In a homomorphism β of G onto H the set of elements t whose image is the identity of H plays a special role. In particular (see 180) these elements t form a subgroup T . Also for any x of G a simple calculation (see 181) shows that $x^{-1}Tx$ is in T , and so $x^{-1}Tx = T$ is a normal subgroup of G . T is called the kernel of the homomorphism. As a result of a calculation (see 182) it is seen that elements in the same coset of T in G have the same image in H , and conversely it is true that elements of G with the same image in H are in the same coset of T in G . As T is a normal subgroup of G , $xT = Tx$. Consequently, considered as sets of elements in G , $TxTy = T(Tx)y = TTxy = Txy$, so that the product of two cosets of T is a definite single coset. This property is not true of subgroups in general. If W is a subgroup of G , then usually the set of elements $WxWy$ make up a number of cosets of W .

If T is a normal subgroup of G , and if $G = T + Tx_2 + \cdots + Tx_m$, the cosets Tx_i may be taken as elements of a new system H . Here if $x_i x_j$ belongs to Tx_k , then it is true that $Tx_i Tx_j = Tx_k$, considered as sets of elements of G . This new system H is a group, and H is called the factor group of G with respect to T , and this is written $H = G/T$. If the coset Tx_i is the element h_i of H , there is a homomorphism β of G onto H with T as kernel, and $(tx_i)\beta = h_i$. Thus, given a homomorphism β of G onto a group H , the kernel T of the homomorphism is a normal subgroup of G , and conversely any normal subgroup T of G is the kernel of the homomorphism of G onto the factor group G/T . In this way homomorphisms, normal subgroups, and factor groups go hand in hand.

As an example of a homomorphism, the group G of the 48 symmetries of the cube may be considered. Coordinate axes x, y, z are taken joining the midpoints of opposite faces. Then every symmetry of the cube determines a permutation of x, y, z and every one of the six permutations arises, giving a homomorphic image H of order 6. The kernel T of the homomorphism of G onto H is generated by the reflections in the three coordinate planes. Here T is of order 8 and in terms of coordinates consists of transformations $(x, y, z) \rightarrow (\pm x, \pm y, \pm z)$, in which all 8 combinations of the \pm signs arise.

A simple group G is a group that has no proper normal subgroup ("proper" meaning "different from itself or the identity"). The finite cyclic groups of prime order have no proper subgroups and thus are simple groups. There are many other simple groups, the smallest being of order 60. There have been many investigations on simple groups; some of the results will be discussed later.

The notation $G \supset H$ is used to denote that G contains H as a subgroup. A normal chain for a group G is a sequence (see 183) in which each G_i is a normal subgroup of G_{i-1} . If it is not possible to insert a group T between G_{i-1} and G_i so that T is normal in G_{i-1} for any $i = 1, \dots, r$, then the chain is said to be a maximal normal chain. In a maximal normal chain every factor group G_{i-1}/G_i , $i = 1, 2, \dots, r$ is a simple group. A celebrated theorem of Jordan-Hölder states that if a group G has two (or more) maximal normal chains, then the chains have the same number of terms, and the simple factor groups G_{i-1}/G_i in a second chain are isomorphic in some order to the simple factor groups G_{i-1}/G_i of the first. This may be considered an analogue of the fundamental theorem of arithmetic, which asserts that the factorization of a positive integer as a product of primes is unique apart from the order of the factors.

A field is a system of elements with both the operations of addition and multiplication such that addition is an Abelian group and multiplication of elements (excluding zero) is an Abelian group. Also the distributive law $(x+y)z = xz + yz$ holds. Of particular interest are fields of numbers, such as \mathbb{C} , the field of all complex numbers. The rational numbers form a field usually designated as \mathbb{Q} . The numbers $a + b\sqrt{2}$ in which a and b are rational, however, also form a field. If $f(x)$ is a polynomial of degree n with coefficients from the rational field \mathbb{Q} , then

The
Jordan-
Hölder
theorem

$f(x)$ has n roots u_1, u_2, \dots, u_n ; that is, $f(u_i) = 0$, $i = 1, 2, \dots, n$, which are numbers in the field \mathbb{C} .

Then with $f(x)$ is associated a field K , in which $K = Q(u_1, \dots, u_n)$ consists of all numbers obtainable from Q and u_1, u_2, \dots, u_n by adding, subtracting, multiplying, and dividing. It can be shown that there is one irrational number v and an exponent m such that $v^m = a_1 v^{m-1} + \dots + a_m$ with a_1, \dots, a_m rational and such that any number w of K has a unique form (see 184) with rational numbers as coefficients of powers of v . Then it is possible to associate with K , and by implication with $f(x)$, a number of mappings $w \rightarrow (w)a$ of K onto itself such that sums map into sums and similarly for products (see 185). These mappings form a group G the order of which turns out to be exactly the number m defined above. G is called the group of the field K or respectively of the polynomial $f(x)$. Galois's great contribution to group theory and to the solution of equations consisted in relating this group G to the matter of the possibility of solving for the roots of $f(x)$ by radicals. In a normal chain for G , $G = G_0 > G_1 > \dots > G_r = 1$ if every factor group G_{i-1}/G_i is a group of some prime order, then $f(x)$ may be solved by radicals, but not otherwise. For this reason such a group is called a solvable group. For an equation of fifth degree G will in general be of order 120 and will have a normal subgroup of order 60, a simple group. In this situation Abel showed that the equation could not be solved by radicals.

DIRECT PRODUCTS; ABELIAN GROUPS

If any two groups G_1 and G_2 are considered, the ordered pairs (x_1, x_2) with x_1 from G_1 and x_2 from G_2 form a group according to the rule that defines products of pairs (see 186). This group is called the direct product of G_1 and G_2 and is written $G_1 \times G_2$. It is easy to see that $G_1 \times G_2$ and $G_2 \times G_1$ are isomorphic. The ordered pairs $(x_1, 1)$ form a subgroup of $G_1 \times G_2$ isomorphic to G_1 and the ordered pairs $(1, x_2)$ a subgroup isomorphic to G_2 , so that in this natural way G_1 and G_2 may be considered as subgroups of $G_1 \times G_2$, and because of a simple relation (see 187) the direct product is generated by G_1 and G_2 . In the same way, for any finite integer n , given n groups G_1, G_2, \dots, G_n the finite sequences (x_1, x_2, \dots, x_n) with x_i from G_i , $i = 1, 2, \dots, n$, and the product rule (see 188) form the direct product $G_1 \times G_2 \times \dots \times G_n$ that contains the G_i as subgroups and is generated by them. If there are infinitely many G_i 's, it is still possible to define a group by the rule that is suggested by the finite case (see 189) and the G_i are subgroups of this group G , called the Cartesian product of the G_i . G , however, is no longer generated by the G_i . The subgroup of G generated by the G_i consists of those sequences $(x_1, x_2, \dots, x_p, \dots)$ that are the identity in all but a finite number of places, and it is this subgroup that is called the direct product of the G_i . If $G_i = \langle a_i \rangle$ with 2th power of a_i equal to 1, $i = 1, 2, \dots$, then the direct product of the G_i contains only elements of finite order, but the element $a = (a_1, a_2, \dots, a_p, \dots)$ is of infinite order in the Cartesian product.

It is easy to see that any relation that holds identically in all groups G_1, G_2, \dots also holds identically in their direct (or Cartesian) product. In particular, if each of $G_1, G_2, \dots, G_p, \dots$ is Abelian and satisfies the identity $yx = xy$, then it is also true that the direct (or Cartesian) product of the G_i is also Abelian.

A fundamental theorem on Abelian groups asserts that a finitely generated Abelian group $G = \langle x_1, \dots, x_n \rangle$ is the direct product $G = C_1 \times C_2 \times \dots \times C_m$ of cyclic groups $C_i = \langle c_i \rangle$ in which $m \leq n$. This representation is not unique, because, for example, the cyclic group of order 6 is the direct product of cyclic groups of orders 2 and 3. If the cyclic groups C_i are restricted to be either of infinite order or of finite prime power order p^i , however, then the representation $G = C_1 \times C_2 \times \dots \times C^m$ is unique apart from the order of the factors. In particular, this result gives a precise description of all finite Abelian groups. This is not to say, however, that all questions of interest are settled with respect to finite Abelian groups.

The description of infinite Abelian groups is far from complete. Every subgroup of an Abelian group is normal, but even in an Abelian group the knowledge of a normal

subgroup and the factor group does not determine the group. As a very simple example of this, an Abelian group of order p^2 (in which p is a prime) has a normal subgroup of order p and a factor group of order p , but the group may be either the cyclic group of order p^2 or the direct product of two cyclic groups of order p . Infinite Abelian groups are usually written with the group operation as addition and terms are changed accordingly, so that the term direct product is replaced by direct sum.

In an infinite Abelian group G the elements of finite order form a subgroup T that is called the torsion subgroup. Here the factor group G/T contains no elements of finite order except the zero element, and such a group is said to be torsion free. In general it is not possible to express G as the direct sum of the torsion subgroup and a torsion-free subgroup, but most study has been devoted either to torsion groups or torsion-free groups.

An Abelian group D (in additive notation) is said to be divisible if for any y of D and any integer n there is an x of D with $y = nx$. Up to isomorphism there are two basic kinds of divisible groups, first the additive group R^+ of the rational numbers, and $Z(p_\infty)$ the multiplicative group of p^m th roots of 1, in which p is a fixed prime and n ranges over all positive integers. A divisible group D is a direct summand of any Abelian group G containing it, and D is in turn a direct sum of groups each of which is isomorphic to R^+ or some $Z(p_\infty)$.

A primary Abelian group P is a group in which every element has order some power of a fixed prime p . Every torsion group G is the direct sum of its primary subgroups, and this effectively reduces the study of torsion groups to the study of primary groups. Primary groups with at most a countable number of elements have been completely described in terms of certain numerical invariants, but this approach is inadequate for primary groups with more than a countable number of elements. Much less is known on the general theory of torsion-free groups.

AUTOMORPHISMS OF GROUPS; SEMI-DIRECT PRODUCTS

An automorphism a of a group G is a one-to-one mapping of the elements of G onto themselves such that $(g_1 g_2)a = (g_1 a)(g_2 a)$ for any g_1, g_2 of G . This is to say that a is an isomorphism of G with itself. As with any set, the one-to-one mappings form a group, and because the product of two automorphisms is again an automorphism, and the inverse of an automorphism is an automorphism, the automorphisms of G themselves form a group $A(G)$. For a fixed element x of G , the mapping $g \rightarrow x^{-1}gx$ for all g of G is an automorphism called an inner automorphism, which is designated as a_x . It is easy to check that $a_x a_y = a_{xy}$ and that $(a_x)^{-1}$ is the inner automorphism associated with x^{-1} . Here $a_x = 1$ if, and only if, $x^{-1}gx = g$ or $gx = xg$ for every g of G . The elements with this property of commuting with every element of G themselves form a subgroup called the centre $Z(G)$ of G . Clearly $Z(G)$ is an Abelian group and is normal in G . The inner automorphisms form a group $I(G)$ that is isomorphic to $G/Z(G)$. $I(G)$ is a normal subgroup of $A(G)$, and the factor group $A(G)/I(G)$ is called the group of outer automorphisms of G . If G is Abelian, then $Z(G) = G$ and $I(G) = 1$, so that all automorphisms of an Abelian group are outer automorphisms.

$$(190) \quad (h_1 k_1)(h_2 k_2) = h_1 h_2 (h_2^{-1} k_1 h_2) k_2 = h_1 h_2 k_1^{h_2} k_2$$

$$(191) \quad (h_1 h_2)^{-1} k (h_1 h_2) = h_2^{-1} (h_1^{-1} k h_1) h_2$$

$$(192) \quad (h_1 k_1)(h_2 k_2) = (h_1 h_2)(k_1 k_2)$$

$$(193) \quad (h_1 k_1)(h_2 k_2) = (h_1 k_2)(k_1^{h_2} k_2)$$

$$(194) \quad H = \langle h \rangle, \quad K = \langle k \rangle, \quad h^4 = 1, \quad k^3 = 1$$

$$(195) \quad h^4 = 1, \quad k^3 = 1, \quad h^{-1} k h = k^{-1}$$

$$(196) \quad G = H + Hx_2 + \dots + Hx_i + \dots + Hx_n$$

If K is a normal subgroup of a group G , then for any x belonging to G , $x^{-1}Kx = K$, and the mapping $k \rightarrow x^{-1}kx$ for k in K is an automorphism of K . It may happen that in $G = K + x_1K + \cdots + x_nK$, it is possible to choose the coset representatives $1, x_1, \dots, x_n$ so that they form a subgroup H . In this case every element h of H is associated with an automorphism $k \rightarrow h^{-1}kh$ of K , and it is convenient to use an exponential notation, writing $h^{-1}kh = k^h$. Then every element x of G has a unique expression in the form $x = hk$ with h from H and k from K . An identity (see 190) gives the product rule for G in terms of the product rule in H , the product rule in K , and the automorphisms of K associated with elements of H . The only requirement on the automorphisms comes from the identity (see 191), which in exponential notation takes a familiar form. This means that the group H is mapped homomorphically onto a group of automorphisms of K . If the automorphism $k \rightarrow k^h$ is always the identity automorphism; i.e., $k^h = k$ in every case, then the multiplication rule takes a form (see 192) so that G is the direct product $H \times K$. In general the product rule (see 193), a slight modification of those considered, and subject to the exponential condition given above, determines a group G known as the semi-direct product of K by H , in which K is a normal subgroup of G , and H is isomorphic to the factor group G/K . This is a useful rule that gives the construction for many groups. An easy example is that in which the fourth power of h and the third power of k are 1 (see 194) and h and h^3 correspond to the automorphism $k \rightarrow k^{-1}$ while 1 and h^2 correspond to the automorphism $k \rightarrow k$. Here $G = HK$ is of order 12 and is fully determined by three particular relations (see 195).

PERMUTATION GROUPS

If G is a permutation group on a set $S = \{1, 2, \dots, n\}$, then G is said to be transitive on S if for every i and j of S there is a permutation x of G for which $(i)x = j$. It is easy to see that if G is transitive, those permutations h that fix 1—i.e., $(1)h = 1$ —form a subgroup H and that G is analyzed as a sum of terms of the type Hx_i (see 196), in which x_i is a permutation such that $(1)x_i = i$. Thus, in a transitive group G on symbols $1, 2, \dots, n$, each symbol corresponds to a coset of a subgroup. Conversely, given a group G and a subgroup H , in which $G = H + Hx_1 + \cdots + Hx_n$, there is a mapping of the elements of H onto permutations of $1, 2, \dots, n$ corresponding to the cosets. In general this mapping is a homomorphism and its kernel K is the largest normal subgroup of G contained in H .

If H is the identity subgroup, then each coset consists of a single element and for each element x of G there is a permutation a_x such that $(y)a_x = yx$ for y belonging to G . The correspondence between x and a_x is easily seen to be an isomorphism so that every G is isomorphic to a permutation group of its own elements. Thus every group may be considered to be a permutation group.

Define the polynomial $\Delta(x_1, \dots, x_n)$ in terms of products (see 197), this being the product of all $x_i - x_j$ with i less than j . Every permutation of x_1, \dots, x_n replaces Δ by Δ or $-\Delta$, and the permutation that interchanges x_1 and x_2 and fixes the rest takes Δ into $-\Delta$. Those permutations that take Δ into Δ form a group A_n , called the alternating group. The group of all $n!$ permutations on x_1, \dots, x_n is called the symmetric group S_n . Here the group A_n consists of half the elements of S_n and is of order $n!/2$.

The permutations that leave an array invariant will form a group. The array of seven triples has the property that every pair of elements occurs in exactly one triple. It can be considered as the set of lines in a finite plane (see 198).

Four permutations leave the array invariant (see 199), and they are symbolized by x, y, z , and w .

Because the group G is transitive on $1, \dots, 7$, the subgroup H is of index 7, $[G:H] = 7$. The subgroup H containing y and z is transitive on $2, \dots, 7$, and so the subgroup T of H that fixes 2 as well as 1 is of index 6 in H , $[H:T] = 6$. T is generated by z and w and is of order 4, $[T:1] = 4$. Hence G is of order 168 as a computation shows (see 200).

Given any two distinct numbers i, j and two other distinct numbers i^*, j^* , there is an element u of G such

that $(i)u = i^*$ and $(j)u = j^*$. For this reason G is said to be doubly transitive. In general, a permutation group G is said to be k -ply transitive if given k distinct numbers i_1, i_2, \dots, i_k and another set of k distinct numbers $i_1^*, i_2^*, \dots, i_k^*$, then there is an element u in G such that u post-multiplies each number of the first set to give another in the second (see 201).

