stamens (male structures) in two whorls of three each, some being represented by sterile structures of varying form, and three carpels (constituting the ovary), the members of successive whorls alternating. The female structure, or ovary, is enclosed by the united basal portions of the other flower parts, which thus appear to arise at the upper end of the ovary, a condition called inferior ovary. The calyx is always different in shape and size from the corolla, and the sepals are free from each other in all families except Zingiberaceae, which has a tubular calyx with small free lobes. The flowers are mostly bilaterally symmetric (zygomorphic), but in some cases they are asymmetric. There are six stamens in the genus *Ravenala* only, the rest of the order exhibiting either five stamens (four families) or one functional stamen, the other stamens represented by a varying array of petallike sterile stamens called staminodes, which form the conspicuous part of the flower (four families).

members
of the
order

Characteristic shape of flowers

Variations on the basic flower structure pattern exist in the families with five and with one stamen. In the former, sepals and petals are the conspicuous parts of the flower; they are often large, and the paired petals are larger than the median one except in *Musa* and the family Lowiaceae. The families with one stamen and a varied number of petallike staminodes show a great range of floral form. The most conspicuous part of the flower in the family Zingiberaceae, usually called the labellum (though it does not consist of the same floral parts as the labellum in the family Lowiaceae and in orchids, in which it is a petal) represents two or three united stamens, and in many genera there is a pair of smaller but conspicuous petallike staminodes, each representing one stamen (in the genus *Zingiber* they are joined to the labellum); the result is a flower of orchidlike aspect, but the parts concerned in orchid and ginger flowers are different and undoubtedly the two have developed along quite different evolutionary lines. In the families Marantaceae and Cannaceae the single stamen is only half functional, the other half being more or less petallike. In both families the staminodes are of varying size and shape, so that their status is not easily decided, and there have been differences of opinion about them. In the family Costaceae the large labellum represents a union of all five nonfunctional stamens, and in some cases it can be seen to be five-lobed.

The fruit is usually dehiscent (splitting open along definite lines), except in *Musa* and *Heliconia*, with several seeds that have attached growths, called arils, of various forms (in the family Marantaceae the arils assist the dehiscence of the fruit). Reduction in the number of seeds, in a few cases to one, occurs independently in the family Heliconiaceae, in various subdivisions of Zingiberaceae, and in Marantaceae. The seeds have abundant endosperm (food storage tissue). The hard seed coat has a little plug opposite the radicle (the portion of the embryo that will become the root) of the embryo, and in germination the base of the cotyledon (the so-called seed leaf) elongates far enough to bring the aerial bud clear of the seed, the cotyledon tip remaining in the seed as an absorbing organ.

EVOLUTION AND PALEONTOLOGY

The order Zingiberales is a group of monocotyledons that has not invaded temperate regions, but its species have spread to seasonal parts of the tropics where they have evolved adaptations involving a period of rest during seasons when growth is impossible because of drought. Other groups of monocotyledons have evolved further by the development of resting organs (rhizomes, corms, and bulbs) that can withstand cold, the result being that monocotyledons of temperate regions (except grasses) are often thought to be characterized by such storage organs and by an adaptation to seasonal growth alternating with rest. It seems probable that monocotyledons began their existence in the wet tropics and that continuous growth on a sympodial pattern is their basic life form. Zingiberales show how this life form can be the basis for evolution of resting organs; there can be no doubt that this order began its diversification in the wet tropics, where it has left no certain fossil record.

It has been stated that the order Zingiberales shows resemblances to the subfamily Asphodeloideae of the Liliaceae (order Liliales). The members of that subfamily, however, are temperate or subtropical plants, mostly geophytes (plants that overwinter below the ground surface) of seasonal growth; furthermore, they do not share any of the peculiar characters common to all Zingiberales species. Evidence has been produced that the woody species of the family Strelitziaceae represent the most primitive element in Zingiberales; if that is so, a common ancestor with the family Liliaceae must go back further than the beginning of the present great diversity of Liliaceae. Some authorities have also suggested that the possibility exists that the monocotyledons as a whole have descended from treelike ancestors. It is, however, equally possible that the woody Strelitziaceae, the palms, and the pandans are independent evolutionary developments exhibiting woody structure and that the original monocotyledons were ancient herbaceous (nonwoody) dicotyledons similar to the family

Nymphaeaceae (order Nymphaeales) but more primitive and less reduced.

Examples of fossil Zingiberales are not certainly known, though there are fossil leaves that may belong to this order. The most likely records are fossil fruits and seeds from Eocene and Oligocene deposits (about 30,000,000 to 50,000,000 years old) in southern England and elsewhere in Europe; these have been given the name *Spirematospermum*. The fruits are somewhat like small bananas, but the inflorescence is more like that of some members of the family Zingiberaceae allied to *Alpinia*; the seeds are also *Alpinia*-like. *Musa*-like leaves have been found in the same formations as these fruits.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. Flowers provide the basis for division of the order into families, though growth habit and inflorescence structure are often also distinctive. Within the family Zingiberaceae, the form of staminodes separates two tribes. Within both Zingiberaceae and Marantaceae it is held by some authorities that inflorescence structure is more important than flower structure in distinguishing genera.

Taxonomic problems. The families with five stamens have, until recently, all been included in the family Musaceae, and the family Costaceae has formerly been included in Zingiberaceae.

Recent studies of the family Musaceae have been undertaken in connection with banana breeding, but accounts of wild species are still inadequate. In the only existing monograph of the family Zingiberaceae (1904) the genera were not clearly defined and several generic names were misused, causing subsequent confusion. Much field work remains to be done throughout the Malayan region, but there is a real danger that many species may be exterminated by clearing of forests before this is accomplished. The genera of Marantaceae in the Old World are also not yet clearly defined. (R.E.H.)

Orchidales (orchid order)

Orchidales is an order of monocotyledonous flowering plants considered by most authorities to contain only one family, the Orchidaceae, or orchid family. The small family Burmanniaceae has sometimes been included within the orchid order, however, and the subfamily Apostasioideae, included here, has sometimes been considered as a separate family (Apostasiaceae) in the order Hemodiales.

The orchid family is regarded by most botanists as the largest family of flowering plants, although it is not yet possible to give an accurate estimate of the size of the family. Educated guesses range from 15,000 to 35,000 species in 400 to 800 genera, but the lower estimates usually fail to consider the diversity of the family in the tropical regions.

GENERAL FEATURES

Discussions about orchids, whether among professional botanists or amateur orchid enthusiasts, often leave the impression that orchids are "somehow different" from other plants. As a group, they are different from other plants but only in the morphological (structural) characters that tend to distinguish them. These characters are associated with the flower and its organization. Even the special characters of orchid flowers, such as the masses of pollen called pollinia, the joining of the stamens (male organs) and pistil (female organ) to form the column, and the tiny seeds without endosperm (starchy nutrient tissue) or organized embryos, are found individually in other groups of flowering plants. Therefore, no single character distinguishes the orchids; however, through the combination of several characters, a family of flowering plants, the Orchidaceae, emerges.

Diversity of structure. Orchids are primarily herbaceous (nonwoody), although some species may be vines, vine-like, or somewhat shrubby. The plants may be free-living or, in a few cases, saprophytic (*i.e.*, obtaining their food from the organic matter of dead and decaying plants), and they may be terrestrial or epiphytic (not rooted in

soil but living among tree branches or on other aerial supports). They may even be parasitic on fungi. Orchid flowers vary tremendously in size from the minute flowers of some species of the genus *Pleurothallis*, which are no more than 0.1 inch (about 2 millimetres) in diameter, to the large ones of *Brassia*, which may be more than 15 inches (about 38 centimetres) from the tips of the lateral sepals (petallike structures) to the tip of the dorsal sepal. Although vegetatively orchid plants are somewhat uniform and do not show the wide range of diversity that may be found in some other families, the plants do offer a number of different growth types. Growth habits vary from those in which the plant is reduced to no more than roots (*Dendrophylax*) to saprophytic plants apparently lacking chlorophyll (*Corallorhiza*) to gigantic plants (*Arundina*) that superficially resemble a bamboo.

The diversity of structure among orchid flowers can be attributed mainly to the methods of pollination found in the family or to the fact that the family is adapted for the utilization of a number of different types of pollinators (animals that carry pollen from one flower to another).

Orchids range from above the Arctic Circle to the tropics, but the majority of species are found in the latter.

Importance. The orchid family is probably one of the most important of plant families from a horticultural point of view. Nevertheless, of the 400 or more genera in the family, only about 50 genera are commonly cultivated. A plant group as large as the orchid family might be expected to contain enough different types of plants to satisfy any horticultural desire, but in the past 100 years more than 60,000 orchid hybrids (crosses between different species) have been produced. A number of these hybrids are used

in the cut-flower trade, and a large number of the plants are grown and exhibited with the flowers intact. The large number of corsage orchids and flowers for the cut-flower trade, however, derive from only about 150 species. Several species from distinct genera are grown as hedges in tropical areas, and a number of species are used as ornamentals in warmer regions.

Other than the horticultural uses to which orchids are put, the family is notably lacking in species from which products are derived. The only commercially important product derived from orchids is vanilla. Most vanilla is produced from one species, *Vanilla planifolia*, although two additional species are also cultivated commercially (*V. pompona* and *V. tahitensis*). In recent years the use of artificial vanilla has even reduced the use of natural vanilla.

The principal vanilla-growing areas are Madagascar, Mexico, French Polynesia, Réunion, Dominica, Indonesia, West Indies, Seychelles islands, and Puerto Rico. Vanilla is grown from sea level to about 2,000 feet (600 metres) in elevation. The plant is a climbing vine that is indigenous to the tropical regions of the Western Hemisphere. Although the flowers of vanilla are attractive, they fade quickly and are not useful for the floral industry.

Primitive peoples throughout the world use various other orchids for a variety of folk medicines and cures. In the West Indies, the bulbs of *Bletia purpurea* are boiled, and the liquid is thought to cure poisoning from fish. In Malaya, women take a drink made from the boiled leaves of *Nervilia aragoana* to prevent sickness after childbirth. In Malacca, boils are treated with a poultice made from the entire plant of *Oberonia anceps*. In Chile, *Spiranthes diuretica* is known to be a strong diuretic. In certain parts

of Ecuador, the mucilage from *Catasetum* is thought to be good for broken bones. In various parts of the world, certain orchids are also used for food or food supplements. In Malaya, the leaves of one species of *Anoectochilus* are sold as a vegetable, and the leaves of *Dendrobium salacense* are cooked as a seasoning with rice. In certain parts of the Asian tropics, the tubers of some species of *Gastrodia* are eaten like potatoes. Throughout the world several species of orchids are used as a glue substitute. In most cases the glue is derived from the pseudobulbs. Salep is derived from the tubers of several species of *Orchis*. The tubers are boiled, then dried and powdered. The resulting preparation is often used as a flour substitute.

FORM AND FUNCTION

The flower. The primary characters that distinguish the orchids as a group are found in the flower. At the bottom of an unspecialized non-orchid flower is the stem that supports it, called the pedicel. Directly above, and at the base of the flower itself, is a whorl of green, leaflike organs called sepals. Above and inside the sepals is a second whorl of coloured petals. These are the asexual parts and are developed to protect the flower or to attract pollinators. Inside (also arranged in whorls) are the sexual portions of the flower. First are the male stamens, which consist of a filament (the slender stalk that supports the anther) and an anther (usually an arrangement of four sacs filled with loose pollen grains). There may be several whorls of stamens. In the centre of the flower is the female pistil, which is composed of an enlarged portion (the ovary) topped by a stalklike style with a stigma at its apex. The pollen in the anther is powdery and is usually carried from the anther of one flower to the stigma of another flower by a pollinating agent.

The previous description is of a generalized flower, and it must be kept in mind that many types of variations may be found. Even though it is a generalized flower, it is not to be considered a primitive flower. The generalized orchid flower is also supported on a pedicel. The ovary, however, with its ovules seems to be an integral part of the pedicel because it is embedded within the upper portion of the pedicel below the attachment of the petals. The orchid flower is thus said to have an inferior ovary. The sepals and petals are usually similar, often highly coloured, and in sets of three. One petal is developed as a landing platform for the pollinator and is called the lip (or labellum).

Sexual organs. The sexual portions of the orchid flower are quite different from other generalized flowers, and they tend to characterize the family. The filaments, anthers, style, and stigma are reduced in number and are usually

fused into a single structure called the column. In one relatively small group (the lady's slippers), two anthers are present, one on each side of the column (some members of the primitive subfamily Apostasioideae have three anthers). The majority of the orchids, however, retain only a single anther at the apex of the column.

In the orchid the ovary is composed of three structures called carpels. The carpels have fused so that the only outward evidence of their existence is the three ridges on the outside of the seed pods. The mature seed pod does not open along the lines of juncture but rather down the middle between the lines of juncture. The ovules, which are arranged along the ridges inside the ovary, do not develop until some time after the flower has been pollinated, thereby contributing to the long delay between pollination and the opening of a ripened pod.

Orchid petals. In most monocots the sepals and petals are so similar that they are not distinguished but fall under the collective term perianth. In the orchids, however, they are usually quite distinct and therefore retain their separate identification. The petal opposite the fertile stamen is the one called the lip, or labellum. Often two, or even all three, of the sepals are joined, and the lip, petals, or the sepals may be joined to the column for some distance. One of the characteristic differences between the orchid family and other advanced monocots is that the fertile stamen or stamens (that is, the one or more that are not completely reduced) are all on one side of the flower opposite the lip. This makes the flower bilaterally symmetrical.

The lip is oriented upward in the bud, but as it later develops, twisting takes place in the pedicel or ovary so that the lip is usually oriented downward by the time the flower opens, a process called resupination.

The presence of the labellum as a landing platform for insect pollinators and the reduction of the stamens and pistil of a flower to a single structure, the column, is certainly the apex of floral adaptation to insects as pollinating agents. Once achieved, this combination provides a foundation for all kinds of specializations for attraction of specific pollinators. The development of the strange and complex reorganizations found in the flowers of many orchid genera are directly attributable to evolutionary forces interplaying on the basis of such a pre-existing foundation.

Nectar-producing organs. There are several types of nectaries in the orchids, including extrafloral types that secrete nectar on the outside of the buds or inflorescence (flower cluster) while the flower is developing. Shallow cuplike nectaries at the base of the lip are common. Some nectaries are in long spurs produced either from the joined sepals or from the base of the lip. Members

of the *Epidendrum* complex have long tubular nectaries embedded in the base of the flower alongside the ovary. Nectaries on the side lobes of the lips are known, and general nectar secretion along the central groove of the lip is common. The nectaries of many species of the Liliales order, a possible ancestral group, are within the septa of the ovary, but the nectaries of the Orchidales are present on the sepals or petals, if they are present at all.

In most of the orchids, the stamen and style are fused completely into a single organ—the column; however, in *Cypripedium*, *Apostasia*, and some higher orchids such as *Spiranthes*, they are only partially united. In some cases an extension of the base of the column with the lip attached at its apex forms the column foot. In many instances this structure exudes nectar.

Anthers and pollen. In most of the orchids the anther is a caplike structure located at the apex of the column. The anther of some of the more primitive orchids is superficially similar to that of a lily or amaryllis. In *Habenaria* and its allies the anther projects beyond the apex of the column but is thoroughly attached. Sometimes the two halves of the anther are widely separated and have led some botanists to believe that they represent two anthers. In one subfamily, Cypripedioideae, two anthers do occur and are attached on each side of the column. These orchids are usually considered to be primitive.

Structure
of orchid
pollinia

In most orchids the pollen grains are bound together by threads of a clear, sticky substance (viscin) in masses called pollinia. Two basic kinds of pollinia exist: one has soft, mealy packets bound together to a viscin core by viscin threads and is called sectile; the other kind ranges from soft, mealy pollinia, through more compact masses, to hard, waxlike pollinia. *Goodyera*, *Habenaria*, and *Spiranthes* have the former, and the latter are found in *Sobralia*, *Phajus*, *Cattleya*, and *Oncidium* (becoming harder in that sequence). The hard, waxy pollinia usually have a small amount of mealy pollen with viscin strands that attach the pollinia to each other or to a viscidium. This portion of the pollinium is termed the caudicle.

The stigma is usually a shallow depression on the inner sides of the column. It is composed of the three stigmatic lobes found in the typical monocot flower, but the three lobes are grown together. Faint lines often can be seen on the surface of the stigma, dividing it into three parts.

In the majority of the orchids, a portion of one of the three stigma lobes is specialized and forms a structure called the rostellum. The rostellum projects down in front of the anther in the form of a flap. As the visiting insect begins to back out of the flower, it brushes the rostellum, which is covered with sticky stigmatic liquid. The pollinia

are then picked up from the anther and stick to the body of the insect. Some primitive species have no rostellum, and the pollinia simply stick to stigmatic liquid that is first smeared on the back of the insect. A further specialization occurs in more advanced orchids in which the caudicles of the pollinia are already attached to the rostellum and a portion of it comes off as a sticky pad called a viscidium. In the most advanced genera a strap of nonsticky tissue from the column connects the pollinia to the viscidium. This band of tissue is called the stipe and should not be confused with the caudicles, which are derived from the anther. Orchids that have a stipe also have caudicles that connect the pollinia to the apex of the stipe. The pollinia, stipe, and viscidium are called the pollinarium.

Seeds and their dependence on fungi. Orchid seeds are extremely small and contain an undifferentiated embryo that lacks endosperm. A single seed pod produces a large number of small seeds, which are ideally suited for dispersal by wind. Orchid seeds need the presence of a fungal mat in order to germinate and grow in nature. This mat is called a mycorrhiza. The fungus apparently penetrates the seed and contributes to the growth of the seedling by producing or supplying some of the necessary nutrients for growth. It has not yet been firmly established whether or not the fungus is necessary for the continued growth of the mature plant, but it appears likely that the presence of the fungus aids in the uptake of nutrients and prevents the leaching of nutrients from the root material of epiphytic species. Although it is possible to grow and germinate some orchids without the fungus in artificial cultures, it is thought that a fungus is necessary for germination and growth in nature.

In some cases the presence of a specific species of fungus is necessary, while in other cases several fungi may have the ability to become involved in the process. The fungi that are involved with mycorrhiza in orchids are of two taxonomic groups: the Fungi Imperfecti (Deuteromycetes) and the Basidiomycetes (fungus order Agaricales), the latter group being that to which the familiar mushrooms belong. Although most, if not all, orchids have mycorrhiza, mycorrhiza are not limited to the orchid family but are found in a large number of other plant families.

Growth habits. The majority of the tropical orchid species are epiphytes; that is, they grow on trees without connection with the ground. Nearly all of the orchids in the temperate zones, however, are terrestrial.

The predominant growth form in a wide range of monocots has been shown to be a type known as the sympodium, and this may reasonably be considered to be the primitive condition in the orchids. Sympodial growth is a

tion

Extreme variations employing habitat.

(Left) *Neottia nidus-avis*, bird's nest orchid, is a nongreen saprophytic orchid. (Right) *Taeniophyllum zollingeri* is epiphytic, with flattened green roots that act as organs of attachment and in place of leaves for photosynthesis.

(Left) C. Foord—EB Inc., (right) W.H. Hodge

creeping habit, and it consists of an axis that appears continuous but is, rather, made up of a succession of elements that each originate not from a terminal bud but as a fork of a dichotomy, the other fork being weaker in growth or suppressed entirely. The usual form of a sympodium is a horizontal rootlike stem structure called a rhizome that turns up at the ends of each "branch." Most primitive orchids have a rather ordinary monocot appearance with a short rhizome stem and erect, nonthickened annual stems having scattered, spirally arranged leaves and a terminal inflorescence (flower cluster).

Another major type of growth form found in the orchid order is the monopodial habit, in which the stem has unlimited apical (terminal) growth and roots are not restricted to its basal portion. In some systems of classification this has been considered to be a distinguishing mark of the subtribe Sarcanthinae; however, the monopodial habit occurs in the subtribes Vanillinae, Cymbidiinae, Maxillariinae, Pachyphyllinae, Thelasiinae, and Oncidiinae and possibly in other groups as well. In some of these groups there exists a graded series from sympodial plants to related monopodial types.

A great many orchids, especially the epiphytic groups, show variously thickened stems, or "pseudobulbs." While these structures are quite diverse in form, they fall into a limited number of morphological types and seem to show some evolutionary trends. One of these seeming trends is from pseudobulbs (or corms, bulblike stem structures) of several or many internodes (nodes are stem regions at which leaves attach, internodes are the stem areas between such nodes) to pseudobulbs of a single internode (as in *Bulbophyllum* and the subtribes Maxillariinae and Oncidiinae). Thickened stem bases may be found in either terrestrial or epiphytic groups, but pseudobulbs of a single internode are restricted to primarily epiphytic groups.

Saprophytic orchids, those that obtain their food from dead organic matter instead of by photosynthesis, are found in at least 12 subtribes of orchids. The majority of orchids pass through a saprophytic seedling stage, which may last for months, especially in terrestrial species. Thus, the evolution of a completely saprophytic life cycle in different groups of orchids is not surprising. The wholly saprophytic orchids pose special classification problems. The adaptations for saprophytism drastically change the vegetative features of the plant, thus obscuring some of the characteristics normally used for determining relationships. Even the reproductive features may be affected by these adaptations. In the genus *Corallorhiza*, for example, the pollen-bearing structures are more simple than in the related genera *Oreorchis* and *Tipularia*. In the absence of these two closely allied genera, *Corallorhiza's* relationship to the Cyrtopodiinae subtribe would be much less clear. The saprophytes are difficult to cultivate and are poorly represented by herbarium specimens, which further complicates their study. Autogamy (self-fertilization) is frequent, and an autogamous saprophyte is nearly the ultimate in taxonomic difficulty.

NATURAL HISTORY

Life. The life cycle of an orchid is not essentially different from that of any other flowering plant. When the pollinator leaves the pollinia on the stigma (the pollen-receiving structure of the female flower parts), the pollen tubes germinate and grow down the centre of the column to reach the ovary. This often causes the sides of the stigma to swell around the stigma and the enclosed pollinia. When the pollen tubes reach the ovules (this often takes six weeks or more, during which time the ovules have been developing), one or more enters and the sperm unites with the egg. The fertilized egg, or zygote, begins to divide to form the mass of cells destined to become the embryo. Most other plants have a slightly different development from that of the orchid. There is usually a double fertilization, one of which forms the zygote and the other an endosperm that nourishes the developing plant upon germination until the plant is able to manufacture its own food.

The orchid seed, however, has no endosperm. The seed consists of a simple, dry, outer coat enclosing a small

mass of undifferentiated cells that form a pro-embryo. This extremely small and light unit can easily be carried in air currents and may travel long distances before coming to rest. The number of seeds in a single orchid capsule is nearly astronomical: close to 2,000,000 seeds have been reported from a single capsule of *Catasetum*. These extreme numbers undoubtedly are correlated with the unlikelihood of a seed's falling in a favourable spot.

Ecology. Orchids have a wide ecological distribution when the entire family is considered. Although the family is primarily tropical, a number of species are found in the northern and southern temperate zones. At least four species have been reported from north of the Arctic Circle. A number of species of the north temperate zone are found in bogs, prairies, grasslands, and hardwood forests.

Several species of *Spiranthes*, *Habenaria*, and other orchids are found in roadside ditches, often in wet, boggy situations. In some areas of the United States, *Habenaria ciliaris* might almost be considered a weed. The introduced Asian species *Zeuxine strateumatica* in southern Florida is now widespread and may be considered a weed.

Orchids grow from sea level to at least 15,000 feet (4,600 metres) in elevation. The greatest number of orchid species is found in cloud-forest associations in tropical regions. These are usually on forested mountainsides where the clouds brush the mountain day and night. Such forests are literally covered with mosses and lichens, and the inclination of the ground permits sunlight to penetrate through the vegetation to the ground. This is a perfect habitat for epiphytic orchids as well as aroids (family Araceae), ferns, gesneriads (family Gesneriaceae), and numerous other epiphytic groups of plants.

Contrary to popular belief, rain forests on generally flat terrain are poor localities for orchids. At Iquitos, on the Amazon River in Peru, only about 125 species of orchids have been reported, and many of these are quite rare. Orchids that do occur in rain forests tend to be in the tops of large trees with little variation in each tree. Often great quantities of a single species inhabit a tree, while another nearby tree may have only one or two additional species. The tropical-deciduous seasonal hardwood forests of the tropics, where marked wet and dry periods occur, often have numerous orchid species; however, this also tends to be the best farmland, and therefore forests do not last long after colonization by man.

A wide range of ecological tolerance is shown by orchids. In addition to those species that are found above the Arctic Circle, a few species of orchids are found in desert conditions; for example, in the dry areas of northern Peru, several species of orchids are found epiphytic on cacti. On the Santa Elena Peninsula in western Ecuador, two species of *Oncidium* as well as one species of *Brassia* are found on cacti. In parts of Central America one species of *Brassavola* is found growing on mangrove roots, often at, or only slightly above, the level of high tide. In Jamaica several species are found growing on bare rocks. In the Everglades, on the other hand, one species of *Habenaria* is almost aquatic. In western Mexico, one species of *Pleurothallis* is epiphytic on lichens.

Orchids vary from those species that are very widespread, such as the species found throughout most of the tropical regions of the Western Hemisphere (e.g., *Ionopsis utricularioides*), to some species that seem to be restricted to a single mountain (some species in the subtribe Pleurothallidinae). In the West Indies, each of the major islands seems to have a fair number of such restricted species.

Pollination. The total orchid flower is an instrument adapted for exact modes of pollination. The function of pollen deposition is centralized precisely in the median plane opposite the lip, or labellum (the large central petal of the flower). Being directed back toward the centre of the flower, the anther deposits pollen on the most advantageous side of the visitor, considering efficiency in reception and deposition. This precision is also expressed by a tendency of orchids to deposit the pollen as one mass, the pollinarium.

The published data are insufficient to establish accurately the relative importance of pollinating agents in the family; however, a rough estimate may be given as in Table 3.

Saprophytic orchids

Desert-dwelling orchids

Orchid seeds

Table 3: Pollinator Spectrum of the Orchid Family*

Hymenoptera	%	other agents	%
Wasps	5	Moths	8
Lower bees	16	Butterflies	3

Social bees	8	Mixed agents	8
Mixed bees	10	Self-pollination	3

*The numbers represent an estimate of the relative importance of various pollinating agents in terms of the percentage of orchid species pollinated by each group.

Such extreme divergence in pollinators testifies for youth, continuing evolution, and adaptive radiation in the family.

Orchids as a group have nectar as the major attractant, whereas pollen, sought by pollinators among lower plant families as a protein-rich food, has been withdrawn. This is tied to the exactness of the mechanics of pollination, but it also means that orchids can no longer provide the only source of sustenance for the pollinator, and other flowers must be present in the biosphere to maintain visitors.

Nectar in orchids is provided in tubular nectaries (*Brasavola*, *Angraecum*, *Compactia*, and other genera), in grooves on the labellum (*Listera*, *Epipactis*, etc.), and at the base of the column and lip (*Dendrobium*, *Scaphyglottis*, etc.). It has been estimated, however, that as many as 8,000 species of orchids, one-third of the family, are nectarless. These orchids have developed other means of attracting pollinators, largely consisting of deceptive attractants in one form or another.

Many orchids produce pseudopollen for the attraction of pollinators. A powdery mass resembling pollen occurs on the labellum of a number of species of *Maxillaria* and *Polystachya*. Sometimes the grains are detached outgrowths called papillae, and sometimes they are disintegrated multicellular hairs that are filled with starch. It has been demonstrated that this pseudopollen is collected by bees at least from the orchid genus *Maxillaria*. It has been noted that in none of the species producing such pseudopollen is nectar produced.

Bee pollination. Flowers pollinated by bees tend to produce agreeable odours, to have bright colours, to be open during the day, to provide a landing platform, to have nectar guides in the form of coloured lines running into the depths of the flower, and to have concealed nectaries. The basal portions of the orchid lip are usually formed into a tunnel with the column forming its upper side. The bee enters the tunnel to get at the nectary, and, as the bee backs out, some of the stigmatic fluid may be rubbed on its back. As the bee backs farther, the pollinia become attached to the sticky material and are carried with the bee to the next flower. In more advanced orchids the pollinia may be attached to a sticky pad, the viscidium, which becomes detached from part of the stigma and sticks to the pollinator.

Some species of orchids are pollinated by bees that are attracted by means of deception. The flowers of the large genus *Oncidium*, for example, are pollinated by male *Centris* bees in what appears to be a case of pseudo-antagonism. The flower seems to simulate an enemy insect, which the male bee tries to drive away from his territory. As the bee strikes at the flower, the pollinia are attached to the head of the bee.

The most exciting and unusual examples of deceit, traps, and manipulation of pollinators are to be found in those orchids that are pollinated by male euglossine bees (species of the bee tribe Euglossini). The syndrome of flowers that are pollinated by male euglossini is based on the attraction of the male bees to the odour of the flower. In no case does the male euglossine bee receive food from the orchid that it visits for the purpose of collecting odour. So far as has been determined, all members of the orchid subtribes Stanhopeinae, Catasetinae, Lycastinae, and Zygopetalinae are pollinated by male euglossine bees, as also are certain genera of the subtribes Oncidiinae and Ornithocephalinae.

The euglossine male bees visit other nectar-producing flowers for their food, but, when the male bees visit the

non-nectar-producing orchid flowers, they rub the surface of the lip with their front feet and collect in special tarsal brushes the odour that is produced there. The bees then launch themselves into the air and transfer the odour to their hind tibiae (leg segments), which have become noticeably swollen. It is in the process of transferring the odour to the hind tibiae that the bee is manipulated by the orchid.

The pollination phenomena of the Stanhopeinae subtribe are based on the same principles as in the Catasetinae, but with the separation of sexes in the flower being in time rather than in space. Self-pollination in the Stanhopeinae subtribe is averted by differences in the maturing time of the male and female reproductive parts, whereas in the Catasetinae there are separate flowers of each sex. The stigma is narrow when the bee first visits, and the pollinia are thick before drying and therefore cannot be inserted into the stigma of the same flower. Powerful fragrances for attraction are present. In the Catasetinae, the male flowers are organized to position the bee perfectly so that when the pollinarium is discharged the viscidium becomes attached at a specific location on the bee. In this manner it will fit properly in the stigmatic cleft of the female flower when the bee visits it. In most species of the Stanhopeinae, the flowers are organized to take advantage of the erratic flight habits and slowed reflexes of the male bees that are collecting odour components. Their pollination mechanisms, in the more spectacular forms, manipulate the bees so as to make them fall either through a chute, down a slide, or into a "bucket" of water.

In the genus *Stanhopea*, for example, some species face downward with the lip and column pendent while the sepals and petals are reflexed upward. The base of the lip is saccate (baglike) and is separated from the arched column. The bee enters at this place rather than at the apex of the lip and column, which are close together, forming a chute. The rostellum (beaklike apex of the female flower parts), with the attached viscidium, projects into the chute. After the bee has landed and brushed at the base of the lip in order to collect the odour, it attempts to fly out of the flower. The column interferes with its flying equilibrium, and it falls, abdomen first, down through the chute, picking up the viscidium under its body (metathorax) as it passes.

Manipulation of bees by orchid flowers

Pseudo-pollen

Odour-collecting bees

Manipulation of pollinators.

(Left) *Coryanthes albo-purpurea* has a water bucket into which a visiting pollinator bee falls. The pollinarium is deposited on the abdomen of the bee as it exits by way of a special tunnel, and pollination occurs when the bee visits another plant. (Right) After rubbing for odour at the base of the lip, a visiting bee (*Eulaema meriana*) falls through the specialized chute of *Stanhopea gibbosa* and either picks up or delivers the pollinarium.

Another variation of pollinator manipulation by orchids is found in the genus *Coryanthes*. The flowers are very large and might even be considered grotesque. The sepals and petals fold back out of the way when the flower opens—like sails on a boat—revealing the strangely formed lip. The lip is divided into three parts: a globular- or hood-shaped portion called the hypochile above; an elongate, sometimes fluted part, the mesochile; and a bucket-shaped epichile. The epichile is partially filled with water during the last few hours before the flower opens and for a short time afterward by two faucetlike organs located at the base of the column, which drip water. Male euglossine bees are attracted by the strong odour produced by the hypochile, where they scratch. In trying to launch into the air to transfer the odour to their hind legs, the bees occasionally

fall into the water-filled bucket. The sides of the bucket are vertical and are very waxy, so that the bee is not able to climb out of the bucket. The only way for the bee to get out is through a small tunnel formed by the apex of the column and the apex of the epichile of the lip. As the bee forces its way out of the tunnel, the pollinarium is deposited on its thorax. The pollinia may then be deposited in the stigma of another flower on a next visit, provided the original pollinia of that flower have already been removed and the stigmatic cleft has opened sufficiently to become receptive.

Moth and butterfly pollination. Moths normally fly at night and are attracted to flowers that produce strong odours and are white or light-coloured. Moths that visit flowers are usually strong fliers and are capable of hovering in front of the flower while extracting the nectar. The typical moth-pollinated flower has a long, slender nectar tube containing abundant nectar. The fragrance produced is typically sweet or musky, and the flowers usually are horizontal or hanging. Butterflies, on the other hand, are day fliers and go to highly coloured flowers that may or may not be fragrant. Butterflies tend to be somewhat erratic fliers and, lacking the ability to hover, usually land on the flower. The flowers are, therefore, usually erect and provide platforms for landing. Often the platform simply consists of a head of erect, densely packed flowers. Butterflies detect colours well, and butterfly-pollinated flowers are usually brightly coloured with red, orange, or yellow predominating. Nectar is commonly abundant and is hidden in deep nectar tubes.

In an often cited case, Charles Darwin, the English evolutionist, predicted that a moth with a 10-inch- (25-centimetre-) long proboscis would eventually be found on the island of Madagascar as the pollinator of the orchid *Angraecum sesquipedale*, since a moth would need a long tongue to reach the nectar hidden in the very long nectary of this species. Such a moth has been found but has not yet been observed to pollinate the flowers of this amazing orchid.

The nectar tube of *Angraecum sesquipedale* is formed by the base of the lip. In most of the moth-pollinated, butterfly-pollinated, as well as bird-pollinated orchids, the nectar tube is arranged to guide the tongue or beak in such a manner that the pollinia are correctly attached to the pollinating organism.

Bird pollination. Flowers adapted to pollination by birds are usually brightly coloured, with reds, blues, and yellows predominating. They are usually tubular in form, often with a long nectary, and nectar is almost always present. Birds have little or no sense of smell, and bird-pollinated flowers tend to lack odour; however, the bright colours serve to attract the birds. Bird-pollinated orchids tend to follow the pattern of other bird flowers; however, in some cases they diverge considerably. Many orchids of the Western Hemisphere appear to have adapted to bird pollination as an extension of butterfly pollination, and, as in the case of *Epidendrum secundum*, birds and butterflies act as copollinators. In such cases, orchid flowers already adapted to butterflies are not greatly changed morphologically. On the other hand, orchids that have adapted directly to hummingbirds from bee-pollinated ancestors have changed fundamentally. The genera *Cochlioda*, *Sophranitis*, *Elleanthus*, *Ischilus*, *Compartmentia*, *Hexisea*, and *Meiracyllium* are all bird pollinated and are remarkably similar in certain aspects. All have bright colours, tubular form, and a callus or hump in the interior of the tube, on the lip, which acts to force the beak of the bird against the column.

Fly pollination. Some flies are important pollinators of flowers, and certain families of flies (e.g., the Syrphidae and Bombyliidae) are restricted to flowers for their food. Unspecialized flowers may attract flies to nectar, which is present in open, shallow nectaries and may emit sweet odours. The flies eat the nectar and do not store it as do bees. More specialized fly flowers may attract flies through deception, imitating decaying substances, dung, or carrion. Many kinds of flies are then attracted and act as effective pollinators. Fly-pollinated flowers have often developed traps for catching and holding unadapted visitors.

They commonly have large landing surfaces and "tails" produced from the flower parts, which function as guides. Their colours are usually checkered or blotched and tend toward dull green, brown, purple, or red. The odours produced are commonly putrescent. Orchids pollinated by flies are common throughout the world. In most fly-pollinated orchids, special adaptations have developed—superimposed on the basic pattern of the bee-pollinated orchid flower—to guide the somewhat poorly oriented flies. Certain of the five petals may be long and taillike (as in *Bulbophyllum* and *Masdevallia*) or joined to form a flat radial flower (as in *Stelis*). The flowers themselves may be arranged to form a larger radial, compound "flower" (as in *Cirrhopetalum*). The petals or lip may be fringed with motile clublike hairs that vibrate in the wind and attract the flies (*Bulbophyllum* and *Cirrhopetalum*). Often the sepals are joined or the lip is saccate to form a trap (*Pragmopeditum* and *Pterostylis*) into which the flies fall and from which they must crawl by way of a tunnel that passes the stigma and anther. A common contrivance by which orchids exploit flies is a hinged, balanced lip that tips with the weight of the fly and launches the pollinator into the flower.

In orchids it is often difficult to decide when simple fly pollination ends and deception that is based on carrion mimicry begins. Many genera have some species whose pollination is based simply on attracting various kinds of flies by means of sweet odours and nectar production, while others attract flies on the basis of rotten odours but provide no food.

Three major groups of orchids have become predominantly fly-pollinated: the subtribe Pleurothallidinae in tropical America, containing about 1,000 species pollinated by flies; the *Bulbophyllum* group of about 1,000 species found mainly in the Old World; and the large genus *Pterostylis* and its relatives in Australia.

Several reports of fly pollination in species from genera otherwise known for bee- or moth- and butterfly-pollinated flowers have been made. *Epidendrum fimbriatum* is pollinated by flies of the family Tachinidae. In the northern United States, several species of *Habenaria* have been shown to be pollinated by mosquitoes.

Self-pollination in orchids. Self-pollination occurs in a significant number of orchids. Several degrees of this phenomenon may be found in a single genus, from species in which accidental self-pollination results in fertilization to those in which the flowers never open, yet are capable of producing fertile seed. In many orchids, self-fertilization is not possible because of genetically controlled self-incompatibility, in which pollen from a plant having a particular combination of genetic factors will not fertilize its own ovules or those of any other plant having the same combination.

In most species the pollen is kept separate from the stigma by a structure called the rostellar flap. This physical barrier is normally quite effective; but, in some species, forms occur in which the rostellum degenerates or becomes stigmatic, and self-pollination results when the pollen germinates on the stigmatic fluid. In most of these forms, normal plants are also found in the same population. Self-pollination may also occur as a result of simple falling of old pollinia, a means of averting sterility at the end of a long normal period when the flower is open but no pollinator arrives.

A kind of mechanical self-pollination occurs in some orchids in which the tissues connecting the viscidium and the pollinia bend downward and carry the pollinia into place on the stigma. Generally speaking, self-fertilization in orchids seems to be a means of averting extinction in plants growing under conditions adverse for normal pollination relationships. Examples include some species of *Orchis* in Europe and several orchids in Florida, such as *Epidendrum nocturnum*, *Encyclia cochleata*, and *Blechnia purpurea*, all of which have cross-pollinated forms in other areas. Seeds blow into Florida from the Caribbean area where normal pollinators exist, but those plants that survive tend to be self-pollinated because they lack their customary pollinators, which are not found in Florida.

Probably more than 200 species of orchids have been

Adapta-
tions
to fly
pollination

Characteristics of

pollination
for
survival

reported to be more or less regularly self-pollinated, and undoubtedly many more exist.

Mimicry and deception—pseudocopulation. Flowers of the genus *Ophrys* deceive and manipulate pollinators mainly through odours, imitating those produced by the abdominal glands of female bees or wasps. Flower shapes, colours (including ultraviolet reflection), and tactile stimuli by the hairs on the lip operate on the sensory organs of the visiting males leading ultimately to the same behaviour as that observed during the initial phases of copulation with female bees. No ejection of sperm occurs, however, but the supernormal olfactory stimulation ensures that the male will remain for a long stay on the flower.

This act of pseudocopulation takes place in such a way that the pollinia are carried off and redeposited on a different plant. Four genera of solitary bees and wasps appear to be the principal pollinators. The species of *Ophrys* that are pollinated by the wasps *Trielis*, *Gorytes*, and the bee *Eucera* induce the insects to attempt copulation with the apex of the lip. Those pollinated by *Andrena* appear, for the most part, to stimulate the bee to reverse its position and copulate with the base of the lip. In the former group the pollinarium is affixed to the head of the pollinator, while in the latter it is attached to the abdomen. Only the introductory behaviour is necessary for pollination of the flower, and the bees do not encounter structures that lead to ejection of sperm. The behaviour is elicited by tactile stimulation from the hairs on the labellum, but the male "suitor" requires simultaneous and continued olfactory stimulation. The glistening pseudonectaries apparently imitate the eyes of the female bee. Metallic-blue mirrorspots similar to those found in the females enhance the effect. Dimensions of the flowers in the various species of *Ophrys* help in determining specificity and success.

Australian orchids of the genus *Cryptostylis* are pollinated by ichneumon wasps of the genus *Lissopimpla*. The wasp, after backing into the stigma, attempts to copulate with the flower by bending its body into an arch, with the base of the lip of the flower held by the claspers of the wasp. The upper side of the apex of the abdomen comes in contact with the viscidium, and the pollinarium becomes cemented in place. The wasp, after a short pause, then flies to another flower, and the same behaviour delivers the pollinia to the stigma.

The South American orchid *Trichoceros antennifera* has flowers that simulate the female flies of the genus *Paragymnomma* to a remarkable degree. The column and base of the lip are narrow, barred with yellow and red-brown, and they extend laterally to simulate the extended

wings of a sitting fly. The base of the lip has no particular similarity to the head and thorax of a fly, but this is probably not necessary to complete the illusion. The stigma of the flower is located more or less at the apex of the "false abdomen" of the flower and reflects sunlight, as does the genital orifice of the female fly. The viscidium, extended over the stigma on the slender rostellum, projects up through the bristles and becomes attached to the basal portion of the abdomen of the fly. The viscidium is flat and padlike in this genus. The male flies, deceived by the simulated female fly and stimulated by the signal from the genital-orifice-like stigma, strike the flower for only a moment and then pass on to other flowers in the same area. The action is sufficient, however, to pick up the pollinarium. The long, slender stipe of the pollinarium bends down slightly and is forced into the stigma when the fly visits a succeeding flower.

Insects attracted for protection. A number of species of orchids have developed nectaries located in places other than the flower. These seem to act to attract ants, which in turn scare away bees that would otherwise rob the flower of its nectar by cutting into the back of the flower. Such extrafloral nectaries also attract wasps, which also function in scaring away insects that might steal the nectar from the flower. These ants and wasps are also thought to keep away grasshoppers, crickets, caterpillars, and other insects that eat the flowers. The symbiotic relationship (i.e., two organisms living together with mutual benefit) between ants and the orchids that grow only in ant nests (e.g., *Coryanthes* and some species of *Gongora*, *Epidendrum*, and *Schomburgkia*) may depend on this defensive mechanism. The plants and flowers of these orchids are extremely susceptible to damage by chewing insects if the ants are destroyed. The ants involved in this relationship do not pollinate the orchids; indeed, no ants are known to pollinate orchids.

EVOLUTION

There are two extremes in the variation patterns shown by living plant groups, apparently depending on rates of evolution and amount of extinction. At one end of the spectrum stand such families as the Magnoliaceae, Annonaceae (both of order Magnoliales), and Nymphaeaceae (order Nymphaeales). These families have the appearance of being "old" groups, in which evolution is proceeding at a leisurely pace and extinction has greatly affected the pattern of variation. The delimitation of genera and tribes within the Magnoliaceae or the Nymphaeaceae is not difficult; however, students of evolution are at a loss in trying to understand relationships or phylogeny (evolutionary descent) in these groups.

The orchids are near the other end of the spectrum. They show little evidence of great age, show signs of relatively rapid evolutionary diversification in geologically recent time, and give much less evidence of extinction. Genera are often difficult to define, and higher categories within the family often seem even more difficult. These hazy boundaries between tribes and subtribes, however, may give clues to the patterns of phylogeny within the family. This is not to say or imply that living groups are derived from other living groups, but excellent evolutionary series can be found for nearly every morphological feature within the orchids. In recent years there has been a healthy skepticism concerning phylogenetic schemes. Even when a good morphological series can be found in some feature, it is often difficult to decide in which direction or directions evolution has occurred. This problem is not so serious in a highly derived group such as the orchid order. In comparing the genera *Cephalanthera* and *Oncidium*, there can be little doubt as to which is derived and which is primitive. In nearly every feature in which these two differ, it is *Cephalanthera* that is the ordinary monocot, easily comparable with other monocot families, while *Oncidium* is so advanced that it can scarcely be understood without comparing it with the less specialized members of the family.

In dealing with the primitive orchids and their evolution from groups now extinct, the bewildering parallelisms to be found in the more advanced groups must be borne in

Rapid evolution in orchids

Orchid flowers resembling female flies

Deception of pollinators.

(Top) *Pleurothallis raymondi* and (bottom) *Trichoceros antennifera* resemble female insects and attract the corresponding males, which carry out pollination while attempting to copulate with the flowers. (Right) *Calopogon pulchellus* has false stamens that act as an attraction to pollen-eating insects.

mind. It is probable that the subfamilies Neottioideae, Orchidoideae, and Epidendroideae evolved from a series of related species or genera having partial union of filaments and style, androecial zygomorphy (bilateral symmetry in the male parts), and a close association of the stigma and the median anther—all features that would predispose the groups to parallel patterns of evolution. Some of the ancestral populations may have been quite similar to the subfamily Apostasioideae, while others were similar to the genus *Selenipedium*, and yet others were quite unlike either. The orchid family is not “unnatural” or polyphyletic (derived from more than one ancestral group) in the strict sense, since the ancestral group was, itself, a natural and closely interrelated group, even though it may have differed from the modern orchids in a number of features. It is fairly certain that the stipe, the divided pollinia, and the viscidium have evolved independently in different groups of orchids. It is quite possible that the rostellum has evolved independently in two or more separate lines and that the reduction to a single median anther is similarly polyphyletic in the unusually “natural” family Orchidaceae.

Extremely small orchids.
The flowers of (top) *Pleurothallis pertusa* and (bottom) *Lepanthes* are only a few millimetres long.

None of the living tribes of orchids could readily be derived from another living tribe, but their derivation from similar or common ancestors is easily visualized. The subfamily Cyripedioideae (lady's slipper orchids) is not very closely related to any other group, its relationship to the subtribe Limodorinae of the Neottioideae subfamily being perhaps quite as marked as its few resemblances to the subfamily Apostasioideae. The lady's slippers clearly diverged early from the main lines of orchid evolution. The Apostasioideae subfamily more nearly approaches the hypothetical ancestral type, the median anther being functional in *Neuwiedia*. It, too, represents a small relic group of somewhat isolated phyletic position, though perhaps closer to the other orchids than to the Cyripedioideae. The Orchidoideae subfamily presumably is derived from *Cephalanthera*-like types, but it would stand quite isolated if it were not for the relic subtribe Epipogiinae, which shows some relationships to both the Neottioideae and the Epidendroideae subfamilies. The Epidendroideae subfamily might be derived from somewhat Neottioideae-like

ancestors, but it shows more primitive seed structure in the Vanillinae subtribe than any living species of Neottioideae, and the two subfamilies apparently diverged at an early stage in orchid evolution. The subtribes of the Neottioideae subfamily that are grouped with the Limodorinae subtribe are primitive and would constitute a relic group were it not for the great evolution of this group in Australia, where several striking specializations occur.

The subfamily Epidendroideae has the most examples of adaptive radiation to various types of pollinators. Apparently evolution in this subfamily has been accentuated by adaptive radiation to different types of pollinators. In this subfamily are found all types of pollinator classes with the exception of bat, rain, and wind pollination.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The Orchidales order may be separated from the Liliales, a closely related order, on the basis of their having an undifferentiated embryo and little or no endosperm, very tiny seeds, the stamens reduced to one (rarely two or three), the fertile stamen adnate (fused) to the style to form a column, the flowers usually strongly zygomorphic (bilaterally symmetrical), the pollen usually coherent in masses called pollinia, and the ovary inferior always. The relationships between the subfamilies of the Orchidaceae are based on the number of fertile stamens, the character of the leaves, the consistency of the pollinia, the number of pollinia, and the associated structures of the pollinarium.

Taxonomic problems. The classification in this article (see above, *Annotated classification*) is one of wide acceptance among orchid taxonomists. Each subfamily is broken down into tribes, and in those cases in which more than one subtribe is found in a given tribe, the tribe is broken down into subtribes.

Although this classification is a recent one, there is still some need of examination of relationships in the orchids. The evolution of similar vegetative and floral structures in different orchid groups (convergent evolution), leading to the exploitation of the same types of pollinators, has resulted in a situation in which many groups appear to be superficially similar. This same adaptation to pollinators has often obscured the actual relationship of numerous other groups. (C.H.D.)

groups

Poales

Poales is an order of flowering plants consisting of a single family, the grass family, called the Gramineae or Poaceae. The family Gramineae probably is the most abundant family of vascular plants, considered in terms of numbers of individuals; it dominates great areas of the Earth's surface, including prairies, steppes, savannas, pampas, and paramos (all types of grassland). The family is also fairly sizable in its number of species, with an estimated 600 to 700 genera containing 6,000 to 10,000 species. It ranks about fifth among the angiosperms (flowering plants) in total number of species. The family is of prime importance to the world's agriculture because it contains all the important cereal grains. Moreover, a large number of species furnish the principal sustenance of grazing livestock and wild herbivores. The group was intimately involved in the evolution of man's domestic animals and very likely of man himself.

A great diversity of products are derived from grasses, but grain is the most important single category. Scarcely less important but more difficult to evaluate are the cultivated and wild forages obtained from grasses. The bamboos, which are highly specialized woody grasses, provide not only building and handcraft material but also paper pulp and edible shoots.

GENERAL FEATURES

Structural diversity and habitat range. Grasses are found in all parts of the land surface of the earth, and their ecological diversity is tremendous. The greatest number of species is found in the tropics, as is true of most plant families. The family as a whole ranges from the tropics to the high Arctic, with two species occurring on the northern

Habitats
occupied
by grasses

extremity of the Antarctic continent. Although the greatest abundance of grasses occurs on open lands, such as the prairies, steppes, and paramos, some species are adapted to many specialized habitats, such as saltwater and freshwater marshes, running or still water, rain forests, deserts, and Alpine or Arctic tundra. Because of their manifold adaptations to varying climates and habitats, the grasses have become an extremely successful family, and, consequently, there are probably more individual grass plants than there are of all other vascular plants combined.

Grasses range from minute forms, such as the annual bluegrass (*Poa annua*) and the high Alpine *Phippsia algida*, which are only a few centimetres tall, to the giant timber bamboos, which may reach 100 feet (30 metres) in height. The stem width is also extremely variable. Small grasses have stems only a millimetre (0.04 inch) or two in diameter, while the larger bamboos have stems as much as 10 inches (25 centimetres) thick. Such large stems are produced only by very old clumps that have a large amount of stored food in their underground parts.

Grass leaf blades are commonly thought of as being ribbon shaped and with parallel veins. While the great majority of grass leaf blades are of this shape, some of the tropical forest grasses have broadly oval blades. One remarkable grass genus, *Pharus*, has broad leaf blades with the veins diverging from the midrib. The leaf blade is attached to a petiole (leafstalk, not a true one in this case), which has a 180° twist, so that the leaf blade is actually upside down. Certain broad-leaved grasses of the genus *Raddia* have short sprays of crowded leaf blades that mimic the appearance of the compound leaves of certain legumes (members of the pea family, Leguminosae or Fabaceae). In this case, the leaf blades even fold up at night as legume leaves do. The leaves of desert grasses, however, are stiff, harsh, and frequently inrolled. In some species they become bristly and are probably unattractive to grazing animals. Aquatic grasses are also known, and some of these are able to float on the surface of the water because of inflated leaf sheaths or waxy, water-repellent leaves.

Economic importance. The grasses are surpassed in numbers of species by the orchids, composites (sunflowers, asters, etc.), legumes, and members of the coffee family. No other plant family, with the exception of the legumes, however, remotely approaches the grasses in agricultural importance. Their principal areas of utility include exploitation for cereal grains, sugar, timber and paper pulp, hay, pasturage, native forage, and numerous other lesser known products.

Cereal grains. Grains, which form the staple foodstuffs for much of mankind, are all derived from grasses. The more important of these are rice, wheat, corn (maize), oats, barley, rye, sorghum, and millets.

Rice (*Oryza sativa*) is an Asiatic tropical grass and is the only semi-aquatic species among the cultivated cereals. Cultivation is widespread in all warm temperate and tropical climates where sufficient moisture is available. Rice is traditionally thought of as a crop grown under flooded conditions, but certain strains will grow under moist conditions without flooding. Such strains are called upland rices, and they generally yield much less grain than does flooded rice. Although statistics are inexact, rice is probably the world's leading grain crop. Recent introduction of semidwarf strains with high productivity has greatly increased rice yields and is helping to make former rice-importing regions self-sufficient.

Wheat (*Triticum aestivum* and other species) originated in the Middle East and has spread to all temperate and cool temperate areas of the Earth, being cultivated widely in southern Europe, the U.S.S.R., the United States, Canada, Argentina, and parts of India, China, and Australia. Wheat grain, containing an abundance of the elastic protein gluten, is the only cereal capable of producing a satisfactory light bread. In quantity of production, it probably ranks second to rice.

Corn, or maize (*Zea mays*), is the only cereal of American origin. Discovered in the primitive wild state by the early Indians of Mesoamerica and developed extensively by them, corn became the principal foodstuff of the great

Indian civilizations of Mexico, Central America, and the Andean countries. Although corn is of tropical origin, man has selected strains that are adapted to temperate climates with warm summer seasons. Its culture is now extended to all the inhabited continents. The principal use of corn is as animal feed, but great amounts are used as human food or as a source of starch, syrup, and alcohol.

Oats (*Avena sativa*), like wheat, are native to Eurasia and probably originated in the Mediterranean Basin. They are widely cultivated in the cooler temperate portions of the Northern Hemisphere and, to a limited extent, in the Southern Hemisphere. The grain is much used for animal feed, with lesser amounts going for human consumption. Cultivation of oats has decreased in recent years, however, probably because of farm mechanization and the decline in numbers of draft animals. Although the grain lacks gluten and cannot be used to make bread, the protein quality is excellent, and the quantity is susceptible to being increased by selective breeding. In Latin America, pulverized oatmeal is frequently mixed with water and used as a cold drink, called *avena*.

Barley (*Hordeum vulgare*) is another small grain of Middle Eastern origin. It is adapted to about the same areas and climatic conditions as is wheat, but barley has notable tolerance to drought and cold. Much of the grain is used in animal feed except in less developed countries. One of the principal uses of barley is the production of malt for use in brewing beer.

Rye (*Secale cereale*) is a comparative newcomer among the cereals, and its cultivation is largely confined to areas of cold climates. As a breadstuff, it scarcely competes with wheat. The grain is also used in the preparation of alcoholic liquors, and the straw is used in hats. Rye is the host plant for the fungus that produces medicinal ergot. In the United States, rye is much used to stabilize the shoulders of new roads because of its ability to grow on poor subsoil.

The sorghums (*Sorghum bicolor*, *S. sudanense*, and others) are the most diverse of the grains, in both aspect and usages. They are of African and Middle Eastern origin and thrive best in warm, often subhumid climates. The various types furnish feed grains, silage, temporary and perennial pasture, syrups, and broomcorn.

The term millet generally applies to various minor and usually inferior grains, mostly grown in less advanced agricultural areas or as emergency crops. The most common types are foxtail millet (*Setaria italica*), proso millet (*Panicum miliaceum*), pearl millet (*Pennisetum glaucum*), and ragi, or coracan millet (*Eleusine coracana*). Millet grain is used in animal feeds, birdseed, and for human food.

Sugar. Sugar derived from grasses is mostly the product of sugarcane (*Saccharum officinarum*). Smaller amounts, nearly all in the form of syrup or molasses, are produced from certain types of sorghum.

Timber and paper pulp. These are the principal products of the bamboos (subfamily Bambusoideae). Certain types of soft construction board, such as Celotex, are often produced from sugarcane refuse (bagasse).

Hay, pasturage, and native range. The total production of these vegetational types is difficult to estimate, but land devoted to them aggregates more total area than all cultivated cropland. Many of these areas can be economically productive only through harvest of forage by grazing animals. The species prevalent in a given area differ greatly among various climatic regions. In the temperate zones some of the principal hay and pasture grasses include timothy (*Phleum pratense*), smooth brome (*Bromus inermis*), orchard grass (*Dactylis glomerata*), redtop (*Agrostis alba*), alta fescue (*Festuca arundinacea*), and Bermuda grass (*Cynodon dactylon*). The widespread Kentucky bluegrass (*Poa pratensis*), a Eurasian species, has assumed the aspect of a native in North America, furnishing large amounts of pasture, as well as being the principal lawn grass in the cooler regions.

In the western Great Plains and the Southwest of the United States, great areas are still populated by native forage grasses, including buffalo grass (*Buchloe dactyloides*) and species of *Bouteloua* (grama grasses) and *Hilaria* (tobosa and galleta grasses). Species of *Panicum*, *Andropogon*

Corn

(bluestem grasses), *Spartina*, and *Sorghastrum* are important in tallgrass areas.

In subtropical and tropical areas of the world, most of the wild and cultivated grasses belong to the subfamilies Eragrostioideae and Panicoideae. Species of *Eragrostis* (love grasses), *Cynodon* (Bermuda grass), *Chloris* (finger grass), *Panicum*, *Paspalum*, *Digitaria* (crabgrass), *Axonopus*, *Andropogon*, and their allies are important in cultivation.

Unusual products. A number of tropical Asiatic grasses produce sufficient quantities of aromatic compounds to merit use in perfumes. The roots of the vetiver (*Vetiveria zizanioides*) of India yield an excellent perfume after drying. The lemon-oil grass, *Cymbopogon citratus*, has a strong lemon scent, and its foliage is widely used in the tropics for tea or medicine. The grass is grown on a commercial scale for production of lemon oil, which is distilled from the leaves. Citronella oil is similarly distilled from the foliage of *Cymbopogon nardus* and is used as an insect repellent, as a perfume in soaps, and in the synthesis of menthol. The stems of sugarcane are covered with quantities of finely powdered wax that gives them a bluish hue. This wax may be recovered in the processing of cane sugar and is used in the manufacture of coatings for carbon paper.

Paper is made from a variety of grasses, including many bamboos and the North African esparto (*Stipa tenacissima*) and alfa (*Lygeum spartum*). The straw of wheat and rye is used in the manufacture of straw hats. In many parts of the world, hay or straw is used for the thatching of roofs, which last for many years when properly laid.

The tropical peoples of the world use the bamboos in a great variety of ways, in addition to their common usage as a timber substitute. Fishing poles and props for banana plants are commonly made from bamboo stems. Larger canes are reamed to remove the partitions at the joints and then serve as water pipes. Thin peelings from the exterior of the stems are used in basketry and mat weaving. Elegant screens of fine bamboo fibres are used to filter the suspended pulp used in the making of paper, and the pulp itself is frequently made from bamboos. Young shoots of certain bamboos are used for food and are commonly found in Oriental cookery. Tabashir, a fine, white powder (colloidal silica) found in the hollow stems of some bamboos, has been used in Oriental folk medicine. Other bamboos are grown as ornamentals for their graceful, wandlike manner of growth or as clipped hedges.

One of the most widespread tropical grasses is Job's tears (*Coix lacryma-jobi*). The hard, bony sheaths that surround the female flowers are excellent natural beads and are extensively used for necklaces and rosary beads.

Brooms are fabricated of many materials, but one of the most common materials is the stiff straw from the seed heads of the broomcorn, a variety of sorghum. The immature seed heads are dried and threshed to provide the common broomstraw of commerce.

Deleterious grasses. A considerable number of grasses are regarded as pests by man. Most of these are weeds that invade clean-tilled croplands, although there are various species that invade ranges and pastures; they are disliked because they are mechanically injurious or of lower feed value than the species they displace. Some species are invaders of lawns, where they are objectionable because of colour, texture, or growth habits.

The majority of grass weeds are annuals of rapid growth, not easily suppressed by the usual tillage methods or by the herbicide 2,4-D. Chemicals, however, are increasingly being used to control such grasses. The following list includes some of the more important annual and short-lived perennial grass weeds of temperate North America, listed with the crops or habitats in which they are important: species of *Aristida* (needlegrasses, in deteriorated ranges and wasteland); species of *Avena* (wild oats, in spring wheat or on dry rangelands of the Southwest); species of *Bromus* (riggum grasses, cheatgrasses, and brome grasses, in grain crops or on deteriorated Southwestern ranges); species of *Cenchrus* (sandburs, in disturbed light soils); species of *Digitaria* (crabgrasses, in lawns, gardens, and crops); species of *Echinochloa* (barnyard grasses, in crops, especially in moist areas); species of *Hordeum* (wild bar-

ley, along roadsides, in pastures and native ranges); and species of *Setaria* (foxtail grasses, in crops).

Long-lived perennial grass weeds (those that live through more than one growing season) of importance are far fewer. In the northern United States and Canada, quackgrass (*Agropyron repens*), a persistent European weed that spreads extensively by rhizomes (underground leafless creeping stems) is the most important species. In the south of the United States, Johnson grass (*Sorghum halepense*), a tall perennial with thick, widely spreading rhizomes, is a major competitor with cotton agriculture. Bermuda grass (*Cynodon dactylon*), while extensively planted for lawns and pasturage, is also a severe pest when it invades fields and gardens. Several species of *Andropogon*, notably *A. virginicus* (broomsedge), are invaders of abandoned fields and have low apparent forage value.

NATURAL HISTORY

Life cycle. The fruit of the grasses is a single-seeded dry grain—the caryopsis, as it is known botanically; it is characteristic of the family. Grains of many grasses are capable of immediate germination, but other species have dormant seeds that require afterripening or chilling to permit germination. Such dormancy has adaptive value in preventing germination in the fall or during dry periods, when the seedling would have little chance of establishment. Cultivated types of oats (*Avena sativa*), for example, are capable of germination immediately after the grain is harvested. Probably because of this trait, the plants are virtually unable to maintain themselves in nature. The wild oat (*A. fatua*), which is a probable parent of many cultivated types, has seed that is dormant when mature. Thus the grain is able to survive the winter without injury and then germinate in the spring. As a consequence, *A. fatua* is a widespread weed. Similar examples of dormancy are widespread among grasses.

In germination, the embryo ruptures the thin ovary wall and any enclosing structures. The first visible signs of germination are the emergence of the tubular sheath (coleoptile) surrounding the young shoot and a similar sheath (coleorhiza) surrounding the primary root. The primary root breaks through the coleorhiza, and then one or more roots (seminal roots) may arise near the attachment of the embryo to a shield-shaped mass of tissue, the scutellum. The coleoptile and the structures it conceals are pushed through the soil by the elongation of the embryonic neck (mesocotyl) until the tip of the coleoptile is exposed to air and light. It is then burst by the emergence of the young leaves. The shape of the first leaf differs in the various subfamilies. In the common grass subfamily Festucoideae of the temperate zone, for example, it is very slender and elongated and tends to be vertical. In the subfamily Panicoideae, whose members are common in warmer climates, the first leaf is short, broad, and horizontal. The young seedling may continue to produce basal leaves for a time, without signs of a visible stem, or it may rapidly produce a flowering stem (culm). Except in rare instances, some form of vegetative multiplication soon becomes evident. Some species, especially perennials, may produce stolons (creeping leafy stems) or rhizomes. Grasses lacking these usually produce new stems by basal branching (tillering), to form larger and larger clumps. Old clumps may decay in the centre, and the segments of the growing periphery become isolated, forming new, small clumps.

The sexual reproductive cycle in grasses is initiated with the development of the embryonic rudiments of a flower cluster hidden within the sheathing leaves at the tip of a culm or one of its branches. The first evidence of incipient flowering may be the swelling of the upper sheath, or "boot." The young inflorescence (flower cluster), with tightly appressed erect branches, begins to emerge, and the branches spread by means of swellings, the pulvini, at their bases (axils). Flowering usually begins at the tip of the inflorescence and proceeds downward and from the branch tips toward their bases. Reversals or alterations of this flowering sequence also occur. The spikelets of the inflorescence mature and begin to flower after emergence from the boot. Some species bloom early in the morning, others at various times of the day.

Pollination. Practically all grasses that have open flowers are exclusively wind pollinated, although a few instances of insect visits to grass flowers are known. The great prevalence of grasses in the world is a strong indication of their evolutionary success in adaptation to wind pollination. Structural specializations contributing to this success include the clustering of the tiny, naked flowers into scaly spikelets and the aggregation of the spikelets into large compound inflorescences, the presence of large anthers (pollen containers) and abundant light, fluffy pollen, and the relatively enormous and extremely feathery stigmas, which are the female structures that receive the pollen. All these factors and the colonial habit increase the chances of pollination.

After pollination has occurred, the open florets (a floret is a flower plus the two modified leaves that enclose it) close once again, and rather rapid development of the caryopsis (grain) occurs. When the caryopsis is mature, the spikelets dry and the grains are dispersed from the parent plant. In many instances, the spikelets break up into individual florets, each enclosing a grain, but, in many other grasses, entire spikelets or spikelet groups fall from the parent plant and serve as means of distribution.

Many grasses have florets that do not open because the lodicules (swollen motor structures at the base of the flower) do not function or because the spikelets are hidden within the sheaths or even, in rare instances, are underground. Such flowers that fail to open are said to be cleistogamous. They are of necessity self-pollinated. There are both evolutionary advantages and hazards in this type of reproduction. If a grass is predominantly or nearly entirely self-pollinated, the population becomes increasingly inbred. At times, this inbreeding may bring out undesirable traits and cause the death or low fertility of the individuals exhibiting them. In other cases, the inbreeding may cause the expression of traits highly desirable in fitting the species into a specific limited type of habitat, and the species may become extremely successful. The homozygous, or inbred, condition of such a species or the individual populations of which it is composed, however, may make it so inflexible that it cannot change rapidly enough to cope with alterations in the environment. Most cleistogamous species, however, have a small percentage of open-pollinated flowers, allowing some crossing. Cleistogamy is especially prevalent in annual grasses, which have to produce a seed crop every year to survive well. A number of species of the genera *Sporobolus* (dropseed grass), *Panicum*, *Amphicarpum*, and *Danthonia* (poverty oats), among others, have well-developed cleistogamous reproduction. In some species, highly specialized hidden spikelets (cleistogenes) occur. Usually these are quite different in appearance from the normal spikelets of the same species and may be hidden within the sheaths. In the genera *Triplasis* and *Danthonia*, the cleistogenes are concealed in the lower sheaths. At maturity the culms disarticulate at the nodes (joints), and the segments of stems, carrying the cleistogenes concealed within the sheaths, serve as disseminules (means of dispersal). In a few extreme cases, grasses produce underground spikelets on the tips of slender rhizomes. This process occurs in the genera *Chloris* and *Amphicarpum*. Despite the apparently considerable advantage of having "preplanted" seeds, such grasses are rare and restricted in range.

Cleistogamy is the dominant mode of reproduction in wheat, oats, and barley. Since there is little open pollination and, hence, little opportunity for crossing, strains of these crops tend to remain pure, even though they are grown in close proximity to one another. Rye (*Secale cereale*), on the other hand, is open-pollinated and crosses so freely that few selected strains exist.

Asexual production of seed. In certain grasses, no sexual fusion of egg and sperm occurs in the production of the seed. The embryo arises from a vegetative cell of the ovule, and the offspring are genetically identical with the maternal parent. Pollination may be necessary in some species to initiate the development of endosperm (the starchy food stored outside of the embryo), even though no fertilization of the egg occurs, and in many cases no egg, as such, is produced. Such asexually produced seed is

said to be apomictic, and this process of seed production is called apomixis. The process is of great importance in the grass family and occurs in many only distantly related grasses. There is a general tendency for apomixis to be more frequent in grasses with high chromosome numbers. It is particularly prevalent in the large temperate-zone genus *Poa* (the bluegrasses) but occurs as well in many tropical grasses, including species of *Panicum*, *Paspalum*, and the numerous relatives of the bluestems (*Andropogon* and related genera).

Like cleistogamy, apomixis has both evolutionary advantages and drawbacks. Since an apomictic plant produces offspring exactly like the maternal parent in genetic composition, it may generate a highly uniform stand, with all individuals adapted to the same conditions and all susceptible to the same diseases. If conditions of climate or growth change radically, the population may be unable to adapt rapidly enough to accommodate to the environmental changes and may be destroyed. It is rare, however, that a species is completely apomictic, and generally a small percentage of sexually produced seed is generated as well. Thus the apomictic mechanism may serve as a stabilizing procedure, serving well to adapt a species to a relatively constant environment, while the occasional sexually produced seed allows the introduction of new variation into the population. Along with cleistogamy and vegetative reproduction, apomixis tends to preserve particularly advantageous genetic combinations but to slow down the rate of evolutionary change.

Grasses are predominantly plants that tend to form large, treeless communities, usually composed of only a few species. Such open areas were undoubtedly responsible for the evolutionary development of the grazing herbivores, and the grasses themselves bear the evidences of evolutionary specialization to accommodate themselves to being grazed. Among these specializations are the great predominance of vegetative reproduction, by stolons, rhizomes, or tillering. Frequently, heavily grazed grasses may survive for years by vegetative spread, where other types of plants that reproduce only by seed are practically eliminated. Certain savanna grasses, growing in areas where fires occur frequently, have survived because they have evolved deep-seated corms (hard, bulblike stem bases) that are immune to fire damage. Many grassland communities occur in areas that are dry at some period of the year. Perennial grasses of such areas are well adapted to surviving seasonal drought by mechanisms that cause folding or rolling of the leaves or by the dormancy of the plants during drought periods.

The slender, erect culms of grasses are often subject to being knocked down or "lodged" by the wind. Stems that have been lodged are often able to erect themselves by the operation of a swollen region of the stem or sheath at the nodes. This swollen area, the pulvinus, is sensitive to position changes, and when a normally erect stem is laid in a horizontal position, the pulvini begin to grow more rapidly on the lowermost side and cause the stems to right themselves.

The grass leaf blade has a growing zone (meristem) near its base, which permits regrowth when the leaf tip is cropped or mowed. This feature of the blades, plus the abundance of basal buds possessed by grasses, serves to permit their survival under intensive grazing or mowing.

Dispersal mechanisms. A great variety of mechanisms has been exploited by the grasses in providing for the dispersal of the plants. Vegetative reproduction is often extremely efficacious in promoting dispersal by means of rhizomes, stolons, or the gradual spread of old clumps. Circumstantial evidence suggests that many colonies of rhizomatous perennial grasses may be hundreds of years old. Grasses of severe habitats, such as the sand binders of coastal dunes (*Ammophila*, *Elymus*, *Uniola*, *Jouvea*, and others) and of continental sand dunes (*Calamovilfa*, *Redfieldia*, *Swallenia*) may reproduce almost entirely by rhizomes or stolons in an environment hostile to the establishment of seedlings. Of all the grasses, the bamboos have most fully exploited vegetative reproduction. Many large colonies of bamboos appear to have originated as single individual plants from one seed (such colonies are

Relation-
ship
between
grass
evolu-
tion and
grazing
animals

Vegetative
reproduc-
tion

Cleistog-
amy

called clones), as is evidenced by the fact that they remain vegetative for many years, and, when flowering finally occurs, the entire colony blooms simultaneously over great areas. The bamboos may produce short, thick rhizomes and hence produce dense clumps, or they may produce very long, slender rhizomes that spread the plants over considerable distances.

Another dispersal mechanism that is essentially vegetative is the production and release of vegetative bulbils in the inflorescence. These are modified spikelets that function in place of seed. Bulbous bluegrass (*Poa bulbosa*), a European species occasionally found in the United States, possesses such bulbils. Most grasses, however, produce normal seed on a regular basis, and the dispersal of the grain, either naked or with accessory structures, is the common method of spread.

Some grasses, such as the cereals wheat and rye, release naked caryopses (grains) from the spikelets. Grains as large as these have great appeal to birds and rodents and apparently are not very efficient disseminules. Many fine-seeded grasses, such as the love grasses (*Eragrostis*), however, produce an abundance of fine grains that have no special means of dispersal. The success of these plants indicates that specialized means of transportation are not always necessary to accomplish dissemination.

In a few cases, especially in the genus *Sporobolus* (dropseed grass), the ovary wall of the mature grain becomes gelatinous and swollen when wet, and such grains often adhere to passing animals. *Sporobolus indicus*, a highly successful pantropical weed, uses this dispersal method.

In most grasses, dispersal is effected by the movement of florets, entire spikelets, or groups of spikelets. In many species, individual florets are released from the plant and may be light or hairy enough to be dispersed easily by the wind. The tremendous range of the common aquatic reed (*Phragmites australis*) is testimony to the effectiveness of this type of wind dispersal of the hairy florets. In the manna grasses (species of *Glyceria*), which usually grow in or around water, the light florets float upon the water surface. Wild rice (*Zizania aquatica*), which grows in water, is similarly dispersed.

A small number of grasses have spikelets enclosed in hard, bony structures that may be disseminated in various ways, including ingestion by animals that cannot digest them. The hard beads of Job's tears (*Coix lacryma-jobi*) and the hardened fruit cases of *Manisuris* and *Tripsacum* are examples of these structures. Similarly, the female spikelets of buffalo grass (*Buchloe dactyloides*) are enclosed in a bony husk that not only retards germination but also protects the grain. Ants may harvest these structures and carry them away. Certain grasses have spikelets that either form or are enclosed in spiny burs that adhere to animals and clothing. The sandburs (*Cenchrus*) are the most common example of this. In the genus *Tragus*, the glumes (outer bracts of the spikelet) are covered with hooks that adhere to the wool of sheep, so that this genus is a commensal of the animals. In the bristly foxtail (*Setaria verticillata*), the sterile branches of the spike-like flower clusters (panicles) have minute backwardly directed barbs, so that the whole inflorescence may be carried away by passersby.

In open areas, some grasses have become tumbleweeds—their entire panicles break loose from the mature plant and roll with the wind, dispersing seed as they go. Witchgrass (*Panicum capillare*) is a common example.

Elaborate self-planting devices have been evolved in certain grasses. Sometimes these work all too well, causing puncture wounds in grazing animals. In the wild barleys (species of *Hordeum*) the mature spike breaks up into individual joints, or internodes, each bearing a triad of spikelets at its apex. The internode has a sharp chisel edge, and the awns, or beards (needlelike projections), of the spikelets have minute, upwardly directed barbs. This combination ensures that spikelet groups placed upon a rough surface tend to move only in one direction, forcing the chisel edge into crevices of the soil or sometimes into animal tissues. Even more elaborate is the ratchet drill device of the genus *Stipa* (porcupine grass, needle and thread). Its lower end, or callus, is extremely sharp-

pointed and is provided with upwardly directed bristles. When this pointed callus has penetrated any object, be it soil, clothing, or animal fur, it is extremely difficult to remove. The upper end of the floret bears a long awn with a highly hygroscopic (water-absorbing), twisted lower segment. As moisture changes occur, this twisted segment winds up (when drying) and unwinds (when moistened). These changes cause the bent awn to flail about until it lodges against an obstacle and then cause the floret to screw itself into the soil or into the unfortunate animal. Similar devices, although fabricated of different anatomical structures, occur in distantly related genera, such as *Heteropogon* and *Trachypogon*.

Finally, some grasses have adapted themselves as parasites of man's agriculture. Two of these are especially notable—chess (*Bromus secalinus*) and goat grass (*Aegilops*). These annual grasses tend to grow with wheat. They mature at the same time wheat does, are harvested along with the grain, and, unless great care is taken with cleaning the crop, will be replanted along with the next year's seed.

Ecology. Great grasslands exist on all the continents with the exception of Antarctica. In such widely separated areas, climatic, physiographic, and soil differences are great, but in general it may be said that grasses occupy areas where there is at least one period of the year with scant moisture (usually the winter). With higher and more evenly distributed rainfall, forests hold dominance over grasslands, although man, fire, and grazing animals have apparently caused the replacement of forest by savanna or grassland in many areas, especially in the tropics. Grassland verges into desert as rainfall becomes increasingly inadequate, while forests penetrate the grasslands in especially favourable situations, as along major streams. Within grassland regions, areas of high rainfall tend to be occupied by sod-forming, often rhizomatous grasses, while scattered bunch grasses live in drier parts. Even in deserts, scattered grasses occur. The so-called six-weeks grasses, including various short-lived annual species of *Festuca* (*Vulpia*), *Bouteloua*, and *Aristida*, may appear in profusion after heavy rains in semidesert areas.

Other grassland types occur above timberline on mountains. The Alpine tundra of high mountains in temperate North America contains many dwarf species of *Poa*, *Festuca*, *Trisetum*, *Calamagrostis*, *Agrostis*, and *Phleum*. There is a gradual transition between these Alpine grasslands and the Arctic tundra of low elevations, which includes many of the same genera. The high-elevation grasslands of the American tropics are often designated as paramo. Such areas contain many grass genera that are typically temperate-zone inhabitants and frequently dwarf bamboos as well.

In addition to the grassland species, there are many grasses that live as secondary or primary components of other vegetational types. In the temperate zone, grasses form a characteristic component of the herbaceous understorey of deciduous forests. In temperate North America, various species of the following genera may be found in such forests; *Agrostis*, *Brachyelytrum*, *Bromus*, *Cinna*, *Elymus*, *Festuca*, *Hystrix*, *Melica*, *Muhlenbergia*, *Oryzopsis*, *Poa*, *Panicum*, and *Schizachne*. In tropical climates, a number of primitive grasses are found in the rain forests. Some of these have broad leaves, very unlike those of typical grasses. Included in this group are such genera as *Streptochaeta*, *Pharus*, *Leptaspis*, *Olyra*, *Raddia*, and others. In open areas of tropical-forest margins or where forests have been destroyed, the bamboos, which are merely giant woody grasses, may form dense, nearly impenetrable stands. In coastal areas, salt marshes are often populated by dense stands of various species of *Spartina* or *Distichlis*. Coastal or inland dunes are stabilized by species of *Uniola*, *Ammophila*, *Jouvea*, *Sporobolus*, *Elymus*, *Redfieldia*, *Calamovilfa*, and others.

The grasses are primarily a group of plants adapted to land habitats, and they are replaced in wet areas by sedges (family Cyperaceae) or rushes (family Juncaceae). A few specialized grass species, however, occur in or around water. The most widespread is the common reed, *Phragmites australis*. The genera *Leersia* and *Glyceria* are also usually confined to wet habitats. Rice (*Oryza sativa*) and wild rice

Wind and water dispersal

Self-planting adaptations

Aquatic and moist-habitat grasses

(*Zizania aquatica*) have previously been noted as aquatic grasses. In many of the major groups of grasses, a few species adapted to moist or wet habitats are to be found. The most truly aquatic of all grasses are *Hydrochloa carolinensis* and *Luziola fragilis*. Both of these species have bases rooted in the mud of ponds or streams. The weak, slender culms allow the foliage leaves and inflorescences to float on the water surface.

At the other ecological extreme, there is a wide variety of grasses adapted to extremely dry habitats. The genera *Aristida*, *Bouteloua*, *Muhlenbergia*, *Hilaria*, *Schismus*, and others occur commonly in desert areas of the American Southwest. The desert grasses are predominantly of two contrasting types. Some, such as the six-weeks grasses, are small, shallow-rooted, short-lived annuals, surviving unfavourable periods in the seed stage. The remainder are harsh perennials with narrow, fibrous, often rolled leaves, propagating largely by rhizomatous spread or by the basal growth of clumps, and are capable of remaining dormant for long periods during drought.

At least 30 percent of the land surface of the world was once grassland, although much of this area has now been put into cultivation. Soils that developed under temperate grasslands are uniquely fertile and form some of the most productive croplands. Grassland areas of great extent are found on all the continents of the world except Antarctica, and, even there, two of the three species of flowering plants that occur are grasses of the genus *Deschampsia*. (For descriptions, maps, and other material relating to these areas see BIOSPHERE: *Grasslands*.)

FORM AND FUNCTION

Vegetative characteristics. The adult grass plant consists of a jointed axis or stem, usually with solid nodes (joints) and hollow internodes (stem regions between nodes). At each node a single leaf, with a sheathing base, is borne. The leaves are arranged distichously (in two vertical rows, 180° apart). Fibrous roots (called adventitious roots) may

be borne at the basal nodes of the stems, forming the majority of the root system. Leafy, rooting portions of the stem (stolons) may creep along the surface of the earth. Beneath the soil surface, scaly, leafless stems (rhizomes) occur. Both stem types (stolons and rhizomes) serve for vegetative reproduction and food storage. Aerial stems, or culms, bear foliage leaves, each of which consists of a sheath (tubular sheathing portion), usually with overlapping edges, that surrounds the stem, and an elongated blade with parallel veins. A hairy or membranous collar, the ligule, arises at the juncture of the sheath and blade. At the base of the internode, inside of the midrib of the sheath, a bud is borne that may give rise to a branch. Between the branch and the main stem, a peculiar two-keeled modified leaf, the prophyllum, occurs. All other vegetative or floral structures of the grass plant may be homologized with one or another of the foregoing structures.

Roots of grasses are usually of small diameter and are much branched, forming the so-called fibrous root system. Except in small, short-lived annual grasses, the primary root and other roots arising directly from the embryo are soon lost, and the remainder of the root system is entirely adventitious (growing from other than the usual place, such as on stems) from the lower stem nodes. In perennials, much of the root system is replaced each growing season.

Rhizomes are extremely important in the economy of many grasses, providing the principal means of reproduction, in addition to storing much food. Creeping leafy stems lying above the soil surface, the stolons, function similarly. Short, leafy basal shoots, without visible stems, are called innovations. Their leaf area may be important in furnishing forage or adding to the quality of lawns. Kentucky bluegrass (*Poa pratensis*), for example, has many such innovations, which are responsible for the density of the grass sward. Erect stems of grasses, which ultimately bear inflorescences (flower clusters), are called culms. The culm terminates in an inflorescence borne on a more or

to grass
identification

Inflorescences. Inflorescences are of many types, but panicles (much-branched flower clusters) are by far the most common. Grass flowers are extremely reduced in size and structure and are always borne in small, scaly-bracted spikes called spikelets. The spikelet, not the individual flower, is the unit of the grass inflorescence. The spikelet, which is basically homologous with a leafy stem bearing branches (the flowers), may be specialized in many diverse ways. Practical identification depends largely on characteristics of the spikelets and other parts of the inflorescence, although these characteristics have proved inadequate for the production of an evolutionary system of classification for the family Gramineae.

The spikelet is usually supported on a stalk conventionally called a pedicel. The central axis, or rachilla, of the spikelet bears at its base two empty bracts (scalelike leaves), the glumes. These, like all the subsequent bracts of the spikelet, are distichous (arranged in two rows), as are the foliage leaves. Above the glumes each node of the rachilla bears a bract, the lemma, hidden inside of which a flower arises. At the base of the flower and actually on the flower branch is another bract, the palea, homologous with the prophyllum at the base of a vegetative branch. The palea is a two-keeled structure, somewhat H-shaped in cross section, having one vascular bundle near each keel but no midrib. The flower is enclosed between the lemma and the palea.

Flowers. Grass flowers are extremely small and simple, usually only a few millimetres long at the time of flowering. The perianth (surrounding flower parts, calyx and corolla) consists of a single cycle of small flattened or fleshy bodies, the lodicules. The number and structure of these vary in the different subfamilies of the grasses. In the bamboos and the subfamily Olyroideae, for example, three lodicules are present, two being placed between the ovary and the lemma and one between the ovary and the palea. The lodicules of bamboos are thin and flat, narrow and pointed, and they have several vascular bundles. In other grasses, two lodicules ordinarily are present, and these are located at the base of the lemma. In grasses of the subfamily Festucoideae they are pointed, nonvascular, and capable of swelling near the base. In the subfamilies Eragrostoideae and Panicoideae, the lodicules are square-tipped and fleshy and contain several vascular bundles. The sole surviving function of lodicules in grass flowers is to become engorged with water at the time of maturity of the flower, thereby forcing the lemma outward and allowing the anthers (pollen sacs) and stigmas (pollen receptors) to emerge.

stamens
and pollen
specialized
to wind
pollination

In the great majority of grasses, 3 stamens (male reproductive structures) are present. Bamboos, however, characteristically have 6 stamens, and one genus (*Ochlandra*) has up to 120. The stamens show high evolutionary specialization toward wind pollination. The filaments (stalks of the anthers) are long and lax, permitting the anthers to dangle well out, exposed to air currents. The centrally attached anthers are proportionally very large and liberate enormous amounts of pollen. A field of rye (*Secale cereale*) during flowering, for example, can be seen to liberate clouds of yellow pollen. Plants of maize (*Zea mays*) often become noticeably dusted with pollen. Because of its abundance, grass pollen is a frequent cause of allergies, often but wrongly called rose fever. This vast excess of pollen is characteristic of wind-pollinated plants in general. The pollen, which is light and fluffy, consists of individual grains that are simple spheres with a single pore and no surface sculpturing. Each pollen mother cell produces four independent pollen grains.

The pistil (female reproductive organ) of grasses is composed of three united segments, or carpels, but produces only a single ovule and one seed. In bamboos and related grasses, three stigmas are usually present but in other grasses only two. In maize the two stigmas have become united, forming the silk. The stigmas are extremely feathery, serving to "comb" pollen out of the air. Despite the great waste of pollen, the combination of large anthers and extremely large stigmas has proved efficient enough to

make the grasses one of the most successful and numerous families of plants.

The flower, the enveloping lemma and palea, and the usually adhering rachilla segment form a unit called a floret. Frequently the floret becomes the disseminule of the plant when the grain (caryopsis) matures.

Grass spikelets have multitudinous forms and structures, and no single description can encompass all of the variations known. Authorities generally agree that the spikelets of the ancestral grasses, typified by those of such present-day types as the bamboos, had bisexual (perfect) flowers that were borne in spikelets of several to many flowers. One common evolutionary tendency is for the loss of some or all of the upper flowers from an ancestrally many-flowered spikelet type, resulting in few-flowered or more commonly single-flowered spikelets. In the subfamily Panicoideae and in a few other forms, the lower flowers are reduced or absent, and only one perfect flower remains at the apex of the spikelet. In certain grasses, notably in the rice subfamily (Oryzoideae), the glumes have become reduced to mere ridges or a minute cup at the tip of the pedicel. In the crabgrasses (species of *Digitaria*), the first glume has been lost or reduced to a rudiment.