The symmetric group S_n is n -ply transitive and the alternating group A_n is $n-2$ -ply transitive. There are many triply transitive permutation groups, but apart from the

$$(197) \quad \Delta = (x_1 - x_2)(x_1 - x_3) \cdots (x_1 - x_n)(x_2 - x_3) \cdots (x_{n-1} - x_n)$$

$$(198) \quad \begin{cases} 1, 2, 4 \\ 2, 3, 5 \\ 3, 4, 6 \\ 4, 5, 7 \\ 5, 6, 1 \\ 6, 7, 2 \\ 7, 1, 3 \end{cases}$$

$$(199) \quad \begin{cases} x = (1, 2, 3, 4, 5, 6, 7) \\ \quad (2, 3, 4, 5, 6, 7, 1) \\ y = (1, 2, 3, 4, 5, 6, 7) \\ \quad (1, 3, 5, 7, 2, 4, 6) \\ z = (1, 2, 3, 4, 5, 6, 7) \\ \quad (1, 2, 5, 4, 3, 7, 6) \\ w = (1, 2, 3, 4, 5, 6, 7) \\ \quad (1, 2, 6, 4, 7, 3, 5) \end{cases}$$

$$(200) \quad [G:1] = [G:H][H:T][T:1] = 7 \cdot 6 \cdot 4$$

$$(201) \quad (i_1)u = i_1^*, \quad \dots, \quad (i_k)u = i_k^*$$

$$(202) \quad \begin{cases} ((x, y)\alpha)_1 = ax + by \\ ((x, y)\alpha)_2 = cx + dy \end{cases}$$

$$(203) \quad \begin{cases} ((x, y)\alpha)_1 = y, & ((x, y)\beta)_1 = y \\ ((x, y)\alpha)_2 = -x - y, & ((x, y)\beta)_2 = x \end{cases}$$

$$(204) \quad \alpha^3 = 1, \quad \beta^2 = 1, \quad \beta\alpha\beta = \alpha^{-1}$$

$$(205) \quad \begin{cases} ((x)\alpha)_1 = a_{11}x_1 + a_{12}x_2 + \cdots + a_{1j}x_j + \cdots + a_{1n}x_n \\ ((x)\alpha)_2 = a_{21}x_1 + a_{22}x_2 + \cdots + a_{2j}x_j + \cdots + a_{2n}x_n \\ ((x)\alpha)_i = a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{ij}x_j + \cdots + a_{in}x_n \\ ((x)\alpha)_n = a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nj}x_j + \cdots + a_{nn}x_n \end{cases}$$

$$(206) \quad \begin{cases} ((x)\beta)_1 = b_{11}x_1 + b_{12}x_2 + \cdots + b_{1j}x_j + \cdots + b_{1n}x_n \\ ((x)\beta)_2 = b_{21}x_1 + b_{22}x_2 + \cdots + b_{2j}x_j + \cdots + b_{2n}x_n \\ ((x)\beta)_i = b_{i1}x_1 + b_{i2}x_2 + \cdots + b_{ij}x_j + \cdots + b_{in}x_n \\ ((x)\beta)_n = b_{n1}x_1 + b_{n2}x_2 + \cdots + b_{nj}x_j + \cdots + b_{nn}x_n \end{cases}$$

$$(207) \quad \begin{cases} ((x)\alpha\beta)_1 = c_{11}x_1 + c_{12}x_2 + \cdots + c_{1j}x_j + \cdots + c_{1n}x_n \\ ((x)\alpha\beta)_2 = c_{21}x_1 + c_{22}x_2 + \cdots + c_{2j}x_j + \cdots + c_{2n}x_n \\ ((x)\alpha\beta)_i = c_{i1}x_1 + c_{i2}x_2 + \cdots + c_{ij}x_j + \cdots + c_{in}x_n \\ ((x)\alpha\beta)_n = c_{n1}x_1 + c_{n2}x_2 + \cdots + c_{nj}x_j + \cdots + c_{nn}x_n \end{cases}$$

$$(208) \quad c_{ij} = a_{i1}b_{1j} + a_{i2}b_{2j} + \cdots + a_{in}b_{nj}, \quad i, j = 1, 2, \dots, n$$

$$(209) \quad A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} = [a_{ij}], \quad i, j = 1, 2, \dots, n$$

Mathieu groups

groups A_n and S_n , there are only four permutation groups known that are as much as quadruply transitive. These are known as the Mathieu groups after the French mathematician Émile-Léonard Mathieu who discovered them in 1860 and 1873. These groups are M_{11} , of order 7920 quadruply transitive on 11 letters, M_{12} of order 95040 quintuply transitive on 12 letters, M_{23} of order 10,200,960 quadruply transitive on 23 letters, and M_{24} of order 244,922,040 quintuply transitive on 24 letters.

GROUP REPRESENTATION

It has been remarked earlier that transformations $(x, y) \rightarrow (ax + by, cx + dy)$ in which $ad - bc \neq 0$ form a group. The transformation value $(x, y)a$ is a pair of real numbers which may be called $((x, y)a)_1$ and $((x, y)a)_2$. This transformation may then be written in the form of two equations (see 202). As an example, take transformations α and β in which the corresponding equations are of the above type (see 203). The group $G = \langle \alpha, \beta \rangle$ is a finite group of order 6 in which the basic properties are easily found (see 204).

Linear transformations of n variables that are one-to-one (and so have inverses) will form a group. If the symbol x denotes a sequence (x_1, \dots, x_n) of numbers, then x_j is the j th term of x . A transformation α taking n -term sequences into n -term sequences can be formed in a fashion similar to the two-term use above. Then $(x)\alpha$ is again a sequence with terms $((x)\alpha)_1, \dots, ((x)\alpha)_n$. A linear transformation is a transformation α that can be defined by a linear system of equations (see 205). If another transformation β is expressed the same way (see 206), then the product $\alpha\beta$ of these transformations is given by another set of n linear equations (see 207) in which in every case the coefficient c_{ij} is given by the rule that identifies a typical coefficient in the equations of the product transformation with sums of products of coefficients in the equations expressing α and β (see 208).

Matrices

Clearly these transformations are determined by the array of coefficients. The square array that results (see 209) is called a matrix, and a product rule is defined, such that ordinary matrix multiplication (see 210) applies in every instance (see 211). The matrices, six in number, with elements composed of $-1, 0$, and 1 (see 212) and containing the identity matrix, as well as two matrices of specific structure, correspond to the group of order 6, $G = \langle \alpha, \beta \rangle$ mentioned above, and themselves form an isomorphic group.

A matrix representation, or, more briefly, representation, of a group G is a homomorphism of G onto a subgroup of the group of matrices of dimension n that have inverses. The elements in the matrices may be complex numbers or may be from any field.

As an example of matrix representation, the symmetries of a cube given above should be considered. The vertices may be given coordinates composed of 1 and -1 (see 213) so that the cube is symmetric about the origin. The symmetries α, β, γ take the form of matrices of nine elements each (see 214), composed of the numbers $-1, 0, 1$.

The determinant of a matrix A , written $\det A$, is a function of the entries of A that can be defined recursively in terms of the dimension n of A . If $n = 1$ and $A = [a_{11}]$, then $\det A = a_{11}$. For n greater than one, the $\det A$ has an expansion in $\det A_{ij}$ (see 215), in which for $j = 1, 2, \dots, n$, A_{ij} is the matrix of dimension $n - 1$ obtained from A by deleting the first row and j th column. Thus for $n = 2$, $\det A = a_{11}a_{22} - a_{12}a_{21}$. Thus the determinant of a matrix the entries of which are in a field F is an element of that field. The most useful property of determinants is the fact that $\det(AB) = \det A \cdot \det B$. The identity transformation 1 , with $(x)1 = x$ for all x , corresponds to the identity matrix I , and if $I = [e_{ij}]$, then $e_{11} = e_{22} = \dots = e_{nn} = 1$ and $e_{ij} = 0$ if $i \neq j$. In this $\det(I) = 1$, and a matrix A has an inverse if and only if $\det A \neq 0$.

A useful operation on a matrix is called the transpose. If $A = [a_{ij}]$, the transpose A^T is defined as $A^T = [b_{ij}]$, in which $b_{ij} = a_{ji}$.

Matrices may also be added if when A and B are expressed in terms of their elements (see 216) the sum $A + B = C$ is defined by addition of corresponding ele-

ments (see 217). If u is an element of the field F , the scalar product uA is defined as the matrix $[ua_{ij}]$. Matrix addition is associative and commutative; matrix multiplication is associative but not commutative ($(AB)C = A(BC)$, but not $BA = AB$). Multiplication is left and right distributive over addition (see 218).

A representation M of a group G is given by matrices $M(x)$ for x in G such that the matrix corresponding to 1 is the identity and the matrix corresponding to a product of elements in the group is a product of corresponding matrices (see 219). If R is any fixed matrix with an inverse R^{-1} , then $R^{-1}M(x)R$ also gives a representation that is considered equivalent to the representation given by $M(x)$. If it happens that for every x of G $M(x)$ is of the form of four blocks, upper left being $M_1(x)$, lower left being $M_2(x)$, and lower right being $M_3(x)$ (see 220), with $M_1(x)$ of dimension r , $M_2(x)$ of dimension s , and the block $[0]$ in the upper right corner consisting entirely of zeros, it is said that M is reducible, and if also $M_{12}(x)$ is identically zero it is said that M is the sum of M_1 and M_2 . If no representation equivalent to M is reducible, then M is said to be irreducible.

For representations of all finite groups over the complex numbers and certain classes of infinite groups, it is true that, up to equivalence, there are only a finite number of irreducible representations and every represen-

$$(210) \quad \begin{cases} B = [b_{ij}], & i, j = 1, 2, \dots, n \\ AB = C = [c_{ij}], & i, j = 1, 2, \dots, n \end{cases}$$

$$(211) \quad \begin{cases} c_{ij} = a_{i1}b_{1j} + a_{i2}b_{2j} + \dots + a_{in}b_{nj} \\ i, j = 1, 2, \dots, n \end{cases}$$

$$(212) \quad \begin{cases} I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} & A = \begin{bmatrix} 0 & 1 \\ -1 & -1 \end{bmatrix} & A^2 = \begin{bmatrix} -1 & -1 \\ 1 & 0 \end{bmatrix} \\ B = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} & AB = \begin{bmatrix} 1 & 0 \\ -1 & -1 \end{bmatrix} & A^2B = \begin{bmatrix} -1 & -1 \\ 0 & 1 \end{bmatrix} \end{cases}$$

$$(213) \quad \begin{cases} 1 = (-1, 1, -1) & 5 = (-1, 1, 1) \\ 2 = (-1, -1, -1) & 6 = (-1, -1, 1) \\ 3 = (1, -1, -1) & 7 = (1, -1, 1) \\ 4 = (1, 1, -1) & 8 = (1, 1, 1) \end{cases}$$

$$(214) \quad \alpha = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad \beta = \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{bmatrix} \quad \gamma = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

$$(215) \quad \det A = a_{11} \det A_{11} - a_{12} \det A_{12} + \dots + (-1)^{j+1} a_{1j} \det A_{1j} + \dots + (-1)^{n+1} a_{1n} \det A_{1n}$$

$$(216) \quad A = [a_{ij}], \quad B = [b_{ij}], \quad i, j = 1, 2, \dots, n$$

$$(217) \quad c_{ij} = a_{ij} + b_{ij}, \quad i, j = 1, \dots, n$$

$$(218) \quad \begin{cases} A + B = B + A \\ (A + B) + C = A + (B + C) \\ A(B + C) = AB + AC \\ (A + B)C = AC + BC \end{cases}$$

$$(219) \quad M(1) = I \quad \text{and} \quad M(x_1 x_2) = M(x_1) M(x_2)$$

$$(220) \quad M(x) = \left[\begin{array}{c|c} M_1(x) & 0 \\ \hline M_{12}(x) & M_2(x) \end{array} \right]$$

$$(221) \quad (AB)^T = B^T A^T \quad \text{and} \quad \det(A^T) = \det A$$

tation is equivalent to the sum of a number of irreducible representations.

If $M(x) = A = [a_{ij}]$, then the quantity $a_{11} + a_{22} + \cdots + a_{nn}$ is called the trace of A , written $\text{tr } A$, and it is known that A and $R^{-1}AR$ have the same trace. If $M(x) = A$, then $\text{tr } A$ is called the character of x and may be denoted as $\chi(x)$. Here a representation M of a group G is associated with a character $\chi(x)$. If M is the sum of M_1 and M_2 , then obviously $\chi(x) = \chi_1(x) + \chi_2(x)$ for the corresponding traces. From this it follows that, over the complex numbers, the representations of all finite groups (and certain infinite groups) are completely determined by the characters of the irreducible representations. The nature of these characters and the relations on them have been the subject of much investigation, and they have been a very valuable technical tool in the study of groups. Some of these relations are not obviously related to the groups themselves and appear to be a sort of "numerology" or "astrology" of groups.

THE CLASSICAL GROUPS; CONTINUOUS GROUPS

The set of all matrices of dimension n over a field F the determinant of which is not zero forms a group called the general linear group of dimension n and is designated as $GL_n(F)$. Because determinants satisfy $\det(AB) = \det A \cdot \det B$, it follows that all matrices of determinant unity, $\det A = 1$, form a subgroup of $GL_n(F)$ known as the special linear group of dimension n and designated $SL_n(F)$. The transpose operation on matrices has the property that it permutes the order of multiplication when applied to a product and leaves the determinant of a matrix unchanged (see 221). From this it follows easily that matrices X with the property $X^T X = I$, I being the identity matrix, form a group, and this is called the orthogonal group $O_n(F)$. The orthogonal group is also the group of linear transformations that leave $x_1^2 + x_2^2 + \cdots + x_n^2$ invariant. For matrices of even dimension $n = 2l$, the particular matrix composed of four blocks, 0's being on the diagonal, and I_l and its negative being in the other two blocks (see 222),

$$(222) \quad A = \begin{bmatrix} 0 & I_l \\ -I_l & 0 \end{bmatrix}$$

$$(223) \quad x_1 \bar{x}_1 + x_2 \bar{x}_2 + \cdots + x_n \bar{x}_n$$

$$(224) \quad F, W^{-1}x^4W, W^{-1}y^3W, W^{-1}x^4yxyW$$

$$(225) \quad R_1(b_1, \dots, b_r) = 1, \dots$$

$$(226) \quad R_1(a_1, \dots, a_r), \dots, R_n(a_1, \dots, a_r)$$

$$(227) \quad N(r) = r + r(r-1)/2 + r(r-1)(r-2)/6$$

is of importance in which I_l is the l -dimensional identity matrix and 0 stands for a block consisting entirely of zeros. A has the property $A^T = -A$. Those matrices X such that $X^T A X = A$ form a group known as the symplectic group, designated as $Sp_n(F)$ with $n = 2l$.

If the field F is the field \mathbb{C} of complex numbers, the mapping $a + bi \rightarrow a - bi$ is an automorphism of order 2 and can be written $x \rightarrow x^*$. Here if x is a complex number $a + bi$, then x^* is the conjugate $a - bi$. In general, if a field F has an automorphism $x \rightarrow x^*$ of order 2, those matrices X such that $Y^T X = I$ form a group, in which Y is obtained from X by replacing every entry x_{ij} by its conjugate x_{ij}^* . This group is called the unitary group $U_n(F)$. The unitary group is a generalization of the orthogonal group and may be considered as the group of linear transformations leaving a sum of products of n complex numbers times their conjugates invariant (see 223).

The general linear group, the special linear group, the orthogonal, symplectic, and unitary groups are known as the classical groups.

Only a little will be said here of continuous groups because they are discussed in the article *GEOMETRY: Topo-*

logical groups and *Differential topology*. In some groups G it is possible to define a distance between elements of the group. For example, if G consists of the rotations of the surface of a sphere, and if x and y are two of these rotations, the distance between x and y , $d(x, y)$ can be defined as the maximum distance between $(p)x$ and $(p)y$ as p ranges over all points of the sphere. In such a case a neighbourhood of a group element x is defined as the set of all elements y such that $d(x, y) < \epsilon$ for some fixed ϵ . Neighbourhoods may also be defined in other ways. The group G is said to be continuous if the product operation xy in G is continuous either in terms of the distance defined or in terms of the neighbourhoods. In some instances continuous groups may be given in terms of continuous parameters (variables that distinguish the elements of the group). For example, the group of orthogonal matrices (an orthogonal matrix is a matrix in which the columns are orthogonal vectors; see above *Linear and multilinear algebra*) over the real field that have determinant one can be parameterized in terms of a number of angles of rotation, and it is a continuous group in terms of these parameters. Continuous groups expressed in terms of parameters are known as Lie groups, after Sophus Lie, who studied them at great length.

Lie groups

FREE GROUPS; THE WORD PROBLEM; THE BURNSIDE PROBLEM

If a_1, a_2, \dots, a_r are elements of a group G , then $H = \langle a_1, a_2, \dots, a_r \rangle$ is said to be the subgroup generated by a_1, \dots, a_r and consists of all finite words, products of the elements $x_1 x_2 \dots x_r$, in which every x_j is some a_i or a_i^{-1} , and also the identity 1 that may be considered the empty word. If $x_j x_{j+1}$ is of the form $a_i a_i^{-1}$ or $a_i^{-1} a_i$, then the same group element is given by $x_1 x_2 \dots x_{j-1} x_{j+2} \dots x_r$. If no $x_j x_{j+1}$ is of the form $a_i a_i^{-1}$ or $a_i^{-1} a_i$, the word $x_1 x_2 \dots x_r$ is said to be reduced. By deleting consecutive inverses every word is equal to a reduced word, including 1 as a reduced word. It can be shown that the order in which these deletions are carried out does not matter and that in this way every word is equal to a unique reduced word. It can be proved that given generators a_1, a_2, \dots, a_r , there is a unique group in which all the distinct reduced words are distinct elements. This group is called the free group F_r generated by a_1, a_2, \dots, a_r , and this is written $F_r = \langle a_1, a_2, \dots, a_r \rangle$.

It is not difficult to show that if G is any group generated by r elements $G = \langle b_1, b_2, \dots, b_r \rangle$, then G is a homomorphic image of $F_r = \langle a_1, \dots, a_r \rangle$ under a homomorphism β with $(a_i)\beta = b_i, \dots, (a_r)\beta = b_r$. The kernel K of this homomorphism consists of those words in the a 's that become the identity in G when the a 's are replaced by b 's. K is, of course, a normal subgroup of F_r and, of course, any normal subgroup of F_r is the kernel of an appropriate homomorphism. Thus every group G is a factor group of a free group F . It is a remarkable fact that every subgroup of a free group is also a free group on an appropriate set of generators.

Free groups give a precise basis for describing defining relations on groups. To say that a group G of order 12 is defined by relations $h^4 = 1, k^3 = 1$, and $h^{-1}kh = k^{-1}$, is equivalent to taking the free group $F_2 = \langle x, y \rangle$ and the least normal subgroup K of F containing x^4, y^3 and $x^{-1}yxy$, and defining G as F_2/K , mapping $(x)\beta = h, (y)\beta = k$. Here, as W ranges over all words of F , terms of the type $W^{-1}UW$, in which U is one of the three listed elements of K (see 224), are elements of K .

The word problem in groups involves the case in which G is generated by a finite number of elements b_1, b_2, \dots, b_r and that these satisfy a finite number of relations (see 225) and no other relations nor consequences of these. Is it possible to decide whether or not two different words W_1 and W_2 represent the same element of G , or equivalently whether or not $W = W_1 W_2^{-1}$ is the identity? In terms of free groups this is the question of deciding whether or not in the free group $F_r = F_r(a_1, \dots, a_r)$ a word W is contained in the least normal subgroup K of F_r that contains the finite number of functions (see 226) that were used to express the relations.

The word problem is in fact unsolvable. No method can

exist that will in general solve all word problems. This was proved in 1955 by the Soviet mathematician Pyotr Sergeyevich Novikov. In 1959 the U.S. mathematician William W. Boone exhibited a particular set of relations R_1, \dots, R_n for which the word problem is unsolvable. This unsolvability has been a major difficulty in various natural problems of group theory.

In 1902 the British mathematician William Burnside raised the following question. If a group G is generated by r elements, $G = \langle b_1, \dots, b_r \rangle$, and if for a fixed n , $x^n = 1$ for every element of G , is G necessarily finite? If $F_r = \langle a_1, \dots, a_r \rangle$ is the free group with r generators and if $K = K_n$ is the subgroup of F generated by x^n for every x of F , then K is necessarily a normal subgroup of F , and $B(n, r) = F_r/K_n$ is a group with r generators and $x^n = 1$ for every element of $B(n, r)$. Any group such as G is necessarily a homomorphic image of $B(n, r)$, and so for given n and r the question is whether or not the group $B(n, r)$ is finite. If r is 1, then $B(n, r) = B(n, 1)$ is the cyclic group of order n . Burnside showed that for $n = 2$, $B(2, r)$ is of order 2^r and is the direct product of r groups of order 2. He also showed that for $n = 3$ the groups are finite, and that for $n = 4$, $r = 2$, $B(4, 2)$ is of order at most $2^{12} = 4096$. In 1933 the mathematicians F. Levi and B.L. van der Waerden found the exact order and structure of the groups $B(3, r)$. The order of $B(3, r)$ is $3^{N(r)}$, in which the exponent of 3 is a specific algebraic function of r (see 227).

In 1940 I.N. Sanov, a mathematician, showed that the groups $B(4, r)$ are finite. It has been shown that Burnside was right about $B(4, 2)$ and that its order is exactly $2^{12} = 4096$, but for $r = 3$ or greater the order is not known. A mathematician, C. Wright, in 1962 found more reasonable bounds on the order and structure of $B(4, r)$ than Sanov had found, but precise information was still lacking in the 1970s.

In 1958 it was shown by the U.S. mathematician Marshall Hall, Jr., that the groups $B(6, r)$ are finite; and from results of the mathematicians P. Hall and G. Higman, it follows that the order and structure of $B(6, r)$ are fully known. $B(6, r)$ is of order 2^{43^B} in which $A = 1 + (r-1)3^{N(r)}$ and with $s = 1 + (r-1)2^r$, $B = N(s)$, in which the exponent of 3 is as above (see 227).

In 1968 it was shown by the mathematicians Novikov and Adjan that $B(n, r)$ is infinite if r is at least 2 and n is odd and at least 4381.

SIMPLE GROUPS

A simple group is a group that has no normal subgroup except itself and the identity subgroup. The Jordan-Hölder theorem shows that these are the building blocks for all groups. Many important questions about groups in general can easily be reduced to problems on simple groups.

The nature of the simple groups remains a challenging and difficult matter. In one case the answer was found by the French mathematician Élie-Joseph Cartan in 1894. For groups that are continuous in terms of real or complex parameters, the Lie groups, a complete list has been found. The classical groups will in general have a centre Z , consisting of those scalar multiples of the identity that are in the group, and in the case of the orthogonal group there may be a normal subgroup with an Abelian factor group. Such a normal subgroup up to certain identification with its centre (that is, modulo its centre) will be in general a simple group. There are four infinite families, A_l corresponding to the special linear group of dimension $l+1$ modulo its centre, B_l and D_l coming from orthogonal groups respectively of dimensions $2l+1$ and $2l$, and C_l coming from another group of dimension $2l$, called symplectic.

There are also five exceptional groups, G_2 , F_4 , E_6 , E_7 , and E_8 , which can be expressed with respectively 14, 52, 78, 133, and 248 parameters. The unitary groups are not technically a part of this list because complex conjugation is part of their definition.

For finite simple groups the situation is much more complicated and is currently the subject of intense research effort. To describe the situation it is first necessary to describe finite fields. Let p be a prime number. It is said that

integers r and s are congruent modulo p if the difference $r - s$ is a multiple of p , and this is written $r \equiv s \pmod{p}$. It is also said that r and s are in the same residue class modulo p , and that either r or s is a representative of the residue class. Hence $0, 1, 2, \dots, p-1$ are representatives of all p residue classes. If $r \equiv s \pmod{p}$ and $t \equiv u \pmod{p}$, then $r + t \equiv s + u \pmod{p}$ and $rt \equiv su \pmod{p}$. The p residue classes form a field, written $GF(p)$. If $q = p^r$ is a power of the prime p , there is always a unique field with q elements, $GF(q)$, the elements of which are polynomials of a single element with coefficients from $GF(p)$. Thus $GF(4)$ has elements $0, 1, u, u+1$, in which $0, 1$ are the residue classes modulo 2. In $GF(4)$, four basic relations hold (see 228, 229) and other relations are consequences of these.

$$\begin{aligned} (228, \quad & \{ GF(4), 1+1=0, \quad u+u=0 \\ 229) \quad & \{ u^2=u+1, \quad u(u+1)=1 \end{aligned}$$

$$\begin{aligned} (230) \quad & \text{Mathieu groups: } M_{11} \quad 2^4 \cdot 3^2 \cdot 5 \cdot 11 \\ & M_{12} \quad 2^6 \cdot 2^3 \cdot 5 \cdot 11 \\ & M_{22} \quad 2^7 \cdot 3^2 \cdot 5 \cdot 7 \cdot 11 \\ & M_{23} \quad 2^7 \cdot 3^2 \cdot 5 \cdot 7 \cdot 11 \cdot 23 \\ & M_{24} \quad 2^{10} \cdot 3^3 \cdot 5 \cdot 7 \cdot 11 \cdot 23 \end{aligned}$$

$$\begin{aligned} (231) \quad & \left\{ \begin{array}{ll} 2^3 \cdot 3 \cdot 5 \cdot 7 \cdot 11 \cdot 19 & \text{Janko} \\ 2^7 \cdot 3^3 \cdot 5^2 \cdot 7 & \text{Hall-Janko} \\ 2^9 \cdot 3^2 \cdot 5^3 \cdot 7 \cdot 11 & \text{Higman-Sims} \\ 2^{13} \cdot 3^7 \cdot 5^2 \cdot 7 \cdot 11 \cdot 13 & \text{Suzuki} \\ 2^7 \cdot 3^6 \cdot 5^3 \cdot 7 \cdot 11 & \text{McLaughlin} \\ 2^7 \cdot 3^5 \cdot 5 \cdot 17 \cdot 19 & \text{Higman-McKay-Janko} \\ 2^{10} \cdot 3^3 \cdot 5^2 \cdot 7^3 \cdot 17 & \text{Held} \end{array} \right. \end{aligned}$$

$$\begin{aligned} (232) \quad & \left\{ \begin{array}{ll} 2^{21} \cdot 3^9 \cdot 5^4 \cdot 7^2 \cdot 11 \cdot 13 \cdot 23 & \text{Conway .1} \\ 2^{18} \cdot 3^6 \cdot 5^3 \cdot 7 \cdot 11 \cdot 23 & \text{Conway .2} \\ 2^{10} \cdot 3^7 \cdot 5^3 \cdot 7 \cdot 11 \cdot 23 & \text{Conway .3} \\ 2^{17} \cdot 3^9 \cdot 5^2 \cdot 7 \cdot 11 \cdot 13 & \text{Fischer } F_{22} \\ 2^{18} \cdot 3^{13} \cdot 5^2 \cdot 7 \cdot 11 \cdot 13 \cdot 17 \cdot 23 & \text{Fischer } F_{23} \\ 2^{22} \cdot 3^{16} \cdot 5^2 \cdot 7^3 \cdot 11 \cdot 13 \cdot 17 \cdot 23 \cdot 29 & \text{Fischer } F_{24} \end{array} \right. \end{aligned}$$

$$\begin{aligned} (233) \quad & \left\{ \begin{array}{ll} 2^8 \cdot 3^7 \cdot 5^6 \cdot 7 \cdot 11 \cdot 31 \cdot 37 \cdot 67 & \text{Lyons-Sims} \\ 2^{14} \cdot 3^3 \cdot 5^3 \cdot 7 \cdot 13 \cdot 29 & \text{Rudvalis-Conway-Wales} \end{array} \right. \end{aligned}$$

The mathematician Claude Chevalley showed in 1955 that all of the Lie groups have finite analogues if the field of real or complex numbers is replaced by any finite field, and that with a very few exceptions, corresponding to fields with 2 or 3 elements, the analogues of the simple Lie groups are simple. This is also true for the unitary groups. Somewhat like the unitary group, there are several families known as twisted Lie groups corresponding to subgroups of the Lie types fixed by a certain automorphism. For instance, if $q = 2^{2m+1}$ is at least 8, there are simple groups of order $(q^2 + 1)q^2(q - 1)$, first discovered by the mathematician M. Suzuki in 1960 in another way. The finite simple groups include the cyclic groups of prime order and the alternating groups A_n in which n is 5 or greater.

The most striking development in the study of finite simple groups was the proof in 1963 by the mathematicians Walter Feit and John Thompson that, apart from the groups of prime order, every finite simple group has even order. Since that time Thompson has determined all minimal simple groups.

Apart from the families of finite simple groups, there are now known 20 finite simple groups, called sporadic simple groups, that do not belong to the known families. It is not clear whether they belong to families not yet discovered or whether they are truly exceptional, and it is not clear whether further finite simple groups exist.

Sporadic
simple
groups

Jordan-
Hölder
theorem

The designations of the known 20 sporadic groups and their orders in factored form are the Mathieu groups (see 230), the groups, respectively, of Janko, Hall-Janko, Higman-Sims, Suzuki, McLaughlin, Higman-McKay-Janko, and Held (see 231), and the groups identified, respectively, as Conway .1, Conway .2, Conway .3, Fischer F_{22} , Fischer F_{23} , and Fischer F_{24} (see 232).

A 19th group predicted by Lyons was constructed by Sims. The 20th, predicted by Rudvalis, was constructed by Conway and Wales (see 233).

(Ma.H.)

Fields

Broadly speaking, a field is an algebraic system consisting of elements that are commonly called numbers, in which the four familiar operations of addition, subtraction, multiplication, and division are universally defined (except for division by zero) and have all their usual properties. Much of the general theory of vectors and matrices (see above *Linear and multilinear algebra* and *MATRIX THEORY*) can be developed over an arbitrary field. In particular, this is true of the general theory of simultaneous linear equations and of their solution by a method known as Gaussian elimination (see below). The study of various special fields also explains which geometric constructions, such as angle bisection and angle trisection, can be made with ruler and compass and which cannot. Moreover, finite fields of 2^n elements have been used to construct the best known error-correcting codes.

Although many particular fields—including especially the rational, real, and complex fields, finite fields and

rational field, commonly denoted Q . Its members are the positive rational numbers m/n (in which m and n are positive integers), the negative rational numbers $-m/n$, and 0. Positive rational numbers are added, subtracted, multiplied, and divided by the rules familiar in the manipulation of fractions (see 234). The behaviour of 0 is somewhat exceptional in that, when added to a rational it yields the same rational and when multiplied by a rational it yields 0 (see 235). The rules for adding, subtracting, multiplying, and dividing negative rational numbers (with each other and with positive rational numbers and zero) are very like those for positive rational numbers listed above.

Because $m/n = km/kn$ for any positive integer k , the same rational number can be represented as a quotient of integers in many ways. Of these, only one is in lowest terms; that is, has numerator and denominator without common factors (relatively prime) and a positive denominator.

The real field. Much more sophisticated than the rational field is the real field, commonly designated by \mathbb{R} . Positive real numbers are most easily visualized as unlimited decimals (see 236). There are also negative real numbers such as $-1.4142 \dots$ and zero, designated $0 = 0.000000 \dots$. Among real numbers, rational numbers can be recognized by the characteristic property that their (unlimited) decimal representation is repeating: from some point on, it consists simply of indefinite repetitions of the same block. Thus $1/24 = 0.04166666 \dots$ (block length one), and $5/7$ has a similar representation with block length 6 (see 237). The fact that every rational number is also a real number (with equivalent addition, multiplication, subtraction, and division rules) can be summarized in the statement that Q is a subfield of the rational field—or in the simple formula $Q \subset R$.

Actually, the rules for adding, subtracting, multiplying, and dividing real numbers are quite sophisticated; they can best be understood in terms of the idea of approximation. Thus, when $\sqrt{2} = 1.4142 \dots$ is written, what is meant is that $14,142/10,000 \leq \sqrt{2} \leq 14,143/10,000$. But now it is easy to add or multiply any two decimal fractions (see 238) by applying the rules of addition and multiplication of rationals (see 239). Subtraction is equally easy, although long division is considerably harder (see *ARITHMETIC*).

To pass from the addition and multiplication of decimal fractions (finite decimals) to that of real numbers (unlimited decimals) is best thought of as a process of successive approximation: arbitrarily close decimal fraction approximations to any two real numbers can be added or multiplied together. Thus an arbitrary close approximation to their sum or product can be obtained.

Real numbers also have a very important and basic geometrical representation as coordinates of points on a straight line. After choosing an origin O and assigning to

it the coordinate 0 (zero), any other point P can be chosen and the coordinate $1 = 1.000000 \dots$ can be assigned to it. By laying off in the same direction equal segments $PQ = OP$, etc., infinite sequences of points P, Q, R, \dots (or P_1, P_2, P_3, \dots) are obtained having positive integral coordinates. The coordinates $-1, -2, -3, \dots$ can then be assigned to a similar sequence of equally spaced points going in the opposite direction. Each segment can also be divided into 10 equal parts, assigning (for example) to the new points between P and Q the (decimal) coordinates $1.1, 1.2, 1.3, \dots, 1.9$. By repeated decimal subdivision, in this way points corresponding to all decimal fractions can be obtained and thus arbitrarily close (decimal) approximations to any real point produced. This gives a simple and natural geometrical interpretation of the decimal (fraction) approximations to arbitrary real numbers.