Relatively few grasses have flowers that are unisexual. Frequently, the rudiments of the organs of the other sex may be detected in flowers of this type. Grasses with unisexual flowers may be monoecious (having both sexes on the same plant) or very rarely dioecious (the two sexes on different plants). Maize (*Zea mays*) is a prime example of monoecious grass. In maize, the male inflorescence (tassel) is situated at the tip of the stem, so that pollen may easily drift down upon the silks (stigmas) of the female spikelets, which are borne on the ear shoot below. The opposite situation occurs in wild rice (*Zizania aquatica*), in which the female spikelets are borne in a bunch at the tip of the stem, and the male spikelets are on lower branches of the same inflorescence. This situation encourages cross-pollination, since most of the pollen tends to drop downward. Grass species that are completely unisexual (dioecious) are much rarer.

Since the grasses are wind-pollinated, there is a great wastage of pollen at any great distance from the parent plant. The difficulty in obtaining good seed set in unisexual grasses has apparently restricted the evolution of such types. The genus *Distichlis*, which occurs in maritime or saline habitats, and the common buffalo grass (*Buchloe dactyloides*) of the American Great Plains are examples of dioecious grasses. In both of these genera and other similar ones, the plants rely largely on vegetative reproduction by stolons or rhizomes, and highly effective sexual reproduction is not essential for the survival of the populations.

Spikelets vary as to the manner in which they or their parts are shed from the parent plant. In the more primitive grasses, the glumes remain on the plant, while the florets (or the grains) are shed individually or, more rarely, in a group. The shedding (disarticulation) of individual grains or florets has the obvious advantage of securing more even dispersal of the seed. In grasses with only one flower per spikelet, the entire spikelet may be shed as a unit, as in the rice subfamily (Oryzoideae) or the subfamily Panicoideae. Certain grasses that have evolved special means of seed dispersal may have clustered spikelets that disarticulate as a group from the plant, often surrounded by hooks or spines, as in the sandburs (species of *Cenchrus*).

In more primitive grasses, spikelets are laterally compressed—that is, they are flattened from the sides—so that the individual bracts are more or less boat shaped. Many common grasses, such as bluegrass (*Poa pratensis*), orchard grass (*Dactylis*), and the species of brome grass (*Bromus*), illustrate this type of structure. In the subfamily Panicoideae, however, the spikelets are flattened from the backs of the bracts (dorsally compressed), as in the genus *Panicum* or crabgrasses (species of *Digitaria*).

Fruit and seed. The fruit of the grasses is ordinarily a grain, or caryopsis. Technically, this differs from other small indehiscent (nonopening) fruits, such as the achene, by having the pericarp, or ovary wall, completely adherent to the seed. The seed coats themselves are usually crushed by the growth of the seed. In a few cases, the ovary wall

Variations in
sexuality

Shedding
of spikelet
parts

may be shed, and in rare instances, especially in the bamboos, other types of fruits may occur.

The seed itself consists of a flattened, more or less boat-shaped embryo lying along one side of a large mass of starchy endosperm (stored food outside of the embryo). The bulk of the embryo consists of a fleshy body, the scutellum, which lies in contact with the endosperm and serves as a digestive and absorptive structure during germination. The true nature of the scutellum is debatable, but it has conventionally been called a cotyledon (seed leaf). The remainder of the embryo is attached on the external surface of the scutellum by its medial portion. The portion above the point of attachment is enclosed by a cylindrical sheath, the coleoptile, which protects the young shoot during germination. Within the coleoptile several embryonic leaves and the apical meristem (growing tip) of the stem are borne. The coleoptile and its contents may be attached directly to the face of the scutellum, or a short internode (embryonic neck or mesocotyl) may intervene. The lower portion of the embryo, which in some grasses is fused to the lower part of the scutellum, is a tubular sheath containing the primordium (the initial tissues) of the primary root. In certain subfamilies of the grasses a small flap of tissue, the epiblast, occurs on the external face of the embryo opposite the point of attachment. Certain features of the embryo have great value in determining the relationship of the grasses.

Leaves. The anatomy of grass leaves has been shown to be indicative of relationships within the order. The leaf epidermis, or outer "skin," in grasses is composed fundamentally of longitudinally elongated cells, usually with rippled walls. Interspersed with these are various specialized short cells, which are either suberized (corky) or impregnated with silica. The simplest of these are found in the subfamily Festucoideae, in which most of the isolated circular silicified cells are accompanied by crescent-shaped suberized cells. The other subfamilies have silicified cells in the form of double-bitted axheads, X's, collapsed quadrilaterals, or other complicated shapes. Frequently, such silicified cells occur in long rows over the vascular bundles. Many grass leaves bear elongated hairs, but these have little importance in determining relationships. Short, stiff, clawlike hairs also are common on leaf margins and may cause cuts when the leaves are handled. Plants of most of the grass subfamilies also bear specialized two-celled microhairs on the leaves. These may be linear and composed of two equal cells, the upper pointed, or they may be blunt or obtuse, with the upper cell smaller than the basal one. The type of microhair is specific to particular subfamilies. Such bicellular hairs are entirely lacking in the subfamily Festucoideae but are present in most of the other subfamilies. The shape of the complex of cells surrounding the stomates (air pores) in the epidermis is of importance in determining the subfamily to which a grass belongs. This group of cells consists, in grasses, of the two guard cells that surround the opening and two additional cells, the subsidiary cells, alongside each guard cell. In the subfamily Festucoideae, the general outline of this group of cells is rectangular, but in the other subfamilies, it varies from broadly oval to rhombic (diamond-shaped).

Internal
leaf
structure

The leaf cross section also reveals many features of importance in the classification of the family. Transverse sections of the leaf blade reveal a series of parallel vascular bundles, at intervals joined by small, transverse connecting bundles. Ordinarily each two large bundles are interspersed with one to several smaller and simpler ones. A typical bundle is surrounded by a thick-walled, woody sheath and often by an external layer of thin-walled, living cells (parenchyma). Internally the bundle contains a patch of phloem (food-conducting vascular tissue), oriented toward the bottom of the leaf, and several xylem vessels (water-conducting tubes). The number and nature of the bundle sheaths often indicate the subfamily to which the grass belongs. In the subfamily Eragrostoideae, for example, the outer sheath consists of large parenchyma cells that store starch, while in the subfamily Arundinoideae it consists of apparently empty cells. The green parenchyma cells filling the leaf are variously arranged. In grasses of the subfamily Festucoideae, the cells are loosely packed and

without apparent order. In those of the subfamily Eragrostoideae, however, the cells are tightly packed and radially oriented in a ring around each vascular bundle. In several subfamilies, especially the Bambusoideae, Olyroideae, and Arundinoideae, the mesophyll cells (middle layers of green parenchyma cells of the leaf) often have folded-in walls or armlike processes (rachymorphous cells). Both the subfamilies Bambusoideae and Olyroideae and a few species of the subfamily Oryzoideae have large empty cells running crosswise in the leaf, between each two vascular bundles. These spindle-shaped, or fusoid, cells appear in the longitudinal sections of the leaf as I-shaped structures with large openings between them. Bulliform cells are enlarged epidermal cells, usually present between the vascular bundles on the upper leaf surface. Their function has been debated, but many authorities have claimed that they aid in folding or rolling the leaf blades at times of water stress, thereby reducing water loss.

Some grass leaf blades, especially those of the subfamilies Bambusoideae and Olyroideae, possess a constriction at the base of the blade that has been called a petiole (leafstalk) or pseudopetiole. Anatomically, it is merely a narrow portion of the leaf blade. Bamboo leaf blades are deciduous (*i.e.*, they fall) from the sheath at this point. Ordinarily, the petioles are only a few millimetres long but may reach several centimetres in *Zeugites* and as much as 13 centimetres (about 5 inches) in *Rattaya petiolata*.

Chromosome numbers. Since the first major compilation of grass cytology in 1931, interest in the correlation of grass chromosomes to the possible phylogenetic relationships within the family has been high, and probably the cytology of the family is better known than that of any other large family. Members of the subfamily Festucoideae, which includes the common grasses of temperate and cold climates, possess relatively large chromosomes, with the basic number of $x = 7$. All other subfamilies of the grasses possess much smaller chromosomes with the basic number of $x = 5, 6, 8, 9, 10$, and 12 . Bamboos, regarded as primitive from the standpoint of floral and spikelet structure, have $x = 10$ or 12 . The evolutionary significance of the differences in chromosome number and size can only be guessed, and trying to assign one subfamily as parental to the others on the basis of cytology or morphology of living forms seems an exercise in futility.

A high percentage of grasses are polyploid; that is, their somatic (body) cells possess more than the two sets of chromosomes typical of ancestral forms. Numerous species with 4, 6, 8, 10, 12, or more basic sets of chromosomes are known. This increase of chromosome number has occurred by natural means, probably after the accidental formation of nearly sterile interspecific hybrids (crosses between species). When the chromosome number of such a hybrid becomes doubled, the offspring (known as an allopolyploid) may be fertile and sometimes highly successful in nature. This spontaneous increase of chromosome numbers has been a major evolutionary method in the grasses and has undoubtedly aided greatly in fitting the members of the family to the exceedingly diverse climatic and soil conditions under which they live. Many of the most valuable agronomic grasses have had this type of origin. Examples of grass allopolyploids include timothy (*Phleum pratense*), orchard grass (*Dactylis glomerata*), wheat (*Triticum aestivum*), oats (*Avena sativa*), and many bluegrasses (*Poa* species).

Polyploidy
among
grasses

Biochemical and physiological features. The grasses are notably free of alkaloids and similar compounds that abound in other monocot families, such as the Liliaceae and Amaryllidaceae. In a few instances, notably in the genus *Sorghum*, young or injured plants may contain amounts of cyanogenetic glycosides, which are organic compounds containing sugar and capable of liberating lethal amounts of hydrocyanic acid when the plants are grazed by livestock. Many grasses also may become infected with various species of ergot fungus (species of *Claviceps*), which renders the seed heads toxic.

A limited number of attempts have been made to determine relationships within the grass family by means of immune reactions similar to those used in blood typing. The results indicate that various genera formerly placed in

the subfamily Festucoideae are more properly attached to the subfamily Eragrostoideae, as has been indicated also by numerous anatomical and cytological data.

EVOLUTION

Since the grasses are primarily herbaceous plants, they have not left an impressive fossil record. While claims have been made for the presence of grasses from the Cretaceous Period of some 65,000,000 to 136,000,000 years ago, all reasonably well identifiable fossil grass remains are from the Tertiary Period (beginning 65,000,000 years ago) or later. Vegetative remains of rhizomes and stem bases ascribed to the genera *Arundo* or *Phragmites* have been described from Europe. An excellent series of fossil grasses from the Great Plains of central North America was described in 1942. These fossils consist mostly of hardened fertile florets of species of grasses related to the living genera *Stipa*, *Oryzopsis*, *Piptochaetium*, *Nassella*, and *Setaria* or *Panicum*. They span the period from the early Miocene Epoch through the Pliocene (beginning about 26,000,000 years ago to about 2,500,000 years ago). Their nature, relationships, and associated plant and animal fossils indicate that they were inhabitants of open, dry plains. It is significant that the first appearance of these fossils of steppe-type grasses coincides closely with the evolution of ancestral horses having high-crowned teeth and strong jaws, suited to eating siliceous dry-land grasses. Their elongated legbones and sharp hooves enabled rapid running. These adaptations indicate that the animals evolved and lived in extensive grasslands. The presence of the grass fossils over a wide area indicates that rather modern type grasses and grasslands were well developed by the Miocene time and that the origin of the family must have occurred much earlier. It is likely that the ancestral grasses were delicate forest inhabitants and were incapable of fossilization. Tropical rain forest areas of the world presently contain various peculiar, frequently broad-leaved grasses that are thought to be primitive in certain respects. The genus *Streptochaeta* of the American tropics is frequently mentioned as the most primitive living grass, yet its spikelets are highly atypical of those of other grasses and may themselves represent reduction from still earlier forms.

The relationships of the grasses to other monocotyledons has been the subject of much speculation. Earlier and undoubtedly erroneous systems of classification developed in the late 19th century were based upon the premise that the grasses are primitively simple—that is, that their small, simple, wind-pollinated flowers represent an early stage in floral evolution. A radically different system, based upon later anatomical studies of flowering plants, was presented early in the 20th century by the American botanist C.E. Bessey. His system, which is basic to most later arrangements, is based upon the idea that the primitive flowering plants are dicotyledons, such as the buttercups and their relatives (order Ranales in older systems, Ranunculales here) and the magnolias and their kin (order Magnoliales). The monocotyledons are regarded as having originated from the older dicotyledon orders. The lily relatives (order Liliales) represent a basic group of monocotyledons from which several lines of specialization arose. The grasses were regarded by Bessey as the apex of the wind-pollinated line of the monocotyledons, derived from the lily order by the loss of sepals and petals and various adaptations to wind pollination. Most recent authorities on plant phylogeny have followed somewhat similar arrangements of the monocotyledon families.

A recent French writer states that the grasses arose in the Cretaceous Period from a lilylike ancestry. The rushes (family Juncaceae), which are wiry, grasslike plants with minute, six-parted green flowers, and the sedges (family Cyperaceae) are thought by this writer to have diverged from the same ancestry at about the same time. As treated here, a similar derivation of the order Poales from the order Liliales is suggested, but the sedges and rushes are separated on a different line of development. A recent system developed in the United States places both the family Cyperaceae (sedges) and the grass family (Poaceae or Gramineae) in one order, called the Cyperales. Both of

these systems propose that the grasses are derived from a line based on the order Commelinales. This order contains insect-pollinated plants whose flowers have both calyx and corolla but lack nectar production. The absence of nectar is regarded as a first step in the derivation of wind-pollinated flowering plants from insect-pollinated ones, since the flowers have lost one of the structures (nectar glands) making flowers attractive to insects. Certain members of the order Commelinales are grasslike in aspect (e.g., the family Xyridaceae), and all have sheathing leaf bases, somewhat similar to those of the grasses. The fruit in these groups, however, is a capsule, and the overall resemblances of these plants to the grasses are rather remote. More directly on the line of descent of the order Poales is the order Restionales. This order includes plants with wind-pollinated, reduced flowers and ovaries that have single ovules in their cavities. They are similar to the grasses in their pollen and in having sheathing leaf bases.

In the absence of a meaningful fossil record for the monocots, all of these varying systems are based upon interpretations of structure of living plants. While the details of the newer systems differ, all are alike in regarding the grasses and their kin as reduced, highly specialized plants rather than primitively simple ones.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. There is no single distinguishing trait of the order Poales. The presence of reduced flowers in scaly spikelets, two-ranked leaves with sheathing bases that have overlapping margins, hollow internodes, two bracts per flower, and a caryopsis as the fruit are the usual features used, but all of these are subject to variation. While the stems are ordinarily annual and herbaceous, they are long-lived and woody in the bamboos.

Plants of three common families, the grasses (Gramineae), the sedges (Cyperaceae), and the rushes (Juncaceae), have a similar aspect and are frequently confused by casual observers. Species of the family Juncaceae are at once separable from the other two families by having flowers with a well-developed, six-parted perianth and a capsular, dehiscent fruit containing three to many seeds. Differences between the Gramineae and the Cyperaceae are summarized in Table 4.

Plants similar to grass in appearance

Table 4: Comparison of Two Easily Confused Families, the Grasses and Sedges		
character	grass family (Gramineae)	sedge family (Cyperaceae)
Leaf orientation	two rows	three rows
Leaf sheath	usually with overlapping edges	always with united edges
Stem structure	usually hollow, cylindrical	usually solid, triangular
Bracts per flower	two: lemma and palea	one: glume
Type of fruit	caryopsis	achene
Habitats	mostly dry land	mostly moist or wet areas

The features most used in modern classifications to subdivide the order Poales include the basic chromosome number and relative chromosome size, nature of specialized epidermal cells, internal leaf anatomy, root hair position on the epidermal cells, embryo structure, structure of the flower (including the number and nature of the lodicules), biochemistry and immunology, ecology, and distribution. The systems of classification produced by use of these and other characteristics must be supplemented with keys based upon easily observed superficial characteristics. Such aids to identification are now beginning to appear in recent works on grasses that use the modern evolutionary classifications as a basis for subdividing the family.

The classification in this article represents a consensus of modern opinions regarding grass classification that has grown up in recent years. Since there is no modern worldwide treatment of the family, some segments of the classification stated here are adapted from different authors.

Alternate systems of classification. Ideas as to the classification of the grasses have undergone a veritable revolution in recent years, unparalleled in any other group

Fossil record

Primitive grasses

Recent concepts concerning relationships

Basis of
early clas-
sification
systems

of angiosperms. The earlier arrangements were based primarily upon the nature of the spikelet, with secondary emphasis given to the form and structure of the inflorescence. Doubts arose as to the validity of this system when the first major compilation of chromosome numbers of the grasses was published in 1931, and the family was divided on the basis of chromosome number and size. The groupings thus defined ran counter to the system of classification current at that time, however, and were not taken up. Shortly thereafter, extensive studies were made on the grass epidermis. The wide variety of specialized cells of the epidermis was used as a basis for dividing the family into new groupings. By 1936 three subfamilies, the Bambusoideae, the Festucoideae, and the Panicoideae, were recognized. The grasses currently grouped in the subfamily Eragrostoideae were uncomfortably wedged into the subfamily Panicoideae. This system of classification, while no longer entirely accepted as to its taxonomic conclusions, was the first to incorporate such features as leaf epidermis, cross-sectional leaf anatomy, chromosome number and size, nature of the embryos and seedlings, starch grains, physiology, and ecology. Publications based upon such data led to a greatly increased interest in the construction of a more truly phylogenetic classification of the grasses. The status of grass classification was the subject of a symposium at the International Botanical Congress in Montreal in 1959. Numerous papers concerning the overall and partial classification of the group have been published since that time. More or less inclusive classifications have been published by grass evolutionists for temperate North America, for tropical Africa, and for the entire world. While these systems are not completely in accord with one another, they all show general similarities.

All of the new systems recognize the bamboos as a separate subfamily. This appears to be entirely justified, since all of this group have woody, perennial stems. In many respects, they are a highly specialized group, although their flower structure is primitive in the order. There is less general accord as to the subfamily Olyroideae, whose members are similar to the bamboos in many anatomical and cytological aspects but lack the woody stems.

The subfamily Festucoideae of the older standard system of classification has suffered the greatest remodelling. As it was originally construed, this group was united only by spikelet characteristics. It was shown by later investigators that the members differed greatly in numerous anatomical characteristics, in their basic chromosome numbers and size, and in their ecological and geographical relationships. The removal of certain genera to the subfamilies Bambusoideae, Eragrostoideae, Arundinoideae, and Oryzoideae has left the subfamily Festucoideae much more homogeneous.

The subfamily Panicoideae, which had long been recognized on the basis of spikelet structure, continues to be accepted in the original circumscription, although with some internal rearrangements.

The subfamily Arundinoideae is the least well characterized of the recently accepted divisions and will probably undergo further revision. A few isolated genera of grasses are so unusual that placement of them in any system of classification is problematical, and they can be only arbitrarily assigned to a subfamily.

In general, the new systems of classification recognize about six or seven major groups (subfamilies or series), based upon numerous criteria, including microscopic anatomy and cytology. One major work on grass classification published in 1954 is at considerable odds with those previously discussed. This system uses nine subfamilies, but their constitution is very different from that proposed by later authors. The large subfamily Festucoideae of this system is even more inclusive than that of the previous standard system containing such aberrant genera as *Phyllorachis*, *Pariana*, *Thysanolaena*, *Arundinella*, *Pappophorum*, *Phragmites*, and others, which are placed in other subfamilies by more recent authors. The subfamily Arundinoideae, containing the giant reed grasses and other grasses, is not recognized, but, on the other hand, the bluestem grasses (*Andropogon* and its relatives) and the maize relatives are separated into a new subfamily, the

Andropogonoideae. This radically different classification has not been favourably received by agrostologists, but the comprehensive nature of the work and its keys to genera make it useful.

The work of the last 40 years on grass cytology, anatomy, physiology, biochemistry, and ecology has succeeded in establishing the general outlines of a new and more informative system of classification. It seems reasonably clear that paleobotany, on the other hand, will do little or nothing to either confirm or contradict the newer classifications.

Future cytological and anatomical research is still needed to fix the positions of many anomalous genera. Since the 1954 proposal of a complete general system, no attempt has been made to provide a worldwide treatment of the grasses at the generic level, using a modern system of classification. Such a treatment would be an excellent skeleton on which to place the accumulating body of data on grasses. There are no world monographs of the great majority of grass genera, even on the level of gross morphology. The availability of such monographs would be a great stimulus to the study of the family in the various parts of the world.

The wet forests of the tropics contain many rare or isolated primitive grasses, especially members of the subfamily Olyroideae. Study of these, which may reveal further clues as to grass relationships, is urgently needed before the surging population pressures of the tropical lands completely wipe out their habitats. (R.W.P.)

Arecales (palm order)

The palm order, Arecales (or Principes), consists of a single family, the Arecaceae (or Palmae), and is generally considered to be second only to the grasses in economic importance. Palms are distinctive in their habit and geography, being characteristically woody in a class of plants (Monocotyledoneae) that is otherwise mostly herbaceous, and being chiefly restricted to the tropics or subtropics, where they are a prominent part of the vegetation. There is a uniformity of aspect to palm leaves that characterizes members of the order despite great differences in the size of various species. Stems may vary from the height and diameter of a pencil to a height of 190 feet (58 metres) or a diameter of 3 feet (1 metre). Leaves of a few inches long to the largest in the plant kingdom, more than 30 feet (9 metres) long, are found in this order, and seeds from the size of buckshot to the largest known, the 20-pound (9-kilogram) double coconut or coco-de-mer (*Lodoicea maldivica*), are found.

GENERAL FEATURES

Distribution. The great centres of palm distribution are in America and in Asia from India to Japan and south to Australia and the islands of the Pacific and Indian oceans, with Africa and Madagascar as a third but much less important palm region. These centres are bounded roughly by latitudes 44° N and 44° S, though the greatest abundance lies primarily between latitudes 30° N and 30° S. These distributions correspond more or less with zones having mean annual temperatures of 60° and 70° F (15° and 21° C) and, with rare exceptions, to areas having 20 inches (50 centimetres) or more of rainfall per year.

The northernmost palm is *Chamaerops humilis*, which grows about the Mediterranean in Europe and North Africa; the southernmost is *Rhopalostylis sapida*, of New Zealand and the Chatham Islands. Although there are species with extensive ranges, especially in America, most are restricted in range, and those of islands, in particular, are frequently found nowhere else. One species, *Liberibaileya gracilis*, is limited to a few limestone outcroppings in the Langkawi Islands off the Malay Peninsula. No species, except *C. humilis* and the pantropical cultivated coconut, occurs on more than one continent; the genera transcending continental bounds are *Chamaerops* in Europe and Africa, *Elaeis* and *Raphia* in Africa and America, and *Borassus*, *Calamus*, *Hyphaene*, and *Phoenix* in Africa and Asia. Numbers of individuals of a species may be few or many; *Copernicia alba* occurs in solid stands hundreds of square miles in extent in the northeastern section of

Basis of
recent classifica-
tion
systems

the Paraguayan Chaco and adjacent Bolivia and Brazil, the largest stands in this region alone containing possibly 500,000,000 plants.

Economic importance. The palms most important in world commerce are the coconut (*Cocos nucifera*) and the African oil palm (*Elaeis guineensis*); both are prime sources of vegetable oil and fat. Probably no plant is as versatile as the coconut. The husk of the fruit is the source of coir, used for ropes and mats; the hard inner fruit layer (endocarp) is used as fuel and to make charcoal, cups, bottles, and trinkets; the coconut milk (liquid endosperm) is used as a beverage and in cooking; the coconut flesh (solid endosperm) is used as raw food or dried to form copra, a source of oil and oil cake, the last used as cattle feed. The sap obtained from tapping the inflorescence, or flower stalk, is drunk unfermented or fermented (toddy) and is a source of sugar, alcohol, and vinegar. Trunks are used in construction and furniture making, and leaves are used in a variety of ways in domestic economies. The African oil palm is important chiefly for the palm oil obtained from the fruit coat and for kernel oil from the seed.

Other palms are used extensively, especially in the Old World. Sugar and alcohol are obtained by tapping inflorescences of the sugar palm (*Arenga pinnata*), the palmyra palm (*Borassus flabellifer*), the wild date (*Phoenix sylvestris*), the fishtail palm (*Caryota urens*), the nipa palm (*Nypa fruticans*), and the buri and talipot palms (*Corypha elata* and *C. umbraculifera*). Wine is made from species of *Raphia* in Africa and from *Acrocomia* and *Jubaea* in America. *Metroxylon sagu* and, to a lesser extent, *Arenga pinnata* and *Corypha elata* are sources of starch obtained from the pith. The fruit of the date palm (*Phoenix dactylifera*) is a staple in parts of Asia Minor, Arabian Peninsula, and North Africa and is also an article of commerce, while that of the peach palm (*Bactris gasipaes*) is eaten in America. Fruits are also widely used fresh, as sources of oil, and in the preparation of refreshing drinks and ice cream. Throughout much of the Asiatic tropics and even in parts of East Africa, the seed of the betel palm (*Areca catechu*) is used, with lime and the leaf of the betel pepper (*Piper betle*), as a chewing substance. Trunks and leaves serve in local construction, in the making of weapons, and as sources of wax (*Ceroxylon*, *Copernicia*). Leaves of *Corypha* are made into umbrellas and books; others provide material for rain capes, baskets, raffia (*Raphia farinifera*), hats, hammocks, and the fibre known as piassava.

Minor uses are so diverse as to defy complete listing, but as examples some of the uses of the sugar palm, *Arenga pinnata*, may be cited. Leafstalk bases are used for cordage and thread; leaflets are used for wrapping material, brooms, basketry, fishing implements, musical instruments, handles, and holders. Leaf midribs and heavy fibers are used for styli, pens, and darts for blowguns, and the principal leaf axes are used for lathing and walking sticks. Fibres of roots are used for weaving, twine, whips, and matting; the hard fibres of the trunk are used for furniture, utensils, swagger sticks, axe handles, and canoes. Split trunks are used for drain pipes, troughs, gutters, conduits, and drums. The feltlike fibres of the leaf sheath provide tinder, caulking, and pillow fillers, and the outer coating of the fruit is used as hog feed and as a source of poison. Seeds are used as touchstones and toys, and other parts are used in local medicine and magic.

Apart from commercial or local uses, palms are extensively planted for ornament in warm regions or indoors when a tropical effect is desired. Ornamental palms for out-of-doors use number several hundred species.

NATURAL HISTORY

Life cycle. The life cycle of a palm is like that of most flowering plants except that the early vegetative phase is often prolonged because the palm stem generally attains its maximum girth below ground before it begins to grow upward. This is because palms, unlike woody broad-leaved plants, do not have the means for growing a thicker trunk; moreover, they have only a single growing point. There is usually an accompanying change from the small and sometimes strap-shaped leaf of the seedling to the leaf of the adult. Some palms grow rapidly, others grow

very slowly. Only by knowing how many leaves a palm produces in a year and by counting leaf scars can an approximation of age be arrived at.

Reproduction may begin very soon in small palms—within two years of germination—or after several years in larger palms. In some it may be suppressed for many years as in the talipot palm (*Corypha umbraculifera*) or the fishtail palm (*Caryota urens*), which flowers once, then dies. In some palms, flowering and fruiting may be continuous or nearly so, but in many there appears to be a periodicity perhaps related to the onset of rains or to light intensity or both. The African oil palm apparently responds cyclically to rain, light, and nutritional levels.

It has long been assumed that palms are wind pollinated, and doubtless many of those that occur in open places or that overtop the forest canopy are so pollinated. Syrphid flies, however, are known to pollinate *Asterogyne martiana*, curculionid beetles to pollinate some species of *Bactris*, and trigonid bees have been seen to visit flowers of both sexes in *Archontophoenix* cultivated in Panama. Obvious adaptations to insect pollination may be observed in other palms, despite lack of documentation. It is noteworthy that among palms, the male flowers usually open and shed pollen before the female flowers become receptive, though *Nypa*, *Bactris*, and probably others are exceptions. Thus, outcrossing is promoted, though self-pollination in palms having flowers of both sexes on one plant is possible when several flower clusters have opened on the same plant.

Upon fertilization, usually only 1 ovule matures into a seed, but in a few genera 2 or 3 or up to 10 may form seeds. Palm fruits for the most part are fleshy, black or brightly coloured, and appear to be adapted for dispersal by birds and mammals. Bats, for example, are said to be fond of the fruit of the talipot palm, and birds that are insect eaters in the north may become fruit eaters in the tropics.

Ecology. Palms have adapted to many habitats within their geographic limits. To the dweller in temperate regions, they tend to be associated with jungle or with tropical shores, where the coconut is often a prominent feature of the landscape. Most palms are inhabitants of tropical forests. There they occur mostly on well-drained acid soils in regions of high though often seasonal rainfall. They range from the lowlands to mountain and cloud forests up to altitudes of 6,000 feet (1,800 metres). Rarely, as in *Ceroxylon* and some species of *Geonoma*, they reach elevations as high as 10,000 feet (3,000 metres) in the Andes. There are exceptions, however, for palms are also found in swamps or poorly drained areas (*Manicaria*, *Mauritia*, *Phoenix paludosa*, *Metroxylon sagu*, *Raphia*) or brackish estuaries and lagoons (*Nypa fruticans*) or areas subject to alternate flooding and drying (*Copernicia alba*). They also occur in deserts or on seashores when underground water is present (*Hyphaene*, *Washingtonia*, *Cocos nucifera*), or in open savanna, grassland, or gallery forest, or restricted to such special habitats as limestone outcrops (*Maxburretia rupicola*), serpentine soils (*Gulubia hombronii*), or river margins (*Astrocaryum jauari*, *Leopoldinia pulchra*) where competition is limited.

The mode of germination of palm seeds appears to have some ecological significance. Forest palms mostly have adjacent ligular germination and seldom succeed when exposed to full sun. Palms of drier or more open areas tend to have a form of germination wherein the seed leaf petiole elongates from 1 inch (2.5 centimetres) to 2 feet (60 centimetres) or more and buries the stem tip well below the surface of the soil. Delayed germination, in which some seeds germinate later than others, ensures replacements for early seedlings that may be lost through adverse climatic effects or other causes.

Trailing underground stems may be assumed to be adaptations to fire, as in *Serenoa repens* of pine woods and sand dunes in the southeastern United States, or to tidal fluctuations (*Nypa*).

FORM AND FUNCTION

Stem and root. Most palm stems are erect and solitary or clustered, but some grow horizontally, becoming

Determination of age in palms

Habitats occupied by palms

procumbent, or trailing, at or below the surface of the soil and producing the crown at ground level, while others are high-climbing vines. Rare instances of regular branching (in *Allagoptera*, *Chamaedorea*, *Hyphaene*, *Nannorrhops*, *Nypa*, *Vonitra*) appear to involve equal or subequal division at the apex that results in a forking habit. The two newly formed branches may continue equally or one may be overtopped by the other (*Nannorrhops*). When thickening occurs, as in the royal palms (*Roystonea*) or in the few that produce conspicuous swellings or "bellies" as in *Colpothrinax*, it is due to an increase in number or size of internal cells and not to new cell production at a cambium, or growing layer. The cortex, or "bark," may be smooth or rough, and it is sometimes fiercely armed with spines or covered with old leaf bases. Nodes, intermittently spaced thickenings of the stem, are often prominent and ringlike.

A typical palm stem, unlike the woody cylinder of a hardwood tree, is composed of hundreds to thousands of conducting strands scattered in softer ground tissue. There are usually two unequal regions, however. The central region is larger and softer than the outer region, which often is composed of densely packed fibres so hard that they quickly dull any cutting instrument. Thus palms are often left in place when forests are cleared for cultivation. Such a construction is a natural example of the best principles of engineering, permitting maximum strength with economic use of strengthening tissues, and it accounts for the ability of palms to withstand winds that break ordinary trees.

The unusual nature of roots in the palms

The first root of palms, unable to increase in diameter as do roots of broad-leaved plants, is eventually replaced by adventitious roots from the basal nodes of the stem. Most roots penetrate the ground, but in some palms, adventitious roots may form a mound above ground or appear at intervals along the stem. In *Cryosophila* and *Mauritia*, roots along the stem are transformed into spines. Stout prop roots forming a dense or open cone are found at successive nodes along the stem of certain varieties of palms.

The leaf. Leaves in the Arecales order are diverse in size, shape, and division. Three distinct but continuous regions are apparent in most: the sheath, petiole or leafstalk, and blade. The sheath, often fibrous, is that lowermost portion of the leaf that partially or completely surrounds the stem. Sheaths sometimes are elongate or tubular, and when they appear to form a continuation of the stem, they are referred to as a crownshaft. A fibrous ligule, a sort of membrane or appendage, is sometimes evident on the upper margin of the sheath on one side or in front of the petiole. The petiole is discernible above the sheath as a supporting axis devoid of leaflets.

The terminal portion or blade of the palm leaf may represent one of two categories for which the terms pinnate (or featherlike) and palmate (or fanlike) are broadly used. The first category embraces those that have distinct pinnae or leaflets or are bipinnate (*Caryota*) or merely pinnately veined. The second includes blades with relatively elongate central veins or ribs (costapalmate) or those in which

segments radiate from a central region at the tip of the petiole. Many palmate and costapalmate leaves have a prominent, often spear-shaped, ridge of tissue at the apex of the petiole known as the hastula.

Leaves are sometimes armed with spines or marginal teeth on sheath, petiole, or blade, or on all parts. Pinnae may be modified into recurved hooks (*Desmoncus*), or the tip of the central axis may be produced into a long slender whiplike strand armed with recurved spines in climbing palms such as *Calamus*.

The inflorescence. The inflorescence unit, the structure with a particular arrangement of flowers on its axis, may be a large and complex panicle (a loose, many-branched cluster) with numerous small leaflike bracts and branches to the fifth order, or it may be reduced to a head or to a spikelike axis with a single bract, or, as in *Calamus*, it may become a slender, clawed climbing organ or cirrus (tendrill). The usual flower unit has a supporting peduncle, or main axis, on which is borne a two-keeled first bract, a large appendage, and usually one or more other sterile bracts below the flowering portion. The flowering portion of the inflorescence is composed of a central axis and branched flowering axes of one or more orders having other bracts nearer each branching.

A small bract (bracteole) usually subtends the flower, each of which is borne on the surface of the final flowering branch of the inflorescence. More rarely, the flower is sunken in pits formed by the union of prominent bracts or by differential growth of the axis. The arrangement of flowers is sometimes complex. Flowers may be arranged singly, in pairs of a staminate (male) or a neuter flower and a functionally pistillate (female) flower; in groups of two staminate flowers and a pistillate or of two staminate flowers only, or of three to many perfect (both sexes in one flower) or staminate flowers.

The arrangement of palm flowers

The flower. Flowers of the Arecales order are attached directly to the flowering branch without "stems" or more rarely may have supporting stems. In either case they exhibit much diversity in structure, size, and colour and are based usually on a three-part plan. Most are less than an inch (2.5 centimetres) in length, but the female flowers of *Phytelephas* may be 10 inches (25 centimetres) long. The least specialized flowers are those with a calyx of three sepals, a corolla of three petals, a male complement of six stamens with slender to fleshy filaments and linear anthers that open by longitudinal slits, and a female structure of three distinct carpels, each with one ovule. Unisexual flowers are often markedly dimorphic (*i.e.*, the male and female forms are very different). The staminate (male) flowers have poorly developed female parts or none at all; the pistillate (female) flowers may have evident stamens or none.

The sepals in all flowers are either overlapping or joined in a lobed cupule and are 3, rarely 2 or up to 10 in number. Petals, similarly, may be 2 or up to 10, but these are usually thicker than sepals, fibrous, and whitish or coloured. They may be distinct and overlapped or they

Drawing by R. Findahl based on (centre) G.H.M. Lawrence, *Taxonomy of Vascular Plants*, copyright 1951 by The Macmillan Company, reprinted with permission of The Macmillan Company; (others) P.B. Tomlinson, *Principes*, vol. 5 (1961)

Growth habits of representative palms.

may meet without overlap, especially in male flowers. Petals also are sometimes partially to completely united. In a few palms the sepals and petals are reduced and united into a thin lobed structure.

Stamens, though most often 6 in number, may rarely be 3 (*Areca triandra*, *Geonoma triandra*, *Nypa fruticans*) or more numerous, ranging from 6 to 36 in *Heterospathes*, to more than 200 in such groups as *Caryota*, *Phytelephas*, and *Veitchia*. The filaments are erect or inflexed at the apex, are often thick and fleshy, and vary in shape. Sometimes they are united with each other or are fused to the petals or female structures. Sterile stamens may differ only slightly from fertile stamens, or they may consist of a filament alone without an anther, or be united in a cup about the base of the female structure or in a tube joined to the petals, or be reduced to minute flaps of tissue. Pollen grains are globose to irregular in shape, but most often they are ellipsoidal. The surface of the grains, however, may be smooth or ridged to warty or spiny.

Carpels, the female parts of the flower, are usually 3 in number, and they arise above the region where sepals, petals, and stamens are joined together. Though sometimes quite distinct, the carpels are most often united in a 3-chambered female structure in which each chamber may contain an ovule or in which 1 or 2 chambers may be reduced or apparently lacking, the pistil then appearing to be 2-chambered or single-chambered. The female part of the flower occasionally, though rarely, consists of 1 or 2 distinct carpels, or it may even have 5 to 10 chambers.

The fruit. Palm fruits, whether large or small, usually do not split at maturity and thus seeds are not shed separately. The fruit coat (pericarp) is three-layered: a smooth, prickly, warty, or scaly outer layer (exocarp); a fleshy, fleshy-fibrous, or fibrous middle layer (mesocarp); and a thin and membranous to thick and bony inner layer (endocarp) surrounding the seed. The mesocarp is sometimes filled with stinging chemical crystals or with "stone cells," thick-walled dense cells. The seed has a thin, often highly vascularized outer layer (testa) over copious, hard, sometimes hollow endosperm in which the pluglike embryo is embedded at either end or on one side.

EVOLUTION

The fossil record

Palms stand by themselves in terms of evolution. They do not appear to be very closely related to any other order of flowering plants unless it be the order Cyclanthales, nor can they be derived clearly from any present or past group of plants. They appear essentially in their present form in fossils from the Upper Cretaceous Period, 65,000,000 to 100,000,000 years ago; indeed, *Nypa* pollen is known from this age in northwest Borneo where the genus still occurs. By Eocene times, about 60,000,000 years ago, palms were widespread, and they are known in some abundance and diversity from such locations as the southern United States and the London clay of England. Pollen of the African oil palm is reported from Miocene deposits (about 30,000,000 years old) in the Niger Delta, and fossil fruits from the Eocene Period of India and the Pliocene Period (about 10,000,000 years ago) of New Zealand have been referred to the genus *Cocos*.

CLASSIFICATION AND TAXONOMIC STATUS

Distinguishing features. The order Arecales, with a single family named Arecaceae (or Palmae), is divided into subfamilies on the basis of leaf characteristics, nature of the inflorescence, and structure of flowers and fruit. The order is set apart from other members of the flowering plant class Liliopsida (monocotyledons) by the combination of woody habit, plicate (pleated) leaves, mostly three-parted flowers that are largely unisexual and usually have bracts and superior ovaries with one ovule per chamber, and seeds with copious endosperm.

Taxonomic problems. The major groups of palms, whether accepted as tribes or subfamilies, have been recognized in large part since about 1883, when six tribes were recognized corresponding to six of the subfamilies presented above. The subfamilies Caryotoideae, Nypoideae, and Phytelephantoideae were included within the tribe Arecaceae at that time.

Largely because of their size, palms have not been as well studied as the majority of plant families. Evidence from many disciplines, which is necessary for an understanding of evolution in the Arecales order, is still being amassed and assessed. Many biological problems, such as detailed studies of pollination, have scarcely been touched. The Arecoideae subfamily in particular is still in need of revision to bring natural groups of genera together at appropriate levels in a taxonomic hierarchy. Four to six distinctive subunits, for example, may eventually be recognized, one of them further divisible into possibly 16 to 17 distinctive groupings. (H.E.Mo.)

TAX, 1:227-305 (1960), a paleobotanical approach to the origin and evolution of the angiosperms; L. CONSTANCE, "The Systematics of the Angiosperms," in *A Century of Progress in the Natural Sciences, 1853-1953* (1955), an excellent review of the influence of research in various fields of botany on ideas concerning the phylogeny of the angiosperms; A. CRONQUIST, *The Evolution and Classification of Flowering Plants* (1968), an excellent book on the evolutionary classification of the angiosperms containing useful keys and many references; P.H. DAVIS and V.H. HEYWOOD, *Principles of Angiosperm Taxonomy* (1963), a most useful and comprehensive single volume but now a little dated; A.J. EAMES, *Morphology of the Angiosperms* (1961), a high-level classic book containing many useful references; A. ENGLER, *Syllabus der Pflanzenfamilien*, 12th ed. rev. by H. MELCHIOR, vol. 2 (1964), a valuable guide, in German, to the current version of the Engler system of classification, including family descriptions, useful keys, and many references; K. ESAU, *Plant Anatomy*, 2nd ed. (1965), probably the best textbook of plant anatomy, containing a comprehensive bibliography; V.H. HEYWOOD (ed.), *Modern Methods in Plant Taxonomy* (1968), a comprehensive review of the application of newer techniques by well-known experts in the field, with many references; J. HUTCHINSON, *The Families of Flowering Plants*, 2nd ed., 2 vol. (1959), containing useful keys, descriptions, and illustrations of the families recognized by the author; C. JEFFREY, *An Introduction to Plant Taxonomy* (1968), an excellent, clearly written semipopular introduction, with a list of additional readings and reference works; G.H.M. LAWRENCE, *Taxonomy of Vascular Plants* (1951), a well-illustrated textbook of college-level difficulty, containing excellent descriptions of the main angiosperm families, and further references, but now somewhat dated; A.C. SMITH, "The Pacific as a Key to Flowering Plant History," University of Hawaii Harold L. Lyon Arboretum Lecture No. 1 (1970), geographical aspects of angiosperm origin; A.L. TAKHTAJAN, *Flowering Plants: Origin and Dispersal* (1969; Eng. trans. from the 2nd Russian ed., 1961), a semipopular treatment of the angiosperms, with an extensive bibliography (including many important Russian works) and an outline of the Takhtajan system of classification; and J.C. WILLIS, *A Dictionary of the Flowering Plants and Ferns*, 7th ed. rev. by H.K. AIRY SHAW (1966), an extremely useful reference book.

Magnoliales. A.J. EAMES, *Morphology of the Angiosperms* (1961)—ch. 11 includes an excellent treatment of primitive families of dicotyledons and monocotyledons, as well as an extensive bibliography.

Laurales. R.L.N. SASTRI, "Comparative Morphology and Phylogeny of the Ranales," *Biol. Rev.*, 44:291-319 (1969), an objective assessment of the relationships and phylogeny of ranalian plant families on the basis of comparative morphology; J.C. WILLIS, *A Dictionary of the Flowering Plants and Ferns*, 7th ed. rev. by H.K. AIRY SHAW (1966), which describes some of the little-known families of the order; L.D. BENSON, *Plant Classification* (1957), a standard textbook that includes ecological data; L.S. COBLEY, *An Introduction to the Botany of Tropical Crops* (1956), a college-level account of the economic importance of the families; and H.N. ANDREWS, JR., *Studies in Paleobotany* (1961), an advanced treatise giving a good account of angiosperm fossils.