The complex field. Much more sophisticated even than the real field is the complex field. Indeed, it is doubtful whether this field would ever have been thought of if man had not been curious about polynomial equations, such as $z^2 = -1$ (or, equivalently, $z^2 + 1 = 0$). It is easy to show that no real number z can satisfy this equation,

The geometrical representation of real numbers

$$(234) \quad \begin{cases} \frac{m}{n} \pm \frac{m'}{n'} = \frac{mn' \pm nm'}{nn'}, & \frac{m}{n} \cdot \frac{m'}{n'} = \frac{mm'}{nn'} \\ \frac{m}{n} \div \frac{m'}{n'} = \frac{mn'}{nm'} \end{cases}$$

$$(235) \quad \frac{m}{n} + 0 = \frac{m}{n}, \quad \frac{m}{n} \cdot 0 = 0 \quad \text{for all } \frac{m}{n}$$

$$(236) \quad 1.414214 \dots, 3.14159 \dots, 2.718281828459 \dots$$

$$(237) \quad \frac{5}{7} = 0.714285714285714285 \dots$$

$$(238) \quad \begin{cases} 1.4142 = 14,142/10,000 & \text{or} \\ 3.14159 = 314,159/100,000 \end{cases}$$

$$(239) \quad \begin{cases} \frac{14,142}{10,000} + \frac{314,159}{100,000} = \frac{455,579}{100,000} \\ \frac{14,142}{10,000} \cdot \frac{314,159}{100,000} = \frac{4,442,836,578}{1,000,000,000} \end{cases}$$

$$(240) \quad (x + iy) \pm (x' + iy') = (x \pm x') + i(y \pm y')$$

$$(241) \quad (x + iy)(x' + iy') = (xx' - yy') + i(xy' + yx')$$

$$(242) \quad z = \frac{u + iv}{a + ib} = \frac{(u + iv)(a - ib)}{(a + ib)(a - ib)} = \frac{ua + vb}{a^2 + b^2} + i \left(\frac{va - ub}{a^2 + b^2} \right)$$

algebraic number fields—were intensively studied in the 17th, 18th, and early 19th centuries, the idea of investigating all possible fields seems not to have been conceived until 1910, when the mathematician Steinitz proposed a systematic scheme for classifying them.

THREE FAMILIAR FIELDS

To illustrate the meaning of the first statement of this section, the three most familiar fields are discussed, namely, the rational field, the real field, and the complex field.

The rational field. The most familiar field of all is the

because the square of any two positive or negative real numbers is necessarily positive (see below *Ordered fields*), while $0^2 = 0$. To remedy this deficiency of the real field \mathfrak{R} , mathematicians invented a new number $i = \sqrt{-1}$, defined by the properties of the equation $i^2 = -1$.

In order to get a field containing $\sqrt{-1}$ (that is, to be able to carry out addition, subtraction, multiplication, and division subject to the usual rules), all complex numbers of the form $x + yi = x + iy = x + y\sqrt{-1}$ were considered more generally. It was decided to add and subtract these by the rules of adding and subtracting separately the terms not involving i and the terms involving i (see 240). Multiplication followed the rule that the first part of the product was a difference of products not involving i , while the second part included i as a factor and a sum of products, the two parts being added to form a new number in the field (see 241). Finally, division (except by zero) was always possible. Specifically, setting $c = a + ib$, $z = x + iy$, and $w = u + iv$, the solution of the equation $cz = w$ can always be evaluated by setting z equal to a complex number, both summands of which have fractional representation with $a^2 + b^2$ in the denominators (see 242) for $c \neq 0$, $a^2 + b^2 > 0$; hence this quotient always exists as a complex number of the prescribed form.

It is quite straightforward to show that the preceding definitions of addition, multiplication, subtraction, and division of complex numbers are the only ones that are compatible with the usual laws of algebra (see below *Postulates for a field*) and the basic equation $i^2 = -1$ given initially above. It can be proved that, conversely, the above operations do obey all the usual algebraic laws; therefore, it is legitimate to speak of the number system just constructed as the complex field \mathfrak{C} .

Just as a real number x can be thought of as the coordinate of a point on an infinite straight line, so each complex number $z = x + iy$ can be thought of as representing a point (x, y) in a plane, the complex plane. The addition and subtraction of two complex numbers $z = x + iy$ and $z' = x' + iy'$ as defined above corresponds to ordinary vector addition and subtraction.

What is more remarkable, the multiplication of two complex numbers also has a simple geometric interpretation, which is most simply explained in terms of polar coordinates. Namely, the vector from the origin $O = 0 + i0$ to $z = x + iy$ has length $r = |z| = \sqrt{x^2 + y^2}$ and makes a certain angle θ with the positive x -axis, called the argument of z . By trigonometry, therefore, $x = r \cos \theta$ and $y = r \sin \theta$, and so z has a representation in terms of r and θ (see 243). If also z' has such a representation, then the multiplication rule (see 241) implies that the product of z and z' is the product of the corresponding r and r' and a complex number whose argument is the sum of corresponding θ and θ' (see 244). In other words, to multiply two complex numbers, multiply their absolute values and add their arguments. These rules can be written in symbols (see 245). As a corollary, it may be stated that for any positive integer n , the absolute value of the n th power of z is the n th power of the absolute value of z , and the argument of the n th power of z is n times the argument of z (see 246). From this, in turn, it follows that any nonzero complex number $c = a + ib$ has exactly n distinct n th roots $c^{1/n}$, all having the same magnitude $|c|^{1/n} = (a^2 + b^2)^{1/2n}$ and having equally spaced arguments $\theta_j = (\arg c)/n + 2\pi j/n$, $j = 0, 1, \dots, n-1$. These n th roots are thus the vertices of a regular polygon of n sides, with its centre at the origin.

ELEMENTARY THEORY OF FIELDS

Postulates for a field. The three number systems \mathcal{Q} , \mathfrak{R} , and \mathfrak{C} defined above have in common a great many properties. In particular, they all admit two binary operations of addition and multiplication, which satisfy the five postulates following:

- F1. $a + b = b + a$ and $ab = ba$ for all values of a, b .
- F2. $a + (b + c) = (a + b) + c$ and $a(bc) = (ab)c$, for all values of a, b, c .
- F3. There exist distinguished elements $0, 1$ such that $a + 0 = 0 + a$ and $a1 = 1a = a$ for all values of a .
- F4. Given a , there exist elements $-a$ and (if $a \neq 0$) a^{-1} such that $a + (-a) = 0$ and $aa^{-1} = 1$.
- F5. $a(b + c) = ab + ac$ and $(a + b)c = ac + bc$, for all values of a, b, c .

Postulate F1 asserts that addition and multiplication are commutative; F2 asserts that they are associative; F3 asserts that any field has identities for addition and multiplication. Postulate F4 asserts that addition and multiplication (except by zero) are invertible operations; the last postulate, F5, is called the distributive law. Fields may now be formally defined.

A field is an algebraic system the members of which, commonly called numbers, can be combined by two universally defined binary operations (addition and multiplication) that satisfy postulates F1–F5 above.

With a little manipulation, it can be shown that (in the presence of F5), F1–F4 can also be summarized in two statements:

1. The numbers of any field form a commutative group (see above *Groups*) under addition.
2. The nonzero numbers of any field form another commutative group under multiplication. This gives a second algebraic characterization of fields.

Many familiar rules of algebra follow directly from postulates F1–F5, which are already redundant. For example, $a + b = a + c$ implies successively several equalities (see 247), which imply the following cancellation law:

In any field, $a + b = a + c$ implies $b = c$.

A similar argument proves a second cancellation law:

In any field, $ab = ac$ implies $b = c$ if $a \neq 0$.

Next, it can be proved that the additive identity 0 is also a zero for multiplication, in the sense that $a0 = 0$ for all values of a . Indeed, $a + 0 = a = a1 = a(1 + 0) = a1 + a0 = a + a0$, from which it follows that $0 = a0$ by the cancellation law. Again, from $1 + (-1) = 0$ there follows $a + (-a) = 0 = 0a = 1 + (-1)a = 1a + (-1)a = a + (-1)a$, from which by cancellation is derived $-a = (-1)a$. Finally, two calculations (see 248 and 249) imply $(-1)(-1) = 1 \cdot 1 = 1$ and a general rule of multiplication of negatives (see 250).

Formal definition of a field

$$(243) \quad z = r[\cos \theta + i \sin \theta]$$

$$(244) \quad zz' = rr'[\cos(\theta + \theta') + i \sin(\theta + \theta')]$$

$$(245) \quad |zz'| = |z| \cdot |z'|, \quad \arg(zz') = \arg z + \arg z'$$

$$(246) \quad |z^n| = |z|^n \quad \text{and} \quad \arg z^n = n \arg z$$

$$(247) \quad \begin{cases} b = 0 + b = [(-a) + a] + b = (-a) + [a + b] \\ = (-a) + [a + c] = [(-a) + a] + c = 0 + c = c \end{cases}$$

$$(248) \quad (-1)1 + (-1)(-1) = (-1)[1 + (-1)] = (-1)0 = 0$$

$$(249) \quad (-1)1 + 1 \cdot 1 = [(-1) + 1]1 = 01 = 0$$

$$(250) \quad (-x)(-y) = [(-1)x][(-1)y] = (-1)(-1)(xy) = xy$$

$$(251) \quad ax + by = e, \quad cx + dy = f$$

$$(252) \quad x = \frac{(ed - bf)}{(ad - bc)}, \quad y = \frac{(af - ce)}{(ad - bc)}$$

$$(253) \quad a_{i1}x_1 + a_{i2}x_2 + \cdots + a_{in}x_n = k_i, \quad i = 1, 2, \dots, n$$

$$(254) \quad \begin{cases} \begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc \\ \begin{vmatrix} a & b & c \\ d & e & f \\ g & h & k \end{vmatrix} = \begin{cases} aek + dhc + bfg \\ -bdh - ceg - fha \end{cases} \end{cases}$$

Gaussian elimination. The rules derived above from postulates F1–F5 lie fairly near the surface and would probably be assumed as postulates if they did not follow anyway. A collection of much deeper results concerning simultaneous linear equations is now considered. The study of these leads in turn to the theory of vectors and matrices with components, or entries, in any field F .

The simplest nontrivial case in point concerns two simultaneous linear equations in two unknowns (see 251), the coefficients and constants in which a, b, c, d, e, f are known numbers; the problem is to determine the unknowns x, y . The answer is given, if the coefficients satisfy $ad \neq bc$, by the formulas that, except for a factor common to both x and y , expresses x in terms of the difference $ed - bf$ and y in the terms $af - ce$ (see 252). This answer is easily checked and most easily found by (i) multiplying the first equation by d , the second equation by b , subtracting the results to eliminate y , and then solving for x ; and after this (ii) multiplying the second equation by a , the first by c , subtracting the results to eliminate x , and then solving for y .

The above procedure is called Gaussian elimination, and it can be generalized to the case of n simultaneous linear equations (see 253) in n unknowns $x_j (j = 1, 2, \dots, n)$. The results can also be presented in the compact notation of determinants (see 254). See MATRIX THEORY for details. The main point to be made here is that the entire theory can be developed over an arbitrary field F . In particular, this is true of the properties of the rank and linear dependence of vectors and matrices.

SOME GENERAL CONCEPTS

Commutative rings; integral domains. First of all, it should be realized that, if the part of postulate F4 that asserts the existence of a^{-1} is omitted, a much wider class of algebraic systems is formally defined as follows:

A commutative ring is an algebraic system having two binary operations (addition and multiplication) that satisfy postulates F1, F2, F3, F5, and F4':

F4'. Every element a has an additive inverse $(-a)$ such that $a + (-a) = 0$.

A commutative ring is an integral domain when postulate F4'' is satisfied:

F4''. If $ab = 0$, then either $a = 0$ or $b = 0$.

The most familiar integral domain consists of the integers $0, \pm 1, \pm 2, \dots$ under ordinary addition and multiplication; it is commonly designated Z . From the domain Z can be constructed a very important class of modular number systems Z^n , one for each positive integer $n > 1$, as follows.

The members of Z^n are the integers $0, 1, \dots, n-1$, which should be thought of as remainders after division by n . To add two members (numbers) of Z^n , their ordinary sum is taken and then its remainder after division by n (the remainder modulo n) is the answer. Likewise, to multiply two members of Z^n , their ordinary product is taken and again the remainder modulo n is the answer. Thus, in Z_{11} , one has $7 + 9 = 5$, $7 \times 9 = 8$, $5 + 10 = 4$, $5 \times 10 = 6$, and so on.

The proof that every Z^n is a commutative ring is omitted; i.e., that F1–F3, F4', and F5 hold in Z^n for every integer $n > 1$. When n is a prime number p , multiplication is also invertible and the preceding construction gives a field (e.g., Z_{11} is a field). The modular fields Z^n are the simplest finite fields; others will be constructed later.

When $n = rs$ ($1 < r, s < n$) is composite, however, it is possible to have $rs = 0$ in Z^n even though $r \neq 0$ and $s \neq 0$. Hence Z^n is not even an integral domain, but only a commutative ring unless n is a prime.

Fields of quotients. There are many integral domains besides Z , however, that are not fields. For example, if J is any integral domain (e.g., if $J = Z$ or if J is a field F), then the domain $J[x]$ of all polynomials over J in the indeterminate x can be formed. Each such polynomial either reduces to 0 or has a canonical form (see 255). (Here and below, the convenient symbol \in is used for "belonging to" or "is a member of.") The nonnegative integer m , the highest power of x , is called the degree of the polynomial $a(x)$. Given $a(x)$ and a second polynomial, the sum

$$(255) \quad \begin{cases} a(x) = a_0 + a_1x + \dots + a_mx^m \\ a_m \neq 0, \quad \text{all } a_j \in J^* \\ b(x) = b_0 + b_1x + \dots + b_nx^n \end{cases}$$

$$(256) \quad a(x) + b(x) = (a_0 + b_0) + (a_1 + b_1)x + \dots + \begin{cases} a_mx^m, & m > n \\ b_nx^n, & n > m \end{cases}$$

$$(257) \quad a(x)b(x) = a_0b_0 + (a_0b_1 + a_1b_0)x + \dots + \left(\sum_{j=0}^k a_jb_{k-j}\right)x^k + \dots + a_mb_nx^{m+n}$$

$$(258) \quad \begin{cases} \frac{a}{b} = \frac{c}{d} \text{ means } ad = bc \\ \frac{a}{b} \pm \frac{c}{d} = \frac{ad \pm bc}{bd} \\ \frac{a}{b} \cdot \frac{c}{d} = \frac{ac}{bd} \quad \text{and} \quad \frac{a}{b} \div \frac{c}{d} = \frac{ad}{bc} \quad \text{if } c \neq 0 \end{cases}$$

$$(259) \quad \begin{cases} [r + (n)] + [r' + (n)] = (r + r') + (n) \\ [r + (n)] \cdot [r' + (n)] = rr' + (n) \end{cases}$$

$$(260) \quad \theta(r \pm r') = \theta(r) \pm \theta(r') \quad \text{and} \quad \theta(rr') = \theta(r)\theta(r')$$

$$(261) \quad m1 \pm n1 = (m \pm n)1 \quad \text{and} \quad (m1)(n1) = (mn)1$$

can be formed [see 256; the case $m = n$ terminates with $(a_m + b_n)x^m$], and the product (see 257), which is always a nonzero polynomial of degree $m + n$ for $a(x)$ nonzero of degree m and $b(x)$ nonzero of degree n . The domain $J[x]$ satisfies postulates F1–F3, F4', and F5 and therefore is always an integral domain.

From any integral domain J , for example, from the domain $Z[x]$ of all polynomials with integral coefficients or the domain $R[x]$ of all polynomials with real coefficients, a field of quotients $Q(J)$ can be constructed the elements of which are the formal quotients a/b ($a, b \in J$ with $b \neq 0$), by adopting definitions of equality, sums, differences, and products (see 258). This construction yields from the integral domain Z of all integers the rational field $Q = Q(Z)$, and from the domain $R[x]$ of real polynomials the field $R(x) = Q(R[x])$ of all real rational functions.

Ideals and quotient-rings. It is possible to greatly generalize the construction of the modular fields Z_n and commutative rings Z_n from the familiar integral domain Z of all integers. The key idea of this generalization is contained in the following basic concepts.

In a commutative ring R , an ideal is a nonvoid subset H such that $h, h' \in H$ imply $h \pm h' \in H$, and $h \in H$ and $r \in R$ imply $rh = hr \in H$. A residue class, or additive coset, of the ideal H is a set $H + x$ consisting of all sums $h + x$ of a fixed element $x \in R$ with variable h of H .

The ideals of the integral domain Z consist of the trivial ideals Z and $(0) = \{0\}$, the subset of zero, and the proper ideals (n) of the set of all multiples kn ($k \in Z$) of a fixed integer $n > 1$. The residue classes $r + (n)$ of any proper ideal (n) are the sets of integers x having a fixed remainder r under division by n , so that $x = qn + r$ for an integer q .