Piperiales. C.K. ATAL and J.N. OJHA, "Studies on the Genus *Piper*, pt. 4, Long Peppers of Indian Commerce," *Econ. Bot.*, 19:157-164 (1965), for the history, uses, chemistry, and descriptions of various species of long pepper; I.H. BURKILL, *A Dictionary of the Economic Products of the Malay Peninsula* (1935), names, uses, and chemistry of species of *Piper*; RONALD GATTY, "Kava—Polynesian Beverage Shrub," *Econ. Bot.*, 10:241-249 (1956), a general discussion of kava; HOWARD SCOTT GENTRY, "Introducing Black Pepper into America," *Econ. Bot.*, 9:256-268 (1955); J.W. PURSEGLOVE, *Tropical Crops*, vol. 2, *Dicotyledons* (1968), discussion of economic species of *Piper* with detailed treatment of *Piper nigrum*; FREDERIC ROSENGARTEN, JR., *The Book of Spices* (1969), discussion of black and white pep-

per with recipes; and TRUMAN G. YUNCKER, "The Piperaceae—a Family Profile," *Brittonia*, 10:1–7 (1958), discussion of the taxonomic history and phylogeny.

Nymphaeales. V.I. CHEADLE, "The Occurrence and Types of Vessels in the Various Organs of the Plant in the Monocotyledoneae," *Am. J. Bot.*, 29:441–450 (1942), the first comprehensive study on this aspect of the subject; A.P. DE CANDOLLE, "Nymphaeaceae," in *Prodromus Systematis Naturalis Regni Vegetabilis*, 1:113–116 (1824), a systematic treatment of angiospermous families known at the time; H. KOSAKAI *et al.*, "Morphological Studies of the Nymphaeaceae: V. Does *Nelumbo* have Vessels?," *Am. J. Bot.*, 57:487–494 (1970), a recent research report on primitive vessels in the genus *Nelumbo*; H. LI, "Classification and Phylogeny of Nymphaeaceae and Allied Families," *Am. Midl. Nat.*, 54:33–41 (1955), a taxonomic study of the Nymphaeales order, including the most extensive available subdivision of the groups within the order; A.D.J. MEEUSE, "The Descent of the Flowering Plants in the Light of New Evidence from Phytochemistry and from Other Sources," *Acta Bot. Neerl.*, 19:61–72, 133–140 (1970), a review of recent phytochemical research on major groups of the flowering plants, and reports of different phyletic interpretations of the results; F.C. RICHARDSON, "Morphological Studies of the Nymphaeaceae: IV. Structure and Development of the Flower of *Brasenia schreberi* Gmel.," *Univ. Calif. Publ. Bot.*, 47:1–101 (1969), a research paper on the vegetative, floral, and developmental anatomy of the genus *Brasenia*; and J.P. SIMON, "Comparative Serology of the Order Nymphaeales. II. Relationships of Nymphaeaceae and Nelumbonaceae," *Aliso*, 7:325–350 (1971), a serological study of relationships among all genera of the order Nymphaeales.

Ranunculales. L.W.A. AHRENDT, "A Taxonomic Revision of *Berberis* and *Mahonia*," *J. Linn. Soc. Botany*, 57:1–410 (1961), the most complete account of these two woody genera; L. DIELS, "Menispermaceae," in A. ENGLER (ed.), *Das Pflanzenreich IV*, 46 (1910), the classical treatment of this family; A.S. FOSTER, "Floral Morphology and Relationships of *Kingdonia*," *J. Arnold Arbor.*, 42:397–410 (1961), and "Floral Morphology of *Circeaster*," *ibid.*, 44:299–321 (1963), detailed studies on two of the smaller groups within the Ranunculales; and W.C. GREGORY, "Phylogenetic and Cytological Studies in the Ranunculaceae," *Trans. Am. Phil. Soc.*, n.s., 31:443–521 (1941), a classical account of the cytology, taxonomy, and evolution of the family.

Papaverales. W.R. ERNST, "The Genera of Papaveraceae and Fumariaceae in the Southeastern United States," *J. Arnold Arbor.*, 43:315–343 (1962), although ostensibly limited geographically, this paper offers an important review of the taxonomy of the Papaverales as a whole; a broad bibliographical coverage is included. J. HUTCHINSON, "The Genera of Fumariaceae and Their Distribution," *Kew Bull.*, 1921:97–115 (1921), is an abbreviated taxonomic treatment of the family with keys to genera and species and includes geographical information. M.A. RYBERG, "A Morphological Study of the *Fumariaceae* and the Taxonomic Significance of the Characters Examined," *Acta Horti Bergiani*, 19:122–248 (1960), includes a general discussion of the geography of the family and a critique of the taxonomy on a worldwide basis.

Sarraceniales. FRANCIS ERNEST LLOYD, *The Carnivorous Plants* (1942), the definitive treatment of all groups of carnivorous plants on a worldwide basis; CLYDE RITCHIE BELL, "A Cytotaxonomic Study of the Sarraceniaceae of North America," *J. Elisha Mitchell Scient. Soc.*, 65:137–166 (1949), the authoritative cytological study and an exhaustive taxonomic and evolutionary study of the family; "Natural Hybrids in the Genus *Sarracenia*," *ibid.*, 68:55–80 (1952), the only comprehensive scientific study of natural hybridization in the genus; CARROLL E. WOOD, JR., "The Genera of Sarraceniaceae and Droseraceae in the Southeastern United States," *J. Arnold Arbor.*, 41:152–163 (1960), an excellent synoptical review of the salient features of the family Sarraceniaceae; WILLIAM R. WEST, "Carnivorous Plants," pt. 1, 4, *Carolina Tips*, 28:31–32, 29:1–2 (1965–66), brief general articles on pitcher plants and the culturing of carnivorous plants; GAYTHER L. PLUMMER, "Foliar Absorption in Carnivorous Plants," pt. 1–2, *Carolina Tips*, 29:25–26, 29–30 (1966), a readable general account of the digestive mechanism of *Sarracenia*; STANWYN G. SHELTER and FLORENCE MONTGOMERY, "Insectivorous Plants," *Smithson. Inf. Leaflet*, no. 447 (1965), a brief popular account of the major groups of carnivorous plants in the world; MARY VAUX WALCOTT, *Illustrations of North American Pitcherplants*, with "Descriptions and Notes on Distribution," by EDGAR T. WHERRY, and "Notes on Insect Associates," by FRANK MORTON JONES (1935), watercolour illustrations of all North American species, and popular descriptions, constituting the best source of information on insect associates; and SOPHIA PRIOR, "Carnivorous Plants and 'The Man-Eating Tree,'" *Chicago Nat. Hist.*

Mus. Bot. Leaflet, no. 23 (1939), a brief account of popular lore on carnivorous plants.

Hamamelidales. A.L. BOGLE, "Floral Morphology and Vascular Anatomy of the Hamamelidaceae: The Apetalous Genera of Hamamelidoideae," *J. Arnold Arbor.*, 51:310–366 (1970), a description of the floral structure, especially of the vascular anatomy of eight genera; P.K. ENDRESS, "Systematische Studie über die verwandtschaftlichen Beziehungen zwischen den Hamamelidaceen und Betulaceen," *Bot. Jb.*, 87:431–525 (1967), on the morphology, anatomy, and ontogeny of certain members of the family Hamamelidaceae, especially of the inflorescences and flowers of *Corylopsis* (discussion of the phylogenetic role of the Hamamelidaceae included); "Die Infloreszenzen der apetalen Hamamelidaceen, ihre grundsätzliche morphologische und systematische Bedeutung," *Bot. Jb.*, 90:1–54 (1970), a description of the inflorescence structure and taxonomic revision of 10 genera; W.R. ERNST, "The Genera of Hamamelidaceae and Platanaceae in the Southeastern United States," *J. Arnold Arbor.*, 44:193–210 (1963), a taxonomic survey of *Hamamelis*, *Fothergilla*, and *Platanus*; E.H. FULLING, "American Witch Hazel: History, Nomenclature and Modern Utilization," *Econ. Bot.*, 7:359–381 (1953), an historical survey of the utilization of *Hamamelis* in America; H. HARMS, "Hamamelidaceae," in A. ENGLER and K. PRANTL, *Die natürlichen Pflanzenfamilien*, 2nd ed., 18a:303–345, 487 (1930), a detailed taxonomic treatment of the whole family Hamamelidaceae; IRMGARD JAGER-ZURN, "Infloreszenz- und blütenmorphologische, sowie embryologische Untersuchungen an *Myrothamnus Welw.*," *Beitr. Biol. Pfl.*, 42:241–271 (1966), an investigation of the family Myrothamnaceae; and H.F. KAMMEYER, "Die schönen Zaubernüsse (Hamamelisgewächse)," *Neue Brehm Büch.* 194 (1957), a popular survey of the ornamental genera of Hamamelidaceae.

Urticales. E.J.H. CORNER, "The Classification of Moraceae," *Gdn. Bull., Singapore*, 19:187–252 (1962), and "An Introduction to the Distribution of *Ficus*," *Reinwardtia*, 4:325–355 (1958), important papers for the advanced botanist on the classification and distribution of the mulberry family, in which the fig genus is estimated to contain about 900 species, a downward revision from earlier estimates that ranged as high as 2,000; B.M. JOHRI and R.N. KONAR, "The Floral Morphology and Embryology of *Ficus religiosa* Linn.," *Phytomorphology*, 6:97–111 (1956), a treatment of the floral structure and development of one of the fig species; H.Y.M. RAM and R. NATH, "The Morphology and Embryology of *Cannabis sativa* Linn.," *ibid.*, 14:414–429 (1964), a detailed account of the form, structure, and development of the hemp plant; A.B. RENDLE, "Urticiflorae" in *The Classification of Flowering Plants*, vol. 2, pp. 41–58 (1925, reprinted 1967), an excellent descriptive account for readers with some background in botany of the elm, mulberry, hemp, and nettle families; T. DOBZHANSKY and J. MURCA-PIRES, "Strangler Trees," *Scient. Am.*, 190:78–80 (1954), a short article for the layperson that describes strangler figs and suggests how they might have evolved; H.C.D. DE WITT, "Urticales," in *De wereld der Planten*, vol. 1 (1963; Eng. trans., *Plants of the World*, vol. 1, 1966), a descriptive account for the layperson of many interesting plants in the nettle order; and N.A. SATA, "A Monographic Study of the Genus *Ficus* from the Point of View of Economic Botany," *Taihoku Univ.*, vol. 32, pt. 1–2, pp. 1–104, and pt. 3–4, pp. 1–289 (1944), an extended and detailed account of the many uses to which members of the fig genus have been put.

Fagales. AIMEE CAMUS, "Les Châtaigniers," *Encyclopédie économique de sylviculture*, vol. 3 (1929), a monograph of the genera *Castanea* and *Castanopsis* with illustrations of all species; "Les Chênes," *ibid.*, vol. 6–8 (1934–54), monographs of *Quercus*, *Cyclobalanopsis*, and *Lithocarpus*, with illustrations of all species; and H. HJELMQVIST, "Studies on the Floral Morphology and Phylogeny of the Amentiferae," *Bot. Notiser*, suppl. vol. 2, no. 1, (1948), on floral morphology, relationships, and subdivision of the Fagales order.

Betulales. The literature on the order Betulales is rather limited, but that on the "Amentiferae," of which the order has long been considered to be a part, is tremendous. In addition to the following works, and others like them, there are many popular guides to trees and shrubs that are helpful in identifying and learning about local species.

HUBERT WINKLER, "Betulaceae," in A. ENGLER, *Das Pflanzenreich IV*, 61 (1904), the most comprehensive treatment of the taxonomy of the Betulales; A. REHDER, *Manual of Cultivated Trees and Shrubs Hardy in North America, Exclusive of the Subtropical and Warmer Temperate Regions*, 2nd ed. rev. (1962), a treatment of those world species hardy in North America; C.S. SARGENT, *Silva of North America*, vol. 9 (1896), a sumptuous treatment of those species native to North America; H.A. FOWELLS, *Silvics of Forest Trees of the United States*, *United States Department of Agriculture Handbook* 271 (1965); J.M. TRAPPE *et al.* (eds.), *Biology of Alder* (1968); *Woody-Plant Seed*

Manual, Misc. Publ. U.S. Dep. Agric. 654 (1948), the last three titles being a few among many specialized and rather local publications that treat the ecological aspects of the Betulaceae; E.C. ABBE, "Studies in the Phylogeny of the Betulaceae," *Bot. Gaz.*, 2 pt., 97:1-67 (1935) and 99:431-469 (1938), a detailed and technical article about floral morphology; J.W. HALL, "The Comparative Anatomy and Phylogeny of the Betulaceae," *ibid.*, 113:235-270 (1952), a technical article about secondary xylem; E. ANDERSON and E.C. ABBE, "A Quantitative Comparison of Specific and Generic Differences in the Betulaceae," *J. Arnold Arbor.*, 15:43-49 (1934), a pioneer article on numerical taxonomy; H. HJELMQVIST, "Studies on the Floral Morphology and Phylogeny of the Amentiferae," *Bot. Notiser*, suppl. 2:122-146 (1948), a different point of view about floral morphology in the group; L.A. KUPRIANOVA, "On a Hitherto Undescribed Family Belonging to the Amentiferae," *Taxon*, 12:12-13 (1963), a paper treating the significance of pollen grains within the Betulaceae; C.R. METCALFE and L. CHALK, *Anatomy of the Dicotyledons*, vol. 2, pp. 1302-1309 (1950), a book about the internal structure of many groups of flowering plants, the pages indicated treating the anatomy of the wood and leaves of representative Betulales; J.C.T. UPHOF, *Dictionary of Economic Plants*, 2nd ed. rev. (1968), a presentation of general economic uses of selected members of the order, as well as of other plants; C. PICKERING, *Chronological History of Plants* (1879), a classic book answering the interesting question of when various members of the Betulales were first mentioned in man's history; and D.C. PEATTIE, *A Natural History of Trees of Eastern and Central North America* (1950), a popular but accurate presentation of information on the tree birches and their relatives.

Juglandales. E.W. BERRY, *Tree Ancestors* (1923), a semipopular book giving the modern and fossil distribution of trees, showing maps of these distributions and notes on fossil history and economic uses; C. HEIMSCH, JR., and R.H. WETMORE, "The Significance of Wood Anatomy in the Taxonomy of the Juglandaceae," *Am. J. Bot.*, 26:651-660 (1939), a technical study of wood structure in the walnut family, pointing out correlation between wood anatomy and morphology of inflorescences in distinguishing primitive from advanced members of the family; H. HJELMQVIST, "Studies on the Floral Morphology and Phylogeny of the Amentiferae," *Bot. Notiser*, suppl. 2:1-171 (1948), a detailed study of flower and inflorescence structure of all Amentiferae, including the Juglandaceae family, with a discussion of relationships between the genera and between the families of that group; J.F. LEROY, "Étude sur les Juglandaceae," *Mém. Mus. Natn. Hist. Nat., Paris (Botanique)*, n.s., ser. B, 6:1-246 (1955), a detailed and thorough study in French of all genera of the Juglandaceae with emphasis on floral anatomy but also treating relationships, fossils, origin of flowers, and taxonomy; W.E. MANNING, "The Morphology of the Flowers of the Juglandaceae," pt. 1, "The Inflorescence," *Am. J. Bot.*, 25:407-419 (1938), technical descriptions of all inflorescences of the six genera recognized by this author and most of the species in them found throughout the world; W.E. MANNING, "The Classifications Within the Juglandaceae," *Annals of Missouri Bot. Garden*, 65:1058-1087 (1979); D.C. PEATTIE, *A Natural History of the Trees of Eastern and Central North America*, 2nd ed. (1966), a popular description of native walnut and hickory trees, and other trees, of the United States with notes on economic importance, interesting facts, and historical incidents; A. REHDER, *Manual of Cultivated Trees and Shrubs Hardy in North America*, 2nd rev. ed. (1940), a basic book with technical descriptions of the Juglandaceae family and other families with keys for separation of all temperate genera, Asiatic as well as North American (including for each a technical description of the genus and most of its species); C.S. SARGENT, *Manual of the Trees of North America (Exclusive of Mexico)* (1933), a basic work containing a technical description of the walnut family, along with all other tree families of the region, with keys for separation of the two genera and all species native to the United States (including descriptions, exact ranges, and a small illustration of each species); D.R. WHITEHEAD, "Pollen Morphology in the Juglandaceae," pt. 2, "Survey of the Family," *J. Arnold Arbor.*, 46:369-410 (1965), a technical study and description of pollen grains of all genera and most species of the Juglandaceae family with a chart of evolution of pollen grains in family; and C.L. WITHNER, "Stem Anatomy and Phylogeny of the Rhoipteleaceae," *Am. J. Bot.*, 28:872-878 (1941), a technical study of the wood structure of the genus *Rhoiptelea* with a comparison to that of the Juglandaceae family and Urticales order.

Caryophyllales. P.C. STANDLEY, "Chenopodiaceae," *N. Am. Flora*, 21:1-93 (1916); A.C. JOSHI, "Contribution to the Anatomy of the Chenopodiaceae and Amaranthaceae," *J. Indian Bot. Soc.*, 10:213-265 (1931); F. PAX and K. HOFFMAN, "Aizoaceae," in A. ENGLER and K. PRANTL, *Die natürlichen Pflanzenfamilien*, 16c:179-233 (1934); P.A. RYDBERG, "Portulacaceae," *N. Am. Flora*, 21:279-336 (1932); and B. MAGUIRE, "Studies in the Caryophyllaceae," *Bull. Torrey Bot. Club*, 73:326 (1946).

Cactales. For a conservative treatment of the genera, see F. VAUPEL, *Cactaceae*, in A. ENGLER and K. PRANTL, *Die natürlichen Pflanzenfamilien*, 2nd ed., vol. 21, pp. 594-651 (1925). For a more radical but general consideration of the entire family, see N.L. BRITTON and J.N. ROSE, *The Cactaceae*, 4 vol. (1919-23, 1937; reprinted in 2 vol., 1963); a supplement to Britton and Rose's work, W.T. MARSHALL and T.M. BOCK, *Cactaceae* (1941); FRANZ BUXBAUM, *Morphology of Cacti*, 3 vol. (1950-55); and VERA HIGGINS, *The Study of Cacti*, 2nd ed. (1946). For a discussion of species native in the United States, see LYMAN BENSON, *The Cacti of Arizona*, 3rd ed. (1969); *The Native Cacti of California* (1969); and "Cactaceae," in C.L. LUNDELL, *Flora of Texas*, vol. 2 (1969).

The following works are of value for horticultural aspects: CURT BACKEBERG, *Die Cactaceae*, 6 vol. (1958-62), with good photographs of many species; J. BORG, *Cacti*, 4th ed. (1970); and W. HAAGE, *Das praktische Kakteenbuch in Farben* (1961; rev. Eng. trans., *Cacti and Succulents: A Practical Handbook*, 1963).

Theales. H.K. AIRY SHAW, "On the Dioncophyllaceae, a Remarkable New Family of Flowering Plants," *Kew Bull.*, pp. 327-347 (1951), a detailed, well-illustrated study of this remarkable family, followed by anatomical notes by C.R. METCALFE (on pp. 351-368); P.S. ASHTON, *A Manual of the Dipterocarp Trees of Brunei State* (1964), a comprehensive manual for identification; F.W. FOXWORTHY, "Dipterocarpaceae of the Malay Peninsula," *Malay. Forest Rec.*, no. 10 (1932), a manual for identification; H. GOTTFELD and N. PARARESWARAN, "Beiträge zur Anatomie und Systematik der Quiinaceae," *Bot. Jb.*, 87:361-381 (1967), a detailed study of the family; C.E. KOBUSKI, many papers, under the general title "Studies in the Theaceae," mostly in the *J. Arnold Arbor.* but also in *Ann. Mo. Bot. Gdn.*, *Bot. Mag., Tokyo*, *Brittonia*, and *Kew Bull.* (1935-61), containing very full taxonomic treatments of many genera of Theaceae and allied groups; N.K.B. ROBSON, "The Genus *Hypericum* in Africa South of the Sahara, Madagascar and the Mascarenes," *Kew Bull.*, pp. 433-446 (1957), a taxonomic study by the foremost authority on the group; R. SCHMID, "Die systematische Stellung der Dioncophyllaceae," *Bot. Jb.*, 83:1-56 (1964), which supplements, in detail, Airy Shaw's work on the same family; J.R. SEALY, *A Revision of the Genus Camellia* (1958), a well-illustrated taxonomic revision of this horticulturally important genus; B.G.L. SWAMY, "A Contribution to the Embryology of the Marcgraviaceae," *Am. J. Bot.*, 35:628-633 (1948), an embryological work, with notes on pollination; and C.F. SYMINGTON, "Forester's Manual of Dipterocarps," *Malay. Forest Rec.*, no. 16 (1941), a manual of identification from the forester's viewpoint.

Violales. A.M. JOHNSON, *Taxonomy of the Flowering Plants* (1931), a work for both the professional and amateur botanist, giving both technical and nontechnical information about the plant families; D. KLABER, *Violets of the United States* (1971), a comprehensive work on the largest family of the Violales order, written for the nonprofessional and beautifully illustrated; and N.H. RUSSELL, "Violets (*Viola*) of Central and Eastern United States: An Introductory Survey," *Sida*, vol. 2, no. 1 (1965), a technical monograph giving taxonomic and evolutionary information about American violets.

Begoniaceae. B.R. BUXTON, *Begonias and How to Grow Them* (1946), containing drawings and photographs; A. DE CANDOLLE, "Mémoire sur la famille des Bégoniacées," *Annls. Sci. Nat. (a) Botanique*, 4th series, 11:93-149 (1859), a classic monographic treatment, in French, still of much interest; C. CHEVALIER, *Les Bégonias* (1938), a classic work in French on cultivated begonias; CHRISTOPHER DAVIDSON, "An Anatomical and Morphological Study of Datisceae," *Aliso*, 8:49-110 (1973), the only complete modern treatment, somewhat technical but with good discussion and illustrations; E. GILG, "Datisceae," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien*, 2nd ed., 21:543-547 (1925), the only general and inclusive treatment of this small family, in German; E. IRMSCHER, "Begoniaceae," *ibid.*, pp. 548-588, the most comprehensive review available—treats the family as a whole, the genera and sections, and names some species in each section but does not give species descriptions; and "Fam. Begoniaceae, Schiefblattgewächse," in *Parey's Blumengärtnerei*, 2nd ed., 2:67-98 (1960), a German work of extreme usefulness for horticulturists and amateurs—deals with species in cultivation as well as hybrids and cultivars on the basis of botanical characters and includes a key to sections and a synoptic key to species considered; HELEN K. KRAUSS, *Begonias for American Homes and Gardens* (1947), containing line drawings and photographs; R.A.H. LEGRO and J. DOORENBOS, "Chromosome Numbers in Begonia," *Neth. J. Agric. Sci.*, 17:189-202 (1969), a well-documented chromosome study for *Begonia*; and R. WILCZEK, "Begoniaceae," in *Flore du Congo, du Rwanda et du Burundi* (1969), a modern floristic treatment in French for tropical Africa.

Capparales. L. BENSON and R.A. DARROW, *The Trees and Shrubs of the Southwestern Deserts*, 2nd ed. (1954), a treatment

of the general features of plants in relation to dry habitats of Arizona, Mexico, Chile, and Argentina; N.C. FASSETT, *A Manual of Aquatic Plants* (1940), a detailed account of water plants; J.B. HARBORNE and T. SWAIN (eds.), *Perspectives in Phytochemistry* (1969), a study of chemotaxonomy and of the biosynthesis of various plant constituents; H.T. HARTMANN and D.E. KESTER, *Plant Propagation: Principles and Practices*, 2nd ed. (1968), containing exhaustive information on seed storage and propagation of selected annuals and herbaceous perennials used as ornamentals; P. MAHESHWARI and U. SINGH, *Dictionary of Economic Plants in India* (1965), which gives extensive information on Indian economic plants, including an alphabetical list of plants; W.C.L. MUENSCHER, *Poisonous Plants of the United States*, rev. ed. (1951), a good account of annual weeds of the United States and Canada and the symptoms of diseases caused by them; O. POLUNIN and A. HUXLEY, *Flowers of the Mediterranean* (1965), containing descriptions of more than 700 species with illustrations and uses covering the entire Mediterranean region; H.N. RIDLEY, *The Dispersal of Plants Throughout the World* (1930), an excellent and voluminous account of various methods of dispersal in an order; and E.J. SALISBURY, *The Reproductive Capacity of Plants* (1942), which gives information on the establishment and growth of plants with reference to their habitats, sexual versus vegetative propagation, and vegetative multiplication in relation to competition, and *Downs and Dunes: Their Plant Life and Its Environment* (1952), a good account of plants and their adaptation to the environment present on dunes and seashores.

Ericales. G.C. AINSWORTH and A.S. SUSSMAN (eds.), *The Fungi: An Advanced Treatise*, 3 vol. (1965–68), a discussion of mycorrhizal relationships; ERIK BJORKMAN, "Monotropa Hypopitys L.—an Epiparasite on Tree Roots," *Physiologia Pl.*, 13:308–327 (1960), an original description of the mycorrhizal role in parasitism of *Monotropa* on roots of other plants; C.G. BOWERS, *Rhododendrons and Azaleas: Their Origins, Cultivation and Development*, 2nd ed. (1960), a comprehensive treatment of native and cultivated rhododendrons and azaleas of the world; C.J. HYLANDER, *The MacMillan Wild Flower Book* (1954), which includes excellent illustrations and descriptions of some of the more beautiful ericads; *North American Flora*, series 1, vol. 29, pt. 1 (1914), containing extensive descriptions of ericad families of North America; ALFRED REHDER, *Manual of Cultivated Trees and Shrubs Hardy in North America*, 2nd ed. rev. (1940), a classic taxonomic treatment of woody ericads under cultivation; and R.W. SCHERY, *Plants for Man* (1952), an interesting discussion of economic aspects of ericalean and other plants.

Ebenales. A. AUBREVILLE, *Sapotacées* (1964), one of the most important monographic studies of recent years; C. BAENNI, *Mémoires sur les sapotacées*, 3 vol. (1938–65); "Sapotacées du Surinam et de la Guyane anglaise," *Candollea*, 14:61–77 (1952); and "Pouteriae novae," *Candollea*, 18:161–176 (1962–63), a series of publications of great interest by one of the most active specialists of his time; R. LETOUZEY and F. WHITE, *Ebenacées*, vol. 11 of A. AUBREVILLE and J.F. LEROY, *Flore du Cameroun* (1970), a taxonomic treatment of the African (Camerounian) species of the family Ebenaceae; E. PERROT, *Matières premières usuelles du règne végétal*, vol. 2, pp. 1707–1737 (1944), a good reference work on plant products, being particularly devoted to products of the Ebenales; W. POPENOE, *Manual of Tropical and Subtropical Fruits* (1927), including much useful data on the fruit of the Ebenales; L. EMBERGER, *Traité de botanique (systématique)*, vol. 2, pp. 849–859 (1960), a recognized treatise on modern systematic botany containing information on the Ebenales; F. WHITE, "Notes on the Ebenaceae," *Bull. Jard. Bot. État Brux.*, 26:237–246 and 277–307 (1956), 27:515–531 (1957), and 33:345–367 (1963); and *Bolm. Soc. Broteriana*, series 2, 36:97–100 (1962), taxonomic treatments of African species of the family Ebenaceae; and C.E. WOOD, JR., and R.B. CHANNELL, "The Genera of the Ebenales in the Southeastern United States," *J. Arnold Arbor.*, 40:1–35 (1960), an excellent reference work with a particularly rich bibliography.

Primulales. WALTER C. BLASDALE, *Cultivated Species of Primula* (1948), a richly illustrated book that gives the history of the genus, descriptions and ranges of the species, and information on horticultural methods; ROY GENDERS, *Primroses* (1959), a short, popular, illustrated account on the propagation of these plants, together with instructions for hybridizing and displaying; DORETTA KLABER, *Primroses and Spring* (1966), a brief, illustrated, popularly written book with information on how to grow primroses; R.B. CHANNELL and C.E. WOOD, JR., "The Genera of the Primulales of the Southeastern United States," *J. Arnold Arbor.*, 40:268–288 (1959), a semitechnical treatment, with keys, descriptions, and illustrations of the 10 genera of the primrose order found in the southwestern United States; CYRUS R. LUNDELL, *The Genus Parathesis of the Myrsinaceae* (1966), a fully illustrated technical taxonomic treatment of this tropical American genus of more than 70 species; SIR W.

WRIGHT SMITH and H.R. FLETCHER, "The Genus *Primula*: Section *Nivales*," *Trans. R. Soc. Edinb.*, 60:563–627 (1942); "Section *Farinosae*," 61:1–69 (1943); "Section *Petiolares*," 61:271–314 (1944); "Sections *Obconica*, *Sinenses*, *Reinii*, *Pinnatae*, *Malacoides*, *Bullatae*, *Carolinella*, *Grandis*, and *Denticulata*," 61:415–478 (1946); "Sections *Cuneifolia*, *Floribundae*, *Parryi*, and *Auricula*," 61:631–686 (1948), a definitive, highly technical taxonomic treatment of the species of primrose; E.H. WALKER, "A Revision of the Eastern Asiatic Myrsinaceae," *Philipp. J. Sci.*, 73:1–258 (1940), a technical taxonomic treatment of the six genera and more than a hundred species of the family occurring in the area; and JAMES DAVIS RAY, *The Genus Lysimachia in the New World* (1956), a technical taxonomic treatment with distribution maps and illustrations.

Malvales. G.K. BRIZICKY, "The Genera of Tiliaceae and Elaeocarpaceae in the Southeastern United States," *J. Arnold Arbor.*, 46:286–307 (1965); and "The Genera of Sterculiaceae in the Southeastern United States," *J. Arnold Arbor.*, 47:60–74 (1966), two review articles; and J.B. HUTCHINSON, R.A. SILOW, and S.G. STEPHENS, *The Evolution of Gossypium and the Differentiation of the Cultivated Cottons* (1947), a classic review of the botany of cottons.

Euphorbiales. F. PAX, "Euphorbiaceae," in A. ENGLER, *Das Pflanzenreich*, vol. 42, 44, 47, 52, 57, and 63 (1910–14), a long series of papers, some exceeding 300 pages in length, making an authoritative monographic treatment of the genera of the order; and F. PAX and K. HOFFMAN, *ibid.*, vol. 68 and 85 (1919–24), which continues the monographic treatment of Euphorbiales genera.

Saxifragales. L.H. BAILEY, *The Standard Cyclopedia of Horticulture*, 6 vol. (1914–17), a well-illustrated, semitechnical dictionary of ornamental and edible plants with descriptions and cultural notes; ALWIN BERGER, "A Taxonomic Review of Currants and Gooseberries," *Tech. Bull. N.Y. St. Agric. Exp. Stn.*, no. 109 (1924), a technical publication on the edible fruit-producing species and varieties of the genus *Ribes* with special reference to those grown in the United States; W.H. BROWN, *Useful Plants of the Philippines*, 3 vol. (1951–58), a profusely illustrated semitechnical series on the edible and the drug-, textile-, timber-, and oil-producing plants of the Philippines and adjacent regions of southeastern Asia; I.H. BURKILL, *A Dictionary of the Economic Products of the Malay Peninsula*, 2 vol. (1935), a semitechnical publication concerning all kinds of useful plants of the southeastern Asia area, the most complete and reputable source for the area; F.J. CHITTENDEN (ed.), *Dictionary of Gardening*, 2nd ed. by PATRICK M. SYNGE, 4 vol. (1956 and suppl. 1969), an outstanding illustrated, semitechnical compilation of ornamental and edible plants with cultural instructions and plant descriptions; U.P. HEDRICK (ed.), *Sturtevant's Notes on Edible Plants* (1919), a semitechnical dictionary of wild and cultivated edible plants of worldwide application, old but still useful; F.E. LLOYD, *The Carnivorous Plants* (1942), technical and well-illustrated but very difficult to read, which considers all kinds of insectivorous plants on a worldwide basis—the only compendium of its kind; S.J. RECORD and R.W. HESS, *Timbers of the New World* (1943), a technical to semitechnical book on woody plants of the Western Hemisphere, poorly illustrated but with excellent technical descriptions of the gross structure and microscopic structure of timber and with lists of vernacular names, uses, properties of wood, working qualities of timbers, sources of supply, and minor forest products—the only book of its kind for the area covered; NORMAN TAYLOR (ed.), *Taylor's Encyclopedia of Gardening, Horticulture, and Landscape Design*, 4th ed. rev. (1961), a semitechnical, highly useful book covering cultural and descriptive aspects of home gardening (well illustrated); and J.C.T. UPHOF, *Dictionary of Economic Plants*, 2nd ed. rev. (1968), a nontechnical list with short descriptions of useful plants, worldwide coverage.

Rosales. L.H. BAILEY, *The Standard Cyclopedia of Horticulture*, 3 vol. (1947), a layperson's guide to cultivated plants, identity, and culture, now somewhat out-of-date but still useful; J.J. and F.C. CRAIGHEAD, JR., and R.J. DAVIS, *A Field Guide to Rocky Mountain Wildflowers from Northern Arizona and New Mexico to British Columbia* (1963), an introduction to the field study of wild plants in nontechnical language with excellent colour plates; M. GRIEVE (comp.), *A Modern Herbal*, 2 vol. (1931), a popular treatment of common plants with folk uses for medicine, food, etc.; A.F. HILL, *Economic Botany* (1952), a classic text for the study of plants of the world that are useful to man; H.W. RICKETT, *Wild Flowers of the United States* (1966—, with additional volumes added from time to time), a series of large volumes written in an easy-to-read, nontechnical style, profusely illustrated by colour plates and line drawings; and E.T. WHERRY, *Wild Flower Guide: Northeastern and Midland United States* (1948), a popular account in lay language for the identification and appreciation of wildflowers.

Fabales. E.G. HALLSWORTH (ed.), *Nutrition of the Legumes* (1958), a broad treatment of the soil factors affecting the growth

of legumes, including the rhizobial (bacteria in root nodules) component; P. TAUBERT, "Leguminosae," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien* (1894), a classical text for the order, with keys and descriptions (in German) to the generic level, copiously documented as to the earlier works on the group and references to these; L. CAPITAINE, *Étude analytique et phytogéographique du groupe des légumineuses* (1912), a treatment of the order in which an attempt is made to show the phytogeographic relationships among the 30 or more tribes; R.O. WHYTE, G. NILSSON-LEISSNER, and H.C. TRUMBLE, *Legumes in Agriculture* (1953), an excellent account of the agronomic value of legumes and their role in agriculture, with consideration of the regional value of both local and worldwide species in the order; and J.B. HARBORNE, D. BOULTER, and B.L. TURNER (eds.), *Chemotaxonomy of the Leguminosae* (1971), a broad treatment of the chemical components (alkaloids, flavonoids, terpenoids, amino acids, proteins, enzymes, etc.) found in the three families, especially as they relate to the systematic treatment of taxa constituting the order.

Nepenthales. CHARLES DARWIN, *Insectivorous Plants* (1875), the classic study of the carnivorous flowering plants, especially the family Droseraceae and particularly *Drosera rotundifolia*, the common sundew; FRANCIS ERNEST LLOYD, *The Carnivorous Plants* (1942), the definitive modern treatment of all groups of carnivorous plants on a worldwide basis; CARROLL E. WOOD, JR., "The Genera of Sarracenaceae and Droseraceae in the Southeastern United States," *J. Arnold Arbor.*, 41:152-163 (1960), an excellent review of the morphological and biological features of the family Droseraceae; FRANCES E. WYNNE, "*Drosera* in Eastern North America," *Bull. Torrey Bot. Club*, 71:166-174 (1944), the latest revision of North American species, with key, descriptions, maps, and illustrations; PATRICIA R. ROBERTS and H.J. OOSTING, "Responses of Venus Fly Trap (*Dionaea Muscipula*) to Factors Involved in Its Endemism," *Ecol. Monogr.*, 28:193-218 (1958), the most comprehensive study of the ecology of this species ever made; WILLIAM R. WEST, "Carnivorous Plants," pt. 2-4, *Carolina Tips*, 28:35-36, 39-40, 29:1-2 (1965-66), containing brief general accounts of *Dionaea* and *Drosera* and on the culturing of carnivorous plants; STANWYN G. SHETLER and FLORENCE MONTGOMERY, "Insectivorous Plants," *Inf. Leaflet. Smithsonian Instn.* 447 (1965), a brief, popular, well-illustrated survey of the major groups of carnivorous plants in the world; TERRY ASHLEY and JOSEPH F. GENNARO, JR., "Fly in the Sundew," *Nat. Hist.*, 80:80-85, 102 (1971), a readable account of modern experimentation with radioactive marking to study digestion; FRANK L. LAMBRECHT, "The Pitcher-Plant: Carnivorous Incubator and Tool of Natural Selection," *Jl. N.Y. Bot. Gdn.*, 21:100-105 (1971), a fascinating narrative of research on animals that exploit the pitchers of *Nepenthes pervillei* in Sri Lanka; and SOPHIA PRIOR, "Carnivorous Plants and 'The Man-Eating Tree,'" *Bot. Leaflet. Field Mus. Nat. Hist.* 23 (1939), a brief account of popular lore on carnivorous plants.

Myrtales. N. HALL, R.D. JOHNSTON, and G.M. CHIPPENDALE, *Forest Trees of Australia*, Australian Forestry and Timber Bureau, 3rd ed. (1968), a text containing good keys, descriptions, and photographs of 118 eucalypts and other myrtaceous trees; and A.R. PENFOLD and J.L. WILLIS, *The Eucalypts: Botany, Cultivation, Chemistry and Utilization* (1961), a very useful discussion of the economic products of eucalypts, containing a good summary of growth habits, floral morphology, and leaf types.

Rutales. C. DE CANDOLLE, "Meliaceae," in ALPHONSE DE CANDOLLE, *Monographiae phanerogamerum* . . . , vol. 1 (1878); and A. ENGLER, "Anacardiaceae," *ibid.*, vol. 4 (1883), monographic treatments of these two families; A. ENGLER, "Coriariaceae" and "Anacardiaceae," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien III*, 5 (1897), general and taxonomic accounts of these families; "Burseraceae, Simaroubaceae, and Rutaceae," *ibid.*, 2nd ed., vol. 19a (1931); and H. HARMS, "Meliaceae," *ibid.*, vol. 19b (1940), general accounts of these families.

Sapindales. G.K. BRIZICKY, "The Genera of Sapindales in the Southeastern United States," *J. Arnold Arbor.*, 44:462-501 (1963), a thorough discussion of the Sapindaceae, Aceraceae, and Hippocastanaceae of the southeastern United States, with good descriptions, drawings, and bibliographies; G. ERDTMAN, *Pollen Morphology and Plant Taxonomy: Angiosperms* (1952), descriptions, with numerous drawings, of the pollen grains of 327 angiosperm families, treated alphabetically; J.W. HARDIN, "A Revision of the American Hippocastanaceae," *Brittonia*, 9:145-171, 173-195 (1957), an authoritative treatment of *Billia* and the American species of *Aesculus*, with discussion of morphology and anatomy, inter- and intra-familial relationships, and evolution in the family, as well as taxonomic revision of the American species; F.R. IRVINE, *Woody Plants of Ghana, with Special Reference to Their Uses* (1961), many sapindaceous trees and *Bersama* described and illustrated and their economic and folk uses discussed; L. VAN DER PIJL, "On the Arilloids of

Nephelium, *Euphoria*, *Litchi* and *Aesculus*, and the Seeds of Sapindaceae in General," *Acta Bot. Neerl.*, 6:618-641 (1957), an important discussion of evolution in the seeds and fruits of Sapindaceae and *Aesculus* as related to their dispersal; and S.J. RECORD and R.W. HESS, *Timbers of the New World* (1943), which gives descriptions and discussions of distributions, uses, and xylem characteristics of the larger American woody plants.

Geraniales. J. HUTCHINSON, "Malpighiales," in *The Genera of Flowering Plants*, vol. 2, pp. 568-621 (1967); E.F. WARBURG, "Taxonomy and Relationship in the Geraniales in the Light of Their Cytology," *New Phytol.*, 37:130-159, 189-210 (1938), an interesting and useful paper dealing with the families Linaceae, Zygophyllaceae, Geraniaceae, Limnanthaceae, Oxalidaceae, Tropaeolaceae, and Balsaminaceae; O. WARBURG and K. REICHE, "Balsaminaceae," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien*, 3:383-392 (1897), a brief conspectus—more recent literature is extensive but scattered; O.E. SCHULZ, "Erythroxylaceae," in A. ENGLER (ed.), *Das Pflanzenreich IV*, 134:1-176 (1907), a very competent monograph, still the only general account of the family; R. KNUTH, "Geraniaceae," and "Oxalidaceae," *ibid.*, vol. 129-130 (1912, 1930), not of outstanding taxonomic merit but the only general treatments of these families available; J. CUATRECASAS, "A Taxonomic Revision of the Humiriaceae," *Contr. U.S. Natn. Herb.*, 35:25-214 (1961), a very fine revision including an account of the relationships and evolution of the family, with an invaluable bibliography; H. WINKLER, "Linaceae," in *Die natürlichen Pflanzenfamilien*, 2nd ed., 19a:82-130 (1931), a rather dated but still useful account, including in subordinate rank the Houmiriaceae, Ixonanthaceae, and Hugoniaceae; J. LEONARD, "*Lepidobotrys* Engl., type d'une famille nouvelle de Spermatophytes: les Lepidobotryaceae," *Bull. Jard. Bot. État. Brux.*, 20:31-40 (1950), which makes the case for the separation of this genus into a new family; C.T. MASON, "A Systematic Study of the Genus *Limnanthes* R. Br.," *Univ. Calif. Publ. Bot.*, 25:455-506 (1952), a sound taxonomic revision of the genus, containing most of the Limnanthaceae, with information on cytology and experimental genetics; F. NIEDENZU, "Malpighiaceae," in *Pflanzenreich IV*, 141:1-870 (1928), of average taxonomic merit, marred by the fact that little or no use was made of the great British or American herbaria in its preparation but still quite invaluable; F. BUCHENAU, "Tropaeolaceae," *ibid.*, 131:1-36 (1902), competent but of limited value since the number of species recognized has now almost doubled; and A. ENGLER, "Zygophyllaceae," *ibid.*, 2nd ed., 19a:144-184 (1931), a brief conspectus of the family.