Z_n can be regarded as the set of all these residue classes, added and multiplied by specific rules (see 259). When constructed in this way, Z_n is called the quotient-ring $Z/(n)$ of Z by the ideal (n) .

Morphisms of rings. The preceding basic construction can also be interpreted in terms of another basic concept, that of morphism. If R and S are any two (commutative) rings, a morphism of rings from R to S is a function $\theta: R \rightarrow S$, which assigns to each $r \in R$ a value $s = \theta(r)$ in S , such that $\theta(1) = 1$ and morphisms of sums, differences, and products are sums, differences, and products

Epimorphism

of morphisms of corresponding elements (see 260). Such a morphism is called an epimorphism when it is onto, in the sense that every $s \in S$ is the image $s = \theta(r)$ of some $r \in R$; if it is also one-one, in the sense that $r \neq r'$ in R implies $\theta(r) \neq \theta(r')$ in S , the (epi)morphism is called an isomorphism. Morphisms of rings are related to ideals and quotient rings by the following basic results:

Theorem: If $\theta: R \rightarrow S$ is any morphism of rings, then the set $\theta^{-1}(0)$ of all elements $r \in R$ such that $\theta(r) = 0$ in S is an ideal J_θ of R . If θ is an epimorphism, then S is isomorphic to the quotient-ring R/J_θ . Conversely, given any ideal J of a ring R , there exists an epimorphism $\theta: R \rightarrow R/J$ under which J is the ideal of all $r \in R$ such that $\theta(r) = 0$ in S .

Subrings and subfields. Here is considered the case in which R is any commutative ring with 1 as its unity element, as postulated in F3. This element is unique because if $1'$ is any other element having the property postulated in F3, then $1' = 1'1' = 1'1 = 1$. S is a set $S = 0, \pm 1, \pm(1+1), \dots$ obtained from 1 by repeated addition and subtraction. These elements are not necessarily distinct (for example, in Z_{11}). For any positive integer n , $n1$ (or just n) is used to designate the sum $1 + \dots + 1$ (with n summands), and $(-n)1$ designates the sum $(-1) + \dots + (-1)$ (again n summands). A final condition is that $0 \cdot 1 = 0$. Using mathematical induction it is then quite easy to prove from the postulates F1–F3, F4', and F5 for a commutative ring that, for all $m, n \in \mathbb{Z}$ (see 261), the function $\mu: n \rightarrow n1$ is a morphism of rings from \mathbb{Z} to R . The set $\{n1\}$ of all natural multiples $n1$ of 1 in R is thus closed under the basic ring operations of addition, subtraction, and multiplication, and it includes the unity 1 of R . A subring of a ring R can be defined to be any subset of R with these properties, and the prime subring can be defined to be the subring $\{n1\}$ just constructed; this prime subring is evidently contained in every other subring: it is the least subring of R .

Characteristic of a ring. Using the results about ideals and quotient-rings in Z stated earlier, one can prove quite easily that the prime subring of any ring is isomorphic to \mathbb{Z} or to \mathbb{Z}_n for some unique integer $n > 1$. (The case $n = 1$ gives the degenerate ring consisting of 0 alone, in which 0 acts as unity, so that $1 = 0$; this is usually excluded from consideration.) This integer n is called the characteristic of the ring; it is the least positive integer n such that $x + \dots + x = 0$ whenever the number of summands is a multiple of n . Rings the prime subring of which is isomorphic to \mathbb{Z} are said to be of characteristic zero (or, more logically, of characteristic infinity, denoted ∞). Rings of characteristic two are quite special; in them, $y = -y$ (because $y + y = 0$), hence $x - y = x + (-y) = x + y$, so that addition is the same as subtraction.

It is easy to show that the characteristic of any field F is a prime p or infinity. In the former case, the prime subring \mathbb{Z}_p is already a field (i.e., closed under division). In the latter case the prime subring \mathbb{Z} can be (uniquely) extended to its field of quotients \mathbb{Q} , which is thus embedded isomorphically in F as its prime subfield; i.e., as a subfield of F contained in every other subfield. To summarize: every field F contains as its smallest prime subfield a copy of \mathbb{Z}_p for some prime p (its characteristic), or of \mathbb{Q} if of characteristic ∞ .

FIELD EXTENSIONS

Simple algebraic extensions. The preceding concepts make possible a far-reaching generalization of the method used to extend the real field \mathbb{R} to the complex field $\mathbb{C} = \mathbb{R}[i]$. Namely, if F is assumed to be any field, and if it is assumed that $p(x)$ is any monic polynomial—i.e., a polynomial with leading coefficient 1 (see 262)—that is irreducible in the sense that it cannot be factored into polynomials of lower degree with coefficients in F , then the multiples of $p(x)$ form an ideal $(p(x))$ in the integral domain $F[x]$ of all polynomials with coefficients in F . Finally, the quotient-ring $F[x]/(p(x))$ the elements of which are the residue classes of this ideal is a field.

Any field constructed in this way is called a simple algebraic extension of F . Each residue class (additive coset) of the ideal $(p(x))$ contains exactly one polynomial of degree less than n , much as each residue class $(p) + n$ of (p) in \mathbb{Z}

$$(262) \quad p(x) = x^n + b_1 x^{n-1} + \dots + b_n$$

$$(263) \quad r(x) = r_0 + r_1 x + \dots + r_{n-1} x^{n-1}$$

$$(264) \quad s(x) = s_0 + s_1 x + \dots + s_{n-1} x^{n-1}$$

$$(265) \quad r(x) + s(x) = (r_0 + s_0) + (r_1 + s_1)x + \dots + (r_{n-1} + s_{n-1})x^{n-1}$$

$$(266) \quad a + bx + cx^2 = a + b\sqrt[3]{2} + c\sqrt[3]{4}, \quad x = \sqrt[3]{2}$$

$$(267) \quad \begin{cases} (a + bx + cx^2)(a' + b'x + c'x^2) = (aa' + 2bc' + \\ + 2b'b'c) + (ab' + ba' + 2cc')x + (ac' + bb' + ca')x^2 \end{cases}$$

$$(268) \quad \begin{cases} x, x^2, x^3, x^4 = x + 1, & x^5 = x^2 + x, & x^6 = x^3 + x^2 \\ x^7 = x^3 + x + 1, & x^8 = x^2 + 1 \\ x^9 = x^3 + x, & x^{10} = x^2 + x + 1 \\ x^{11} = x^3 + x^2 + x, & x^{12} = x^3 + x^2 + x + 1 \\ x^{13} = x^3 + x^2 + 1 \\ x^{14} = x^3 + 1, & x^{15} = x^0 = 1 \end{cases}$$

$$(269) \quad GF(16): x, x^2, x^4, x^7, x^8, x^{11}, x^{13}, x^{14}$$

$$(270) \quad R(x) = p(x)/q(x) \quad \text{with } q(x) \neq 0$$

contains exactly one of the remainders $0, 1, \dots, p-1$ commonly used to represent elements of $\mathbb{Z}/(p) = \mathbb{Z}_p$. Similarly, the polynomial $r(x)$ (see 263) belonging to any given coset $(p(x)) + f(x)$ can be computed from any member of the coset—e.g., from $f(x)$ —as its remainder after polynomial long division by $p(x)$.

Hence the polynomials of degree less than n , such as $r(x)$ (see 263) and x (see 264), can be used to represent the elements of $F[x]/(p(x))$ symbolically. They can be added like ordinary polynomials (see 265). To multiply them, their ordinary product is formed (257), then the remainder under division by n is taken. Thus, if $p(x) = x^3 - 2$, the elements of $\mathbb{Q}[x]/(x^3 - 2) = \mathbb{Q}[x]/(x^3 - 2)$ can be taken as all expressions of the form that results (see 266) by replacing x^3 by 2 wherever it occurs; the product (see 267) is obtained in which $2^{1/3}$ could be written for x and $2^{2/3}$ could be written in place of x^2 , throughout.

Finite fields. The preceding construction gives all finite fields: any finite field of characteristic p is a simple algebraic extension of its prime subfield \mathbb{Z}_p . In more detail, any such field contains p^n elements for some positive integer n and is $\mathbb{Z}_p[x]/(p(x))$ for some irreducible monic polynomial of degree n . Moreover, all fields of the same finite order p^n are isomorphic; because they were first constructed by Galois, it is therefore reasonable to speak of the Galois field $GF(p^n)$ of any given prime-power order p^n . As an example, $GF(16) \cong \mathbb{Z}_2[x]/(x^4 + x + 1)$ consists of 0 and the 15 different powers of x (see 268). Under multiplication, the nonzero elements of $GF(16)$ thus form a cyclic group, consisting of the powers of x , or any of the other primitive roots of 1 (see 269) the exponents of which are relatively prime to 15.

The preceding example is typical: in any finite field $GF(p^n)$, the $p^n - 1$ nonzero elements are all powers of some one primitive $(p^n - 1)$ th root of unity, which can be taken to be x .

Transcendental extensions. Fields have many extensions besides the simple algebraic extensions discussed above. For example, if F is assumed to be any field, and $F[x]$ is assumed to be the integral domain of all polynomials $p(x)$ in the symbol (indeterminate) x with coefficients in F , then because $F[x]$ is an integral domain, the formal quotients of polynomials (rational forms; see 270) constitute a field $F(x)$ under the definitions (see 258) given earlier for constructing the field of quotients of the domain $F[x]$. An extension E of F that can be

constructed from F in this way using a suitable element x of E is called a simple transcendental extension of F . When F is infinite, one can interpret the expressions $R(x)$ (see 270) as rational functions from F to F , defined except for a finite set of values x_i of F in which $q(x_i) = 0$.

By repeating the preceding construction, multiple transcendental extensions of F can be obtained. Thus, for any positive integer n , the field $F(x_1, \dots, x_n)$ can be constructed of all rational expressions (or forms) in the n indeterminates x_1, \dots, x_n as the field of (formal) quotients of polynomials in x_1, \dots, x_n with coefficients in F : the field of quotients of the polynomial ring $F[x_1, \dots, x_n]$.

Multiple algebraic extensions can be constructed similarly. Before considering the general nature of such multiple algebraic extensions, a special case of multiple quadratic extensions of the rational field \mathbb{Q} that has applications to geometry must be considered.

Pythagorean numbers. A real or complex number is called Pythagorean when it can be expressed in terms of rational numbers through a finite number of rational operations and square root extractions; i.e., when it belongs to a multiple quadratic extension of \mathbb{Q} . Because the mapping $z \rightarrow z^*$ that carries each complex number $x + iy$ into its conjugate $z^* = x - iy$ is an automorphism of the complex field \mathbb{C} , and $x = (z + z^*)/2$ and $y = (z - z^*)/2i$, the real and imaginary parts of any Pythagorean number are themselves Pythagorean. Conversely, $z^2 = c = a + ib$ is equivalent to two simultaneous quadratic equations (see 271). Therefore a complex number $z = x + iy$ is Pythagorean if,

$$(271) \quad \begin{cases} x^2 + y^2 = \sqrt{a^2 + b^2} & \text{and} & 2xy = b \\ x \pm y = [\sqrt{a^2 + b^2} \pm b]^{\frac{1}{2}} \end{cases}$$

$$(272) \quad x^2 + y^2 + Ax + By = C, \quad 4C > A^2 + B^2$$

$$(273) \quad C = R[\sqrt{-1}] = \frac{R(x)}{x^2 + 1}$$

$$(274) \quad p(z) = c_0 + c_1 z + c_2 z^2 + \dots + c_n z^n, \quad c_n \neq 0$$

$$(275) \quad p(z) = c_n(z - z_1)(z - z_2) \dots (z - z_n), \quad \text{all } z_k \in \mathbb{C}$$

$$(276) \quad (z - z_k)(z - z_k^*) = z^2 - (z_k + z_k^*)z + z_k z_k^*$$

$$(277) \quad \begin{cases} x = 0010 & x^6 = 1100 & x^{11} = 1110 \\ x^2 = 0100 & x^7 = 1011 & x^{12} = 1111 \\ x^3 = 1000 & x^8 = 0101 & x^{13} = 1101 \\ x^4 = 0011 & x^9 = 1010 & x^{14} = 1001 \\ x^5 = 0110 & x^{10} = 0111 & x^{15} = 0001 \end{cases}$$

and only if, x and y (its real and complex parts) are both Pythagorean.

The subfield of all Pythagorean numbers has an interesting relation to ruler-and-compass constructions in plane geometry. In the complex z -plane, a point is called Pythagorean when its coordinate is a Pythagorean number. A straight line that passes through two Pythagorean points is called a Pythagorean line; the angle between two Pythagorean lines, a Pythagorean angle; and a circle that has a Pythagorean centre and a Pythagorean radius, a Pythagorean circle.

It can be proved very easily that a straight line is Pythagorean if and only if its standard equation ($y = ax + b$ or $x = c$) has (real) Pythagorean coefficients. For, any line having such an equation passes through the Pythagorean points $(0, b)$ and $(1, a + b)$, while if $y_i = ax_i + b$ for two Pythagorean points (x_1, y_1) and (x_2, y_2) , then $a = (y_2 - y_1)/(x_2 - x_1)$ and $b = y_2 - ax_2$ must be Pythagorean numbers.

A circle is Pythagorean if and only if its equation, written in the customary way as a sum of squares and a linear component (see 272), has coefficients that are (real) Pythagorean numbers. The circle through any three

Pythagorean points z_1, z_2, z_3 is Pythagorean; this can be demonstrated by setting $x = x_i$ and $y = y_i$ ($i = 1, 2, 3$) (see 272) and solving for the unknowns A, B, C .

Likewise, it is easy to show that two Pythagorean lines or circles can only intersect in Pythagorean points. To show this, it suffices to solve for the coordinates (x_i, y_i) of the points of intersection in terms of the (Pythagorean) coefficients of the equations.

From the preceding, it follows that the set of all Pythagorean points, lines, and circles is precisely the set of all points, straight lines, and circles that can be constructed from a given line segment [drawn between $(0, 0)$ and $(1, 0)$], using a ruler and compass.

Finally, the set of all Pythagorean angles must be determined. Using Galois theory (see below), it can be shown that $1/n$ is a Pythagorean number if and only if n is the product of a power of two and a Pythagorean prime p_i such that p_i is one plus a certain power of two. The first few Pythagorean primes are $2 = 2^0 + 1$, $3 = 2^1 + 1$, $5 = 2^2 + 1$, $17 = 2^4 + 1$, and $257 = 2^8 + 1$. It can be shown that they are all of the form $2^{2^x} + 1$, in which $x = 2^n$. Correspondingly, 90° , 72° , 60° , and 45° are Pythagorean angles, but 20° is not.

Fundamental Theorem of Algebra. Now the most remarkable property of the complex field \mathbb{C} is reached, which can also be characterized as the simple algebraic extension (see 273) of the real field \mathbb{R} . This property will be stated now as a theorem, omitting its proof (which is not algebraic, but depends basically on considerations from analysis). This theorem is called the Fundamental Theorem of Algebra.

For any polynomial of degree $n > 0$ (see 274), with complex coefficients $c_k \in \mathbb{C}$, there exists a complex number $z_i \in \mathbb{C}$ such that $p(z_i) = 0$.

A corollary is that the polynomial $p(z)$ (see 274) can always be (uniquely) factored into linear factors (see 275).

As a further corollary, the only polynomials that are irreducible over \mathbb{C} are linear polynomials, from which it follows that \mathbb{C} has no proper algebraic extensions.

When the coefficients of $p(z)$ (see 274) are real, its complex roots z_k occur in conjugate pairs, giving real quadratic factors (see 276) with negative discriminant $4x_k^2 - 4(x_k^2 + y_k^2) < 0$. It follows that any real polynomial can be factored into real linear and quadratic factors.

APPLICATIONS TO CODING

Binary codes. Finite fields $GF(2^n)$ of characteristic two are widely used in the design of codes for detecting and correcting errors in the transmission of digital information (see INFORMATION PROCESSING AND INFORMATION SYSTEMS AND COMBINATORICS). Such information is commonly transmitted as a sequence of signals of two kinds; for example, dots and dashes, or timed pulses and non-pulses. These can be interpreted as strings of 0's and 1's; the elements of $GF(2^n)$ can also be represented very compactly as strings of binary digits, or bits, 0 and 1. Thus, in $GF(16)$, the x^k , the remainders of which after division by $x^4 + x + 1$ were listed above (see 268) as polynomials, can be expressed in the more compact form of quadruples of binary digits (see 277). Thus, if a message consisting of sequences of binary digits is broken down into segments (words) of length four, each word can be interpreted as an element of $GF(16)$.

Because the transmission of messages consisting of such four-bit (or longer) words is not infallible, it is common practice to add check digits to a given message, so the actual (binary) code word sent is longer than the message word containing the actual information to be transmitted. One speaks of an (m, n) -code ($m < n$) if the binary code words transmitted all have the same length n , greater than the length m of the message words.