Cornales. J. HUTCHINSON, "Araliales," in *The Genera of Flowering Plants*, vol. 2, pp. 41-89 (1967), which includes descriptions of the genera in the families Cornaceae (under which Mastixiaceae and Toricelliaceae are also treated), Alangiaceae, Garryaceae, Nyssaceae (including Davidiaceae), and Ariliaceae (including Helwingiaceae); S. BLOEMBERGEN, "A Revision of the Genus *Alangium*," *Bull. Jard. Bot. Buitenz.*, series 3, 16:139-235 (1939), a good revision of the larger of the two genera in the family Alangiaceae, comprising all but three of the species in the family; H. HARMS, "Araliaceae," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien*, 3:1-62 (1898), a good general view of the family, although out-of-date; R. VIGUIER, "Recherches anatomiques sur la classification des Araliacées," *Annls. Sci. Nat.*, series 9, 4:1-207 (1906); and "Nouvelles recherches sur les Araliacées," *ibid.*, 9:305-405 (1909), two contributions forming a fairly extensive and detailed treatment of the anatomy of the family as it bears on taxonomy; W. WANGERIN, "Cornaceae," "Garryaceae," and "Nyssaceae," in A. ENGLER, *Das Pflanzenreich IV*, 229:1-110, 56a:1-17, and 220a:1-19 (1910), dated but still good treatments of these families; H. LI, "Davidia As the Type of a New Family Davidiaceae," *Lloydia*, 17:329-331 (1954), which gives the case for treating *Davidia* as a separate family; A.S. HORNE, "The Structure and Affinities of *Davidia involucreata*, Baill.," *Trans. Linn. Soc. Lond.*, 2nd series, 7:303-326 (1909), a classic study on the internal and external morphology of this remarkable plant; F.A. HALLOCK, "The Relationship of Garrya," *Ann. Bot.*, 44:771-812 (1930), a thorough and detailed study of *Garrya*, supporting Engler's position for the Garryaceae; R.H. EYDE, "Morphological and Paleobotanical Studies of the Nyssaceae, I. A Survey of the Modern Species and Their Fruits," *J. Arnold Arb.*, 44:1-59 (1963); and with E.S. BARGHOORN, "... of the Nyssaceae, II. The Fossil Record," *ibid.*, pp. 328-376 (1963), important studies involving *Mastixia* and *Davidia* as well as the family Nyssaceae in the strict sense; O. DRUDE, "Umbelliferae," in *Die natürlichen Pflanzenfamilien*, 3:63-250 (1898), an excellent review of the family, not yet superseded; and H. WOLFF, "Umbelliferae (Saniculoideae, Apioideae, Ammineae)," in *Pflanzenreich IV*, vol. 228, pt. 43, 61, and 90 (1910-27), the standard work on these tribes, thorough and reliable.

Celastrales. H. HAROLD HUME, *Hollies* (1953), a well-written, authoritative, and interesting book giving considerable back-

ground information on hollies in general, as well as detailed information about particular species and varieties; *American Horticultural Magazine* (Fall 1970), a special issue devoted entirely to hollies, with well-written and extremely interesting articles on almost every aspect of the genus, from folklore and legends to holly propagation and varieties of hollies now commercially available; E. BERKELEY, "Morphological Studies in the Celastraceae," *J. Elisha Mitchell Scient. Soc.*, 69:185-208 (1953), a detailed anatomical floral study investigating the relationships of several genera within the family, fairly difficult for the nonbotanist; R.A. HOWARD, "Studies of the Icacinaceae, I. Preliminary Taxonomic Notes," *J. Arnold Arbor.*, 21:461-489 (1940), a discussion of the historical taxonomic problems in the family Icacinaceae, and an interesting preliminary report on the nature of the research to be done to resolve these problems; and I.W. BAILEY and R.A. HOWARD, "The Comparative Morphology of the Icacinaceae," 4 pt., *ibid.*, 22:125-568 (1941), an excellent, thorough study of several morphological structures, clarifying trends of specialization and relationships of genera within the family but requiring a botanical background.

Rhamnales. HERMANN HARMS, "Reihe Rhamnales: Geschichtliche Entwicklung der Ansichten über die Umgrenzung der Reihe," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien*, 2nd ed., 20d:1-6 (1953), the classical summary of the historical underpinnings of the modern taxonomic circumscription of the order; KARL SUESSENGUTH, "Rhamnaceae," "Vitaceae," and "Leeaceae," *ibid.*, 2nd ed. 20d:7-390 (1953), the basic modern reference to these families, with an extensive bibliography indispensable for study of these groups; and GEORGE K. BRIZICKY, "The Genera of Rhamnaceae in the Southeastern United States," *J. Arnold Arbor.*, 45:439-463 (1964), and "The Genera of Vitaceae in the Southeastern United States," *J. Arnold Arbor.*, 46:48-67 (1965), valuable sources for the entire order even though they give details only for the genera occurring in the southeastern United States.

Oleales. P.S. GREEN, "The Olive Family in Cultivation," *Arnoldia*, 25:13-27 (1965), a review of cultivated members of the olive family; L.A.S. JOHNSON, "A Review of the Family Oleaceae," *Contr. N.S.W. Natn. Herb.*, 2:395-418 (1957), a review of classification within the family; A. LINGELSHEIM, "Oleaceae-Fraxineae et Syringae," in A. ENGLER (ed.), *Das Pflanzenreich IV* (1920), a monograph of a few genera; S.D. MCKELVEY, *The Lilac: A Monograph* (1928), on *Syringa*; H. TAYLOR, "Cyto-Taxonomy and Phylogeny of the Oleaceae," *Brittonia*, 5:337-367 (1945), a review of intrafamilial classification; and K.A. WILSON and C.E. WOOD, "The Genera of Oleaceae in the Southeastern United States," *J. Arnold Arbor.*, 40:369-384 (1959), a discussion, with bibliography, of eastern North American genera.

Santalales. J. KUIJT, "Mutual Affinities of Santalalean Families," *Brittonia*, 20:136-147 (1968), a historical resumé of the composition of Santalales, with an exposition of newly conceived evolutionary relationships, *The Biology of Parasitic Flowering Plants* (1969), a worldwide treatment of all parasitic groups of angiosperms, with special sections on history, folklore, haustorium, physiology, evolution, and each parasitic group; and B.A. BARLOW, "Classification of the Loranthaceae and Viscaceae," *Proc. Linn. Soc. N.S.W.*, 87:51-61 (1969), a formal recognition of two mistletoe families and natural grouping within each.

Polemoniales. LEROY ABRAMS, *Illustrated Flora of the Pacific States*, vol. 3, *Geraniums to Figworts* (1951), an illustrated guide to many western North American Polemoniales; K. FAEGRI and L. VAN DER PIJL, *The Principles of Pollination Ecology* (1966), a critical treatment of pollination biology with several detailed case histories; VERNE GRANT, *Natural History of the Phlox Family*, vol. 1, *Systematic Botany* (1959), an exhaustive presentation of the systematic botany of the family Polemoniaceae; and with KAREN GRANT, *Flower Pollination in the Phlox Family* (1965), a summary of pollination biology in the Polemoniaceae including detailed documentary descriptions for many species of the family, especially from western North America; JOB KUIJT, *The Biology of Parasitic Flowering Plants* (1969), a worldwide treatment of all groups of parasitic angiosperms including original observations on the family Lennoaceae; ROBERT SCHERY, *Plants for Man* (1952), an economic botany textbook that includes many obscure and little-known aspects of plant utilization; and L. VAN DER PIJL, *Principles of Dispersal in Higher Plants* (1969), a critical presentation of the biology of dispersal in plants, emphasizing ecological and evolutionary aspects.

Scrophulariales. CHARLES B. HEISER, JR., *Nightshades: The Paradoxical Plants* (1969), a fine popular account of the best-known members of the potato family, including the potato, red peppers, tomato, tobacco, eggplant, and others; JOB KUIJT, *The Biology of Parasitic Flowering Plants* (1969), a well-illustrated

account, including the broomrape family and the parasitic members of the figwort family; FRANCIS ERNEST LLOYD, *The Carnivorous Plants* (1942), which includes much data on the bladderwort family; EDWIN A. MENNINGER, *Flowering Trees of the World for Tropics and Warm Climates* (1926), containing discussions of flowering trees, including those of the Scrophulariales (well illustrated, with many colour plates); *Flowering Vines of the World* (1970), containing discussions of flowering vines, including those of the Scrophulariales (well illustrated, with many colour plates); C.D. SCULTHORPE, *The Biology of Aquatic Vascular Plants* (1967), which gives data on the structure, biology, and ecology of aquatic plants, including those of the Scrophulariales; STANWYN G. SHETLER and FLORENCE MONTGOMERY, *Insectivorous Plants* (1965), which considers, among others, the carnivorous members of the Scrophulariales—the bladderwort family—and includes references for further reading, both popular and technical; and R.N. SALAMAN, *The History and Social Influence of the Potato* (1949), a long and detailed account of the impact of this basic food plant on man.

Lamiales. J. BRIQUET, "Verbenaceae," "Labiateae," and "Phrymaceae," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien*, vol. 4, pt. 3a, pp. 132-182, 183-375, and pt. 3b, pp. 361-362 (1897), a classic treatment in German (no comparable work in English) that describes the families, their vegetative and floral organs, fruit development, pollination, and geographic distribution; K. FAEGRI and L. VAN DER PIJL, *The Principles of Pollination Ecology* (1966), a general discussion of pollination, the different kinds of pollination mechanisms in flowering plants, and pollinating agents (the chapter entitled "Case Histories" discusses, with examples, pollination within some of the Labiateae); HANS MELCHIOR in A. ENGLER, *Syllabus der Pflanzenfamilien*, 12th ed. vol. 2 (1964), an excellent summary treatment in German in which the families and their respective subfamilies, sections, genera, and geographic distributions are described; F. PAX, "Callitrichaceae," in ENGLER and PRANTL, *op. cit.*, vol. 3, pt. 5, pp. 120-123 (1897), a classic treatment in German of the family, with its single genus, *Callitriche*, that discusses vegetative and floral organs, pollination, and geographic distribution; and J.C.T. UPHOF, *Dictionary of Economic Plants*, 2nd ed. rev. (1968), a standard reference of useful plants that includes genera of Verbenaceae and Labiateae used for food, shelter, and medicine.

Campanulales. H.C. CROOK, *Campanulas: Their Cultivation and Classification* (1951), a nicely illustrated book, containing descriptions of many *Campanula* species (especially of horticultural value); S. SCHONLAND, "Campanulales," in A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien IV*, 5:40-84 (1894), a classic in German, now in some respects outdated but still the most complete survey available to all the genera of the order; R.C. CAROLIN, "The Structures Involved in the Presentation of Pollen to Visiting Insects in the Order Campanulales," *Proc. Linn. Soc. N.S.W.*, 85:197-207 (1960), a very clearly illustrated treatment of the pollen presentation in the bellflower order; E.A. BRUCE, "The Giant Lobelias of East Africa," *Kew Bull.*, pp. 61-88 (1934), a treatment of the remarkable giant lobelias; L. HAUMAN, "Les 'Lobelia' géants des montagnes du Congo Belge," *Mem. Inst. R. Colon, Belge, Sect. Sci. Nat. Méd.* 8°, 2:3-50 (1933), a description, with photographs, of a number of giant lobelias occurring in the Congo; R. MCVAUGH, "Studies in the Taxonomy and Distribution of the Eastern North American Species of *Lobelia*," *Rhodora*, 38:241-298, 305-329, 346-362 (1936), a historical survey of the literature of North American *Lobelia* species with keys and descriptions to 22 species, distribution maps, and a literature survey; W.M. BOWDEN, "Phylogenetic Relationships of Twenty-One Species of *Lobelia* L., Section *Lobelia*," *Bull. Torrey Bot. Club* 86:94-108 (1959), a very nice example of modern research in a group of the genus *Lobelia*; and T.W.J. GADELLA, "Some Notes on the Delimitation of Genera in the Campanulaceae," *Proc. K. Ned. Akad. Wet.*, sect. C, 69:502-521 (1966), a survey of the literature pertaining to difficulties in classifying the species in the family Campanulaceae.

Asterales. ARTHUR CRONQUIST, "Phylogeny and Taxonomy of the Compositae," *Am. Midl. Nat.*, 53:478-511 (1955), the most widely accepted interpretative synthesis for the group; GEORGE BENTHAM, "Notes on the Classification, History, and Geographical Distribution of the Compositae," *J. Linn. Soc.*, 13:355-577 (1873), the running explanation to go with the Bentham and Hooker *Genera Plantarum*, a technical work including an authoritative and still useful treatment of the Asteraceae (Compositae) family; SHERWIN CARLQUIST, "Wood Anatomy of Compositae: A Summary, with Comments on Factors Controlling Wood Evolution," *Aliso*, 6:28-44 (1966), interpretation and conclusions based on the author's previous papers dealing with the individual tribes; and JAMES SMALL, "The Origin and Development of the Compositae," *New Phytol.*, 16:157-177, 198-221, 253-276 (1917), 17:13-40, 69-94, 114-142, 200-230

(1918), and 18:1–35, 65–89, 129–176, 201–234 (1919), a scholarly and thorough effort to interpret the Compositae in terms of the now discredited Age and Area Hypothesis.

Alismales. A. ARBER, *Water Plants: A Study of Aquatic Angiosperms* (1920), a classic study of water-habitat plants; C.D. SCULTHORPE, *The Biology of Aquatic Vascular Plants* (1967), an up-to-date and comprehensive monograph on water plants in general; and M.Y. STANT, "Anatomy of the Alismataceae," *J. Linn. Soc.*, 59:1–42 (1964); and "Anatomy of the Butomaceae," *J. Linn. Soc.*, 60:31–60 (1967), the only comprehensive accounts on vegetative morphology and structure of members of the Alismales order.

Liliales. I.H. BURKILL, "The Organography and Evolution of Dioscoreaceae, the Family of the Yams," *J. Linn. Soc. (Bot.)*, 56:319–412 (1960); G.L. DAVIS, *Systematic Embryology of the Angiosperms* (1966), the only available summary of the embryology of the angiosperms, with all families of the Liliales included; E.B. GRANICK, "A Karyosystematic Study of the Genus *Agave*," *Am. J. Bot.*, 31:283–342 (1944), an important paper on the relationship of *Agave* and *Yucca* on the basis of chromosome complement; S.M. HUANG and C. STERLING, "Laticifers in the Bulb Scales of *Allium*," *Am. J. Bot.*, 57:1000–1003 (1970), a report on important work concerning laticifers in *Allium* species; and "Notes on the Laticifers of *Allium*, *Caloscordum*, *Nothoscordum*, *Tristagma*, and *Tulbaghia*," *Pl. Life*, 28:43–46 (1972); R. HEGNAUER, *Chemotaxonomie der Pflanzen*, vol. 2, *Monocotyledoneae* (1963), an important summary of the research in chemistry of the monocots, correlating it with the gross morphology of the plants; WILLIAM HERBERT, *Amaryllidaceae* (1837), a facsimile reprint of Herbert's *Amaryllidaceae*, 1837, preceded by an introduction by H.P. TRAUB (1970), a still valid classic of the Amaryllidaceae in the wider sense; H.P. TRAUB, "The Tribes and Genera of the Agavaceae," *Pl. Life*, 9:134–137 (1953) and 28:137–138 (1972), the grouping of *Hosta* with the Agavaceae; *The Genera of Amaryllidaceae* (1963), a late revision of the family Amaryllidaceae with information also on the Alliaceae; "The Subgenera, Sections and Subsections of *Allium* L.," *Pl. Life*, 24:147–163 (1968) and 28:132–137 (1972), a grouping of the species of *Allium* into subgenera and sections; "The Order Liliales," *ibid.*, 28:129–132 (1972); and "Class Liliida, of Superclass Monocotydras," *ibid.*, vol. 30 (1974), a disposition of 20 families formerly grouped under order Liliales; and T.W. WHITAKER, "Chromosome Constitution in Certain Monocotyledons," *J. Arnold Arbor.*, 15:135–143 (1934), an important paper on the chromosome complement of nine species of the Agavaceae and *Hosta*.

Iridales. L.H. BAILEY (ed.), *Standard Cyclopaedia of Horticulture*, 2nd ed., 3 vol. (1958), a standard work with a wealth of information on the cultivation of ornamental, vegetable, and fruit plants of the United States and Canada, including a treatment of the iris-order plants of economic importance; L. DIELS, "Iridaceae," in A. ENGLER and K. PRANTL, *Die natürlichen Pflanzenfamilien* (1930), a descriptive monographic treatment of the iris family; A. ENGLER, "Burmanniaceae," in *Die natürlichen Pflanzenfamilien*, vol. 2, pt. 6 (1889), a descriptive and taxonomic treatment still useful; J.B. HARBORNE, *Comparative Biochemistry of the Flavonoids* (1967), a modern textbook on flavonoids describing their presence in major plant groups and their use in taxonomy; R.E. HOLTUM, "Growth-Habits of Monocotyledons: Variations on a Theme," *Phytomorphology*, 5:399–413 (1955), an important treatment of the unusual growth forms of the monocots (grasses, lilies, irises, orchids, and others); and J. LOWE, "The Phylogeny of Monocotyledons," *New Phytol.*, 60:355–387 (1961), an authoritative treatment of the evolutionary position of the monocotyledons.

Zingiberales. A. ENGLER and K. PRANTL (eds.), *Die natürlichen Pflanzenfamilien*, 2nd ed., vol. 15a (1930), contains a comprehensive account of the order (in German). The account of Zingiberaceae is based mainly on an earlier work by Schumann; some generic concepts are confused and several generic names misused. C.A. BACKER and R.C. BAKHUIZEN VAN DEN BRINK (eds.), *Flora of Java*, vol. 3 (1968), gives a full systematic account in English of the Zingiberales species of Java, both native and cultivated. P.B. TOMLINSON, "Commelinales-Zingiberales," in C.R. METCALFE (ed.), *Anatomy of the Monocotyledons*, vol. 3 (1969), is a detailed account of anatomy, with a discussion on the interrelationships of families. R.E. HOLTUM, *Plant Life in Malaya*, ch. 3 (1954), discusses the growth habits of Zingiberaceae compared with other monocotyledons (see also ch. 8 on *Musa* and bananas). Other writings by Holtum on this subject include "Growth-Habits of Monocotyledons: Variations on a Theme," *Phytomorphology*, 5:399–413 (1955), showing that the great majority of monocotyledons, though of many diverse growth habits, have basically the same type of sympodial branching, which is directly related to lack of secondary thickening; "The Zingiberaceae of the Malay Peninsula," *Gdms. Bull. Singapore*, 13:1–249 (1950), the only modern treatment

of a considerable part of the family (150 species), containing an introductory discussion on morphology and classification and critiques of former work; and "The Marantaceae of Malaya," *ibid.*, pp. 254–296 (1951), a description of all species, with an introductory discussion on morphology and generic concepts, some of which are still open to question. N.W. SIMMONDS, *The Evolution of the Bananas* (1962), is an account of the natural subdivisions of the genus *Musa*, based on cytotoxiconomic and genetic studies and on the origin of cultivated bananas.

Orchidales. General references: C.L. WITHNER (ed.), *The Orchids: A Scientific Survey* (1959), containing a complete bibliography of orchid literature by geographical regions; F.S. SHUTTLEWORTH, H.S. ZIM, and G.W. DILLON, *Orchids* (1970); C.H. DODSON and R.J. GILLESPIE, *Biology of the Orchids* (1967); A.D. HAWKES, *Encyclopaedia of Cultivated Orchids* (1965).

Floristic works (New World): D.S. CORRELL, *Native Orchids of North America, North of Mexico* (1951); L.O. WILLIAMS, "The Orchidaceae of Mexico," *Ceiba*, vol. 2, no. 1–4 (1951, reprinted 1965); O. AMES and D.S. CORRELL, "Orchids of Guatemala," *Fieldiana, Bot.*, vol. 26, no. 1–2 (1952, 1953); R.E. WOODSON, JR., et al., "Flora of Panama (Orchidaceae)," *Ann. Mo. Bot. Gdn.*, vol. 33, no. 1–4 (1946), vol. 36, no. 1–2 (1949), reprinted 1965; G.C.K. DUNSTERVILLE and L.A. GARAY, *Venezuelan Orchids Illustrated*, 4 vol. (1959–66); C. SCHWEINFURTH, "Orchids of Peru," *Fieldiana, Bot.*, vol. 30, no. 1–4 (1959–61); F.C. HOEHNE, *Iconografia de Orchidaceas do Brasil* (1949); and W. FAWCETT and A.B. RENDLE, *Flora of Jamaica (Orchidaceae)* (1910, reprinted 1963).

Floristic works (Old World): R.E. HOLTUM, *Flora of Malaya*, vol. 1, *Orchids* (1953); F. PIERS, *Orchids of East Africa*, rev. ed. (1968); and A.W. DOCKRILL, *Australian Indigenous Orchids*, vol. 1 (1969).

Orchid pollination: CHARLES DARWIN, *On the Various Contrivances by Which British and Foreign Orchids Are Fertilised by Insects*, 1st and 2nd ed. (1862, 1877); B. KULLENBERG, *Studies in Ophrys Pollination* (1961); and L. VAN DER PIJL and C.H. DODSON, *Orchid Flowers: Their Pollination and Evolution* (1966).

Orchid classification: R.L. DRESSLER and C.H. DODSON, "Classification and Phylogeny in the Orchidaceae," *Ann. Mo. Bot. Gdn.*, 47:25–68 (1960); and L.A. GARAY, "On the Origin of the Orchidaceae," *Bot. Mus. Leaflet Harv. Univ.*, 19:57–96 (1960). These two references contain excellent reviews of the literature on orchid classification.

Orchid journals: *American Orchid Society Bulletin*, *Orchid Review*, *Orchid Digest*, *Die Orchidee* (in German), *Orquideologia* (in Spanish), *Malayan Orchid Review*, and *Australian Orchid Review*.

Poales. AGNES ARBER, *The Gramineae: A Study of Cereal, Bamboo, and Grass* (1934), a comprehensive study of grass anatomy; J.W. BEWS, *The World's Grasses: Their Differentiation, Distribution, Economics and Ecology* (1929), a standard reference with keys but no descriptions, now obsolescent; W.E. BOOTH, *Agrostology* (1964), discussions of the history of agrostology, vegetative and reproductive morphology, cytology, evolution, classification, nomenclature, culture, diseases, and grass identification, with extensive citation of literature; E.G. CAMUS, *Les Bambusées*, 2 vol. (1913), the only taxonomic work on bamboos claiming to be complete, now obsolescent; AGNES CHASE, *First Book of Grasses: The Structure of Grasses Explained for Beginners*, 3rd ed. (1959); F.W. GOULD, *Grass Systematics* (1968), including discussions of structure, relationships, utility, reproduction and cytogenetics, and modern classification and its bases, with keys to genera and descriptions and illustrations of genera of U.S. grasses; A.S. HITCHCOCK, *Manual of the Grasses of the United States*, Misc. Publs. U.S. Dep. Agric. 200, 2nd ed. rev. by AGNES CHASE (1951), a standard reference abundantly illustrated, with full descriptions, keys, and distribution maps; H. JACQUES-FELIX, *Les Graminées (Poaceae) d'Afrique tropicale*, vol. 1, *Généralités, classification, description des genres* (1962), valuable for its modern approach to the tropical grasses, including much anatomical and cytological information; F.A. MCCLURE, *The Bamboos: A Fresh Perspective* (1966), an extended treatment (not primarily taxonomic) of seedlings, mature vegetative plants, flowering and fruiting, classification, culture, and propagation; R. PILGER, "Das System der Gramineae," *Bot. Jb.*, 76:281–384 (1954), an attempt at a complete classification of the Gramineae but regarded as containing many unacceptable features; R.W. POHL, "The Grasses of Iowa," *Iowa St. J. Sci.*, 40:341–566 (1966), containing keys and notes, illustrations, and distribution maps; *How to Know the Grasses*, rev. ed. (1968), a guide for collection and study, with illustrated keys to common North American grasses, including distributions, notes, and descriptions; R.J. POOL, *Marching with the Grasses* (1948), a popular treatment of the grass family, largely from an agricultural standpoint; G.L. STEBBINS and B. CRAMPTON, "A Suggested Revision of the Grass Genera of Temperate North America," *Recent Advances in Botany*, 1:133–145 (1961), the

first formulation of an entirely modern system of grass classification; and UNITED STATES DEPARTMENT OF AGRICULTURE, *Grass: Yearbook of Agriculture for 1948* (1948), a sourcebook of much general information on grasses, legumes, and grassland agriculture.

Arecales. O. BECCARI, *Asiatic Palms*, vol. 11-13 (1908-33), the most elaborate and useful series of monographs on palms published, with analytical and large photographic plates, *Palme della tribù Borasseae* (1924), a monographic account of the Borassoideae in Italian, and with R.E.G. PICHI-SERMOLLI, "Subfamiliæ Arecoidearum Palmae Gerontogaeæ tribuum et generum conspectus," *Webbia* 11:1-187 (1955), a conspectus of the Old World genera of Arecoideae and a summary of subfamilies with text in Italian, descriptions in Latin, and many line drawings of floral and fruit details (the basis for subfamilies as currently

accepted); E.J.H. CORNER, *The Natural History of Palms* (1966), a popular account copiously illustrated with line drawings and photographs but with somewhat unreliable text; J.D. HOOKER, "Palmae," in G. BENTHAM and J.D. HOOKER, *Genera Plantarum*, 3:870-948 (1883), a critical study of palm classification with unrivalled detailed descriptions of genera in Latin; R.B. LEDIN (ed.), "Cultivated Palms," *Am. Hort. Mag.*, 40:1-189 (1961), a popular and principally horticultural account; C.F.P. VON MARTIUS, *Historia naturalis palmarum*, 3 vol. (1823-53), a classic and still fundamental work in Latin, handsomely illustrated with hand-coloured folio plates; and E. POTZTAL, "Reihe Principes," in H. MELCHIOR (ed.), *Engler's Syllabus der Pflanzenfamilien*, 12th ed., 2:579-588 (1964), a synoptic account, in German, of the order Arecales (as Principes) with descriptions of subfamilies and tribes but not of genera.

Animals

Animals make up one of the three kingdoms of multicellular eukaryotic organisms (*i.e.*, as distinct from bacteria, their deoxyribonucleic acid, or DNA, is contained in a membrane-bound nucleus). Unlike fungi (Mycota) and plants, the other two kingdoms of multicellular eukaryotes, animals have developed muscles and hence mobility, a characteristic that has stimulated the further development of tissues and organ systems.

Animals dominate human conceptions of life on Earth not simply by their size, abundance, and sheer diversity but also by their mobility, a trait that humans share. So integral is movement to the conception of animals that sponges, which lack muscle tissues, were long considered to be plants. Only after their small movements were noticed in 1765 did the animal nature of sponges slowly come to be recognized.

In size animals are outdone on land by plants, among whose foliage they may often hide. In contrast, the photosynthetic algae, which feed the open oceans, are usually

too small to be seen, but marine animals range to the size of whales. Diversity of form, in contrast to size, only impinges peripherally on human awareness of life and thus is less noticed. Nevertheless, animals represent three-quarters or more of the species on Earth, a diversity that reflects the flexibility in feeding, defense, and reproduction which mobility gives them. Animals follow virtually every known mode of living that has been described for the creatures of Earth.

Animals move in pursuit of food, mates, or refuge from predators, and this movement attracts attention and interest, particularly as it becomes apparent that the behaviour of some creatures is not so very different from human behaviour. Other than out of simple curiosity, humans study animals to learn about themselves, who are a very recent product of the evolution of animals.

THE ANIMAL KINGDOM

Animals evolved from unicellular eukaryotes. The presence of a nuclear membrane in eukaryotes permits separation of the two phases of protein synthesis: transcription (copying) of deoxyribonucleic acid (DNA) in the nucleus and translation (decoding) of the message into protein in the cytoplasm. Compared to the structure of the bacterial cell, this gives greater control over which proteins are produced. Such control permits specialization of cells, each with identical DNA but with the ability to control finely which genes successfully send copies into the cytoplasm. Tissues and organs can thus evolve. The semirigid cell walls found in plants and fungi, which constrain the shape and hence the diversity of possible cell types, are absent in animals. If they were present, nerve and muscle cells, the focal point of animal mobility, would not be possible.

A definition of animals. A characteristic of members of the animal kingdom is the presence of muscles and the mobility they afford. Mobility is an important influence on how an organism obtains nutrients for growth and reproduction. Animals typically move, in one way or another, to feed on other living organisms, but some consume dead organic matter or even photosynthesize by housing symbiotic algae. The type of nutrition is not as decisive as the type of mobility in distinguishing animals from the other two multicellular kingdoms. Some plants and fungi prey on animals by using movements based on changing turgor pressure in key cells, as compared with the myofilament-based mobility seen in animals. Mobility requires the development of vastly more elaborate senses and internal communication than are found in plants or fungi. It also requires a different mode of growth: animals increase in size mostly by expanding all parts of the body, whereas plants and fungi mostly extend their terminal edges.

All phyla of the animal kingdom, including sponges, possess collagen, a triple helix of protein that binds cells into tissues. The walled cells of plants and fungi are held together by other molecules, such as pectin. Because collagen is not found among unicellular eukaryotes, even those forming colonies, it is one of the indications that animals arose once from a common unicellular ancestor.

The muscles that distinguish animals from plants or fungi are specializations of the actin and myosin microfilaments common to all eukaryotic cells. Ancestral sponges, in fact, are in some ways not much more complex than aggregations of protozoans that feed in much the same way. Although the sensory and nervous system of animals is also made of modified cells of a type lacking in plants and fungi, the basic mechanism of communication is but a specialization of a chemical system that is found in protists, plants, and fungi. The lines that divide an evolutionary continuum are rarely sharp.

Mobility constrains an animal to maintain more or less the same shape throughout its active life. With growth, each organ system tends to increase roughly proportionately. In contrast, plants and fungi grow by extension of their outer surfaces, and thus their shape is ever changing. This basic difference in growth patterns has some interesting consequences. For example, animals can rarely sacrifice parts of their bodies to satisfy the appetites of predators (tails and limbs are occasional exceptions), whereas plants and fungi do so almost universally.

History of classification. Except perhaps for the possession of collagen, the criteria used above to distinguish animals from other forms of life are not absolute. The first catalogs of animal diversity were based on overall form and similarity. Aristotle and other early biologists regarded all organisms as part of a great chain, divisions of which were more or less arbitrary. The 18th-century Swedish

Importance
of mobility

botanist Carolus Linnaeus divided all animals into six classes: Mammalia, Aves, Amphibia (including reptiles), Pisces, Insecta (Arthropoda), and Vermes (other invertebrates). In the early 1800s the French zoologist Georges Cuvier recognized that vertebrates were substantially different from invertebrates, and he divided most animals on the basis of form and function into four branches: vertebrates, arthropods (articulates), mollusks, and radiates (animals with radial symmetry). Cuvier's divisions formed the basis for all subsequent classifications.

Homology

Just after Cuvier's classification, the French naturalist Étienne Geoffroy Saint-Hilaire outlined the importance of homologous structures. Homology is correspondence between features caused by continuity of information. Thus, a bird's wing is homologous to a bat's wing insofar as both are forelimbs, but they are not homologous as wings. Homologous structures need not resemble each other; for example, the three bones in the middle ear of humans are homologous to three bones in the jaw apparatus in fishes because the genetic and developmental information controlling them has been continuous through evolutionary change.

Before evolution was generally accepted, homologies among different animals, when they were recognized at all, were regarded as aspects of God's pattern. Evolution provided a testable explanation for homologies. By carefully tracing selected homologies, it has been possible to show that previously proposed classifications established inappropriate relationships based solely on form or function, or both; for example, the radial symmetry of starfishes is not homologous to that of coelenterates (such as jellyfish).

Protozoans were once considered to be animals because they move and do not photosynthesize. Closer study has shown, though, that their movement is by means of nonmuscular structures (cilia, flagella, or pseudopods) and that photosynthesis in them has often been lost and gained. Protozoans do not, therefore, form a natural group but with algae form a eukaryotic kingdom separate from plants and animals, called Protista.

Like plants and animals, fungi arose from protists and are now accorded a kingdom of their own.

ANIMAL DIVERSITY

The diverse appearance of animals is mostly superficial; the bewildering variety of known forms, some truly bizarre, can be assorted among a mere half-dozen basic body plans. These plans are established during the embryonic stages of development and limit the size and complexity of the animals. Symmetry, number and relative development of tissue layers, presence and nature of body cavities, and several aspects of early development define these fundamental modes of organization.

Parazoa: a cellular level of organization. Although the two phyla in this subkingdom, Porifera (sponges) and Placozoa, lack clearly defined tissues and organs, their cells specialize and integrate their activities. Their simplicity has been adaptive, and sponges have remained important in benthic marine habitats since their origin. The sessile, filter-feeding way of life shown by sponges has favoured a body plan of radial symmetry, although some members have become asymmetrical. The shape of the creeping, flattened placozoans is irregular and changeable.

Radiata: a tissue level of organization. The two coelenterate phyla (Cnidaria and Ctenophora) advanced in complexity beyond the parazoa by developing incipient tissues—groups of cells that are integrally coordinated in the performance of a certain function. For example, coelenterates have well-defined nerve nets, and their contractile fibres, although only specialized parts of more generalized cells, are organized into discrete muscle units. Because discrete cells of different types do not carry out the internal functions of the animals, coelenterates are considered to be organized at only a tissue level.

The integration of cells into tissues, particularly those of nerve and muscle, permits a significantly larger individual body size than is possible with other modes of body movement. Flagella and cilia become ineffective at rather small size, and amoeboid movement is limited to the size a single cell can attain. Muscles contract by a cellular

mechanism basically like that used in amoeboid locomotion—interaction of actin and myosin filaments. Through coordinated contraction of many cells, movement of large individuals becomes possible.

Coelenterates, like parazoa, have only two body layers, an inner endoderm primarily for feeding and an outer ectoderm for protection. Between the endoderm and the ectoderm of coelenterates is the mesoglea, a gelatinous mass that contains connective fibres of collagen and usually some cells. Both layers contain muscle fibres and a two-dimensional web of nerve cells at the base; the endoderm surrounds a central cavity, which ranges from simple to complex in shape and serves as a gut, circulatory system, and sometimes even a skeleton. The cavity is also used for gamete dispersal and waste elimination.

Cleavage of a fertilized egg produces a hollow sphere of flagellated cells (the blastula). Invagination of cells at one or both poles creates a mouthless, solid gastrula; the gastrula is called the planula larva in species in which this stage of development is free-living. The inner, endoderm cells subsequently differentiate to form the lining of the central cavity. The mouth forms once the planula larva has settled. Although the details of early development are different for parazoa and coelenterates, most share a stage in which external flagellated cells invaginate to form the inner layer, which lines the cavity, of these diploblastic (two-layered) animals. This is characteristic of invagination during the development of all animals.

All coelenterates are more or less radially symmetrical. A radial form is equally advantageous for filtering, predatory, or photosynthetic modes of feeding. Tentacles around the circumference can intercept food in all directions.

Bilateria: an organ level of organization. All animals except those in the four phyla mentioned above have bilaterally symmetrical ancestors and contain three body layers (triploblastic) with coalition of tissues into organs. The body plans that are generally recognized are acoelomate, pseudocoelomate, and coelomate.

Acoelomates have no internal fluid-filled body cavity (coelom). Pseudocoelomates have a cavity between the inner (endoderm) and the middle (mesoderm) body layers. Coelomates have a cavity within the mesoderm, which can show one of two types of development: schizocoelous or enterocoelous. Most protostomes show schizocoelous development, in which the mesoderm proliferates from a single cell and divides to form a mass on each side of the body; the coelom arises from a split within each mass. Deuterostomes show enterocoelous pouching, in which the endoderm evaginates and pinches off discrete pouches, the cavities of which become the coelom and the wall the mesoderm. The animals in these major divisions of the Bilateria differ in other fundamental ways, which are detailed below.

Unlike sessile sponges or floating jellyfish, the Bilateria typically move actively in pursuit of food, although many members have further evolved into sessile or radial forms. Directed movement is most efficient if sensory organs are located at the head or forward-moving end of the animal. Organs of locomotion are most efficiently arranged along both sides, a fact that defines the bilateral symmetry; many internal organs are not in fact paired, whereas muscle layers, limbs, and sensory organs almost invariably are. The diffuse nerve net of coelenterates coalesces into definite tracts or bundles, which run posteriorly from the anterior brain to innervate the structures of locomotion.

Acoelomates. Flatworms (phyla Platyhelminthes, Nemertea, and Mesozoa) lack a coelom, although nemerteans have a fluid-filled cavity at their anterior, or head, end, which is used to eject the proboscis rapidly. The lack of a fluid-filled cavity adjacent to the muscles reduces the extent to which the muscles can contract and the force they exert (see below *Support and movement*). Because most also lack a circulatory system, supplying muscle tissues with fuel and oxygen can be no faster than the rate at which these substances diffuse through solid tissue. Flatworms are thus constrained to be relatively flat and comparatively small; parasitic worms, which do not locomote, can achieve immense lengths (e.g., tapeworms), but they remain very thin. The larger of the free-living flatworms

Endoderm,
ectoderm,
and
mesoglea

Flatworms

have extensively divided guts, which reach to within a few cells of the muscles, thus compensating for the lack of a circulatory system. Most flatworms have but one opening to the gut. Nemerteans, in addition to a coelom-like housing for their proboscis, have attained a one-way gut and a closed circulatory system. Both increase their ability to move food and oxygen to all parts of the body. Flatworms are considered to be the ancestors of all other Bilateria.

Pseudocoelomates, or aschelminths. The pseudocoelomates include the nematodes, rotifers, gastrotrichs, and introverts. Some members of some other phyla are also, strictly speaking, pseudocoelomates. These four phyla of tiny body size (many species no larger than the bigger protozoans) are placed together in part because they lack mesoderm on the inner side of the body cavity. Consequently, no tissue, muscular or connective, supports the gut within the coelomic fluid. For tiny organisms, this is advantageous for conservation of tissue: there is no reason to evolve or to maintain a tissue that is not functionally important. The inconspicuousness of most of these phyla has led to a slow advancement in understanding their phylogenetic position in the animal kingdom.

Coelomates. The advantage of a true coelom is the ability of the inner mesenteric (mostly connective tissue) layer to suspend the central gut in the middle of the animal. Otherwise, in those animals with a body cavity used in locomotion, gravity would pull the gut down and severely curtail body size. Coelomates have attained vastly larger body sizes than has any other group of animals. Within the coelomates, the coelom has been of variable significance to the form and diversity of the various phyla. For example, it is essential for the burrowing abilities of annelids and related phyla. It has largely lost this significance in the arthropods, however, which have transferred locomotion to limbs supported by an exoskeleton rather than a coelomic hydroskeleton. Suspension is the main function of the coelom in vertebrates, which achieve the largest body sizes among animals by virtue of an endoskeleton that does not need to be shed during growth.

Protostome
and deu-
terostome
coelomates

The protostome coelomates (acoelomates and pseudo-coelomates are also protostomes) include the mollusks, annelids, arthropods, pogonophorans, apometamerans, tardigrades, onychophorans, phoronids, brachiopods, and bryozoans. Deuterostomes include the chaetognaths, echinoderms, hemichordates, and chordates.

In early development protostome coelomates mostly differ from deuterostome coelomates in the following ways: (1) The mouth of protostomes is the blastopore, the original opening into the developing gut which is formed during the invagination of cells during gastrulation; that of deuterostomes is a secondary opening, with the blastopore becoming the anus. (2, 3) Early cleavage is typically spiral and determinate in protostomes, which means that the dividing cells are oriented at an angle to one another and that the ultimate fate of the cells is mostly determined from the beginning. Deuterostomes, in contrast, show indeterminate, radial cleavage, with the dividing cells becoming layered and the fate of early cells a product of where they are positioned later in development. (4) Coelom formation is schizocoelous in most protostomes, whereas enterocoelous development is typical of deuterostomes. (5) For those with a larval stage, the characteristic larval forms also differ.

The two phyla that have clearly dominated both land and sea since nearly the beginning of animal evolution are the arthropods and chordates, protostomous and deuterostomous coelomates, respectively. A key to arthropod success has been the differentiation of many serially repeated parts, in particular jointed appendages with a rigid exoskeleton, to perform the varied functions necessary to maintain life. The exoskeleton, however, sets a moderate upper limit to body size. In contrast, vertebrates share all habitats with arthropods by virtue of the larger maximum size permitted by the development of an internal rigid skeleton. More than does a coelom, the evolution of rigid, jointed skeletons has allowed these two phyla to dominate most animal communities.

Social levels of organization. Large size is often competitively advantageous but unobtainable by many animals

because of constraints of basic body plan. Intrinsically small animals sometimes become large in the same way that protozoans evolved into metazoans: they multiply the number of individuals by asexual reproduction (thus maintaining the same genotype) and remain attached, with the option that individuals can be modified during their development for a specialized function. This type of asexual sociality forms the colonoids of sponges, coelenterates, bryozoans, hemichordates, and tunicate chordates, all of which were primitively small, sessile filter feeders. Staying together after asexual budding of new individuals gave a competitive edge to monopolizing available space. With slight modifications so that all individuals in the colony could share equally in the gains, these larger entities had the energy reserves necessary to outcompete smaller organisms for space. This type of sociality has evolved in ways that complicate the definition of individuality. For instance, Portuguese men-of-war and their kin (some hydrozoan coelenterates) look and act like single individuals, yet their components develop as genetically identical units, each homologous to a whole jellyfish or polyp. It is a question whether such an animal should be considered one individual or many.

A different type of sociality emerged among mobile complex animals that can individually attain large size. In fact, the largest known living animals, the whales and elephants, comprise two of a very few mammalian orders that contain only social species. The pattern of evolution on Earth has favoured sociality in the smallest and the largest (mostly vertebrates) of animals, albeit for different reasons. The smallest seek the advantages of being large, as protozoans did to form the first animals. The large animals can communicate; they spread out to find food, which all can share, and they protect one another. Among the social groups of large animals, only humans have differentiated their functions to such an extent that their societies begin to behave as individuals.

Insect societies show behaviours halfway between societies based on genetically identical members and those created by genetically different individuals; such properties largely reflect their intermediate degree of genetic relatedness. Insects are more cooperative and show a greater degree of altruism than is true of vertebrate societies.

Sociality

individuals

FORM AND FUNCTION

To stay alive, grow, and reproduce, an animal must find food, water, and oxygen, and it must eliminate the waste products of metabolism. The organ systems typical of all but the simplest of animals range from those highly specialized for one function to those participating in many. The more basic functional systems are treated below from a broadly comparative basis.

Support and movement. A skeleton can support an animal, act as an antagonist to muscle contraction, or, most commonly, do both. Because muscles can only contract, they require some other structure to stretch them to their noncontracted (relaxed) state. Another set of muscles or the skeleton itself can act as an antagonist to muscle contraction. Only elastic skeletons can act without an antagonist; all antagonistic muscles act through a skeleton, which can be either rigid, flexible, or hydrostatic.

Types of skeletons and their distribution. Hydrostatic skeletons are the most prevalent skeletal system used by animals for movement and support. A minimal hydroskeleton resembles a closed container. The walls are two layers of muscles (antagonists) oriented at right angles to one another; the inside contains an incompressible fluid or gel. The contraction of one set of muscles exerts a pressure on the fluid, which is forced to move at right angles to the squeezing antagonist. The movement of the fluid stretches the other set of muscles, which can then contract to stretch its antagonist back to its relaxed position. The net result is an alternating change in the shape of the container. Locomotion as varied as crawling, burrowing, somersaulting, looping, or even walking is possible when the container has some means of traction against a substrate: the system extends forward from the point of attachment, attaches at a more forward point, releases posteriorly, and contracts forward. Hydroskeletons are also important

Importance
of hydro-
skeletons

in nonlocomotory muscular systems, such as hearts or intestines, which move blood or food, respectively. Contraction-relaxation cycles push in one direction only when the system has structures that prevent backflow.

Hydroskeletons become less efficient when fluid is lost. The optimal volume of fluid for a particular system must remain constant for effective contraction and expansion of the antagonistic muscles. If too much fluid is lost, the animal becomes limp and neither muscle can stretch; when too much fluid is gained, the animal becomes bloated and neither muscle can contract. Those coelenterates that use a hydroskeleton regularly face a loss of pressure because their skeleton is also their gut. Freshwater animals tend to become bloated as water diffuses into their salty cells, but terrestrial animals with hydroskeletons tend to become limp as they dry. Solutions to water loss tend to be partial because impermeable barriers, such as a shell, tend not to be very flexible, thus negating the use of a hydroskeleton for movement. Terrestrial animals with locomotory hydroskeletons (*e.g.*, snails and earthworms) are restricted in their activity to moist conditions.

Partitioning a hydroskeleton into many small, separate, but coordinated units facilitates locomotion. In an earthworm, for example, a front group of segments narrows together, thereby elongating that part of the worm. If there were no partitions between the segments, the fluid would flow farther back, providing little elongation. Widened segments behind these initial segments anchor the worm, and its head moves forward. The process then reverses in a wave, and the posterior end moves forward. Metamerism, or the partitioning of the coelom, is thought to have evolved in ancestral annelids to improve their ability as burrowers in the bottom mud of the ocean. It undoubtedly explains the unrivaled success of this phylum among worms and helps to explain the extraordinary success of one of its relatives, the arthropods, which remained segmented even after the skeletal function of the coelom was lost.

Elastic skeletons do not change shape but simply bend when a muscle contracts. Muscle relaxation results either from a muscle contracting in the opposite direction to its antagonist or from the skeleton resuming its original position. The tentacles of many hydrozoan coelenterates, the mesoglea of jellyfish, the hinge of clamshells, and the notochord of chordates are examples. The high-pressure coelom contained in the rigid but flexible cuticle of nematodes also functions like an elastic skeleton.

Rigid,
jointed
skeletons

Rigid, jointed skeletons achieve movement through a lever system. The elements of the skeleton are rigid segments attached together by flexible joints. Muscles span the joints and attach at each end to different elements. The more stable attachment site of a muscle is called the origin, the other the insertion. One muscle contracts and moves the skeletal element on which it is inserted, and an antagonistic muscle contracts and moves the skeletal element in the opposite direction. The biceps and triceps of the upper arm in humans are such a set of antagonistic muscles that bend and straighten, respectively, the lower arm. The control of movement can be quite precise with jointed skeletons. Muscles can bend or rotate skeletal elements whose length, shape, and number contribute to the resulting action. The dexterity of the hands is an example of the complexity of controlled movements made possible by a jointed skeleton.

Important to the speed and force of a movement are the length of the skeletal element and the size of the contracting muscle. Short limbs with thick muscles have more power than long limbs with slender muscles, but the latter have more speed. Limbs thus reveal a great deal about how an animal moves. Likewise, the relative massiveness of jaws reflects the toughness of the food eaten.

Two animal phyla, Chordata (vertebrates only) and Arthropoda, exploit jointed skeletons. Although the skeleton is internal in vertebrates and external in arthropods, the principles of movement are the same. A jointed skeleton is ideal for moving on land because adaptations for protection against dehydration (such as the cuticle) do not interfere with the action of the skeletal system. Indeed, the arthropod cuticle serves jointly a protective and a skeletal

role. Moreover, the diverse range of precise movements made possible by this skeleton facilitates all sorts of locomotory patterns: swimming, digging, running, climbing, and flying. Jointed skeletons are also used directly for feeding (jaws). Arthropod jaws are derived from legs, while vertebrate jaws are derived from gill arches.

Translating movement into locomotion and feeding. Although all animals can move, not all locomote or displace the body over a distance. Locomotion serves the animal in finding food and mates and in escaping predators or unsuitable habitats. These functions of locomotion are typically correlated among different animals, so that those using the same mechanism of locomotion usually also feed, seek mates, and avoid danger in similar ways.

Some of the correlations between mode of locomotion and mode of feeding are described here, but space precludes discussion of the rich diversity found among animals past and present. The locomotory/feeding system of animals is the heart of their adaptation to their physical and biotic environments. Locomotory strategies for finding or gathering food include the following techniques.

Sitting still and waiting for food to arrive is particularly prevalent in aquatic habitats but is not rare on land. Sessile animals tend to develop strong defenses that are sometimes incompatible with effective locomotion. They rely on water or air currents or on the locomotion of their potential prey to bring food within reach. Because food may come from any direction, many sessile animals evolve radial symmetry. Settlement may be permanent or temporary, but in all cases one stage of the life cycle is capable of moving actively or passively from its place of origin. The choice of attachment site can also be active or passive; passive choice is often associated with an ability to grow in such a way as to maximize feeding efficiency. As with plants, passive settlers do well only with luck. The retention of locomotory capabilities requires energy and nutrients that can otherwise be diverted into growth or the production of offspring. Sessile feeders need to move if feeding and resting sites differ. Sessile animals include filter feeders, predators, and even photosynthesizers; the latter include corals that house symbiotic algae. Internal parasites are usually sessile because they live within their lifetime food supply. Mobile animals that pursue sedentary strategies for seeking prey include web-spinning spiders (a terrestrial mode of filter feeding) or deep-sea fishes with morphological adaptations that lure prey.

Burrowing animals typically eat the rich organic substrates they move through. Others burrow for protection and either temporarily emerge and gather organic sediments at the top of their burrows or pump water with potential food through the burrow. Instead of digging or finding burrows, some animals move into the centre of sponges, where they find protection and a renewing source of food.

Active movement in search of food requires energy, but this expenditure is more than made up for by an ability to seek out areas of concentrated food. This method of feeding applies to burrowing animals that eat the substrate through which they move, as well as to animals that move over solid surfaces, swim, or fly. Actively moving animals can feed on organisms that do not move, a rich variety coating virtually the entire solid surface of the Earth from the depths of the oceans to the peaks of many mountains. The main problem with this most productive avenue of food gathering is protection. Shells and poisons are the major types of defenses, although innovative detoxification metabolism and jaws of various kinds breach the defenses in part. This is an escalating battle, with the defenses, as well as the weapons to penetrate them, continually improving. Nudibranchs, shell-less marine snails, incorporate the defensive stinging cells of prey cnidarians into their own skin. Poisonous plants are eaten by specialized insects that avoid or detoxify the poison. In fresh water, for reasons not known, the arms race has not proceeded as far as in the sea.

Cooperation of individuals enables social animals to obtain food in novel ways. Uncannily like humans, some ants farm and herd other organisms for food. For example, some cultivate a fungus on leaves they cannot directly

Methods
for finding
food

Coopera-
tion among
animals

digest, while others herd aphids from which they milk nectar (actually the phloem sap of plants). Some ants even raid the nests of other species and make slaves of them. Another form of cooperation is the mutualism between species that trade advantage for advantage. Some fishes feed on parasites on the surfaces of other fishes, which benefits all but the parasites. In many animals, including termites and ruminants, microorganisms thrive in the gut and digest cellulose for them.

The nervous system. Coherent movement results only when the muscles receive a sensible pattern of activating signals (for example, antagonists must not be activated to contract simultaneously). Animals use specialized cells called neurons to coordinate their muscular activity; nerves are bundles of neurons or parts thereof. Neurons communicate between cells by chemical messengers, but within a single cell (often extremely long) they can send high-speed signals through a wave of ionic polarization (analogous to an electric current) along their membranes, a property inherent in all cells but developed for speed in nerve cells by special modifications.

A system of communication requires three parts: a collector of outside information, an integrator to evaluate that information and decide upon its relevance, and a transmitter to convey the decision to the motor unit. In animals, sensory nerves and organs such as eyes collect the information; associative nerves usually concentrated into a brain integrate, evaluate, and decide its relevance; and effector or motor nerves convey decisions to the muscles or elsewhere. Although all three parts of the nervous system have kept pace with increases in the size and complexity of animals, the simplest systems found among animals (those of parazoans and coelenterates) are nevertheless capable of intricate feats of coordination. All ends of a coelenterate bipolar neuron can both receive and transmit an impulse, whereas the unipolar neurons of more derived animals receive only at one end (dendrite) and transmit at the other (axon). A neuron can have multiple dendrites and axons.

The earliest animals were probably radial in design, so that bipolar neurons arranged in a netlike pattern made sense. In such a design, a stimulus impinging at any point on the body can travel everywhere to alert a simple array of myofilaments to contract simultaneously. In the case of directed locomotion and relevant sensory input received at the head end of a bilateral animal, unidirectional transmission of nerve impulses to muscles becomes the only way to communicate effectively. The location of the brain in the head also reflects efficiency and the speed of receipt of information, because this position minimizes the distance between sensory and associative neurons as well as concentrates these two functions in a small, protected part of the body. In most animals nerve cells cannot be replaced if lost, although axons can be. Nerve cells tend to be concentrated centrally in ganglia or nerve cords, with long axons extending peripherally. Although certain animals may lose tails or limbs to predators or in accidents and then regenerate them, loss or damage to the central nervous system means death or paralysis.

The nervous system uses the transmission properties of neurons to communicate. Within a neuron, propagation of an impulse by an ion wave can be extremely rapid, but the wave can pass along the length of only one cell's membrane. To pass to the next cell at a synapse, where an axon meets a dendrite, a chemical transmitter is required. This molecule diffuses to the dendrites of a connecting neuron, where it initiates an ionic wave that propagates along the length of the cell's membrane. Although chemical transmission is considerably slower than the ionic wave, it is more flexible. For example, learning involves in part increasing the sensitivity of a particular nerve pathway to a stimulus. The sensitivity of a synapse can be altered by increasing the amount of transmitter released from the axon per impulse received, increasing the number of receptors in the dendrite, or changing the sensitivity of the receptors. Bridging the synapse directly by the formation of membrane-bound gap junctions, which connect adjacent cells, enables an impulse to pass unimpeded to a connecting cell. The increase in speed of transmission provided by a gap junction, however, is offset by a loss

in flexibility; gap junctions essentially create a single neuron from several. The same result can be achieved more effectively by lengthening the axons or dendrites, making some nerve cells metres in length. Situations arise where gap junctions become desirable, however. Gap junctions are found in vertebrate cardiac and smooth muscles, both of which transmit impulses along their cells to others. This ability makes these muscles somewhat independent of nervous-system control. A body can thus be kept partly functioning for some time without the activity of a brain.

Nerve impulses travel faster along axons of greater diameter or along those with good insulation against ion leakage (except at spaced nodes required for recharging). Vertebrates use their unique myelinated axons to increase the transmission rate of nerve impulses, whereas invertebrates are limited to using axons of greater diameter. As a result, vertebrates can concentrate more small neurons into a body of a particular size, with the potential for greater complexity of behaviour.

Memory is still a poorly understood aspect of the nervous system. As in learning, both short- and long-term memories seem to involve alterations in the ease with which subsequent impulses travel a particular pathway after it has been used. Transfer of memory through direct ingestion of the brain has not been confirmed experimentally. Although the underlying mechanisms are only dimly understood, it is known that there is a correlation between learning and memory capacity. The capacities for both increase with the number of associative neurons and the number of branches or interconnections formed. Since learning is a process of associating incoming cues with appropriate motor or internal response, greater memory capacity of a brain gives a more rapid learning process. Memory of inappropriate responses to an incoming set of cues can be used without motor repeat.

The degree to which the neurons of a brain develop interconnections is correlated with the complexity of its environs while growing. Consequently, a brain with fewer neurons but with more interconnections can be more "intelligent" than one with more neurons. Basic, repeated behaviours are inherited or learned by the development of fixed pathways by which an environmental signal reaches the motor nerves rapidly with little or no variation (reflex arcs). Nonreflex behaviour requires a decision to be made in the brain, with the resulting pathway to the motor nerves becoming more fixed (habitual) as one particular decision seems always to be correct. Reflexes are faster than decisions, but their relative adaptiveness depends on context. Animals vary in the degree to which they use reflexes or make decisions, patterns that are strongly correlated to brain size. Habitual actions are perhaps the most prevalent response, a compromise between the speed of a response and its appropriateness to context.

The senses. Appropriate behaviour relies on receiving adequate information from the environment to alert an animal to the presence of food, mates, or danger. Although sensory nerves carry this information to the brain, they do not always directly perceive the external world. Other modified cells intervene to convert light waves into vision, pressure waves in air or water into sound, chemicals into smell or taste, and simple contact into touch. Some animals have other senses, as for electric or magnetic fields.

In vision, for example, a photosensitive molecule changes shape and thereby sets off a chain of reactions that ultimately depolarize the dendrite of a sensory nerve. The associative neurons in the brain interpret the pattern of incoming impulses into a composite picture. What is "seen" may not entirely map what is really there: a great deal of filtering occurs, with editing by the brain to eliminate less important details so that only the most important are perceived. The accuracy of what is seen increases with brain size and the complexity of the visual gathering system, or eyes. Animal eyes range from being able to discern only the presence or absence of light to being able to see objects in vivid colour and great detail. Some animals see in ranges beyond unaided human vision. Pollinating insects in particular discern the colour of flowers differently than do humans; the ultraviolet reflection patterns of flowers do not always coincide with their coloured ones. Bees and

Trans-
mission
of nerve
impulses

Vision

birds perceive polarized light and can orient themselves by it. Some animals perceive long wavelengths, which are associated with heat (infrared), and can locate the presence of warm-blooded prey by such a mechanism.

Chemoreceptors are usually little-modified sensory neurons, except for the taste receptors of vertebrates, which are frequently replaced cells in synaptic contact with permanent sensory neurons. Chemoreception is based on the recognition of molecules at receptor sites, lipid-protein complexes that are liberally scattered on the dendrites of a sensory neuron. When the receptor recognizes one particular molecule by shape and sometimes chemical composition, it fires an impulse. The pattern of firings set off in the receptors of a certain molecule provides the information that the brain interprets as an odour or a taste. The details of how animals smell and taste are not as well understood as are the other senses. In many animals, chemoreceptors are not concentrated into obvious organs as they are in vertebrates, making even their location difficult to discern. Most animals possess some sort of chemoreception, and in many the sense is a major part of the animal's perception of its environment, far more so than it is for humans.

Sounds are waves of molecular disturbance that move through air, water, or solids, and their perception by animals simply uses sensitive mechanoreceptors. (Loud sounds can also be felt by the general touch receptors of the body and thereby influence its sense of well-being.) Sound receptors are sensitive hair cells or membranes that depolarize a sensory neuron when bent by the passage of a sound wave. Direct deformation of the dendritic membrane or release of transmitters by the hair cells fire the sensory neurons. Aside from a few insects, only vertebrates have organs with which to hear. Fishes and aquatic amphibians use a lateral-line system, and other vertebrates use ears; both organs use hair cells as phonoreceptors. Sound waves directly stimulate the hair cells of lateral-line systems, while sound waves only indirectly stimulate the hair cells of ears through an amplifying system of membranes and bones, which reaches a peak of complexity in mammals. Some animals (*e.g.*, most bats and whales, and even whirlingig beetles) use sound to "see" by echolocation. Sound is the preferred medium of communication between animals that hear. It can be used over longer distances than vision, and it can be used when vision is not possible. The signals decay more rapidly than do those of odours, and therefore the information can be more precise.

Mechano-
receptors

Mechanoreceptors also respond to touch, pressure, stretching, and gravity. They are located all over the body and enable an animal to monitor its state at any moment. Much of this monitoring is subconscious but necessary for normal functioning. Mechanoreceptors are often just sensory nerves, but other cells may be involved. Unlike other senses, that of touch is found in all animals, even sponges, where it reflects a general cellular trait of eukaryotes.

Hormones. Hormones are the chemical integrators of a multicellular existence, coordinating activities from daily maintenance to reproduction and development. The neurotransmitters released by axons are one class of chemical communicators that act on an adjacent cell, usually a muscle cell or another neuron. Hormones are a mostly distinct class of chemical communicators secreted by nerves, ordinary tissue, or special glands; they act on cells far removed from the site of their release. They can be proteins, single polypeptides, amines, or steroids or other lipids. Hormones travel to their place of action via the circulatory system and then match their particular configuration with a specific receptor molecule attached to a cell membrane or, more usually, located within the cell.

The nervous system coordinates the more rapid activities of animal life, such as movement, while the hormones integrate everything else. Only the larger, more complex animals, such as vertebrates and some arthropods, have special endocrine glands to produce hormones; other animals use nerve cells or tissues such as the gonads. Endocrine glands are another example of a partitioning of functions into separate organs, a system that increases efficiency but that requires a relatively large size to maintain. Greater specialization is also associated with greater diffi-

culties in regenerating lost parts or preventing breakdowns in functions.

Although the list of hormones found in the mammalian body may seem large, the numbers are surprisingly low for the variety of functions they influence. Which of the multiple functions any one hormone regulates depends on the specificity of the receptors on or within cells. Because all hormones bathe all cells as a result of their transport by the circulatory system, it is more efficient to have a general messenger transported to a cell, where it elicits only one of many possible outcomes. As in the nervous system, the specificity of response lies in the organ that responds and not with the messenger that merely commands action.

Chemicals that allow communication among individuals are called pheromones. Sexual attractants are the most common, but there are many other kinds.

Digestion. In contrast to plants, the essential nutrients that animals require to sustain life and to reproduce come packaged with their source of energy—the flesh or organic remains of other organisms. More complex animals tend to shorten and even eliminate many synthetic pathways, because most of the essential building blocks of their own complex molecules are present in their food. Reducing synthetic flexibility, however, inhibits a radical alteration in diet. The digestive and synthetic chemistry of animals strongly reflects their diets; some of this design may be altered with diet, and some may not. No matter how many leafy vegetables humans consume, for example, the cellulose remains undigested because appropriate microorganisms are not present in the digestive tract and they cannot be obtained at will. Consequently, essential nutrients are species-specific and tend to include only molecules adequately available in the usual diet.

The structure of a digestive system reflects its typical diet. Its purpose is to process food only to the point at which it can be transported to other cells for use as either fuel or structural material. In the simplest animals, such as sponges or some coelenterates, digestion is entirely intracellular, and some of the products of digestion are transported to nondigestive cells. As animals began to catch larger types of food, more of the digestive process had to be handled extracellularly. At the simplest level, seen in coelenterates or flatworms, large food items are held in an internal cavity (the gut) or even externally where certain cells release digestive enzymes. The food is broken down only to the stage at which it can be ingested by cells, which finish the process intracellularly. In more complex animals extracellular digestion accounts for virtually all breakdown of food before the products are transported to nondigestive cells.

Chemical digestion, whether intracellular or extracellular, is a relatively slow way to decompose a large item. Thus, animals begin to break it apart mechanically before exposing it to digestive enzymes. Teeth, the molluscan radula, and muscular gizzards are organs that speed up the digestive process by macerating food into finer particles.

Very early in their evolution animals acquired a one-way gut (gastrointestinal system), with the mouth typically armed with the macerating equipment and the terminal stretch sometimes specialized to retrieve excess water or other nutrients. Often a single passage through the digestive system leaves a great deal of useful material unclaimed. Because food moves along at a characteristic rate, which is sometimes influenced by how much is coming in, not all can be fully digested. Some animals regularly eat their feces to retrieve nutrients that may have escaped during first passage. If not recycled by their owners, feces are consumed by a diverse set of organisms.

A common specialization of the gut is the stomach or crop—a highly extensible part of the digestive tract that is used to hold a large amount of food and partially digest it before it enters the intestines, where most of the chemical breakdown and absorption of nutrients occurs. Most animals eat intermittently; the less often they eat, the larger the relative stomach size. Internalizing as much food as possible when it is available prevents potential food from being taken by a stronger competitor or enables a feeder to retreat to safety while digesting its meal. Ceca and second stomachs provide symbiotic microorganisms with a safe

Purpose
and
structure of
the gut

Digestion
before
ingestion

area within the gut to digest cellulose. Excess microorganisms mixed in with the partly digestible wastes contribute a steady protein-rich fare to the host in exchange for an optimal place to consume cellulose.

Stomachs predominate as a gut specialization because they allow animals to keep food from competitors or other dangers, but a few animals have developed ingenious methods of digesting their food before ingesting it. Humans are latecomers to this practice and have not yet carried it very far. Starfish exploit secondary radial symmetry and tube feet to open bivalved mollusks only enough to inject their stomachs, digest their meal within the protected shell, absorb the products, and leave the wastes behind. Spiders immobilize prey by silk wrappings and venoms, inject digestive enzymes, and drink the brew. Some primitive animals, like placozoans and certain flatworms, simply hunch over their prey as they digest it externally, a practice that leaves them vulnerable to other predators.

Animals use surfaces in many ways but no more strikingly than in the gut. Nutrients enter the body proper through the surface membrane of the gut; the larger the animal, the larger this surface area must be. The gut is probably the system that best reflects an animal's ecology. The simplest guts, found in animals from sponges to flatworms, simply branch like trees as the animal increases in size; the gut itself reaches all parts of the body to within the distance of a few cells and thus can serve for nutrient transport. As muscle masses become more prominent, the gut is squeezed into a more compact form. The gut compensates for this lack of space by internalizing its foldings. For example, the lining of the mammalian small intestine, the major site of digestion and absorption, is not only folded but each cell also has numerous outpocketings (microvilli), which increase the surface area 25-fold. Mammals and birds that primarily eat plants have longer intestines than those that favour meat. Warm-blooded animals, which maintain constant internal temperatures, require a great deal more energy than cold-blooded ones and thus tend to concentrate more surface area into a gut. Although they are not efficient energy users, it is to their advantage to obtain more usable energy even if efficiency is lost in the process.

Water/vascular systems. Animals live in an aquatic environment even on land. Each cell is in contact with the ocean or its aqueous equivalent, which carries food and oxygen to the cells of the animal and carries its metabolic wastes away. The water/vascular systems found in animals vary from the nonexistent to the complex, with the complexity correlated with body size and level of activity. Smaller animals simply use the fluid-filled coelom for transport. Increasing size, however, places too many cells beyond diffusion distance from either the coelom or the outside. A muscular pump attached to muscular vessels has arisen in larger animals to move the interstitial fluid surrounding the cells. Most animals have open circulatory systems. Those few animals with closed circulatory systems have a continuous series of vessels to circulate fluid to the vicinity of all cells, whereas those with open systems have vessels only near the heart. (Actually, no system is entirely closed or open.) In open systems the interstitial fluid and the circulatory fluid are the same, but in closed systems the two fluids can differ considerably in composition.

Closed circulatory systems have several advantages that make them more appropriate than open systems for large, active animals: active animals, in fact, tend to possess closed systems even though their relatives may not. For example, cephalopods, alone among the mollusks, and nemerteans, the most active of acoelomates, have closed systems, as do all annelids and vertebrates. Decapod crustaceans, the largest living arthropods, have nearly closed systems. The most fully open systems have a heart with a few vessels leading from it, while fully closed systems both leak fluid (which is reclaimed by the open lymphatic system) and have open sections. For example, blood flow in the vertebrate liver is partly open.

In closed systems, blood flow can be both higher and directed more often to tissues that require a greater perfusion of blood. If blood is confined within discrete vessels,

most of which are muscular, contractions can vary the flow rate according to need by altering the amount of constriction. Thus, the heart beats faster during exercise, when the muscles need more oxygen. Fear changes the distribution of blood flow to ready the muscles for possible imminent action. The more muscular arteries, which carry oxygenated blood to the tissues, can proliferate more finely in active tissues so that more cells are closer to the capillaries, where exchange takes place.

Another advantage of a closed system is the ability to carry a high density of oxygen-bearing cells. Such cells cannot flow smoothly through the sometimes tight interstitial spaces and thus are not much used by animals with open systems. A great deal more oxygen, however, can be carried if the oxygen carrier (such as hemoglobin) is packed into cells. The viscosity of the blood is a function of how many discrete particles are contained within it, and size is of little influence. If all the hemoglobin in the blood of humans were released by dissolving the cell membranes, it would be a thick gel unable to flow. Animals with open systems do aggregate their oxygen carriers into giant polypeptides, but single molecules have limits to their size. Myriapods and insects, highly active arthropods with open systems, circumvented this problem by evolving a tracheal system of respiration, as have some other groups: molecular oxygen is carried by branching tubes to within a few cell lengths of any cell.

A few types of cells protect organisms from a potentially hostile outside environment. Internal cells thus can eliminate any unnecessary ancestral life-support components as they specialize for various functions. This cooperation maintains an ideal internal environment for the members of the society of cells but only at the cost of active labour and expenditure of energy. In particular, the proper water/salt balance of the interstitial fluid is crucial to prevent the cell from shrinking or bloating.

Problems of water/salt balance are usually handled by the same system that eliminates the poisonous ammonia derived from metabolizing nitrogen-containing compounds, such as nucleotides or amino acids. Ammonia dissolves readily in water and thus is removed from an animal that needs to rid itself of excess water anyway. (In small animals the ammonia diffuses into the surrounding water.) With large size or a need for water conservation, animals excrete urea, a less toxic compound but one that also contains carbon and oxygen and thus potential energy. Urea also is highly soluble in water, but its low toxicity means that it can be concentrated before being excreted. Terrestrial animals with problems of water conservation either convert urea into uric acid, a solid compound that can be stored indefinitely in the body or voided with the feces, or develop efficient excretory organs (e.g., the mammalian kidney) that can concentrate the urea. Although water balance is usually handled by the kidney, salt balance is sometimes a specialized function of other organs. For example, because freshwater fish tend to lose a great deal of salt through their gills, they simply expend energy to concentrate salt against a gradient at this location.

Reproduction and life cycles. Primitive members of all major taxa of animals reproduced sexually, and virtually all animals still do at some time or another. In contrast to other activities, that of reproduction and life history may be most complex in the more simply structured animals. If little energy is put into complex maintenance systems, more is left for reproduction, the central focus of an animal's life. Thus, although locomotion constrains the reproductive strategy of an animal, the possibilities with any locomotory mode are diverse. For example, although sessile animals need not expend energy attracting a mate, they do face the problem of getting their gametes in contact with those of the opposite sex. Sometimes both sexes release gametes in immense swarms in which the probability of contact with the opposite sex is high. Often the female harbours large eggs, and the smaller, more mobile sperm are released to find them. In sponges, sperm simply enter with food. Hermaphroditism (the possession of both male and female capabilities) and parasitism by males are ways by which sessile, slow-moving, or sparsely distributed animals cope with finding mates. Barnacles,

Removal
of
ammonia

Open and
closed
systems

which are sessile crustaceans, elongate one limb to transfer sperm directly to another barnacle. (The hermaphroditism of barnacles lets any individual's neighbours be potential mates.) Some barnacles and other animals have small males that are parasitic on the females.

Competition for mates

Mobile animals employ many kinds of devices for signaling their availability to the opposite sex. Pheromones, sound, and visual cues are used singly or in combination. Competition for mates may lead to elaborate courtship rituals, which enable a female to choose a suitable male; to size increases of males that fight for control of a harem; or even to size diminution and ultimately parasitism as males compete for a mate. In some species, sex changes with age, with males turning into females as they get larger. In a few animals, the sex depends on whether the individual settles on the substrate (becoming female) or on another individual (becoming a parasitic male).

Finding a mate is but one aspect of a reproductive strategy. The size of eggs is intimately related to the stage of development at which the young emerge to independent life, which in turn correlates with the habitat or mode of locomotion. For example, marine animals at one extreme produce vast numbers of tiny eggs, which hatch at an early developmental stage (*e.g.*, the planula larva of coelenterates), or fewer, larger eggs, which hatch at a much later stage in the development toward adulthood. Smaller larvae spend more time feeding in the plankton before settling down to adult life, and during this time they are vulnerable to predation; however, they can disperse more widely, and their vast numbers give a positive chance that some will survive at each reproductive period. Terrestrial animals always produce relatively large, developmentally advanced young (spending the larval time in the egg), because the rigours of living on land demand immediately functional organ systems to sustain a free-living life.

Another problem faced by animals as well as plants is whether to breed only once during life, and thus to put all gathered energy into the effort, or to spend less energy during each reproductive period in order to grow and survive to reproduce for many years. A major factor affecting the evolution of a system of reproduction is whether the adult or the juvenile has the greater likelihood of survival. Some insects, such as mayflies, spend so little time as an adult (not much more than a day) that they have lost their feeding structures so as to allot more energy and space to reproduction. Breeding sooner means more descendants faster and more surely, so that mutations which are harmful late but helpful early are selected for. Therefore humans too senesce, unlike an amoeba.

Simple and complex life cycles

Simpler animals can pinch or bud off replicas of themselves, a mode of reproduction used by some animals that individually cannot get very large because of the simplicity of their organ systems. Such asexual reproduction is a form of growth but rarely of dispersal—the bud is usually sessile like the parent and thus remains adjacent to it. Mobility apparently requires such an integration of the nervous and muscular systems that it usually inhibits budding or fission.

Complex life cycles are an extreme variant on the usual life cycle of animals. The juvenile or larval stage is simply more prolonged and complex; it is also structurally quite different from the sexually reproductive adult. Transformation to the adult may occur by asexual budding (*e.g.*, coelenterates) or individual remodeling (*e.g.*, insects or frogs). A complex life cycle enables an animal to feed in two different environments. It is not usually equally advantageous for the animal in both environments, so that one stage typically lasts longer than the other. For example, insects can become parasites without the usual problems of dispersal to a new host; the winged adult is admirably suited to find the correct host. Frogs can take advantage of ephemeral ponds or ditches of water without competition from fish because in their terrestrial adult phase frogs can survive on land and thus locate new ponds when and where they become available. The cnidarian life cycle is also commonly one of alternation between a mobile and sessile form. Some animals alternate between reproduction from unfertilized eggs (all females) and sexual reproduction. The all-female generations can

reproduce faster to take advantage of seasonally excessive resources (*e.g.*, aphids or many freshwater crustaceans).

ECOLOGY AND HABITATS

Animals evolved in the seas but moved into fresh water and onto land in the Ordovician Period, after plants became available as a food source. A simple history of animal ecology centres on the theme of eating some organisms for food while providing food for others. The realities of how animals have done so are richly varied and complex. The ecology of animals and other organisms is reflected in their phylogenetic radiations (*i.e.*, the diversification of lineages). Ecologies are as numerous as species, but, just as species can be grouped into higher taxa, so too can a classification be made of the ways by which animals find adequate food to reproduce and the ways they remain alive while doing so.

Competition and animal diversity. The majority of animal phyla are, and have always been, confined to the sea, a comparatively benign environment. Marine animals need not osmoregulate, thermoregulate, or provide against desiccation. The energy procured can thus be used mostly for growth, reproduction, and defense. Even reproduction can be simple: shunting millions of eggs and sperm into the water and letting them fend for themselves. Developing embryos do not need the protection of a womb because the ocean provides a suitable environment.

Despite the simplicity an animal's life can attain within the ocean, most oceanic animals have not remained simple. Competition and predation, two major components of any habitat, have complicated the lives of animals, leading to ever more novel ways of surviving. No matter how inimical to life, the physical components of environments are relatively predictable elements to which adaptation is often comparatively easy, if costly. Competition and predation, in contrast, relentlessly challenge all forms of life no matter how perfect they become for an instant in time. Adaptations often become obsolete as soon as they are successful, because successful life forms become a prime source of food for others.

Given the simple thesis that competition drives much adaptation, the ecological diversity of animals can be sketched readily. Form, function, and phylogenetic history reflect the roles that animals assume in the evolutionary drama. Throughout a billion-year history, the animal actors have changed many times, but they perform variations on the same theme and the backdrops look much the same. For example, shortly after plants became well established, forests of giant lycopods (club mosses) and tree ferns provided food and shelter for numerous arthropods, including winged insects, on which four-legged amphibious vertebrates fed. Larger amphibians and reptiles later turned to smaller ones for food. Some of the arthropods and other terrestrial animals in turn were parasitic on the vertebrates. Later, different groups of plants, insects, and vertebrates enacted the same scene. First gymnosperms and then angiosperms became the dominant components of forests. Amphibians yielded dominance to mammallike reptiles (some of which became herbivorous), which gave in to dinosaurs; the latter were replaced by mammals and, most recently, by humans. In aquatic habitats the same drama has unfolded, with ever-changing actors. Reefs, for example, have entirely disappeared several times, with each subsequent avatar built mostly from different kinds of organisms. A historical perspective illustrates the underlying direction provided by competition and predation.

Evolution of ecological roles. Animals arose from protozoans and initially were simply larger, more complex, and successful competitors for the same sources of food. The early animals (parazoans, coelenterates, flatworms, and extinct groups) exhibited the same basic strategies of obtaining food as did the protozoans. Because of their larger size, however, they had an advantage over protozoans: they could prey on them and oust them from their attachment sites on the ocean floor. The early basic strategies of animal life reflected two different means of competing for food, that fixed by photosynthetic and chemosynthetic organisms and that provided by the wastes and decaying tissues of life forms. Almost all the free energy fixed is

Importance of competition

ecological
roles

used by one organism or another, so that what one animal wins is lost to the rest. Animals do whatever they can to acquire all the energy they can use, and in this basic sense each is competing with all the others. Ultimately, predation is a mode of competition that simply involves eating the potential competitor rather than finding another way to share the same resource.

Three early ecological roles of animals were as filter feeders, predators, and scavengers. The filtering of comparatively tiny organisms and organic detritus is a form of predation that was easily acquired when an animal became immense relative to potential food. Sponges were the earliest filter-feeding animals and still dominate certain marine habitats.

Predation on relatively large organisms relies on capture and subsequent subjugation of the prey until it can be ingested. Predation grades into filter feeding when the prey is very small in relation to the predator and into parasitism when very large. Among the early animals, coelenterates were the initial predators. Either attached to the bottom or floating near the surface, they paralyzed potential prey with their stinging and muscular tentacles and pushed it into their guts to digest it at leisure. Placozoans and flatworms preyed somewhat less effectively; they crept over a sessile or slow-moving potential prey, formed a pocket around it, and then ejected digestive enzymes to break it into smaller pieces that could be ingested.

Scavengers feed on the remains of dead organisms. A layer of energy-rich organic matter continuously settles on the ocean bottom, where it is recycled by diverse organisms. As animals evolved, they became essential as garbage eliminators because their remains (and those of plants and some fungi) are only slowly decomposed by microorganisms. Without animal scavengers, ocean bottoms and land surfaces would be cluttered with the refuse of dead organisms. Among the early animals, flatworms were the primary scavengers on the ocean bottoms.

Although the early radiation of animals admirably filled the major ecological roles, they had structural, physiological, and behavioral limitations that left some options open. For example, there were no potential predators of the surface-creeping flatworms or placozoans or of the cnidarians, with their stinging cells. There were no burrowers that could penetrate the layer of detritus which undoubtedly accumulated on the ocean floor. With the acquisition of a coelom or pseudocoel, animals could burrow into the detritus layer, consuming it as they went, as earthworms do on land.

Well-developed organ systems permitted an increase in body size, which gave rise to successive levels of predators. Quite early in the rapid diversification of animal life, protective hard shells appeared, a defense against predators but later also a means of enabling animals to expand outward from the seas. The intertidal areas, with partial exposure to the atmosphere, became a livable habitat. Jaws were an important innovation to predators. They are particularly central to the overwhelming success of arthropods and vertebrates, especially on land, where most plants and animals possess a tough drought- and injury-resistant covering. Most mollusks have a filelike radula that is well suited for breaking down tough plant or animal tissue into ingestible pieces and even adequate for drilling through the thick shells of their own group.

Large size, made possible by rigid skeletal support, particularly for reef-forming animals, provided shelter and thus more variations on the common themes. Corals and some other animals shelter algae, particularly in the nutrient-poor tropical seas, and obtain their food directly from their symbionts. This was probably more common in the Vendian (the last interval of the Precambrian, from 670 to 590 million years ago on certain geologic time scales), when thin animals could bask in the water without predators. Most of the deep sea is sparsely populated, its animals living on what settles down from above, but volcanic and other deep-sea vents emit gases that can be oxidized to provide energy. Some animals have symbiotic bacteria that do this, and they reach high densities there. Photosynthetic reef builders create forests in the seas that are analogous to those on land.

Large body size also favours the rise of parasitism, the consumption of living tissue that typically does not kill the host organism outright. Too heavy a load of parasites weakens an animal and makes it more susceptible to predation or other forms of death. Parasites have evolved in many phyla, the most important being platyhelminths, nematodes, and arthropods. Several taxa of high level are entirely parasitic. A disadvantage of parasitism, particularly on land, is dispersal to another host. Intermediate hosts are sometimes used if direct passage cannot be made. Enormous reproductive output is the rule (other organ systems can be minimal because the habitat is so congenial). The extraordinary number of species of winged insects attests to the success of the parasitic way of life. Insects can actually feed in the dispersal stage and thus survive longer while seeking the appropriate host.

Humans and the environment. Humans have had two major effects on their environment, neither of which is original but both of which are greater in consequence than those of any other single species. These two impacts are expected outcomes of natural selection, but their magnitude is of an unprecedented order.

All animals pollute their environs with their wastes, but only when animals are too crowded does a buildup of wastes impair their health. As mentioned above, the wastes of organisms normally become the food of others and thus usually are eliminated almost as rapidly as produced. Leaf litter in the humid tropics, for example, is almost nonexistent because of low seasonality, but elsewhere it can accumulate to some depth. Pollution becomes a problem only when waste cannot be eliminated. For example, the first great pollution episode in life's history, which formed oxygen, was a product of more efficient photosynthesis. Oxygen is a poison to cells, but it is also among the best acceptors of electrons in the breakdown of molecules for energy. Organisms thus developed defenses against oxygen so that they could use it advantageously in their metabolic pathways—a pollutant turned essential to most life.

Humans have only seriously started to pollute their environment in the past two centuries. By their sheer increase in numbers, humans crowd out many other species, particularly those that are large in size but also those that live in habitats humans preempt. Humans have eliminated countless tiny species without realizing their existence. The number of extinctions humans have been directly and indirectly responsible for ranks as one of the major extinction events in Earth's history.

EVOLUTION AND PALEONTOLOGY

All the adaptations in the living world have been produced by natural selection. This selection acts continuously, on many levels and time scales. Thus, an animal may become well adapted to an ecological niche that then disappears, forcing the animal either to evolve rapidly to fill another or, more likely, to become extinct. Another animal, adapted to a more permanent niche, survives. There is also long-term selection on the ability to adapt, as well as on current adaptation, for environments change, in both their physical and biotic components. Mass extinctions of the past testify to major changes, some perhaps catastrophic, the causes of which are still debated. These mass extinctions tended to eliminate more active and specialized groups, partly setting broad-scale evolution back and selecting for the inactive and resistant.

Evolution proceeds by the incremental acquisition of adaptations. It may be impossible for a lineage to evolve into a more effective way of life, because its present adaptations would have to be lost first. An adaptive zone is the niche of a (perhaps large) group of species; in general, the more different and basic the overall adaptive zone, the higher the rank of the taxonomic group. When an adaptive transition has occurred, a new group has arisen.

It is possible to turn this process around and to infer the course of evolution from its results. Species that share a derived character are likely to have had a common ancestor with that character, although there are many exceptions. Incorporating as much evidence as possible, morphological and molecular, makes the inference more likely. Fossils help too, letting scientists know what actually did live at

Parasitism

Natural
selection

each time. Only hard skeletons are ordinarily preserved intact or as fossils, though, so that groups without them have a sparse record or none. Simpler skeletons are sometimes ambiguous as to what animal they came from, and many groups have existed that have no close relatives today. There are nevertheless several dozen faunas through the geologic record that preserve soft-bodied animals and thereby help fill in the historical record of animals.

Animals first appeared in the Vendian, soft-bodied forms that left traces of their bodies in shallow-water sediments. The best-known are coelenterates of various sorts, including some that were more irregular than any today, and there are several groups with unclear affinities. At least some of the latter groups probably left no descendants. Most of the Vendian animals were thin, with each cell able to diffuse nutrients from the water, and many may have photosynthesized with symbiotic algae. No sponges are known to have existed in the Vendian, but they probably had already arisen from choanoflagellate protists.

First mass extinction

The first known mass extinction ended the Vendian. In the Cambrian Period (570 to 505 million years ago) began the great evolutionary radiation that produced most of the known phyla. Evolution occurred rapidly then, as it ordinarily does when adaptive zones are more or less empty and evolutionarily accessible. More soft-bodied faunas show that there were a number of sorts of animals that have no apparent relation to known phyla. It is unclear how many of these are aberrant members of known phyla and how many are more basically different. Although natural selection adapts the parts of animals to function and develop harmoniously with one another, at such an early time much of this internal coadaptation may not yet have occurred, making it easier to change in major ways. There were many groups of arthropods and echinoderms that also have unclear specific affinities with their longer-lasting relatives. Priapulid worms, a minute component of the modern free-living biota, were abundant and diverse. Coeloms evolved and many animals burrowed, and burrowing has increased throughout the Phanerozoic (from roughly 570 million years ago to the present). The Cambrian was also the time when hard skeletons originated in many groups and predators began to prowl the ocean floor.

The probability that a taxonomic family of animals would become extinct in a million years was highest in the Cambrian and declined exponentially until a mass extinction occurred in the late Permian Period (about 260 to 245 million years ago). It then declined again exponentially thereafter. This pattern is due entirely to the decline and extinction of whole groups that are more susceptible to extinction; within each group the probability of extinction stays about constant except during mass extinctions. The probability that a family will give rise to a new family usually has declined exponentially both within groups and overall, however, so that most groups tend to decline in large-scale diversity over time. There has been nevertheless an overall increase through the Phanerozoic in the number of taxa at levels from species to family as new groups like mammals and teleost fishes have originated and as others, like clams and insects, have gradually diversified. Extinction is the common fate of a lineage, while the survivors multiply disproportionately.

Sponges are first definitely known in the Cambrian, including a short-lived major group, the Archaeocyatha. They have not evolved much since then. Some of their larvae became sexually mature without growing up and gave rise to the coelenterates and perhaps the placozoans. Most groups of coelenterates also appeared early and evolved slowly. All corals of the Paleozoic Era (570 to 245 million years ago) belong to groups that are restricted to that era. After the Permian extinction, a group of sea anemones evolved a skeleton and diversified into modern corals. In the Cretaceous Period (144 to 66.4 million years ago), some clams became corallike, even with symbiotic algae, and for a while outcompeted the corals on reefs.

The fossil record is uninformative for flatworms and pseudocoelomates. The interrelations of these groups have also not yet been studied adequately by modern comparative methods. They probably form an adaptive radiation distinct from that of the coelomates, however.

Some anatomic evidence suggests that the pseudocoelomates were all derived from gnathostomulid-like Platyhelminthes. The Introverta seem related to the rotifers, and the gastrotrichs to the nematodes. The Mesozoa may be an unnatural group, with its classes being simplified descendants of different phyla, while the Nemertea are probably derived from turbellarian Platyhelminthes.

Coelomates appear to have had a single origin, probably from ancestral turbellarian Platyhelminthes. They were already diverse in the early Cambrian, and the hydroskeletal function of the coelom in small animals suggests that the ancestor was a burrowing worm. Segmentation arose very early in the group and is retained in its probably primitive form by most annelids. Leeches arose from freshwater oligochaetes, and oligochaetes probably from ancestral polychaetes. Annelid fossils merely show that they have been around since the Cambrian.

Origin of coelomates

Arthropods have been the most diverse phylum since the Cambrian. Trilobites and crustaceans dominated then, with the former declining in abundance through the Paleozoic and the latter expanding into great adaptive diversity. Chelicerates also arose in the early Paleozoic and later radiated widely on land. Myriapods are a terrestrial group and gave rise to insects about 400 million years ago (during the Devonian). Insects were already diverse in the Carboniferous (360 to 286 million years ago), and modern orders have gradually originated and then replaced many of the earlier ones. The interrelations among the four major arthropod groups are unclear, as is the position of the Onychophora. The latter, a relative of annelids and known as early as the Cambrian, may be ancestral to myriapods, in which case the Arthropoda must be divided into two phyla. The position of the weakly segmented Tardigrada is even less clear, as they show special similarities to both the Onychophora and the Gastrotricha.