The simplest code consists of one check digit, usually taken to be 1 if the number of digits 1 in the actual message is odd and 0 if it is even. Thus, for the four-bit message words listed above, the code words would be: 00101, 01001, 10001, 00110, 01100, 11000, 10111, 01010, 10100, 01111, 11101, 11110, 11011, 10010, and 00011. The set of all code words clearly consists of just those strings of five 0's and 1's that have an even number

Simple codes

of 1's. Note that the set of code words contains with any two code words their sum (all digits being added mod 2); thus $00101 + 10001 = 10100$ ($x + x^3 = x^9$).

The preceding code is error-detecting: if there is only one error made in transmitting a given code word, this error can be detected because the received word will have an odd number of 1's. More elaborate codes are error-correcting. A simple error-correcting code would consist in repeating each message word three times, so that $x^8 = 0101$ would be transmitted as 0101010101 . If at most one error is made in transmitting each digit of the given message, then the correct message can be decoded by assigning to each near code word the message that gives each digit correctly two or more times. Thus, 011100010100 would still be correctly deciphered as the message 0101 , even though it has three errors of transmittal.

Note that in the preceding triple repetition code, the set of all code words is also closed under addition. This is characteristic of the group codes commonly used in practice.

Optimal binary codes. The triple repetition (4, 12)-code just described will correct all single errors, but not all double errors. A much better code for correcting 4-bit messages can be constructed using $GF(8) = Z_2[x]/(x^3 + x + 1)$, as follows. Given a 4-bit message $a_0a_1a_2a_3$, form the product (see 278) of the corresponding binary message polynomial $a(x)$

$$(278) \quad a(x)g(x) = (a_0 + a_1x + a_2x^2 + a_3x^3)(1 + x + x^3)$$

$$(279) \quad a(x)g(x) = b(x) = b_0 + b_1x + b_2x^2 + \cdots + b_6x^6$$

$$(280) \quad a(x)g(x) = (a_0 + a_1x + \cdots + a_6x^6)(1 + x + x^2 + x^4 + x^8)$$

$$(281) \quad g(x) = 1 + x + x^2 + x^4 + x^8 \\ = (1 + x^3 + x^4)(1 + x + x^2 + x^3 + x^4)$$

$$(282) \quad a(x)g(x) = b_0 + b_1x + b_2x^2 + \cdots + b_{14}x^{14}$$

with the fixed encoding polynomial $g(x) = 1 + x + x^3$, and transmit the 7-digit code word $b_0b_1b_2 \cdots b_6$ corresponding to the product in $Z_2[x]$ (see 279). Because the roots of $x^3 + x + 1 = 0$ are primitive 7th roots of unity in $GF(8)$, all code words differ in at least three digits.

Advantages of the (4, 7)-code

Indeed, the (4, 7)-code just constructed is a perfect code in the sense that each 7-digit word not a code word can be corrected to precisely one code word by changing one digit. Because it transmits as much information as the triple repetition (4, 12)-code in less than 60 percent as much time and has roughly the same error-correcting capabilities, it is clearly superior.

Similarly, one can use the field $GF(16)$ to construct a (7, 15) binary code that will correct two errors with certainty and is far superior to the (5, 15) triple repetition code. Namely, given a 7-bit message word $a_0a_1 \cdots a_6$, the product formed (see 280) is of the corresponding binary message polynomial $a(x)$ with the fixed encoding polynomial $g(x)$ (see 281). The product polynomial with typical coefficient b_k (see 282) is transmitted as the 15-digit code word $b_0b_1b_2 \cdots b_{14}$. Because the roots of both of the factors of $g(x)$ above are primitive 15th roots of unity in $GF(16)$, it can be shown that it takes five changes to convert one code word into another, and that each 15-digit word differs in two or fewer letters from at most one nearest code word. That is, the preceding code corrects all double errors. Moreover, it is not far from optimal.

GALOIS THEORY

Algebraic number fields. If E is any extension of a field F —that is, if F is any subfield of the field E —then E can be considered as a vector space over F , which is the field of scalars. A number $x \in E$ is then said to be algebraic over F when it generates with F a finite-dimensional subspace of E . This is the case if, and only if, the powers $1 = x^0, x, x^2, \cdots$ of x are linearly dependent over F , so that x satisfies a polynomial equation with coefficients in F .

In particular, a real or complex number z is called algebraic when it is algebraic over the rational field Q , which is, of course, the prime subfield of C (and R). That is, z is algebraic precisely when it satisfies a polynomial equation with rational coefficients, hence an irreducible polynomial equation $p(z) = 0$, so that the extension of Q by z is the simple algebraic extension $Q[z]/(p(z))$. (Actually, every finite-dimensional extension of Q or any Z_p is just such a simple algebraic extension.)

When E itself is a finite-dimensional vector space over F , its dimensionality (over F) is called its degree as an extension of F , and this degree is written symbolically as $[E:F]$. In such cases, every element of E is algebraic over F , and E may properly be called an algebraic extension of F .

More generally, if E is any extension of a field F , the set of all numbers $x \in E$ that are algebraic over F is a subfield. Thus, the set of all algebraic (complex) numbers is a subfield A of C , which is algebraically complete (or closed) in the sense that any polynomial $p(z)$ of degree $n > 0$ with coefficients in A has a root z_1 in A . This is a proper subfield of C , because it fails to contain e , π , and other transcendental numbers (a transcendental number is a number that is not the root of a polynomial with integral coefficients).

Still more generally, if F is any field and $p(x)$ any polynomial with coefficients in F , then x will be a root of $p(x) = 0$ in the simple algebraic extension $F[x]/(p(x))$. By repeated extensions, using transfinite induction if necessary, an algebraically complete algebraic extension of F can always be constructed, in which an analogue of the Fundamental Theorem of Algebra holds.

Splitting fields. If F is assumed to be any field, and $p(t)$ any polynomial with coefficients in F , a splitting field of $p(t)$ over F is defined as an extension E of F over which $p(t)$ can be factored into linear factors. To construct a least such splitting field, the following procedure is followed.

First, if it is supposed that $p(t)$ is factored into factors irreducible over F , it is easy to show that such a factorization exists. If the irreducible factors are all linear—that is, of degree one—there is nothing to prove ($E = F$).

Otherwise, $p(t)$ will have an irreducible factor $p_i(t)$ of degree $n > 1$, in which case the simple algebraic extension $E_1 = F[x]/(p_i(x))$ is formed. In E_1 , the polynomial p_i , which was written as $p_i(t)$ to avoid confusion between t and the indeterminate x in E_1 , will have the root x and hence the linear factor $(t - x)$. Hence $p_i(t)$, and so $p(t)$, can be factored into more factors over E_1 .

Repeating this construction at most n times, an extension will be obtained, $E = E_k$ of F over which $p(t)$ can be factored into linear factors. Because E is generated by F and roots x_1, \cdots, x_k of $p(t) = 0$, it is evident that E is a minimal splitting field (it is called the root field of $f(t)$ over F). To prove this rigorously, however, requires a more careful study of isomorphisms and their extensions.

Galois theory of fields. This study, and many other aspects of the deeper algebraic theory of fields (including that of the algebraic solvability of polynomial equations), involves so-called Galois theory, which in turn depends on the concept of a group (see above Groups).

For Galois theory, the concept of a normal field extension is indispensable. An extension E of a field F is called a normal over F when E is a splitting field for every polynomial $p(x)$ that is irreducible over F and has one root in E . Equivalently, the condition is that, if $p(x)$ has one root in E and is irreducible over F , then all its roots are in E . Thus the complex field C is a normal extension of the real field R , and the field $Q[(1+i)/\sqrt{2}]$ obtained by adjoining the fourth root $\omega = (1+i)/\sqrt{2}$ of -1 to the rational field Q is a normal extension of Q (it is the root field of $x^4 + 1$ over Q , whose other roots are $\omega^3, \omega^5, \omega^7$).

If it be assumed that E is a normal extension of a field F , then the Galois group of E over F is defined as the group of those automorphisms γ of the field E that leave every element of F invariant; i.e., satisfy $\gamma(x) = x$ for all $x \in F$.

It is known that if x_1 and x_2 are any two roots in E of a polynomial $p(x)$ that is irreducible over F , then there exists an automorphism in the Galois group of E over F that carries x_1 into x_2 . Thus, i and $-i$ are the two roots

Normal
field
extension

of $x^2 + 1 = 0$ in the normal extension \mathfrak{C} of \mathfrak{R} ; the automorphism $\gamma: z \rightarrow z^*$ of \mathfrak{C} carries i into $-i$. Likewise, there exist automorphisms of $Q[(1+i)/\sqrt{2}]$ over Q that carry $\omega = (1+i)/\sqrt{2}$ into ω^3 , ω^5 , and ω^7 .

A complex number can be shown to be Pythagorean if and only if the smallest normal extension of Q that contains it has a Galois group (over Q) the order of which is a power of two. (The order of any algebraic system is the cardinal number of its elements.) It follows from this and Lagrange's theorem in group theory that no Pythagorean number can satisfy an irreducible equation the degree of which is not a power of two. On the other hand, using analytic geometry, it can be shown that angle trisection is equivalent to solving a cubic equation that is in general irreducible, as in the case of trisecting an angle of 120° to get an angle of 40° . It follows in general that an angle cannot be trisected by a finite construction with ruler and compass; in particular, an angle of 120° or 60° cannot be so trisected.

One can show that the Galois group of any binomial $x^n - a$ is solvable in a sense defined above in the section *Groups*. More generally, this is true of any normal field extension obtained by successive adjunctions of roots $a^{1/n}$ of constants a already constructed. It follows that if a polynomial equation $p(x) = 0$ over a field F can be solved by radicals, in the sense that its roots can be expressed in terms of the elements of F using only rational operations and root extractions, then the Galois group of the root field of $p(x)$ over F is solvable. The converse is also true: if $p(x)$ is a polynomial the root field of which has a solvable group, then the roots of $p(x) = 0$ can be expressed in terms of its coefficients using only rational operations and root extractions.

On the other hand, the Galois group of an irreducible polynomial equation of degree n over Q is, in general, the symmetric group of all permutations of its n roots x_1, \dots, x_n . Moreover, this symmetric group is solvable if and only if $n \leq 5$ (the proof of this is quite technical). It follows that any quadratic, cubic, or quartic equation is solvable by radicals, but that quintic and higher degree polynomial equations in general are not.

ORDERED FIELDS

Positivity. To define the real field, to establish the deeper properties of the real and complex fields, and in particular to construct the real field from the rational field, more than the four rational operations of addition, multiplication, subtraction, and division must be considered. For example, these operations fail to distinguish $\sqrt{2}$ from $-\sqrt{2}$: the Galois group of \mathfrak{C} over Q interchanges $\pm\sqrt{2}$.

The simplest and most natural concept with which to construct \mathfrak{R} from Q and to establish its deeper properties (along with those of \mathfrak{C}) is the order concept or, equivalently, that of positivity. These concepts are now defined. A field F is said to be ordered when it contains a set P of positive elements having three properties stating that the sum and product of any two elements in P belong to P and that for every x , exactly one of the following is true: $x = 0$, x is in P or $-x$ is in P (see 283).

In an ordered field, $x > y$ is defined to mean that $(x - y) \in P$. Then $x \in P$ is equivalent to $x > 0$, and the properties of P can be used to prove the transitive property of the order relation, its preservation when elements satisfying it are replaced by their sums or products with appropriate field elements, and the threefold alternative of order between any two elements (see 284). Conversely, in any field F having an order relation satisfying these properties (see 284), the set P of all elements x such that $x > 0$ satisfies the definition of an ordered field (see 283), while $u > v$ if, and only if, $(u - v) \in P$; indeed, these results hold more generally in integral domains.

It is a familiar fact that Q and \mathfrak{R} are ordered fields with the usual order. Indeed, in \mathfrak{R} , P can be defined as the set of all nonzero a such that \sqrt{a} exists in \mathfrak{R} , giving a purely algebraic characterization of the order relation. As a result, there are no nontrivial field automorphisms of \mathfrak{R} .

On the other hand, there is no way to make the complex field \mathfrak{C} or any field such as Z_p of finite characteristic into an ordered field. This is because, if x is any nonzero

$$(283) \quad \begin{cases} x \in P \text{ and } y \in P \text{ imply } x + y \in P \\ x \in P \text{ and } y \in P \text{ imply } xy \in P \\ x = 0, x \in P, \text{ or } -x \in P \end{cases}$$

$$(284) \quad \begin{cases} \text{If } x > y \text{ and } y > z, \text{ then } x > z. \\ \text{If } a \in F \text{ and } x > y, \text{ then } a + x > a + y. \\ \text{If } a > 0 \text{ and } x > y, \text{ then } ax > ay. \\ \text{Given } x \text{ and } y, \text{ precisely one of the following} \\ \text{alternatives holds:} \\ x = y, \quad x > y, \quad \text{or} \quad y > x \end{cases}$$

$$(285) \quad x_1^2 + x_2^2 + \dots + x_n^2 = 0 \text{ implies } x_1 = x_2 = \dots = x_n = 0$$

$$(286) \quad \overbrace{n \text{ summands}} \quad n\delta = \delta + \dots + \delta > M$$

$$(287) \quad \lim_{n \rightarrow \infty} \frac{1}{n} = 0$$

$$(288) \quad f(x) = x^r(a_0 + a_1x + \dots + a_nx^n + \dots)$$

$$(289) \quad \begin{aligned} & [x^r(a_0 + a_1x + a_2x^2 + \dots)] \cdot \\ & \quad \cdot [x^s(b_0 + b_1x + b_2x^2 + \dots)] \\ & = x^{r+s} [a_0b_0 + (a_1b_0 + a_0b_1)x + \\ & \quad + (a_2b_0 + a_1b_1 + a_0b_2)x^2 + \dots] \end{aligned}$$

element of an ordered field, then by the second property of the definition of an ordered field (see 283) $x^2 = (-x)^2$ must be positive; hence any sum of squares must be positive. It follows that if a field can be made into an ordered field, then it must satisfy the implication that each of n elements are 0 if the sum of their squares is 0 (see 285). Fields having this property are called formally real; it has been shown that a field cannot be ordered unless it is formally real.

Using the concept of a formally real field, the mathematician Artin solved in 1926 a famous problem of Hilbert, showing that a real polynomial $p(x_1, \dots, x_n)$ assumes positive values for all real x_1, \dots, x_n if, and only if, it is a sum of squares of polynomials.

Archimedean fields. As will be shown, there is a vast variety of ordered fields. The familiar ordered fields Q and \mathfrak{R} have a property that sets them apart from many others, the Archimedean property, as follows.

The definition is that an ordered field (or integral domain or even additive group) is called Archimedean when, given $\delta > 0$ (no matter how small) and $M > 0$ (no matter how large), there exists a positive integer n such that its product with δ , defined in terms of the addition of n summands, is greater than M (see 286).

In fields, but not necessarily in integral domains, the preceding condition is equivalent to either of the following:

- (i) The set $\{n\}$ of all positive integers has no upper bound.
- (ii) The set $\{1/n\}$ of all reciprocals of positive integers has greatest lower bound 0.

[Explanation: Condition (i) implies the Archimedean property (see 286), because it allows the choice of $n > M/\delta$; by an upper bound of a set S is meant as usual a number λ such that $\lambda \geq x$ for all $x \in S$.]

Condition (ii) can also be written in the form of a vanishing limit of reciprocals of n as n approaches ∞ (see 287), which means simply that, given $\varepsilon > 0$, n can be found such that $n < 1/\varepsilon$; in other words, that there is no $\varepsilon > 0$ such that $1/n \leq 0$ for all positive integers n . Because 0 is obviously a lower bound to $\{1/n\}$, this is equivalent to saying that it is the greatest lower bound.

An interesting non-Archimedean field is provided by the set consisting of 0 and all extended formal power series, whether convergent or not, expressed with a factor x^r common to all terms and a first coefficient a_0 (see 288), in which r can be any integer, the coefficients c_k belong

The Archimedean property

to a specified ordered field F , and $a_0 \neq 0$. The extended formal power series f (see 288) is called positive if, and only if, $a_0 > 0$, while the sum and product of two such series are defined by the usual formal rules (see 289). It is then straightforward to show that the above construction gives a non-Archimedean ordered field. In this ordered field, the set of all ordinary power series—i.e., extended formal power series (288) with $r \geq 0$ —is a subring, hence a non-Archimedean ordered domain.

It is evident that any subfield S of an ordered field F is itself an ordered field (positivity having the same meaning), and that S is an Archimedean ordered field if F is.