Segmentation has been reduced or lost in many groups. The Pogonophora retain segmentation mostly at their hind end. Another annelid relative known since the Vendian, this group has gutless members that get nutrients only from symbiotic bacteria and what is dissolved or suspended in the water. The Apometamera show traces of segmentation in the Echiura but none in the overall more-derived Sipuncula. Apometamera are also annelid relatives but may be even closer to mollusks. They lack useful fossils, unless the tube-forming Hyolitha, which may alternatively be annelids or a separate phylum and which lived throughout the Paleozoic, belong here.

Some living mollusks retain traces of segments, and the Machaeridia, an early Paleozoic group probably at the base of this phylum, were highly segmented. The Mollusca can be said to have originated when the radula did. The primitive Aplacophora lack a shell and are unknown as fossils, while their relatives the chitons come from the Cambrian. The Monoplacophora are mostly Paleozoic and gave rise to snails, cephalopods, and the Paleozoic class Rostroconchia of semibivalves. From the latter originated the clams (which have lost the radula) and the scaphopods, always a sparse group. Clams and snails have gradually expanded, the latter especially since the Cretaceous, when one group evolved a movable proboscis. Cephalopod evolution has been more rapid and complex, with nautiloids dominant in the early Paleozoic and ammonoids from then to their final extinction at the end of the Mesozoic Era (*i.e.*, 66.4 million years ago), after having nearly disappeared three times before. Octopuses and squids grow too rapidly to form an external shell, but one group with an internal shell is known to have thrived in the Mesozoic.

Three phyla of annelid relatives feed by a lophophore and are probably related to each other. They too have nearly lost segmentation. Phoronids lack a useful fossil record and probably have always been sparse. Brachiopods and the colonoid bryozoans, on the contrary, were the predominant filter feeders of the Paleozoic Era. Most brachiopods succumbed to the Permian extinction, and the phylum has never recovered. A group of bryozoans, though, has managed to diversify since the middle Cretaceous.

Chaetognaths, abundant but with few species, lack a useful fossil record (unless some Cambrian teeth came from them) but appear related in some way to the remaining

phyla. Echinoderms had remarkable structural diversity in the early Paleozoic, with no less than 20 classes usually recognized then: some asymmetric, stalked, helical, mobile, or cemented down, with multiple origins of adaptively similar forms. Most were both rare and with few species, but blastoids were abundant in the later Paleozoic, and crinoids were a major group throughout that era. Blastoids became extinct in the Permian, and crinoids nearly so. Most later crinoids are free-swimming rather than stalked like their ancestors. An expansion of powerful general predators (crabs and fishes) in the Jurassic Period (208 to 144 million years ago) reduced the numbers of crinoids and some other groups.

Hemichordates are another group now inconspicuous but diverse in the Paleozoic. Most of the latter are called graptolites, colonoids abundant in the Ordovician Period (505 to 438 million years ago) and Silurian Period (438 to 408 million years ago). Hemichordates are very primitive deuterostomes related to both echinoderms and chordates. Of the latter, tunicates lack useful fossils, but a Cambrian cephalochordate shows the early existence of human ancestors. Small pelagic animals called Conodonts, with phosphatic teeth and segmented muscles but no hard skeleton, are most likely cephalochordates but may have been very primitive fishes. They also appeared in the Cambrian and were among the most abundant animals to the end of the Triassic Period (*i.e.*, 208 million years ago). They may have filtered through their spiny teeth rather than through their gills as their ancestors did.

Vertebrates are not known until the Ordovician, when the first of a series of mostly heavily armoured jawless fishes appeared, probably mud-grubbers and filter feeders. Predaceous jawed fishes appeared in the Silurian, perhaps even with a separate origin of bone, and divided into three large groups. One, the placoderms, was more or less dominant in the Devonian Period but rapidly became extinct at its end. Sharks and their relatives have had a series of adaptive radiations, each mostly replacing the previous. The same is true for bony fishes, but the teleosts have been successful to an unprecedented degree. Lungfishes are mollusk-crushers and have declined in numbers since the Devonian.

Amphibians crept from the water in the Devonian and fed on arthropods, which had done so first. They were derived from distant relatives of the modern coelacanth. Many archaic amphibians were large, a metre or two long. Frogs and salamanders first appeared in the early Mesozoic. Reptiles lay eggs that can withstand dry external conditions, and they evolved from amphibians early in the Carboniferous. They were subordinate until the drier Permian, when they began a series of adaptive radiations that put some groups back in the sea and others into the air. Dinosaurs arose in the Triassic and were cut down about the end of the Cretaceous, as were many other groups. Birds evolved from dinosaurs in the Jurassic but apparently expanded greatly only in the Cenozoic.

Mammals arose in the Triassic from reptiles that had separated from the rest in the Carboniferous. They too have undergone sequential adaptive radiations, some of which occurred in the Mesozoic when they were kept small by the dinosaurs. Placentals and marsupials began in the Cretaceous, the latter in North America, from which they invaded South America with some placentals at the beginning of the Cenozoic, replacing an archaic fauna there. They then went on alone across Antarctica to Australia, meanwhile becoming extinct in the north. Placentals themselves had an early radiation that was mostly replaced in the Eocene Epoch (57.8 to 36.6 million years ago) by the modern orders to which it had given rise.

CLASSIFICATION

Diagnostic features. Animals are multicellular eukaryotes whose cells are bound together by collagen. They have sperm and form polar bodies in oogenesis. Animals lack semirigid cell walls, and movement is effected through muscle and nerve cells. They usually gain energy from other organisms or their products. Animals are found almost everywhere on Earth where there is life.

Annotated classification.

Phylum Porifera (sponges)

Sessile; vary in form from amorphously matted to delicately sculptured; distinctive flagellated collar cells pump water and extract food; models of efficient flow design; 2 cell layers with gelatinous mesenchyme containing various types of cells, including those producing supporting spicules; colonoid; marine and some freshwater species; filter feeders; Cambrian to recent; 9,000 species.

Phylum Placozoa

Flattened, 2 flagellated cell layers; fluid mesenchyme with a few cells and connecting fibres; similar to the larvae of primitive animals, from which they may be derived; digestive method unknown; shape irregular and changing; marine; predators or scavengers; recent; 1 species.

Phylum Cnidaria

Possess tentacles with stinging cells (nematocysts) for paralyzing prey or repelling predators; sessile (polyp) and floating (medusa) forms; many have both stages alternating in complex life cycles; medusae with well-developed mesoglea used as elastic skeleton for jet propulsion; muscle cells epithelial; solitary to the most complex of animal colonoids; marine and freshwater species; predators or scavengers with some filter-feeding species; Vendian to recent; 9,000 species.

Phylum Ctenophora (comb jellies)

Long tentacles of most have sticky lasso cells (colloblasts) to secure prey; comb plates of fused cilia (ctenes) used for swimming; separate muscle cells; marine; predators; Devonian to recent; 100 species.

Phylum Platyhelminthes (flatworms)

Lack anus except perhaps in the class Gnathostomulida; no circulatory system; mouth ventral; mesoderm of loose cells (parenchyma); marine and freshwater species, with some terrestrial species known; predators or scavengers, with some parasitic species known; recent; 20,000 species.

Phylum Mesozoa

Among simplest animals; only organ the gonad; 2 classes probably arose separately; dicyemids with unique within-cell embryo formation; marine; parasitic; recent; 100 species.

Phylum Nemertea (Rhynchocoela; ribbon worms)

Proboscis in fluid-filled cavity not attached to gut; anus present; closed circulatory system; marine, with some freshwater and terrestrial species known; predators; Carboniferous to recent; 900 species.

Phylum Gastrotricha

Wormlike pseudocoelomates; ventral ciliation used to glide over surfaces; use muscular pharynx to pump in small prey or organic debris; marine and freshwater; predators or scavengers; recent; 450 species.

Phylum Nematoda (roundworms)

Found almost everywhere animals exist; thick, complex cuticle permits high pressure on internal fluid and acts as elastic skeleton; only longitudinal muscles; many internal structures reflect high internal pressure; unique type of excretory organ; some have jaws; marine, freshwater, and terrestrial species; predators or scavengers or parasites; Carboniferous to recent; 12,000 species.

Phylum Rotifera (wheel animals)

Distinctive corona of cilia used in pulling cellular food into gut; most have elaborate jaws; some with telescoping bodies; marine and freshwater; predators or filter feeders, with some parasitic species known; Eocene to recent; 1,800 species.

Phylum Introverta

Spiny retractable proboscis (or introvert) at head of wormlike body functions in burrowing through soft substrates or guts; marine and freshwater species; predators or parasites; parasitic forms lack a gut; Cambrian to recent; 900 species.

Phylum Annelida

Segmented worms; paired appendages or setae on segments used in locomotion; protonephridia or metanephridia; closed circulatory system; some with jaws; some sedentary or sessile; some secrete tubes around them; marine, freshwater, and terrestrial; predators, scavengers, or filter feeders, with some parasitic species known; Cambrian to recent; 15,000 species.

Phylum Pogonophora

Deep-sea, sedentary, tube-building worms with 3 body divisions; long, ciliated tentacles with microvillus-like extensions of single cells; no mouth or digestive system; symbiotic bacteria in characteristic organ; closed, well-developed circulatory system; Vendian to recent; 150 species.

Phylum Tardigrada (water bears)

Tiny; secrete cuticle; epidermal cell number constant; metameric nervous system; 4 pairs of legs; reduced coelom functionally replaced by hemocoel; extraordinary ability to withstand desiccation and other stresses; mostly terrestrial, with some marine and freshwater species known; predators or scavengers; Cretaceous to recent; 400 species.

rise of
vertebrates

Phylum Onychophora

Wormlike, with many pairs of stubby legs; jaws are modified legs; thin secreted cuticle; annelid-like body plan; tracheal respiratory system; terrestrial; predators; Cambrian to recent; 80 species.

Phylum Arthropoda

A rigid, jointed cuticle used as skeleton; lack epithelial cilia entirely; open circulatory system; segmented, with each segment bearing a pair of appendages primitively; much fusion of segments and use of appendages for functions other than locomotion; many with compound eyes; respiratory systems highly varied; complete range of habitats and feeding modes; Cambrian to recent; more than 1,000,000 species.

Phylum Mollusca

Ciliated epithelia; ventral surface forms muscular foot, primitively used for locomotion but variously modified; dorsal and lateral surfaces usually form shell-secreting mantle that protects external gills; unique chitinous scraping radula aids feeding and burrowing; coelom reduced; open circulatory system serves as hydroskeleton; many species moderate to large in size; marine, freshwater, and terrestrial species; predators, scavengers, filter feeders, and grazing species, with some parasitic species known; many derived forms are sessile; Cambrian to recent; 50,000 species.

Phylum Apometamora

Unsegmented worms; food-gathering proboscis with cilia below or in tentacles; sedentary tube dwellers; metanephridia; marine; filter feeders; Devonian to recent; 400 species.

Phylum Phoronida

Wormlike; sedentary in chitinous tube; lophophore; closed circulatory system; metanephridia; marine; filter feeders; Devonian? to recent; 15 species.

Phylum Bryozoa (moss animals)

All but a few commensal species are colonoid, forming large matlike or plantlike forms; sessile; lophophore; tiny individual zooids; reduced organ systems; marine and some freshwater species; filter feeders; 2 subphyla, Ectoprocta and Entoprocta; Ordovician to recent; 4,600 species.

Phylum Brachiopoda (lamp shells)

Calcareous, bivalved shell with mantle; lophophore; open circulatory system; metanephridia; marine; filter feeders; Cambrian to recent; 340 species.

Phylum Chaetognatha (arrowworms)

Swimming marine predators; head with grasping spines, jaws, and eyes; coelom lacks mesodermal lining; Cretaceous to recent; 100 species.

Phylum Echinodermata

Unique water/vascular system (tube feet) used mainly for locomotion and feeding; lack heads, brains, and segmentation; internal calcareous skeleton; circulatory system open; pentamerous, nearly radial symmetry in recent classes; marine; predators, scavengers, or filter feeders; Cambrian to recent; 7,000 species.

Phylum Hemichordata

Wormlike or colonoid; tripartite coelom; construct mucus-lined U-shaped burrows or proteinaceous tubes; open circulatory system; dorsal and ventral nerve cords, the dorsal one partly hollow; some with branched tentacles to gather food; pharyngeal gill slits used for exit of sediment-bearing water entering mouth and for gas exchange; marine; filter feeders; Cambrian to recent; 85 species.

Phylum Chordata

Elastic notochord used as skeleton when present; dorsal hollow nerve cord; postanal tail; pharyngeal slits used originally in feeding and later in gas exchange; all habitats and feeding modes, but rarely parasitic; 50,000 species.

Subphylum Tunicata (Urochordata)

Secrete a thick tunic or a filtering device of complex composition around body; most adults lack notochord and head; circulatory system open; coelom reduced; pharyngeal cavity well-developed; solitary or colonoid; sessile or pelagic; marine; filter feeders; Silurian? to recent; 3,000 species.

Subphylum Cephalochordata (Acrania)

Fishlike; persistent notochord; segmental muscles but no hard skeleton or heart; protonephridia; Cambrian to recent; 23 species.

Subphylum Vertebrata (Craniata)

Skeleton of bone or cartilage; heart; kidneys; myelinated axons; includes the agnathans, Chondrichthyes, Osteichthyes, amphibians, reptiles, mammals, and birds; Ordovician to recent; 47,000 species.

Critical appraisal. This classification includes only extant groups. Because the aschelminths have not been stud-

ied adequately by modern methods, there is no consensus on their classification, and the system used here differs in some respects from that in the article ASCHELMINTHS. The classification in this article is based on morphological work carried out in the late 1980s and remains to be tested by RNA sequence studies and other comparisons. This classification defines the phylum Introverta as containing the classes Kinorhyncha, Loricifera, Priapulida, and Acanthocephala and the phylum Nematoda as containing the classes Ademophorea, Secernenta, and Nematomorpha.

BIBLIOGRAPHY. Technical descriptions of almost all taxa to the family level are presented in SYBIL P. PARKER (ed.), *Synopsis and Classification of Living Organisms*, 2 vol. (1982). The most detailed survey of animals is found in PIERRE P. GRASSÉ (ed.), *Traité de zoologie: anatomie, systématique, biologie* (1948–), an ongoing multivolume work, published in parts. LIBBIE H. HYMAN, *The Invertebrates*, 6 vol. (1940–67), is a classic, unfortunately incomplete, but careful, fairly detailed, and still mostly accurate.

A survey of animal diversity is found in C. BARRY COX and PETER D. MOORE, *Biogeography, an Ecological and Evolutionary Approach*, 4th ed. (1985). Developments in the preservation of biological diversity are discussed in EDWARD O. WILSON and FRANCES M. PETER (eds.), *Biodiversity* (1988). Laws of physics that directly influence the size and shape of living organisms are addressed in STEVEN VOGEL, *Life's Devices: The Physical World of Animals and Plants* (1988); and R. MCNEILL ALEXANDER, *Animal Mechanics*, 2nd ed. (1983). KNUT SCHMIDT-NIELSEN, *Scaling: Why Is Animal Size So Important?* (1984), discusses the significance of animal body size.

For discussion of form and function, see ALFRED SHERWOOD ROMER and THOMAS S. PARSONS, *The Vertebrate Body*, 6th ed. (1986), a classic text; and E.J.W. BARRINGTON, *Invertebrate Structure and Function*, 2nd ed. (1979), a survey by system. ROBERT D. BARNES, *Invertebrate Zoology*, 5th ed. (1987) and RICHARD C. BRUSCA and GARY J. BRUSCA, *Invertebrates* (1990), are surveys by group. W.N. BEKLEMISHEV, *Principles of Comparative Anatomy of Invertebrates*, 2 vol. (1969; originally published in Russian, 1944; 3rd Russian ed. 1964), provides good coverage of invertebrate development. Research-level reviews of reproduction in many groups are available in ARTHUR C. GIESE and JOHN S. PEARSE (eds.), *Reproduction of Marine Invertebrates*, vol. 1–5 (1974–79), with a concluding synthesis provided in vol. 9 (1987) and intermediate volumes scheduled for publication in the 1990s. See also B.I. BALINSKY, *An Introduction to Embryology*, 5th ed. (1981), a standard text that focuses on vertebrates only. A review of research on energy metabolism in most major animal groups is offered in T.J. PANDIAN and F. JOHN VERNBERG (eds.), *Animal Energetics*, 2 vol. (1987). MARCEL FLORKIN and BRADLEY T. SCHEER (eds.), *Chemical Zoology*, 11 vol. (1967–79), surveys the chemicals important to animal structure, physiology, and behaviour, organized by taxonomic group. KNUT SCHMIDT-NIELSEN, *Animal Physiology: Adaptation and Environment*, 4th ed. (1990), is a comprehensive introduction.

For more detailed treatment of the fauna and ecology of major terrestrial and aquatic ecosystems, see the multivolume series *Ecosystems of the World*, published by Elsevier Scientific since 1977. F. HARVEY POUGH, JOHN B. HEISER, and WILLIAM N. MCFARLAND, *Vertebrate Life*, 3rd ed. (1989), presents a broad overview from paleontology to animal behaviour. ROBERT E. RICKLEFS, *Ecology*, 3rd ed. (1990), is an authoritative work. THOMAS C. CHENG, *General Parasitology*, 2nd ed. (1986), provides a detailed introduction to the subject.

For explorations of evolution and paleontology, see DOUGLAS J. FUTUYUMA, *Evolutionary Biology*, 2nd ed. (1986), a general introduction; MARTIN F. GLAESSNER, *The Dawn of Animal Life: A Biohistorical Study* (1984), a useful discussion of the first recorded radiation of animals; RUDOLF A. RAFF and THOMAS C. KAUFMAN, *Embryos, Genes, and Evolution: The Developmental-Genetic Basis of Evolutionary Change* (1983), a causal rather than descriptive approach to embryology in all animals; and ROBERT L. CARROLL, *Vertebrate Paleontology and Evolution* (1988), a standard survey. RAYMOND C. MOORE (ed.), *Treatise on Invertebrate Paleontology* (1953–), a basic source of information, with descriptions and illustrations to generic level, is an ongoing multivolume work published in parts; newly revised editions of some parts began to appear in 1970, ed. by CURT TEICHERT. Paleontological topics are thoroughly reviewed in RICHARD S. BOARDMAN (ed.), *Fossil Invertebrates* (1987); and STEVEN M. STANLEY, *Extinction* (1987). On the origin and diversification of hormones, see E.J.W. BARRINGTON (ed.), *Hormones and Evolution*, 2 vol. (1979). ERNST MAYR, *Populations, Species, and Evolution* (1970), is a revised abridgement of the author's classic book on speciation and other relevant topics.

(V.C.M./L.M.V.V.)

Annelids

The Annelida, or segmented worms, constitute a major invertebrate phylum of the animal kingdom. The group numbers more than 9,000 species and includes three classes: the marine worms (Polychaeta), which are divided into free-moving and sedentary, or tube-dwelling, forms; the earthworms (Oligochaeta); and the leeches (Hirudinea). Annelids, named for the transverse rings, or annulations, of the body, are segmented animals with a body cavity (coelom) and movable bristles (setae). The coelom is reduced in leeches, and setae are lacking in a few specialized forms, including leeches.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 313.

GENERAL FEATURES

Distribution and abundance. Annelids are found worldwide in all types of habitats, especially oceanic waters, fresh waters, and damp soils. Most polychaetes live in the ocean, where they either float, burrow, wander on the bottom, or live in tubes they construct; their colours range from brilliant to dull, and some species can produce light. The feather duster (*Manayunkia speciosa*) inhabits the Great Lakes and some rivers of the United States. The polychaetes include more than 6,000 known species, which are about evenly divided between free-moving and tube-dwelling forms. The oligochaetes number about 3,250 known species. Oligochaetes, including earthworms, burrow into soil; certain small oligochaetes are found in fresh water, and a few are marine, usually inhabiting estuarial or other shallow waters. Leeches, which number about 300 species, inhabit freshwater or humid environments and are carnivorous or parasitic on other organisms—e.g., all marine leeches are parasitic on fish.

Size range and diversity of structure. The length of annelids varies from a fraction of an inch to more than six metres (about 20 feet). The width may exceed 2.5 centimetres (about one inch) in the contracted state. Free-moving polychaetes and earthworms include the largest species. Leeches attain lengths of about 0.4 metre in the contracted state.

Polychaetes. The body of free-moving polychaetes (see Figure 3) consists of a head, or prostomium, which may bear two or more eyes; a preoral segment, with such appendages as antennae, tentacles, and palpi (fleshy sensory projections); a trunk divisible into distinct segments; and a tail, or pygidium, which may bear anal cirri (fleshy projections) or plaques and a terminal anus. Each body segment following the second segment (peristome) usually has paired parapodia; i.e., fleshy, lateral outgrowths used

in feeding, locomotion, or breathing. The parapodia, generally prominent in free-moving polychaetes, bear bundles of setae, which can be extended, and aciculae (needlelike structures), which are used for support.

The heads of sedentary polychaetes (see Figure 3) may be distinct or indistinct. Forms with a distinct head generally lack head appendages. Branchiae, or gills, which serve for respiration and as food-gathering organs, are well-developed in many of the tube-dwelling forms. Some have tentacles at the anterior (front) end, and gills arise from the dorsal (upper) surface of a few anterior segments. In these species food is gathered by the tentacles and respiration is confined to the gills. The rest of the body is divided into thoracic and abdominal regions. Parapodia, if present, are generally simple lobes; frequently the setae project directly from the body wall. Many sedentary polychaetes construct tubes made from a substance secreted from cells that constitute the epidermis, or skin. Tubes may consist of calcium carbonate, parchment, or mucus, to which sediment adheres. The anus is at the posterior tip. Tube dwellers generally have an external fecal groove along which fecal material passes forward. Eyes are occasionally present on gills, along the sides of the body, or on the pygidium in sedentary forms that do not live in tubes.

Oligochaetes. The body of oligochaetes (Figure 1) is uniformly segmented and has conspicuous segmental lines. The prostomium is usually a simple lobe overhanging the mouth and lacking appendages. The microscopically small eyes are scattered over the body. The clitellum, a saddle-shaped thickening of the body wall, is present at sexual maturity. The anus is at the posterior tip. Setae generally arise from the ventral (lower) surface of the body.

Leeches. Leeches (see Figure 4) have 34 segments, and elongation occurs by the subdivision of these segments. Leeches have a small sucker at the anterior end and a large sucker at the posterior end. A clitellum is present in the mid-region during the reproductive period. The poorly developed eyes are paired structures at the anterior end. Setae are absent.

Importance. Large earthworms, or night crawlers (*Lumbricus terrestris*), are cultivated and sold as bait for freshwater fishes and as humus builders in gardens. The sludge worm *Tubifex*, abundant near sewer outlets and thus an indicator of water pollution, is collected and sold as food for tropical fish. Polychaetes play an important role in turning over sediment on the ocean bottom.

The medicinal use of leeches, which dates from antiquity, reached its peak in the first half of the 19th century. The European species *Hirudo medicinalis* formerly was exported throughout the world, and native species also were used. Hirudin, an extract from leeches, is used as a blood anticoagulant.

The estuarine flats of Maine and Nova Scotia are the principal sources of the bloodworm (*Glycera dibranchiata*), which is used as bait for saltwater fishes. Reproduc-

Environ-
ments

tive parts of the palolo (*Palola siciliensis*), which break off and are found in great numbers during the reproductive period, are used as food in Samoa in the south Pacific.

NATURAL HISTORY

Life cycle. Reproduction. In the polychaetes, sexes are usually separate but cannot be distinguished in the immature state until gametes (eggs and sperm) appear. Gametes are derived from the mesodermal linings around the digestive tract. The developing gametes are shed into the coelom, where they are nourished by nurse cells (eleocytes). The gametes, especially eggs, are nourished by the breakdown products of muscle tissue, which are passed on to the gametes via the eleocytes. Ripe eggs and motile sperm may leave the body through gonoducts, or tubes for the passage of reproductive cells; through excretory, or nephridial, pores; or through ruptures of the body wall.

Most polychaetes shed their gametes into the water. Various major body changes may precede the emission of gametes, the two most profound being epitoky (maturation into a modified, fertile form) and stolonization (the development of stemlike growths). In species of *Nereis*, morphological changes include enlargement of the eyes, enlargement of a specific number of parapodia, replacement and alteration of setae, and development of an anal organ (rosette) for the emission of sperm. Morphological changes occur in species of *Syllis* as well, but they involve only the part that is shed in stolonization. At sexual maturity these polychaetes leave their burrows and swim in groups before releasing gametes.

The removal of the brain of a nereid that normally undergoes epitoky causes morphological changes without the subsequent formation of gametes. Nereids that normally do not undergo epitoky are unaffected by the removal of the brain. This suggests that apparently the hormone which stimulates epitoky is present only in species that normally undergo this phenomenon. In syllids, stolonization may produce one or more stolons, or stems, containing developing gametes; epitoky is controlled by a nerve ganglion in the proventriculus part of the digestive tract. Epitokous females produce a pheromone that stimulates the male to spawn. The presence of the sperm in the water initiates spawning in the female. Swarming in certain epitokous species coincides with a specific phase of the Moon, but the causes of such behaviour are unknown. Palolos of the Pacific, for example, swarm on a specific day at certain places each year, an event that can be predicted with precision.

Another type of epitoky occurs in some sedentary polychaetes; in these worms, the parapodial lobes develop long, thin setae. Either the entire animal or only the posterior portion (e.g., the palolo) leaves the tube or burrow and swims before releasing gametes.

Hermaphroditism—that is, the production of eggs and sperm in one individual—rarely occurs in polychaetes. The free-moving polychaete *Ophryotrocha*, however, shows marked sexual variability; individual males or females may exist in association with hermaphroditic forms. Experiments with *Ophryotrocha* suggest that the age at which transition from one sex to another occurs may differ among groups within certain species.

Asexual reproduction is known in a few sedentary polychaete species. In some genera—*Ctenodrilus*, *Pygospio*, and *Sabella*—fragmentation of the body occurs, sometimes forming single segments, from which new individuals can develop.

Reproduction in oligochaetes is primarily hermaphroditic; the number, arrangement, and location of the male and female gonads and their pores vary considerably among the various species. Lower oligochaetes (Microdrili) have one pair of testes and one pair of ovaries in successive segments. Higher oligochaetes (Megadrili) retain the two pairs of testes in segments 10 and 11 and the pair of ovaries in segment 13. Developing sperm are frequently stored in seminal vesicles before transfer to female receptacles. Sperm ducts lead from the seminal vesicles to male pores located one or more segments behind the testes. The ovaries are simple outpouchings (ovisacs), with oviducts leading to female pores in the next posterior segment.

Copulation in oligochaetes is reciprocal—that is, both sperm and eggs are exchanged—and takes place in a head to tail position, with the two ventral surfaces in contact (see Figure 2). In lower oligochaetes, the male pores of one worm and the female pores of another are opposite each other, and sperm pass directly from the male pores into the seminal receptacle of the female. Cells associated with the brain secrete a hormone that stimulates gamete development. The worms separate after the gametes have been exchanged.

The clitellum of the earthworm secretes a case, or cocoon, into which is secreted a material that serves as nourishment for the young and a mucous substance that aids in copulation. The cocoon slips forward and receives eggs as it passes the female pores and sperm as it passes the male pores. Fertilization, therefore, takes place within the cocoon. The cocoon slides over the peristome, becoming completely sealed as it does so.

Asexual reproduction is common in aquatic oligochaetes; indeed, sexual reproduction is virtually unknown in certain nauid species. Some oligochaetes divide to form a chain of two or more individuals that later break off as young worms. In many genera, individuals lay self-fertilized eggs capable of development. Others exhibit parthenogenesis—the production of young without fertilization—a phenomenon associated with polyploidy (multiple sets of chromosomes) in earthworms and accompanied by degeneration of male gonads.

All leeches are hermaphroditic, and reproduction is always sexual. The testes, from four to 10 pairs, are arranged by segments, beginning with segment 12 or 13. The testes on each side of the body are connected with the vas deferens, a duct that leads indirectly to the male pore. The female reproductive system consists of one pair of ovisacs containing the ovaries, which, although located in front of the testes, may extend some length posteriorly, depending on the animal. The ovaries connect to form an oviduct that forms either a female pore or, in those species that copulate, a vagina.

In one leech family (Gnathobdellae), sperm are transferred by the penis of one animal into the vagina of another. In two other families (Rhynchobdellae and Erpobdellidae), sperm are transferred by sperm capsules, or spermatophores, onto the body of the leech, after which the sperm leave the spermatophore and enter the ovary through the female pore to unite with the eggs. Leech eggs, numbering from one to more than 100, are usually deposited in cocoons, which may be oval or elongated in shape and are generally attached to rocks or vegetation. Glossiphoniids produce a membranous cocoon and attach it to their ventral surface, where development takes place. A clitellum, which forms only during the reproductive period, secretes the cocoon and material (albumin) to nourish the developing young.

Development. Annelid eggs, like those of flatworms and mollusks, exhibit spiral, or determinate, cleavage, so called because early differentiation of various regions occurs; in indeterminate cleavage (in echinoderm and chordate eggs), early differentiation does not occur.

In annelids, the first four cells (blastomeres) give rise, by alternating clockwise and counterclockwise divisions, to a cap of smaller cells, called micromeres, at one end of the egg and a cap of larger cells, called macromeres, at the other end.

All cells divide simultaneously during the early stages of annelid development; during later stages, however, macromeres divide more slowly than micromeres. As a result, a ball of cells (solid gastrula) forms as the mi-

Figure 2: *Enchytraeus albidus* in copulation, the male pore, on segment 12, being directly opposed to the spermathecal pore of the other worm, between segments 4 and 5.

Fertilization in earthworms

Determinate cleavage

Epitoky and stolonization in polychaetes

cromeres grow over the macromeres. The gastrula may form by invagination (infolding of cells), epiboly (overgrowth and lengthening), or by both processes. Some of the micromeres become arranged in a characteristic pattern known as the annelid cross.

Trochophore
larva of
polychaetes

A free-swimming immature form called the trochophore larva develops in the polychaete annelids and during the development of certain other invertebrate groups—mollusks, sipunculids, and lophophores. The trochophore larva of polychaetes is typically diamond-shaped with a circle of short, hairlike projections (cilia), called the prototroch, around the thickest part of the body. Cells bearing the prototroch develop from specific micromeres at the 16-cell stage. The four cells of the annelid cross frequently give rise to a so-called apical tuft of cilia at the anterior end. A tuft of cilia (the telotroch) may appear later at the posterior end.

The upper half of the trochophore—that portion above or in front of the prototroch—will become the prostomium (head) containing the brain, the eyes, and the prostomial appendages, if present in the adult polychaete. The lower half of the trochophore contains the digestive tract, excretory organs, and other internal organs; it is also the site of future segmentation. The mouth and anus form during the trochophore stage, but the digestive tract may or may not be functional at that point.

Typically, the first three segments form almost simultaneously in the lower half of the trochophore. Development of the parapodial lobe and the appearance of larval bristles (setae) follow shortly thereafter. The body grows in length by the addition of new segments from the preanal segment (pygidium or tail), which is the site of all additional segment formation. The setae generally fall off the first segment, which becomes the adult peristome, or first post-toral segment. The parapodial lobes of this segment either develop peristomial appendages or atrophy, depending upon the polychaete species. Adult setae gradually replace larval setae on the second and third segments.

Although the features of the trochophore larva are relatively uniform among species within an order, the nature of the larva also depends upon other factors—e.g., egg size and larval ecology. Species lacking a pelagic trochophore stage show special adaptive features—e.g., protection by a parent, formation of an egg capsule, the discharge of eggs within one of the parent's tubes, or viviparity (live birth rather than hatching from eggs). The young of species with a short pelagic larval life—a few days or less—either are protected by a parent throughout much of larval life or are hatched from small eggs, with little or no yolk. The most common polychaete trochophore feeds and has a long pelagic life; food consists of microscopic organisms such as diatoms or dinoflagellates. Structural modifications, usually large numbers of setae or bands of cilia around each newly formed segment, facilitate the long pelagic life. After settling, the young polychaete quickly loses its trochophore characteristics and begins to resemble the adult.

Development of
oligochaetes in
cocoons

Development in oligochaetes takes place entirely within the cocoon; there is no free-living larval stage. The cocoon of the aquatic lower oligochaetes contains large eggs and relatively little albumin. The cocoon of the terrestrial higher oligochaetes contains small eggs but large amounts of albumin, which nourishes the developing embryos. The oligochaetes undergo a highly modified form of spiral cleavage. The ectoderm, endoderm, and mesoderm, however, arise in the same manner as in the polychaetes. The elongated gastrula has a ventral mouth at the front end and a posterior anus. At the gastrula stage, earthworms begin to feed on the albumin, the embryo elongates, and the mesoderm bands break into units to form the walls, or septa, of individual segments; the worm then leaves the cocoon and begins to construct a burrow nearby.

Early development in the leeches is similar to that of the oligochaetes. The mesodermal bands form the individual segments as in the oligochaetes, beginning anteriorly. As these mesodermal bands hollow out to form the coelom, mesenchymal cells from the lining of the coelom begin to form one large coelomic cavity extending the entire length of the worm; as the number of mesenchymal cells

increases, however, the coelom becomes filled with them. This is the characteristic state of adults. Young leeches hatch from cocoons after feeding upon albumin.

Life-span. Since both the polychaetes and oligochaetes are able to regrow lost parts—i.e., regenerate (see below)—it may appear that they are essentially ageless. Few longevity studies have been carried out with polychaetes, however. Most of the adults of species studied have a characteristic number of segments, which form rapidly during early life and prior to the appearance of gametes. Many polychaetes, especially among the nereids, reproduce only once and then die. In nature these worms, usually quite sluggish after spawning, are eaten by fish and other animals. Species of polychaetes are known to live from one month (*Dinophilus*) to three years (*Perinereis*). Species that form stolons (stems), such as the syllids, or whose posterior end breaks off, such as the palolo, are capable of repeating the process; but the number of times and the length of time they are able to do so have not been established. Most sedentary polychaetes survive following spawning, but, again, it is not yet known how often this process can be repeated.

The life-span of oligochaetes is better established because they are frequently used in laboratory experiments. Asexual reproduction for 130 generations has been reported in one aquatic species. Some earthworms are believed to live as long as 10 years. Senescence, or aging, is known to occur in oligochaetes; *Eisenia*, for example, lives beyond a reproductive period with a progressive loss of weight. Aging oligochaetes darken in colour, largely as a result of an increase in pigment deposition. In addition, the metabolic rates decrease, and their physiological processes slow.

Little is known about the life-span of leeches. One species of *Erpobdella* requires a year to reach sexual maturity, after which it lays cocoons once and dies. Another species breeds once a year for two years and dies during the third.

Regeneration. It has been said that annelids are the most highly organized animals with the power of complete regeneration. The powers of regeneration are greater in the polychaetes and lower oligochaetes than in the higher oligochaetes; leeches lack the ability to regenerate. Most polychaetes and oligochaetes can regenerate a new tail. The ability to replace an amputated part is usually restricted to the anterior end, where lost segments are replaced either by the same number or fewer; if fewer segments form, internal reorganization of the organ system follows. Regeneration from a single segment occurs naturally in the polychaetes *Ctenodrilus* and *Dodecaceraia*.

The process of regeneration occurs in a series of steps. First the wound seals over; then a structure (blastema) forms on the surface of the wound. New tissue probably arises from preexisting parent tissue, although mesodermal regenerative cells known as neoblasts, which migrate to the site of the injury, are found in polychaetes and lower oligochaetes. As healing begins, RNA (ribonucleic acid) accumulates at the wound site, first in the epidermal cells and later in mesodermal cells. The amount of glycogen, a complex carbohydrate that serves as an energy source in animals, in the oligochaete *Eisenia* decreases markedly near the point of injury, returning to normal only after regeneration is complete.

There is evidence that specific hormones control regeneration in both polychaetes and oligochaetes. A hormone from the posterior part of the brain is essential for posterior regeneration; its presence is apparent only after the second or third day following injury. A mature *Nereis* is unable to regenerate unless brains from young worms with tails removed are implanted in its coelom.

Reversal of anterior-posterior polarity has been obtained in an earthworm (*Perionyx excavatus*). A piece removed from the anterior end regenerates a head at both cut ends if the cuts are made simultaneously. If the new anterior head then is removed, the posterior head becomes dominant and evokes tail regeneration at the surface from which the new anterior head was removed.

Ecology. There are no marine habitats containing specific polychaetes as there are for mollusks and echinoderms. Many species, such as *Neanthes arenaceodentata* and *Capitella capitata*, cosmopolitan in distribution, are

Aging in
oligo-
chaetes

Steps
involved in
regeneration

found throughout the world. Aquatic oligochaete species are widespread in suitable environments; terrestrial forms are less widely distributed, except for the earthworm and others that have been transported to new habitats, generally inadvertently, by humans. The distribution of leeches is similar to that of oligochaetes, with the aquatic forms more widely distributed.

Mechanisms of adaptation

Some oligochaete species can secrete a tough mucous covering to protect themselves against either summer heat or winter cold. Some terrestrial burrowing forms burrow deeper into the ground during periods of adverse conditions. Some aquatic leeches burrow deep into the bottom of a pond or stream during the warm months. Polychaetes have no known mechanism for adapting to adverse conditions.

Locomotion. The basic features of locomotion in annelids are most easily observed in the earthworm because it lacks appendages and parapodia. Movement involves extending the body, anchoring it to a surface with setae, and contracting body muscles. When the worm begins a forward movement, circular muscles at the anterior end contract, extending the head forward. At the same time the anterior end lifts from the surface to facilitate forward movement. A wavelike contraction originating in the circular muscles then passes toward the posterior end. When the wave of contraction nears the mid-region of the body, longitudinal muscles contract, thereby shortening the region. A wave of contraction of longitudinal muscles follows, and the cycle is repeated. The setae of a segment are extended by certain body muscles to prevent backward movement of the segment during the contraction of the longitudinal muscles. The setae are retracted during the circular contraction period. Muscular movement is aided by the compartmentalization of the segment—coelomic fluid, confined by the segment walls, provides a substance against which the muscles can work. The earthworm is capable of reversing the direction of its movement; the waves of contraction pass forward.

Locomotion in free-moving polychaetes is accomplished by circular, longitudinal, and parapodial muscles and by coelomic fluid. When a worm such as *Nereis* moves slowly, the contractual force comes from the sweeping movement of the parapodia. The parapodia of each segment are not aligned, and the effective stroke is the backward one, in which the aciculae (needlelike processes) are projected beyond the parapodium and come in contact with the crawling surface. In the recovery, or forward, stroke, the aciculae retract, and the parapodium lifts free of the surface. When a parapodium ends its backward stroke, the next parapodium initiates one. Body undulations, which help the worm to move rapidly, are produced by the contraction of longitudinal muscles stimulated by the backward stroke of parapodium of a particular segment.

Locomotion in the burrowing polychaetes, especially those forms lacking anterior appendages, is similar to that of the earthworm. In tube-dwelling sedentary forms, such as the Sabellidae, locomotion is restricted to movement within the tube. In this group, the parapodia are reduced or absent; specialized setae, the uncini, function in much the same way as do parapodia in free-moving forms.

Use of suckers in leeches

Locomotion in the leech may be compared, in part, to that of the inchworm (immature members of the moth family Geometridae); the anterior and posterior suckers serve as points of contact. When the posterior sucker attaches to a surface, the circular muscles contract, beginning at the posterior end. The leech thus elongates and the anterior sucker fastens to the surface. When the posterior sucker is released, a wave of contraction of the longitudinal muscles moves in a forward direction; this completes one cycle. During swimming, the dorsoventral muscles maintain a contracted state, and undulations of the body are produced by waves of contraction of the longitudinal muscles.

Food and feeding. The nature of the food and feeding methods of the polychaetes is closely related to the structure of the species, particularly of the anterior end. Those species that feed on large particulate matter have a pharynx either with jaws (*Glycera*) or without (*Phyllodoce*); both types can be either herbivorous or carnivorous feed-

ers. Those species that feed on fine particulate matter may be filter feeders, surface-deposit feeders, or burrowers. Filter feeders either capture floating material with ciliated tentacles (*Sabella*) or pump water through their burrows and capture the fine material on a mucous secretion, upon which they feed (*Chaetopterus*). Surface-deposit feeders may take in material through a pharynx provided with jaws (*Neanthes*), with an unarmed pharynx (*Cirriiformia*), or with numerous long ciliated tentacles capable of extending one metre or more (*Terebella*). Burrowers have a structure similar to that of surface-deposit feeders and can be related species. *Pectinaria* lives with its anterior end in the sediments and feeds on fine material with its tentacles.

The diet and feeding mechanisms in oligochaetes are not as varied as those in polychaetes. Terrestrial oligochaetes, such as the earthworm, are scavengers and feed upon decaying organic material, especially of plant origin. Some aquatic oligochaetes, aside from being scavengers, feed on micro-algae or protozoans and other microscopic animals.

Leeches are primarily bloodsuckers. The medicinal leech *Hirudo* feeds principally on mammalian blood, but it also sucks blood from snakes, tortoises, frogs, and fish; when young, it may eat oligochaetes. Feeding is facilitated by the secretion of hirudin. The leech detaches after becoming engorged with blood, and it may not attempt to feed again for up to 18 months. Marine leeches attach to, and feed directly from, the gills of fish. Other leeches are carnivorous and feed on oligochaetes and snails.

Behaviour and associations. Various polychaetes (for example, *Syllis*, *Chaetopterus*, *Cirratulus*, *Terebella*) are bioluminescent—that is, capable of producing light. The phenomenon occurs within the cells of *Polynoe*; the lower surfaces of some scale worms (*Halosydna*) have special photocells that produce light when stimulated. *Odontosyllis* light production is related to sexual maturity and swarming, which is influenced by lunar cycles. The female produces a bright luminescence that attracts the luminescent male; light production decreases in the female following the release of gametes. In the order Chaetopterida, the process, which involves the discharge of a luminescent secretion from certain segments and from the antennae, is under nervous control; in *Chaetopterus*, light can be produced in the parapodia by stimulating the ventral nerve. The significance of light production in this genus is unknown, however, because it lives in a tube through which light rays cannot pass. When stimulated, some earthworms produce a luminescent slime from the mouth, anus, dorsal pores, or excretory pores; it is possible that the light is produced by bacteria living in the worm. Luminescence is unknown in leeches.

Bioluminescence

Polychaetes, especially the tube-dwelling Sabellida, generally respond to changes in light intensity by withdrawing into their tubes.

Aggressive behaviour has been reported in several species of nereids (a group of free-moving polychaetes); they respond to a stimulus by extending the proboscis (feeding organ) to expose the jaws. *Neanthes arenaceodentata* fights members of its own sex but not those of the opposite sex. The response may be related to spawning since this species does not swarm but lays gametes in the tube of another individual; fighting thus prevents the occupation of one tube by two individuals of the same sex.

Both polychaetes and oligochaetes can learn to choose between favourable and unfavourable environments. In an experiment earthworms try about 12 times to bring into their burrow a leaf made immobile by attachment to some object; when an unattached leaf is presented to the worm, it turns to it and ignores the immobilized leaf thereafter.

Commensalism, a beneficial relationship between two types of organisms, is common among certain scale worms (Phyllodocida, an order of polychaetes). These worms may be found in the tubes of sedentary polychaetes, in the mantle cavity of mollusks, such as chitons and limpets; and on certain echinoderms, such as the starfishes and in the rectums of sea cucumbers. The scale worm *Arctonoe*, which normally lives on starfishes, is attracted to water flowing from the host starfish but not to that from other starfish species. It has been established that the attractant in the water is a chemical secreted by the host, but its

Commensalism and parasitism

nature is unknown. Tube-dwelling polychaetes, such as *Chaetopterus*, may be the host to scale worms, pea crabs, or fish, which eat material carried in by water currents produced by the host. Commensalism occurs in some aquatic oligochaete species. The posterior end of *Aspidodrilus*, for example, is modified as a large sucker for attachment to other worms.

Parasitism is rare in polychaetes. Myzostomida, an atypical polychaete group, are commensal or parasitic either on the surface of or within echinoderms, primarily the crinoids. Polychaete species that live on the surface feed on fine particles carried to the mouth of the crinoid. Parasites that live within crinoids may be found in the body wall, the coelom, or the digestive tract. Parasitic infestations by polychaetes are frequently severe enough to cause wartlike growths on the surface of the host; such growths have been noted on the surfaces of fossil crinoids of the Paleozoic Era (more than 225,000,000 years ago), indicating that these parasites established themselves early. Some forms, such as *Iphitime*, are parasitic in the branchial chamber of crabs. The young stages of the cosmopolitan polychaete species *Arabella iricolor* develop in the coelom of species of another polychaete (*Diopatra*). Some aquatic oligochaetes live in the ureters of toads or in the eyes of frogs. All members of the order Branchiobdellida are parasitic in the brood chambers of the crustacean isopods or on the gills of crayfish, where they suck blood. Many leeches, all of which feed on blood, attach to the host only during feeding. Marine leeches, however, attach permanently to their fish host.

FORM AND FUNCTION

External features. The body of an annelid is often described as a tube within a tube. The inner tube, or digestive tract, is separated from the outer tube, or body wall, by the coelom. The head region (prostomium) is followed by a series of segments similar to each other in appearance. The body in many species, especially in the sedentary polychaetes, is separated into two or three regions. The cells constituting the epidermis (outermost cell layer) are usually simple columnar epithelial cells covered

by a cuticle; parts of the body may be ciliated, especially in smaller forms. The cuticle consists of thin layers of protein similar in composition to that of the collagen found in some vertebrate tissues.

The body form of polychaetes (see Figure 3) varies, depending on whether the polychaete is free-moving, sedentary, or pelagic (ocean-dwelling). The first segment, the prostomium, is in front of the mouth and may be a simple lobe or a highly developed projection. The next segment, the peristome, surrounds the mouth and is followed by a series of segments, the total number of which may be limited or unlimited. The parapodia, fleshy outgrowths on each segment following the peristome, contain bundles of setae (movable bristles), which differ in structure and function among species and thus provide a key to species identification. A seta consists of a basal portion within a follicle and a shaft projecting from the follicle; it is secreted from an epidermal cell, which encloses both the ciliary apparatus from which the seta arises and the lacuna in which the seta develops and through which it pushes to the outside. Composite, or pointed, setae are formed from two or more epidermal cells. New setae form in reserve follicles and move forward to replace old ones, which are discarded.

Branchiae, or gills, are not found in polychaete species that breathe through the body wall. When present, they are simple filaments or tufts near the anterior end of the worm. A mass of feeding structures in sabellid and serpulid polychaete worms, called a tentacular crown, functions both for food gathering and for respiration. Polychaete sensory receptors include eyes, lateral organs, dorsal ciliated ridges, statocysts (organs of balance), taste buds, papillae (blunt-shaped projections), and stiff hairs. The eyes, which range in complexity from simple pigment spots to eyes with lenses, may be found on the prostomium, on the peristome, on the pygidium, along the sides of the body, or on the tentacular crown.

The oligochaete body (see Figure 1) is usually cylindrical, is sometimes flattened, and rarely has projecting structures. Segmental lines are usually conspicuous, and secondary segmentation may occur in larger forms. The

Polychaete structure

number of segments varies from seven in some aquatic species to 600 in the earthworms. Setae, embedded in the body wall, may be simple, S-shaped, forked, or hairlike. Except for the first, each segment may have either two pairs of S-shaped setae or a circle of setae. Many transitional forms of setal arrangement occur, and copulatory setae are found on some segments in certain species. All sexually mature oligochaetes have a clitellum (a glandular structure derived from the epithelium), which secretes the egg capsule; it may be saddle-shaped or ring-shaped. In lower oligochaetes it consists of a single layer of modified epithelial cells; in higher forms, such as earthworms, it may have many layers.

The ends of nerves, which probably respond to touch, heat, and pain, branch among the epidermal cells of oligochaetes. Epithelial sense organs resembling taste buds occur in the skin and mouth cavity; they probably function as chemoreceptors (*i.e.*, smell and taste receptors). Photoreceptors, or light-sensitive organs, are abundant at the anterior and posterior ends of earthworms. Earthworms respond negatively to strong light but are attracted to weak light. All oligochaetes are strongly stereotactic (attracted to surfaces). Some forms have pressure receptors, sensory hairs, and pits.

A leech (see Figure 4), which has 34 segments, may increase in length as a result of subdivision and elongation of the annuli, or rings, that divide each segment. The typical number of annuli per segment in the mid-region is three to five. The anteriorly located eyes usually vary in number from one to five pairs. The clitellum, which is present during reproduction, extends from segments 10 through 12. The most conspicuous of the external features of the leech are the small anterior and the large posterior suckers.

Internal features. *Tissues and fluids.* The body cavity of annelids is lined by epithelium. Successive body segments are separated by walls that correspond to the external rings. In grooves between the segments of some oligochaetes are dorsal pores through which coelomic fluid may be discharged. As the leech develops, its coelom becomes nearly filled with connective tissue. Internal features of the three annelid classes are shown in Figures 1 (oligochaetes), 3 (polychaetes), and 4 (leeches).

The coelomic fluid of annelids plays a role in many important functions—*e.g.*, locomotion and regulation of fluid transfer through the body wall (osmoregulation). Many metabolic processes occur in the coelom, which also serves as a site for temporary food storage, for excretion of nitrogen-containing wastes, and for maturation of gametes. The coelomic walls of earthworms contain cells, called chloragocytes, that store and metabolize oil and glycogen and produce ammonia and urea. The chloragocytes eventually disintegrate in the coelomic fluid, and their granules are taken up by amoebocytes, which increase in size, becoming large brown bodies that are never eliminated from the body.

Osmo-
regulation

The fluids of marine polychaetes have the same salt balance as (*i.e.*, are isosmotic with) the surrounding seawater and thus can tolerate no more than a moderate change in the salt (*i.e.*, ion) content of the salt water. Coelomic fluids contain little or no protein. Certain aquatic oligochaetes, however, which live exclusively in fresh water, are capable of regulating the internal medium because, although their coelomic fluid contains fewer salts than does that of polychaetes, it contains more proteins. Freshwater leeches have osmoregulatory mechanisms similar to those of oligochaetes.

The body wall of a typical marine polychaete, such as *Perinereis cultrifera*, which cannot adapt to salinity fluctuations of seawater, swells and bursts if salinity is reduced to 20 percent that of seawater because the worm has no physiological mechanism for the control of water intake. On the other hand, certain individual *Nereis diversicolor* worms are capable of tolerating intertidal changes of salinity because they have enlarged nephridia that enable them to excrete excess water.

Nervous system. The nervous system of free-moving polychaetes is similar to that of oligochaetes. It consists of a dorsal brain, or supraesophageal ganglion, which is a dis-

Figure 4: The internal structure of leeches.

From D.J. Reish, *Laboratory Manual for Invertebrate Zoology*

crete mass of nervous tissue in the prostomium; a pair of nerves united ventrally to form the ventral subesophageal ganglion; and paired nerve cords with one ganglion per segment. In sedentary polychaetes, the brain may become highly modified.

The muscles of annelids are coordinated both by the ventral nerve cord, which is composed of two strands and extends the length of the worm, and by a ganglion and nerves located within each segment. The nerves within each segment carry impulses away from the ganglion (motor nerves) or toward it from a sensory receptor (sensory nerves). The cell bodies of sensory nerves are located beneath the surface epithelium; those of motor nerves are either within the ganglion or in separate parapodial ganglia. Each segmental nerve innervates those components of the body wall, parapodia, and the digestive tract found in its segment.

The nerve cord of many annelids has giant nerve fibres (neurochords), which may have either a simple or a compound structure. Simple neurochords are very large single nerve cells; their axons arise from cells situated in either the brain or a segmental ganglion. Compound neurochords are multiple structures; each axon is connected to numerous cell bodies along its course. The function of the giant nerve cord is the rapid transmission of impulses from one end of the worm to the other; this enables the longitudinal muscles of each segment to contract at about the same time. The value of rapid contraction is evident in the escape reaction of tube-dwelling sedentary polychaetes.

Some giant nerve fibres convey impulses as fast as vertebrate nerve fibres (about 21 metres per second); annelid fibres, however, are larger in diameter (1.5 millimetres in *Myxicola*) and lack a thick insulating sheath (myelin). Not only is recovery from the passage of impulses slower in giant nerve fibres than in other annelid nerves but the former are also the last component to develop in the nerve cord of a growing worm. The nerve cord of *Myxicola* contains one giant nerve fibre, which is used to study the properties of the nerve impulse. In *Myxicola*, an impulse may be conducted in either direction along the nerve, unlike *Nereis* or the earthworm; may be initiated at any level; and is an all-or-none action.

Digestive system. The polychaete digestive system is

Compar-
ison with
vertebrate
fibres

generally a straight tube; a mouth leads into an esophagus, which is followed by the intestine and the anus. Some free-moving forms have a proboscis that can be thrust forward by being turned inside out—that is, the proboscis is eversible. In oligochaetes such as the earthworm, the mouth opens into a muscular pharynx, which opens to the esophagus and then to a muscular gizzard. The intestine, which extends most of the length of the worm, terminates in an anus. In leeches, the mouth, surrounded by the anterior sucker, opens into the esophagus; the crop and intestine follow—each with minute pockets (diverticula)—then the rectum and anus.

Most annelids, except leeches, either lack or have poorly developed diverticula, minute pockets that serve as digestive glands. Instead, the gut lining contains secretory cells (concentrated in the foregut) and absorptive cells (concentrated in the hindgut). Digestive enzymes are most active in the gut. Digestion within cells has not been demonstrated in annelids. A lengthwise fold, the typhlosole, hangs downward in the intestinal cavity of oligochaetes. The absorptive surfaces of the typhlosole and of the anterior intestine may have a brush border; fats are absorbed only in this region.

Calciferous glands, found only in certain earthworms, apparently excrete calcium by secreting granules of calcium carbonate that are transformed into calcite crystals in the intestine.

Excretory system. The basic units of the annelid excretory system are either protonephridia, which have tubules (solenocytes) that end blindly within cells, contain flagella (whiplike projections), and are joined to a common duct that drains to the outside; or metanephridia, which are funnel-shaped structures containing cilia (short, hairlike processes) that open to the outside.

Ammonia is the chief nitrogen-containing end product of protein metabolism in aquatic annelids; earthworms, adapted to living in the soil, excrete more of another nitrogen-containing compound, urea, probably as part of a mechanism to control salt and water balance in the worm. The sea mouse *Aphrodita*, a polychaete, excretes 80 percent of its nitrogen as ammonia, which is also the primary nitrogenous excretory product in leeches (smaller amounts of urea also are excreted). Part of the ammonia excreted by leeches may come from bacteria in part of the leech's excretory system (nephridial capsules). The ability of leeches to withstand high concentrations of ammonia is believed to result from a protective effect provided by high levels of calcium in their cells.

Three aspects of nephridial function in annelids correspond to those of the vertebrate kidney—filtration, resorption, and secretion. Coelomic fluid filters through solenocytes. The ciliated funnels of metanephridia retain minute particles and those of moderate size. In oligochaetes, whose coelomic fluid contains proteins, particles are actively absorbed in the ciliated region of the tubule. The tubules of earthworms also resorb inorganic ions such as sodium and calcium and can selectively eliminate excretory products from both the coelomic fluid and the bloodstream.

Respiratory system. Gas exchange generally takes place through the skin, but it may occur through gill filaments in some polychaetes or through the rectum of aquatic oligochaetes. Although oxygen may be transported directly in the blood, it is usually carried by a respiratory pigment, either hemoglobin or chlorocruorin. Hemoglobin, the most common pigment, is present in most free-moving and some sedentary polychaetes and in most oligochaetes and leeches. Chlorocruorin is found in several polychaete groups (Flabelligerida, Terebellomorpha, and Serpulimorpha). A few free-moving polychaetes, some oligochaetes, and rhynchobdellid leeches have colourless blood. The blood of the polychaete *Serpula vermicularis* contains both pigments, the young having more hemoglobin and the old more chlorocruorin.

Annelid hemoglobin molecules have several properties in common with the hemoglobin found in vertebrates but differ in molecular weight and in the relative amounts of certain constituents. Chlorocruorin differs from hemoglobin in having a lower affinity for oxygen and in being green in dilute solutions, red in concentrated ones.

The properties of annelid respiratory pigments are associated with the mode of life of the worm. The hemoglobin of the lugworm *Arenicola*, a polychaete, releases oxygen to the tissues only under conditions of extreme oxygen deficiency. The hemoglobin of some earthworms takes up oxygen from a normal atmosphere but releases it only when tissue oxygen is low and, thus, may protect the worm from oxygen poisoning.

Circulatory system. The circulatory system in the lower oligochaetes consists of a dorsal vessel that arises from a blood sinus or capillary network surrounding the intestine and conveys blood forward; a ventral vessel that conveys blood backward; and connective vessels between the two. The blood vessel walls consist of an outer membranous (peritoneal) layer containing muscle fibres, a middle region of collagenous material, and an inner lining of thin cells (endothelium). In higher oligochaetes, one or more pairs of hearts connect the dorsal and ventral vessels and propel the blood. In free-moving polychaetes the dorsal vessel is the chief propulsive force, and networks of small vessels connect the dorsal and ventral ones. In some leeches the blood is propelled by a dorsal vessel connected by loops at both ends to a ventral one.

Blood is moved by wavelike contractions of the blood vessels, by the beating of cilia, or by pumping provided by hearts. In *Arenicola* and the earthworm the heartbeat apparently is initiated in nerve cells rather than in muscle tissue, as occurs in vertebrates. The blood apparently carries nitrogen-containing products to the nephridia for excretion. The only blood cells are amoebocytes, which are free-moving cells that engulf particles.

Hormones. The brain contains several types of cells whose secretory activities relate to phases of the life cycle, especially those of reproduction, growth, and regeneration.

Neurosecretory cells, which are nerve cells that produce hormones, are found in the brain; their structure, similar to that of nonsecretory nerve cells, consists of fine projections (an axon and neurofibrils) and a cell body. The secretions of neurosecretory cells, which terminate in the walls of a blood vessel, in other fluid systems, or in the epidermis, are in the form of microscopic droplets or granules. Neurosecretory cells seem to be derived from epidermal secretory cells that have been incorporated into the central nervous system.

Inhibitor hormones are known in some Phyllodocida, and a stimulator substance has been identified in Drilomorpha, both of which are polychaete groups. (For a discussion of inhibitor hormones in nereids and syllids, see above *Reproduction*.) The maturation of gametes is apparently inhibited in nephtyid polychaetes by neurosecretions of the brain. The brain of the lugworm *Arenicola* stimulates maturation of gametes.

The brain has been shown to play a role in the regeneration of the posterior end of the body of polychaetes such as nereids and nephtyids, but the effect may be an indirect one involving the genital inhibiting hormone. Neurosecretory cells occur in the brain and subesophageal ganglia of several terrestrial and aquatic oligochaete species. Removal of the brain from sexually maturing earthworms causes degeneration of the clitellum and prevents gamete formation. The brain also plays a role in osmoregulation, as indicated by the increase in chloride concentration in the urine of oligochaetes lacking a brain. The neurosecretory cells in the brain of leeches control gamete formation.

EVOLUTION AND PALEONTOLOGY

The annelids are considered to have evolved in the sea, perhaps from an ancestral flatworm that evolved through the trochophore larva, the characteristic early stage of polychaetes. The oligochaetes are thought to have developed from polychaete stock; the leeches, which have the clitellum in common with the oligochaetes, probably evolved from the latter (see Figure 5).

The question of which polychaete order preceded the others remains unresolved. The Archiannelida were long considered to have been the earliest polychaete group because of their primitive condition; however, some members (e.g., *Polygordius*) that lack setae and external segmentation and have simple nervous, muscular, and circulatory

basic
elements

Neuro-
secretory
cells

respiratory
pigments

Early de-
velopment

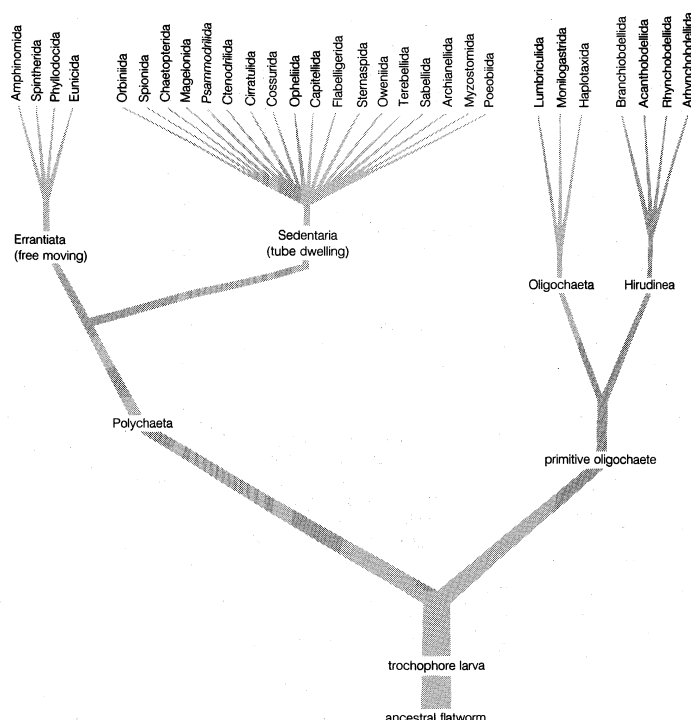

Figure 5: Possible origin of relationships among annelids.

systems are now considered to be a specialized group. *Polygordius* species typically are small in size; they have cilia on their surfaces for locomotion, respire through the skin, and have internal fertilization. Finally, the larvae undergo non-pelagic development. The polychaetes appear therefore to have undergone radiative evolution, in which every character has been modified independently of the others. There is thus little basis for regarding any one order as ancestral to the others.

Adaptation
to fresh
water

The evolution of oligochaetes from polychaetes may be related to the change from a marine to a freshwater habitat. One view is that oligochaetes evolved in marine swamps and were subjected to periodic drying; survival during dry periods would have been made possible by egg cocoons. A contrary hypothesis is that the primitive oligochaete was adapted to permanent freshwater conditions rather than to a terrestrial habitat. Some authorities consider the oligochaetes to have evolved from some members of the order Eunicida (e.g., the family Lumbrineridae) or the order Capitellida (e.g., the family Capitellidae), but this may result from a superficial resemblance in body form and thus may be of little evolutionary significance.

Reproductive structures provide not only the main criteria for understanding the course of evolution within the oligochaetes, but the basis for the classification of oligochaetes as well.

Each of the oligochaete orders, Lumbriculida, Monilogastrida, and Haplotaenida, is considered to have evolved separately from primitive oligochaetes. Many, however, believe that two paths of evolution occurred. In one pathway, the vas deferens (the tube carrying sperm from the testes) opened outward on the segment immediately behind the segment that contains the testes and evolved into two lines differentiated on the basis of whether the seminal receptacle (a storage cavity) opened in front of the testes, or at the same segment, or posterior to the testes. In the second principal pathway, the vas deferens opened a few segments behind the testes.

There is little doubt that the leeches evolved from the primitive oligochaetes, since both groups have a clitellum, at least during the reproductive period, and both are hermaphroditic. The Acanthobdellae are considered to be the link between the oligochaetes and leeches because they possess setae and walls between segments; the order contains only one known species, however. The three remaining orders of leeches evolved into two lines based on whether or not the animals have jaws.

The fossil record of annelids is limited because they have almost no hard body parts. Tubes constructed by polychaetes and polychaete jaws are the most commonly encountered fossil specimens. Most fossil records of oligochaetes are doubtful, and fossil leeches are unknown. Some burrows, or tubes, have been interpreted as belonging to wormlike creatures from Precambrian strata (more than 620,000,000 years old). Fossils resembling the scale worm *Halosydna* and the sea mouse *Aphrodita*, *Nereis*-like forms, and calcareous tubes similar to present-day *Serpula* and *Spirorbis* species have been described. The shells of Paleozoic mollusks (more than 230,000,000 years old) are occasionally marked by U-shaped tubes similar to those made by the polychaete *Polydora*, a modern-day pest of oysters. The tough jaws of polychaetes, containing minute spiny black teeth known as scolecodonts, occur from the Cambrian Period (about 570,000,000 to 500,000,000 years ago) onward.

Fossil
record

CLASSIFICATION

Distinguishing taxonomic features. Classification of free-living and sedentary polychaetes relies almost exclusively on external characters, such as the shape of the head, and on the number and nature of structures, such as appendages (including anal ones), parapodia, and setae, and on tube construction. Oligochaete classification relies largely on internal structures, especially the arrangement and number of gonads, the position of the gonoducts, and particularly the location of the male pore. Setal characteristics are generally uniform among species. Leech classification is based on the presence or absence of setae and the nature of the mouth, proboscis (feeding organ), jaws, suckers, eyes, and reproductive system.

Annotated classification. The following classification incorporates the views of several authorities.

PHYLUM ANNELIDA (segmented worms)

Body wall covered with a cuticle secreted by the epidermis and containing an outer circular and inner longitudinal muscle layer; chitinous (tough, complex carbohydrate material) setae usually present, secreted by follicular cells and arranged segmentally; head or prostomium preoral, with or without appendages; closed circulatory system, with blood often containing a respiratory pigment; coelom, of schizocoelomic origin, divided segmentally into compartments by walls, or septa; nervous system includes a dorsal, bilobed brain and a pair of connective nerves that encircle the digestive tract and unite to form a ventral nerve cord with 1 ganglion per segment.

Class Polychaeta (marine worms)

Paired lateral appendages, or parapodia, bearing chitinous setae; name of group refers to the many setae per segment; head with or without appendages; sexes generally separate with gametes discharged directly into the water, where fertilization and development occur; the free-swimming larva called a trochophore; more than 6,000 living species; free-moving and sedentary (tube-dwelling) forms.

Order Aphroditomorpha (scale worms)

Free-moving; dorsally rounded, with flattened pairs of scales more or less alternating with the dorsal cirri (slender projections); head with 1 or 3 tentacles, 2 palpi (fleshy sensory projections), and 4 tentacular cirri used for feeding and respiration; projecting (protrusible) proboscis cylindrical in shape, with border of soft papillae (nipplelike projections) and 4 chitinous jaws; size, 0.5 to 25 cm; examples of genera: *Aphrodita* (sea mouse), *Halosydna* (common scale worm), *Arctonoe*.

Order Amphinomida

Free-moving; prostomium with 1 to 5 antennae, 2 palpi, and a caruncle (posterior ridge) deeply set into anterior segments; parapodia with 2 lobes and branchiae (gills); size, 0.5 to 35 cm; examples of genera: *Eurythoe* (fireworm), *Euprosyne*.

Order Spintherida

Body oval; median antenna on prostomium; pharynx retractable; dorsal surface with membranous ridges; ventral setae strongly curved; found on sponges; small; single genus, *Spinther*.

Order Phyllodocida

Free-moving; a large group characterized by a protrusible proboscis that may or may not be armed with chitinous jaws, teeth, or papillae; prostomium with 1 to 5 antennae, with palpi, and with 0 to 3 pairs of eyes; parapodia well developed into 1 or 2 lobes usually bearing compound setae; size, 0.2 to over 1 m; examples of genera: *Anatides*, *Syllis*, *Hesione*, *Nereis*, *Glycera* (bloodworm), *Nephtys*, *Halosydna*.

Order Eunicida

Free-moving; head with or without appendages and eyes; proboscis with dorsal maxillae (upper jaws) of 1 to many paired pieces, a ventral pair of mandibles (lower jaws) more or less fused along the median line, and a pair of embedded maxillary carriers; parapodia single-lobed, often with many aciculae (needlelike structures); size, minute to 3 m; examples of genera: *Palola* (palolo), *Eunice*, *Stauronereis*, *Lumbineris*, *Onuphis*.

Order Orbiniida

Sedentary; head pointed or rounded without appendages; proboscis eversible and unarmed; body divided into distinct thorax and abdomen; gills arise dorsally from thoracic region; size, minute to 40 cm; examples of genera: *Scoloplos*, *Paraonis*.

Order Spionida

Sedentary; at least 2 long feeding tentacles adapted for grasping and arising from prostomium; size, 0.5 to 25 cm; examples of genera: *Spio*, *Polydora*.

Order Chaetopterida

Two to 3 distinct body regions; prostomium with palpi; modified setae on segment 4; tube dweller; examples of genera: *Chaetopterus* (parchment worm), *Spiochaetopterus*.

Order Magelonida

Long, slender bodies divided into 2 regions; prostomium flattened with 2 long palpi arising from the ventral surface at the junction of the prostomium and next segment; capillary and hooded hooks; single genus, *Magelona*.

Order Psammodrilida

Prostomium and peristome lack appendages; parapodia in mid-region long and supported by aciculae; minute; 2 genera, *Psammodrilus* and *Psammodriloides*, each with a single species.

Order Ctenodrilida

No prostomial appendages; no parapodial lobes; setae arise directly from body wall; all setae simple; minute; examples of genera: *Ctenodrilus*, *Zeppilina*.

Order Cirratulida

Sedentary; prostomium pointed and without appendages; 1 or more pairs of tentacular cirri arising from dorsal surface of anterior segments; gills, if present, long and slender, inserted above parapodia; size, minute to 20 cm; examples of genera: *Cirratulus*, *Cirriiformia*.

Order Cossurida

No prostomial appendages; a single median tentacle arises from the dorsum between segments 2 and 6; parapodia biramous with weakly developed lobes; all setae simple; size, usually less than 2 cm; *Cossura*.

Order Opheliida

No prostomial appendages; body with limited number of segments; setae all simple; size, 1 to 10 cm; examples of genera: *Ophelia*, *Polyophthalmus*, *Scalibregma*.

Order Capitellida

No prostomial appendages; 1 or 2 anterior segments without setae; parapodia biramous; setae all simple; size, 1 to 20 or more cm; examples of genera: *Capitella*, *Notomastus*, *Arenicola*, *Maldane*, *Axiiothella*.

Order Flabelligerida

Sedentary; setae of anterior segments directed forward to form a cephalic (head) cage; prostomium and peristome retractile, with 2 palpi and retractile branchiae; size, 1 to 10 cm; examples of genera: *Flabelligera*, *Stylariodes*.

Order Sternaspida

Sedentary; anterior setae short and thick; posterior end with ventral shield bearing radiating setae and anal branchiae; size, 3 cm; genera include *Sternaspis*.

Order Oweniida

Sedentary; anterior end with or without divided lobed membrane; anterior segments long; dwelling tube mucoid, coated with sand or shell fragments; size, 0.2 to 10 cm; genera include *Owenia*.

Order Terebellida

Sedentary; head concealed by filamentous tentacles; branchiae, simple or branched, arising from dorsal surface of anterior end; body divided into thorax and abdomen; tube of mucoid substance to which sediment adheres; size, 1 to 40 cm; examples of genera: *Amphicteis*, *Terebella*, *Pista*, *Thelepus*.

Order Sabellida (feather dusters)

Sedentary; head concealed with featherlike filamentous branchiae; body divided into thorax and abdomen; tube mucoid or calcareous; size, minute to 50 cm; examples of genera: *Sabella*, *Eudistylia*, *Serpula*, *Hydroides*.

Order Archiannelida

Minute, primitive, with ciliated epidermis; prostomium small, with or without appendages; parapodia absent; septa reduced or absent; size, minute. Contains 4 groups of poorly known species considered separate orders by some (Nerillida, Dinophilida, Polygordiida, Protodrilida); genera include *Dinophilus* and *Polygordius*.

Order Myzostomida

Body disk-shaped or oval without external segmentation; external or internal commensals or parasites of echinoderms, especially crinoids; size, minute to 1 cm; genera include *Myzostoma*.

Order Poeobiida

Body saclike without external segmentation; anterior end with circle of tentacles; 2 internal septa only polychaete characteristics; pelagic; single genus, *Poeobius*.

Class Oligochaeta

Primarily freshwater or terrestrial with setae arising directly from body wall; name of group refers to the few setae per segment; head and body appendages generally lacking; hermaphroditic, with testes located anteriorly to ovaries; gonoduct system complex; seminal receptacle used to store sperm; reproduction by copulation, with fertilized eggs laid in a cocoon secreted by clitellum; development direct, without larval stages; about 3,250 living species.

Order Lumbriculida (earthworms)

Male gonopores several segments behind segments containing the testes or, when 2 pairs of testes are present, in more posterior segment; size, minute to 30–40 cm; examples of genera: *Haplotaxis*, *Eisenia*, *Lumbricus* (earthworm), *Megascolides*.

Order Moniligastrida

Male gonopores, 1 or 2 pairs on segment posterior to testes; clitellum 1 cell thick; 4 pairs of setae per segment; size, minute to 3 m; examples of genera: *Moniligaster*, *Drawida*.

Order Haplotaxida

Chiefly aquatic worms; male gonopores in segment immediately behind testes; seminal receptacle at or near segment containing testes; size, minute to 1–3 cm; examples of genera: *Nais*, *Tubifex* (sludge worm).

Class Hirudinea (leeches)

Primarily freshwater, but also terrestrial and marine forms; small sucker at anterior end, large sucker at posterior end; fixed number of body segments at 34; body cavity filled with connective tissue; hermaphroditic, with fertilized eggs laid in a cocoon secreted by clitellum; development direct without larval stages; about 300 living species.

Order Branchiobdellida

Head modified as sucker with fingerlike projections; posterior segments also modified to form sucker; body with 14 to 15 segments; all species parasitic or commensal on freshwater crayfish; size, minute; *Stephanodrilus*.

Order Acanthobdellida

Primitive group; setae present on 5 anterior segments; no anterior sucker; parasitic on fish in Lake Baikal (U.S.S.R.); size, small; genera include *Acanthobdella*.

Order Rhynchobdellida

An eversible pharynx used to penetrate host tissue; jawless; distinct blood vessels contain colourless blood; freshwater or marine inhabitants; size, minute to 20 cm; examples of genera: *Glossiphonia*, *Piscicola*, *Pontobdella*.

Order Arhynchobdellida

Pharynx with 3 toothed jaws or none, noneversible; terrestrial or freshwater; bloodsuckers or carnivorous; size, minute to 20 cm; examples of genera: *Hirudo*, *Haemopsis*, *Erpobdella*.

Critical appraisal. Most authors accept the annelids as having three major classes: Polychaeta, Oligochaeta, and Hirudinea. Older systems would place the polychaetes and oligochaetes under the class Chaetopoda because both groups possess setae. Other systems would join the oligochaetes and leeches in a single class, called the Clitellata, because both groups possess a clitellum. The Archiannelida and Myzostomida treated as polychaete orders in the classification system above have been considered as separate classes in the past. The Branchiobdellida are considered an order of Hirudinea, but they have been considered as a separate class in the past or as an order of Oligochaeta. Depending upon the author, annelids could consist of as many as six classes.

Orders were frequently ignored in the past, especially with the polychaetes, but authors have come to greater

agreement as to the placement of families within orders. Placement of annelids within orders has been difficult because of the tremendous diversity in structure and specialization in habitat, especially in the polychaetes.

The class Polychaeta has also been divided into subclasses or orders, the Errantiata (free-moving forms) and Sedentaria (sedentary, or tube-dwelling, forms), based on the mode of living. This arrangement, while convenient, is not based on morphology and is not generally used. The classification system given above lists 23 orders (Archiannelida was considered as one order in the classification above, while other schemes divide the group into four orders). There are approximately 87 known families of polychaetes.

The oligochaetes are divided into three orders based especially on the placement of the male gonopores. There are approximately 43 families in the class. The families of leeches, organized into the four orders outlined above, are generally accepted.

(D.J.R.)

Antarctica

Lying almost concentrically around the South Pole, Antarctica—the name of which means “opposite to the Arctic”—is the southernmost continent, a circumstance that has had momentous consequences for all aspects of its character. It is the fifth largest continent, covering about 5,500,000 square miles (14,200,000 square kilometres), and would be essentially circular except for the outflaring Antarctic Peninsula, which reaches toward the southern tip of South America (some 600 miles [970 kilometres] away), and for two principal embayments, the Ross Sea and the Weddell Sea. These deep embayments of the southernmost Pacific and Atlantic oceans make the continent somewhat pear shaped, dividing it into two unequal-sized parts. The larger is generally known as East Antarctica because most of it lies in east longitudes. The smaller, wholly in west longitudes, is generally called West Antarctica. East and West Antarctica are separated by the 1,900-mile-long Transantarctic Mountains. Whereas East Antarctica consists largely of a high, ice-covered plateau, West Antarctica consists of an archipelago of mountainous islands covered and bonded together by ice.

The continent is almost wholly overlain by a continental ice sheet, containing approximately 7,000,000 cubic miles (30,000,000 cubic kilometres) of ice and representing about 90 percent of the world's ice. The average thickness is about 6,500 feet (2,000 metres). Many parts of the deep embayments of the Ross and Weddell seas are covered by ice shelves, or ice sheets floating on the sea. These shelves—the Ross Ice Shelf and the Ronne and Filchner ice shelves—together with other shelves around the continental margins, constitute about 10 percent of the area of Antarctic ice. Around the Antarctic coast, shelves, glaciers, and ice sheets continually “calve,” or discharge, icebergs into the seas.

Because of this vast ice, the continent supports only a primitive indigenous population of cold-adapted land plants and animals. The surrounding sea is as rich in life as the land is barren. With the decline of whaling and sealing, the only economic base in the past, Antarctica now principally exports the results of scientific investigations that lead to a better understanding of the total world environment. The present scale of scientific investigation of Antarctica began with the International Geophysical Year (IGY) in 1957–58. Although early explorations were nationalistic, leading to territorial claims, modern ones have come under the international aegis of the Antarctic

Treaty. This treaty, which was an unprecedented landmark in diplomacy when it was signed in 1959 by 12 nations, preserves the continent for nonmilitary scientific pursuits.

Antarctica, the most remote and inaccessible continent, is no longer the most unknown area in the world. All of its mountain regions have been mapped and visited by teams of geologists, geophysicists, glaciologists, and biologists. Many hidden ranges and peaks are known from geophysical soundings of the Antarctic ice sheets. By using sophisticated radio-echo sounding instruments, systematic aerial surveys of the ice-buried terrains can be made, and some of these are almost as well mapped as the exposed ones.

The ice-choked and stormy seas around Antarctica long hindered exploration by wooden-hulled ships. No lands break the relentless force of the prevailing west winds as they race clockwise around the continent, dragging westerly ocean currents along beneath. The southernmost parts of the Atlantic, Pacific, and Indian oceans converge into a cold, oceanic water mass with singularly unique biologic and physical characteristics. Early penetration of this Antarctic (or Southern) Ocean, as it has been called, in the search for fur seals led in 1820 to the discovery of the continent. Icebreakers and aircraft now make access relatively easy, although still not without hazard in stormy conditions. Many tourists have visited Antarctica, and it seems likely that, at least in the short run, scenic resources have greater potential for economic development than do mineral and biologic resources.

The term Antarctic regions refers to all areas—oceanic, island, and continental—lying in the cold Antarctic climatic zone south of the Antarctic Convergence, an important boundary with little seasonal variability, where warm subtropical waters meet and mix with cold polar waters. For legal purposes of the Antarctic Treaty, the arbitrary boundary of 60° south latitude is used. The familiar map boundaries of the continent known as Antarctica, defined as the South Polar landmass and all its nonfloating grounded ice, are subject to change with future changes of climate. The continent was ice-free during most of its lengthy geologic history, and there is no reason to believe it will not become so again in the probably distant future. When it does, the inhabitants will know a continent (East Antarctica) and nearby island archipelago (West Antarctica) of about the size of Australia and Indonesia today.

Physical geography

THE LAND

Geologic record. *Antarctica and continental drift.* The geological evolution of Antarctica has followed a course generally similar to that of the other southern continents. The earliest chapters in Antarctica's rather fragmentary record extend far back, perhaps as much as 3,000,000,000 years, into early Precambrian time. Similarity in patterns of crustal and biologic evolution in the southern continents extends up until some 150,000,000 years ago, and evolu-

tionary courses began to diverge conspicuously by about 70,000,000 years ago, or the early Cenozoic Era. Plant and animal migration routes that had apparently freely interconnected all of the southern continents were largely cut off by the beginning of the Cenozoic. Antarctica became isolated at a time when land mammals diversified and flourished elsewhere, populating all the other continents of the world. Antarctica had long been thought to be a migratory path for marsupials moving between southern continents in early Cenozoic time. Documentation for the theory was not discovered, however, until 1982, when the

first mammal remains, a marsupial fossil, were discovered on Seymour Island in the Weddell Sea. The subsequent growth of Antarctica's ice sheets cut off any further migrations by land animals into or across the continent.

Now bathed by polar ice, Antarctica has abundant fossil evidence that its climate and terrain at one time supported far more populous flora and fauna than today's few seedless plants and primitive insects. Remains of a luxuriant extinct flora, as well as fossils of Mesozoic reptiles and amphibians that have been discovered, compare so closely to those of other southern continents that many geologists have postulated former contiguity of these lands in a single, giant continent called Gondwanaland. Continental stratigraphic evidence and the dating of seafloors seem to indicate that the supercontinent broke apart along Jurassic rift faults, and fragments such as Africa and Australia separated from Antarctica in Cretaceous and early Cenozoic times. Early stages of rifting were marked by immense outpourings of plateau lavas (Kirkpatrick Basalt, on Mt. Kirkpatrick) and by related sill intrusions (Ferrari Dolerites) across Antarctica, including one of the world's

largest layered gabbroic igneous complexes, the Dufek intrusion, in the Pensacola Mountains.

Modern theory ties mobile zones to the interaction and jostling of immense crustal plates (see PLATE TECTONICS). Modern plate boundaries may be far different from ancient ones presumably marked by old fold belts. Ancient Antarctic mobile belts, such as are followed by today's Transantarctic Mountains, terminate at continental margins abruptly, as if sliced off, and seemingly reappear in other lands across young ocean basins. Much research has been concentrated on attempting to match intercontinentally the detailed structure of opposed coasts, such as between Antarctica and Australia, in an effort to learn whether they had been actually connected before the latest cycle of crustal spreading from intervening midoceanic ridges.

Structural framework. Most of the Antarctic geologic record lies hidden beneath the vast regions of snow and ice that make up more than 95 percent of the continent's surface terrain. No one knows what important segments of the record lie concealed in buried ranges such

(Left) Researchers working on Seymour Island, where the fossil of a marsupial was discovered in 1982. Among the evidence of former plant and animal life on Antarctica are (top right) the fossil of a leaf, from southern Victoria Land, and (bottom right) the fossil of the skull, nearly 61 centimetres (24 inches) in length, of a capitosaurid amphibian, from the Transantarctic Mountains.

as the Gamburtsev Mountains, the topography of which has been mapped only by seismic reflections through the great East Antarctic Ice Sheet. The extraordinarily thick cover, the extremely difficult working conditions, and the tremendous expense of mounting expeditions into remote areas have long held geologic knowledge of Antarctica far behind that of other continents. Great advances by geologists of many Antarctic Treaty nations, however, have yielded geologic maps of at least reconnaissance scale for virtually all exposed mountain areas.

From results mainly of British expeditions early in the 20th century, the concept arose that Antarctica is made up of two structural provinces—a long, stable Precambrian shield in East Antarctica and a much younger Mesozoic and Cenozoic mobile belt in West Antarctica—separated by the fault-block belt, or horst, of the Transantarctic Mountains. East and West Antarctica have come to be known respectively as the Gondwana and Andean provinces, indicating general affinities of each sector with other regions—that is, the east seems to have affinity with the Gondwana region of peninsular India, and the west seems to represent a southerly continuation of the South American Andes. As new expeditions study and restudy each range in ever-increasing detail, concepts of the geological structure are continually modified. Antarctica's structural record is now known to be more complex than that implied in the past by the simple two-fold continental subdivision.

Crustal
thickness
and
mobility

The average thickness of the Earth's crust for both East and West Antarctica approximates that of other continents. Although it has been postulated that West Antarctica might be an oceanic island archipelago if the ice were to melt, its crustal thickness of about 20 miles indicates an absence of oceanic structure. This thickness is similar to that of coastal parts of other continents. The crust thickens sharply along the Transantarctic Mountains front, possibly a deep crustal fault system, and averages about 25 miles thick in East Antarctica. Significant earthquakes are not known along this or other faults in Antarctica, now the most seismically quiet of all continents. Seismic activity occurs chiefly along surrounding oceanic ridges, with rare minor activity associated with volcanoes of the continent or nearby islands.

The ancient crust of Antarctica must have been highly mobile and the configuration of the continent many hundreds of millions of years ago in the Precambrian far different from today's. Ancient marine and lake basins were

filled with a variety of sedimentary and volcanic debris eroded from primeval lands. During mountain-building episodes these materials were complexly deformed and re-crystallized deep within the crust to form, particularly in East Antarctica, great crystalline-rock complexes. At the surface, rocks were uplifted and mountains were carved by erosion as sediments filled new basins, and new folds of the Earth's crust were formed. Again and again this cycle was repeated during the evolution of Antarctica. Mobility ceased approximately 400,000,000 years ago in the Transantarctic Mountains. Between that time, in the Devonian Period, and about 160,000,000 years ago, in the Jurassic Period, a series of mainly quartzose sediments was laid down in ancient lakes and shallow seas in the sites of former mountain chains that had been carved away by erosion. Known as the Beacon Sandstone, this formation of platform sediments contains a rich record of extinct Antarctic life forms, including freshwater fish fossils in Devonian-age rocks; ancient, temperate forests of trees known as *Glossopteris* in coal deposits of Permian- and Triassic-age rocks (roughly 280,000,000 to 190,000,000 years ago); and large reptiles, such as *Lystrosaurus*, and amphibians in Triassic-age rocks. Tillites—rocks deposited by ancient glaciers—underlie Permian-age coal beds in numerous places in Antarctica just as they do in the other southern, including now tropical, continents. The widespread occurrence of glacial erratics, containing microfossils of Cretaceous and Cenozoic age, indicates the presence of rocks younger than the Beacon Sandstone under ice sheets near the Transantarctic Mountains. The youngest mountain chain in Antarctica is the southward extension of the Andes that makes up the Antarctic Peninsula, Ellsworth Land, and part of Marie Byrd Land.

Beacon
Sandstone

Relief. There are two faces of the present-day continent of Antarctica. One, seen visually, consists of the exposed rock and ice-surface terrain. The other, seen only indirectly by seismic or other remote-sensing techniques, consists of the ice-buried bedrock surface. Both evolved through long and slow geological processes.

Effects of glacial erosion and deposition dominate everywhere in Antarctica, and erosional effects of running water are relatively minor. Yet, on warm summer days, rare and short-lived streams of glacial meltwater do locally exist. The evanescent Onyx River, for example, flows from Lower Wright Glacier terminus to empty into the nondrained basin of Lake Vanda near McMurdo Sound. Glacially sculptured landforms now predominate, as they

must have some 300,000,000 years ago, in an earlier period of continental glaciation of all of Gondwanaland. Through most of its history, however, Antarctica was affected by more normal processes of erosion and deposition, as are other continents today.