Limits and convergence. In any ordered set, whether a field or not, one can speak of limits and convergence. Namely (see 287), if x_1, x_2, x_3, \dots is any infinite sequence of elements of an ordered set C , it may be said that the sequence $\{x_n\}$ converges to the limit a (see 290) if, and only if, for every $\varepsilon > 0$ there exists an n so large that $a - \varepsilon < x_m < a + \varepsilon$, whenever m is greater than n .

$$(290) \quad \lim_{n \rightarrow \infty} x_n = a \quad \text{or simply } x_n \rightarrow a$$

$$(291) \quad \begin{cases} \{.3, .33, .333, .3333, .33333, \dots\} \rightarrow \frac{1}{3} \\ \{.7, .67, .667, .6667, .66667, \dots\} \rightarrow \frac{2}{3} \\ \{3, 1, 3.14, 3.141, 3.1415, 3.14159, \dots\} \rightarrow \pi \end{cases}$$

$$(292) \quad \{x_1 \leq x_2 \leq x_3 \leq \dots \leq x_n = \dots\}$$

$$(293) \quad \{x_n\} = \{y_n\} \text{ means that } \lim_{n \rightarrow \infty} (x_n - y_n) = 0$$

$$(294) \quad \begin{cases} |0| = 0, & |x| > 0 \quad \text{if } x \neq 0 \\ |a + b| \leq |a| + |b| \\ |ab| = |a| \cdot |b| \\ |(|a|)| = |a| \end{cases}$$

$$(295) \quad |z| = \sqrt{x^2 + y^2}, \quad z = x + iy$$

$$(296) \quad q = (r/s)p^v$$

$$(297) \quad \begin{cases} \phi_p(0) = 0, & \phi_p(q) > 0 \quad \text{if } q \neq 0 \\ \phi_p(a + b) \leq \phi_p(a) + \phi_p(b) \\ \phi_p(ab) = \phi_p(a) \phi_p(b) \\ \phi_p(a + b) \leq \text{Max}\{\phi_p(a), \phi_p(b)\} \end{cases}$$

Monotone sequences

The most familiar examples of convergent sequences are provided by the successive lower and upper n -place decimal approximants to a given number. Thus, $1/3$ may be expressed as a limit of decimal fractions composed successively of greater numbers of the digit 3 (see 291) and so on.

The preceding examples are monotone; i.e., increasing or decreasing. Limits of monotone sequences have an especially simple characterization. Thus, if a "less than or equals" relation holds between any pair of elements with adjacent subscripts in a sequence (see 292)—that is, if the sequence is any increasing (or non-decreasing) sequence of numbers from an ordered field F —then $x_n \rightarrow a$ if, and only if, a is the least upper bound (l.u.b.) of the set of $\{x_n\}$. By this it is meant that: $a \geq x_n$ for all n , and $b \geq x_n$ for all n implies $b \geq a$. The fact that an increasing sequence $\{x_n\}$ converges to a is often written $x_n \uparrow a$. Likewise, one writes $x_n \downarrow a$ to signify that the sequence $\{x_n\}$ is decreasing (or non-increasing), with greatest lower bound (g.l.b.) a .

Completeness. Now the deepest property of the real field \mathfrak{R} is reached: the property of completeness, which distinguishes it from all other ordered fields. Actually, there are two kinds of completeness, which will be discussed in turn.

First, there is sequential, or Cauchy, completeness. If $\{x_n\}$ is any convergent sequence in an ordered field with limit

a , then the doubly infinite set of differences $\{x_m - x_n\}$ has the property of being a Cauchy sequence in the following sense.

A sequence $\{x_n\}$ of numbers of an ordered field F is defined to be a Cauchy sequence when, given $\varepsilon > 0$, there exists N so large that $m, n > N$ imply $-\varepsilon < x_m - x_n < \varepsilon$.

In the real field \mathfrak{R} , the converse is also true: any Cauchy sequence has a limit to which it converges. This property defines sequential completeness.

An ordered field (or group) F is complete in the sense of Cauchy when every Cauchy sequence converges to some limit.

The real field is complete in the sense of Cauchy. For, choosing $\varepsilon = 10^{-r}$ ($r = 1, 2, 3, \dots$), from any Cauchy sequence $\{x_n\}$ can be obtained a subsequence $\{x_{n(r)}\}$ of decimal fractions, such that $x_{n(r)}$ differs from all later terms at most in the r th decimal place.

The real field \mathfrak{R} can be constructed from the rational field Q as follows, using the property of Cauchy completeness. The elements of the field \mathfrak{R} can be constructed as the limits of Cauchy sequences of rational numbers with the identification of two such sequences (see 293) meaning that the limit of the difference of corresponding terms is 0.

Second, there is a more powerful, but less constructive, characterization of completeness, which may be expressed as follows.

An ordered field (or other set) F is defined to be complete in the sense of Dedekind when every bounded set of its elements has a least upper and a greatest lower bound.

It is easy to show that any ordered field that is complete in the sense of Dedekind is Archimedean, and complete in the sense of Cauchy. Conversely, an ordered field F that is Archimedean and complete in the sense of Cauchy is necessarily complete in the sense of Dedekind. What is even more important, however, the following results are true.

Theorem: An ordered field is Archimedean if and only if it is isomorphic with a subgroup of the real field. An ordered field is isomorphic to the real field if and only if it is complete in the sense of Dedekind.

The deepest questions of all are now reached: those of the existence and uniqueness (up to isomorphism) of complete ordered fields. As will be seen, the notion of an absolute value or valuation plays a central role in discussions of these questions.

VALUATIONS

Underlying ideas. The reader may be familiar with the distinction between the sign \pm and the magnitude of a real number. More generally, in an ordered field, the absolute value $|x|$ of any number x can be defined as having the value x if x is positive or zero and the value $-x$ otherwise. From this definition such standard relations as those that relate to the absolute value of 0 and of sums, products, and absolute values (see 294) can be easily derived.

Even though the complex field cannot be made into an ordered field, the definition of the square root of the sum of squares of components of a complex number (see 295) defines an absolute value function sharing the formal properties (294). The notion of absolute value with this definition (295) is indispensable in complex analysis, the theory of functions of a complex variable.

There are many analogues and generalizations of the preceding absolute-value function. An interesting analogue is defined, on the rational field Q , for any prime number p , by the following observation. Each rational number $q = m/n$ (m, n in lowest terms) is uniquely expressible in the form of a ratio of r and s times a power of p (see 296), in which r and s are relatively prime to each other and to p , and $s > 0$.

Given the decomposition (see 296), the number $\phi_p(q) = p^{-v}$ is called the p -adic valuation of q .

This valuation is counterintuitive (contrary to one's intuitive feeling): for example, $\phi_2(1024)$ is very small, whereas $\phi_2(1/1024)$ is a million times as large. Nevertheless, it shares (see 297) the first three formal properties of the more familiar absolute value function (see 295). Only the fourth property fails. By way of compensation, the p -adic valuation of q has a sharper property (see 297) than that of the second property of absolute value, which one can

Dedekind completeness

Cauchy completeness

strengthen to an inequality involving the maximum of two p -adic valuations rather than the sum.

There are many other important generalizations of the absolute value concepts to systems other than fields: the absolute value $(x^2 + y^2 + z^2 + t^2)^{1/2}$ of a real quaternion $q = t + xi + yj + zk$; the norm $N(a + b\sqrt{2}) = a^2 - 2b^2$ of a number $c = a + b\sqrt{2}$ in $Q(\sqrt{2})$; the norm of an element of a Banach space; and so on.

Completing fields. The way will now be described by which any valuation having the first three properties of the p -adic valuation (see 297) or their equivalents, the first three properties of absolute value (see 294), can be used to complete a given field. The field extension construction to be described gives the real field \mathbb{R} from the rational field Q ; the complex field \mathbb{C} from the field $Q(\sqrt{-1})$ of all rational complex numbers $r + s\sqrt{-1}$ ($r, s \in Q$); and a new family of p -adic number fields from the p -adic valuations of Q . It involves the notion of a Cauchy sequence, which is generalized in the following definition:

Let F be any field with a real valuation ϕ satisfying the first three properties of the p -adic valuation (see 297). A sequence $\{x_n\} = \{x_1, x_2, x_3, \dots\}$ of elements x_n of F is called a Cauchy sequence (for the valuation ϕ) when, given $\varepsilon > 0$, there is an integer N such that the value of ϕ at the difference of two elements with subscripts sufficiently large is less than ε (see 298).

Cauchy
sequence

$$(298) \quad \phi(x_m - x_n) < \varepsilon \quad \text{if } m, n > N$$

$$(299) \quad \begin{cases} \{x_n\} + \{y_n\} = \{x_n + y_n\} \\ \{x_n\} \cdot \{y_n\} = \{x_n y_n\} \end{cases}$$

$$(300) \quad \lim_{n \rightarrow \infty} \phi(x_n - y_n) = 0$$

$$(301) \quad x = p^n(a_0 + a_1 p + a_2 p^2 + a_3 p^3 + \dots)$$

$$(302) \quad u = \cos \frac{2\pi}{n} + i \sin \frac{2\pi}{n}, \quad u^n = 1$$

$$(303) \quad a_0 + a_1 u + \dots + a_{n-1} u^{n-1}$$

$$(304) \quad x^n = (z - y)(z - uy) \dots (z - u^{n-1}y)$$

$$(305) \quad F_s(x_1, \dots, x_n) = 0, \quad s = 1, \dots, r$$

The sum and product of two Cauchy sequences can be defined by obvious formulas (see 299). Under these definitions the Cauchy sequences form a commutative ring F_ϕ (a subring of F^ω), which is, however, not even an integral domain, let alone a field. To make it into a field, the following equivalence relation must be introduced. (In the language of the theory of commutative rings [see below *Rings*], a maximal ideal M of F_ϕ must be constructed; the quotient-ring F_ϕ/M will then be a field.)

Two Cauchy sequences as defined are concurrent when the limit of the valuation ϕ for differences of corresponding terms in the two sequences is 0 (see 300).

In the construction of the real field \mathbb{R} from the (ordered) rational field Q , typical Cauchy sequences consist of decimal (or binary) approximations to a given unlimited decimal number; two such Cauchy sequences are concurrent when they ultimately agree to any preassigned number of decimal (or binary) digits, leaving aside decimal numbers such as $0.999999 \dots = 1.000000 \dots$ themselves. In this case, the field constructed is not only complete in the sense of Cauchy, it is also an Archimedean ordered field that is complete in the sense of Dedekind. The positive numbers of F_ϕ are the Cauchy sequences $\{x_n\}$ the terms of which are ultimately all positive, and that are not null sequences (do not converge to zero, are not concurrent to $\{0, 0, 0, \dots\}$).

To recapitulate, the real field \mathbb{R} is not only Archimedean and complete in the sense of Cauchy; it is also complete in the sense of Dedekind. Conversely, it can be shown

that any field that is complete in the sense of Dedekind is Archimedean and complete in the sense of Cauchy. Moreover, in it, one can reconstruct all numbers as limits of decimal fractions in the usual way and derive the usual laws for adding and multiplying the resulting infinite decimals.

This sequence of arguments shows that any ordered field that is complete in the sense of Dedekind is isomorphic to the real field: up to isomorphism, there is one and only one such field. On the other, the field $\mathbb{R}[[x]]$ of all extended formal power series with real coefficients is a non-Archimedean ordered field (see 288), which is complete in the sense of Cauchy.

Finally, it may be remarked that for $\phi = \phi_p$, the previous field extension by Cauchy sequences (modulo null sequences) gives the so-called p -adic numbers of Hensel. These constitute for each prime p a p -adic field, the nonzero elements of which can be thought of as extended formal series in the symbol p with integral coefficients a_k , first coefficient with subscript 0, and with a factor common to each term of the form p^a (see 301), in which a is an arbitrary integer, every a_k is one of the integers $0, 1, \dots, p-1$, and $a_0 \neq 0$. Though the p -adic fields have characteristic zero, they are not to be thought of as ordered fields, still less as Archimedean ordered fields.

(G.Bi.)

Rings

The notion of a ring has been mentioned at the beginning of this article and used in the preceding section *Fields*. It is a set of elements that can be added, subtracted, and multiplied and in which these three operations obey (more or less) the usual rules. A more formal definition will be given later. In particular, if R is a set of real or complex numbers such that the sum, the difference, and the product of any two elements of R is in R , then R is a ring for the usual operations. It is not required that the division by a nonzero element of a ring be always possible; thus the divisibility problem for elements of a ring is important, as it is for the ordinary integers.

The rings introduced by the German arithmeticians of the 19th century for studying problems involving divisibility and factorization were, in fact, mostly sets of complex numbers (more precisely of algebraic integers) as above. The main impetus came from the intensive study of Fermat's equation $x^n + y^n = z^n$, stated without proof by the French mathematician Pierre de Fermat to have no solution (x, y, z) in integers greater than 1 for exponents n greater than 2.

Fermat's
equation

It has been proved that Fermat's statement is true for many exponents n , but the general case is still open. The most fruitful approach to the problem introduces a complex n th root of unity (see 302) and the numbers which are polynomials in such an n th root, coefficients a_i (see 303) being ordinary integers; these numbers form a ring R . Fermat's equation can be written (see 304) in a way that is related with the problem of decomposing x^n in the ring R . If the analogue of the unique decomposition of an integer into prime factors is true in R , then Fermat's statement can be proved. This method (or a variant) works for some values of n (e.g., $n = 3, 5, 14$), but the German mathematicians Peter Gustav Lejeune Dirichlet and Ernst Eduard Kummer noticed that the analogue of the unique decomposition is not true in general. As a remedy, Kummer and Richard Dedekind, introduced the notion of an ideal, which proved to be of fundamental importance for ring theory.

At the end of the 19th century another impetus came from algebraic geometry. Roughly speaking, this branch of mathematics studies the n -tuples (x_1, \dots, x_n) of complex numbers that satisfy a given finite system of polynomial equations (see 305); these n -tuples form what is called an algebraic set, and the polynomial functions on such an algebraic set H form a ring, its coordinate ring, for addition and multiplication in a modified sense, called value-wise addition and multiplication. An important paper of Dedekind and Weber, published in 1882, showed that when this algebraic set H is a curve—i.e., has dimen-

sion one—the coordinate ring of H has many properties in common with the rings of algebraic integers studied by the arithmeticians, a striking parallelism between geometry and arithmetic, which has been intensively generalized and fruitfully studied since. In 1893 the German mathematician David Hilbert introduced powerful ideal theoretical methods in the study of general polynomial rings and coordinate rings, proving the important finite basis theorem and the “zeroes theorem.” In this theory the substitute for prime decomposition is the primary decomposition of ideals, discovered and studied in 1905 by E. Lasker in Germany and around 1915 by F.S. Macaulay in England. The study of general commutative rings was inaugurated by the German mathematician Emmy Noether around 1925, with a special emphasis on the rings that are now called Noetherian. In the second half of the 20th century the mathematician A. Grothendieck has introduced a far-reaching generalization of both commutative ring theory and algebraic geometry.

Non-commutative rings

Noncommutative rings also exist, the first examples of them coming from elementary geometry. The study of rotations in ordinary 3-space led the Irish mathematician Sir William Rowan Hamilton to discover in 1843 the ring of quaternions, a noncommutative division ring in which every nonzero element has an inverse. At the same time, motivated by the study of linear spaces, the German mathematician Hermann Günther Grassmann introduced what is now called the exterior algebras. The English mathematician Arthur Cayley introduced matrices around 1850 for describing linear transformations, and the fact that the square matrices form a ring was pointed out by the mathematicians B. and C.S. Peirce in 1870. In the second part of the 19th century these rings were studied under the name hypercomplex systems. Around 1930, the tools of the commutative and of the noncommutative theories were unified, giving to the latter one its proper degree of power and generality. Rings of linear transformations in infinite-dimensional spaces and related rings were studied by the Hungarian-born U.S. mathematician John von Neumann and his followers.

DEFINITION AND EXAMPLES

Definition. A ring R is defined to be a set endowed with two binary operations satisfying the axioms that are listed below. The first operation, called addition, associates to every pair x, y of elements of R a well-defined element of R , denoted by $x + y$; this addition satisfies the axioms of associativity, commutativity, the existence of a zero element, and the axiom assuring that for every element there is an opposite (or negative) element:

- A1. $x + (y + z) = (x + y) + z$ for all x, y, z in R (associativity).
- A2. $x + y = y + x$ for all x, y in R (commutativity).
- A3. There exists an element 0 of R such that $0 + x = x + 0 = x$ for every x in R (zero element).
- A4. For every x in R , there exists an element (denoted by $-x$) such that $x + (-x) = (-x) + x = 0$ (opposite).

In other words, R is a commutative group for the addition.

The second operation, called multiplication, associates to every pair x, y of elements of R a well-defined element of R , denoted by xy or $x \cdot y$; this multiplication satisfies the associativity axiom and two distributive axioms:

- (M) $x(yz) = (xy)z$ for all x, y, z in R .
- (D) $x(y + z) = xy + xz$, $(y + z)x = yx + zx$ for all x, y, z in R .

It is easily proved that $x \cdot 0 = 0 \cdot x = 0$ for every x in R . If R contains an element e such that $ex = xe = x$ for every x , R is called unitary; the element e (necessarily unique) is called the unit element of R and is usually denoted by 1 . Most rings encountered in mathematics are unitary. A ring R such that $xy = yx$ for all x, y in R is called commutative.

Examples of rings. The set Z of ordinary positive and negative integers $(0, 1, 2, \dots, -1, -2, \dots)$ is a unitary commutative ring for the usual addition and multiplication; its zero element is 0 , its unit element is 1 , so that the general notation for rings coincides with the usual notation for integers.

$$(306) \quad 0 + 0 = 0, \quad 0 + 1 = 1 + 0 = 1, \quad 1 + 1 = 0$$

$$(307) \quad 0 \cdot 0 = 0 \cdot 1 = 1 \cdot 0 = 0, \quad 1 \cdot 1 = 1$$

$$(308) \quad \begin{array}{cc} & \begin{array}{cc} \text{addition} & \text{multiplication} \end{array} \\ \left\{ \begin{array}{cccc} 0 & 1 & a & b \\ 1 & 0 & b & a \\ a & b & 0 & 1 \\ b & a & 1 & 0 \end{array} \right. & \begin{array}{ccc} 1 & a & b \\ a & b & 1 \\ b & 1 & a \end{array} \end{array}$$

$$(309) \quad \left\{ \begin{array}{cccc} 0 & 1 & e & f \\ 1 & 0 & f & e \\ e & f & 0 & 1 \\ f & e & 1 & 0 \end{array} \right. \quad \begin{array}{ccc} 1 & e & f \\ e & e & 0 \\ f & 0 & f \end{array}$$

$$(310) \quad \left\{ \begin{array}{cccc} 0 & 1 & 2 & 3 \\ 1 & 2 & 3 & 0 \\ 2 & 3 & 0 & 1 \\ 3 & 0 & 1 & 2 \end{array} \right. \quad \begin{array}{ccc} 1 & 2 & 3 \\ 2 & 0 & 2 \\ 3 & 2 & 1 \end{array}$$

Another example is the set of two elements, “even” and “odd.” This set is made into a ring F_2 by using the following natural definitions of addition and multiplication:

A. even + even = even, even + odd = odd + even = odd, odd + odd = even.

B. even · even = even · odd = odd · even = even, odd · odd = odd.

Here “even” is the zero element and “odd” the unit element. In the general notation for rings, if the digits $0, 1$ replace the elements “even” and “odd,” the elements of F_2 satisfy other formulas (see 306, 307) instead of (A) and (B).

They have a familiar form, except the strange formula $1 + 1 = 0$. Here, it should be remembered that the symbols $0, 1$ used here do not stand for the usual numbers. The risks involved with such unusual formulas seem much smaller than the benefit of computing with the symbols $0, 1$ according to deeply ingrained habits.

Now three examples of rings with four elements are considered. The elements of the first one are called $0, 1, a, b$. Addition and multiplication are given by tables: the value of the sum $x + y$ is obtained by looking, in the addition table, at the element the row of which begins with an x and the column of which begins with a y ; similarly for multiplication, except that products of the form $0 \cdot x$ or $y \cdot 0$ are not given, because their values are 0 (see 308). For example, $1 + a = b$, $b + a = 1$, $b \cdot b = a$.

The elements of the second ring are called $0, 1, e, f$, with the tables also used to define addition and multiplication (see 309). For the elements of the third one, the symbols $0, 1, 2, 3$ are used, and tables are also used (see 310).

It is easy to verify that the axioms for rings hold. These three rings are commutative and unitary. The additions in two of the examples (308 and 309) are the same, provided a corresponds to e and b to f . Their multiplications, however, are distinct because in the first (308) the product of any two nonzero elements is distinct from 0 , whereas in the second (309), $ef = 0$; such elements are called zero divisors. Furthermore, in the first, every nonzero element has an inverse; for example, a and b are inverses of one another because $ab = ba = 1$. More generally, a unitary ring R in which every element $x \neq 0$ has an inverse—i.e., an element x' such that $xx' = x'x = 1$ —is called a division ring; if R is commutative, it is called a field.

The additions in two of the examples (309 and 310) are not the same, because $x + x = 0$ for every x in one example (309), whereas $3 + 3 = 2 \neq 0$ in the other example (310). Also a new feature occurs in one of the multiplications (310): the product $2 \cdot 2$, which can be written as 2^2 with the usual convention for exponents, is equal to zero. An element x of a ring R such that some power x^n of x is

equal to 0 is called a nilpotent element of R . So 2 is nilpotent (see 310). The rings in the first two examples (308 and 309), however, have no nilpotent elements except 0.

The fourth example involves polynomials and power series with coefficients a_k in R , a commutative unitary ring. A letter X and formal finite sums of coefficients times integer powers of X are considered. These formal sums, called polynomials over R , are to be added coefficientwise (see 311) and multiplied in such a way that exponents of products of powers are added (see 312).

$$(311) \quad \begin{cases} (a_0 + a_1X + \cdots + a_nX^n) + (b_0 + b_1X + \cdots + b_nX^n) \\ = (a_0 + b_0) + (a_1 + b_1)X + \cdots + (a_n + b_n)X^n \end{cases}$$

$$(312) \quad \begin{cases} (a_0 + a_1X + \cdots + a_pX^p)(b_0 + b_1X + \cdots + b_qX^q) \\ = c_0 + c_1X + \cdots + c_{p+q}X^{p+q} \\ c_j = a_0b_j + a_1b_{j-1} + \cdots + a_{j-1}b_1 + a_jb_0 \end{cases}$$

$$(313) \quad a_0 + a_1X + \cdots + a_nX^n + a_{n+1}X^{n+1} + \cdots$$

$$(314) \quad \text{If } xx'' = x''x = 1, \text{ then } x' = x' \cdot 1 = x'(xx'') \\ = (x'x)x'' = 1 \cdot x'' = x''.$$

$$(315) \quad \begin{cases} \text{Because } (2 + \sqrt{3})^2 = 7 + 4\sqrt{3}, \\ \text{it follows that } a_2 = 7, \quad b_2 = 4 \text{ and} \\ 7^2 - 3 \cdot 4^2 = 49 - 48 = 1. \end{cases}$$

$$(316) \quad f(x+y) = f(x) + f(y), \quad f(xy) = f(x)f(y) \\ \text{for all } x, y \text{ in } R$$

A polynomial over R may be viewed as the infinite sequence $(a_0, a_1, \dots, a_n, 0, 0, \dots)$ of its coefficients, only a finite number of terms a_i being unequal to 0. These sequences are to be added termwise and multiplied according to the given rule. Then the letter X corresponds to the sequence $(0, 1, 0, 0, \dots)$.

If the restriction that only a finite number of terms of the sequences be unequal to 0 is removed, the formal power series over R is obtained (see 313).

Either the polynomials or power series over R form a commutative unitary ring for the above defined addition and multiplication; it is denoted by $R[X]$ for polynomials, $R[[X]]$ for power series. By iterating the process, the polynomial and power series rings in several variables over R are obtained. The former kind of ring is important in algebraic geometry, and the latter in analysis.

Multiplicative groups. If one forgets about multiplication in a ring R , its additive group, a commutative one, is obtained. This group is not much more interesting than a general commutative group; for example, the problem of which commutative groups are additive groups of rings is rather trivial.

Much more interesting is the multiplicative group of a unitary ring R . An element x of R for which there is an element x' of R such that $xx' = x'x = 1$ is called invertible; such an x' is necessarily unique, as a simple calculation shows (see 314). It is called the inverse of x and denoted by x^{-1} . If x and y are invertible, so is xy because it admits $y^{-1}x^{-1}$ as an inverse. Thus the invertible elements of R form a group for the multiplication, called the multiplicative group of R , and sometimes denoted by R^* .

The multiplicative group of the ring Z of integers is $\{+1, -1\}$. In the example of the set with elements "even" and "odd," and the second and third of the four-element rings above (see 307, 309, and 310), it is reduced to 1. For the first four-element ring above (see 308) it is the 3-elements group $\{1, a, b\} = \{1, a, a^2\}$, with $a^3 = 1$. If R has no zero divisors, the invertible polynomials over R are the invertible constants—i.e., 1-term polynomials a_0 —so that $R[X]^* = R^*$. The invertible power series $a_0 + a_1X + \cdots$ is the power series with an invertible constant term a_0 . In the ring of numbers $a + b\sqrt{3}$ ($a, b \in Z$), the invertible

elements are the powers $(2 + \sqrt{3})^n$ ($n \in Z$) of $2 + \sqrt{3}$, and their negatives (notice that $(2 + \sqrt{3})(2 - \sqrt{3}) = 4 - 3 = 1$); writing $(2 + \sqrt{3})^n = a_n + b_n\sqrt{3}$ ($a_n, b_n \in Z, n \geq 0$) the pairs (a_n, b_n) provide all the solutions in positive integers of the equation $x^2 - 3y^2 = 1$. An example is easily constructed (see 315).

Homomorphisms. Modern mathematics has shown the importance not only of sets endowed with some structures, such as groups, rings, and metric spaces, but also of interesting classes of mappings from one of these sets into another one of the same type. To be interesting, such a mapping must be, in some sense, compatible with the given structures. In algebra, it has to preserve the operations. For example, interesting mappings of a ring R into a ring R' are the homomorphisms; that is, the mappings $f: R \rightarrow R'$ such that sums and products are preserved (see 316). It follows that $f(0) = 0$, $f(-x) = -f(x)$. If R and R' are unitary, it is usually also required that a homomorphism f carry the unit element of R to the unit element of R' (i.e., $f(1) = 1$). For example, for every integer $x \in Z$, $f(x)$ may be called the remainder of division of x by 4. It is one of the integers 0, 1, 2, 3; e.g., $f(7) = 3$, $f(18) = 2$, $f(-3) = 1$, $f(-12) = 0$. Now if R is the set $\{0, 1, 2, 3\}$ endowed with the ring structure defined in the third example of a four-element ring (see 310), it is easily checked that f is a homomorphism of Z into R .

Similarly, for $x \in Z$, $g(x) = \text{even, if } x \text{ is even, and } g(x) = \text{odd, if } x \text{ is odd, may be defined; then } g \text{ is a homomorphism of } Z \text{ into the two-elements ring described in the second example given earlier (see 307).}$

For a ring homomorphism $f: R \rightarrow R'$, the image $f(R)$ —i.e., the set of all $f(x)$ with x ranging over R —is a subring of R' ; it is a subset of R' stable under sums, differences, and products. The kernel of f , $\ker f$, is the set of all elements x of R such that $f(x) = 0$. Given two elements y, z of R , $f(y) = f(z)$ if, and only if, $(y - z) \in \ker f$. The kernel I of f satisfies the conditions: (K.1) If $x, y \in I$, then $(x + y) \in I$, and $-x \in I$; i.e., I is a subgroup of the additive group of R . (K.2) For any $x \in I$ and any $a \in R$, $ax \in I$ and $xa \in I$.

A subset I of a ring R that satisfies conditions (K.1) and (K.2) is called a two-sided ideal of R ; such a subset is called simply ideal when R is commutative.

Conversely, any two-sided ideal I of a ring R is the kernel of some homomorphism of R . Namely, the binary relation $(x - y) \in I$ between elements of R is an equivalence relation. Given two elements a and b of R , the equivalence classes of $a + b$ and ab depend only on the equivalence classes of a and b . Thus the set of equivalence classes denoted by R/I is endowed with an addition and a multiplication. It is a simple matter to check that R/I is a ring; it is called the factor ring of R by I . The mapping, which associates to every $x \in R$ its equivalence class, is a homomorphism $R \rightarrow R/I$ of R into R/I , and its kernel is I . Many properties of R , such as commutativity and unit element, are transmitted to R/I . For example, if $n \geq 1$ is an integer, the set Zn of multiples of n in the ring Z of integers is an ideal of Z . The factor ring Z/Zn has n elements, namely, the equivalence classes of $0, 1, 2, \dots, n-1$. The invertible elements of Z/nZ are the classes of the integers prime to n . Thus Z/nZ is a field if, and only if, n is a prime number.

Another example involves a set X and a commutative ring K , such as the field of real or complex numbers, the mappings of X into K , called functions, forming a commutative ring for value-wise addition and multiplication (in which addition and multiplication of functions are defined by addition and multiplication of corresponding function values). A subring R of this ring can be considered, such as the subring of continuous, or analytic, or polynomial functions, if it makes sense. If X' is a subset of X , the elements $g \in R$ such that $g(X) = 0$ for every $x \in X'$ form an ideal I of R . The factor ring R/I may be viewed as a ring of functions on X' , namely, the restrictions to X' of the functions $y \in R$.

ALGEBRAS

The hypercomplex systems alluded to earlier will now be defined. Consideration is given to a field K (such as the fields of real numbers \mathfrak{R} or complex numbers \mathbb{C}), an inte-

$$(317) \quad \begin{cases} (\xi_1, \dots, \xi_n) + (\eta_1, \dots, \eta_n) = (\xi_1 + \eta_1, \dots, \xi_n + \eta_n) \\ \alpha(\xi_1, \dots, \xi_n) = (\alpha\xi_1, \dots, \alpha\xi_n) \end{cases}$$

$$(318) \quad \begin{aligned} e_1 &= (1, 0, 0, \dots, 0), & e_2 &= (0, 1, 0, \dots, 0) \\ e_n &= (0, 0, \dots, 0, 1) \end{aligned}$$

$$(319) \quad \alpha(xy) = (\alpha x)y = x(\alpha y), \quad x, y \in K^n, \quad \alpha \in K$$

$$(320) \quad (\xi_1 e_1 + \dots + \xi_n e_n)(\eta_1 e_1 + \dots + \eta_n e_n) = \sum_{i,j} \xi_i \eta_j (e_i e_j)$$

$$(321) \quad e_i e_j = \sum_{k=1}^n \gamma_{ijk} e_k, \quad \gamma_{ijk} \in K$$

$$(322) \quad \sum_{n=1}^n \gamma_{ijp} \gamma_{pkm} = \sum_{p=1}^n \gamma_{ipm} \gamma_{jpk}$$

$$(323) \quad \begin{cases} e_1^2 = e_1 & e_1 e_2 = e_2 e_1 = e_2 \\ e_2^2 = \alpha e_1 + \beta e_2, & \alpha, \beta \in K \end{cases}$$

$$(324) \quad f^2 = \alpha + \beta f$$

$$(325) \quad (\lambda + \mu i)(\lambda - \mu i) = \lambda^2 + \mu^2$$

$$(326) \quad \begin{cases} i^2 = j^2 = k^2 = -1, & ij = k, & ji = -k \\ jk = i, & kj = -i, & ki = j, & ik = -j \end{cases}$$

$$(327) \quad \begin{aligned} (\alpha + \beta i + \gamma j + \delta k)(\alpha - \beta i - \gamma j - \delta k) \\ = \alpha^2 + \beta^2 + \gamma^2 + \delta^2 \end{aligned}$$

$$(328) \quad e_g e_{g'} = e_{gg'}, \quad g, g' \in G$$

$$(329) \quad \begin{cases} \alpha_{11} & \alpha_{12} & \dots & \alpha_{1n} \\ \alpha_{21} & \alpha_{22} & \dots & \alpha_{2n} \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \alpha_{n1} & \alpha_{n2} & \dots & \alpha_{nn} \end{cases}$$

ger $n \geq 0$, and the set K^n of all n -tuples of elements of K . These n -tuples can be added together and multiplied by elements of K , according to the rules that are expressed in terms of addition and multiplication of components (see 317).

The n -tuples form a commutative group for this addition and, furthermore, a vector space over K (see *Linear algebra*). The n -tuples are called a basis that are written with all components 0 except for a single component 1 (see 318). They are expressed as e_1, e_2, \dots, e_n .

Every element $x = (\xi_1, \dots, \xi_n)$ of K^n can be written in a unique way as $x = \xi_1 e_1 + \dots + \xi_n e_n$ ($\xi_i \in K$). Thus, if a multiplication distributive with respect to addition and satisfying a specific condition of associativity (see 319) is to be defined on K^n , it is sufficient to define the n^2 products $e_i e_j$ ($1 \leq i, j \leq n$), because then products of n -tuples are expressed in terms of products of the basis elements (see 320). Because $e_i e_j$ is an element of K^n , it may be written in a unique way as a linear combination of basis elements (see 321).

These formulas (321) are called a multiplication table and the elements γ_{ijk} the structural constants. Endowed with its addition and with the multiplication defined above (see 320 and 321), K^n is called an algebra, or a hypercomplex system over K . Here this algebra will be denoted by A ; as a mathematical object A is distinct from K^n because one of the many possible multiplications in K^n is given in A . All the ring axioms are true in A , except possibly the associativity of multiplication. For this associativity to be true,

it is necessary and sufficient that it be true for the basis elements e_i ; that is, that $e_i(e_j e_k) = (e_i e_j)e_k$ for all indices i, j, k . This equality can be translated in terms of structural constants (see 322) by means of the multiplication table (321) for all i, j, k, m . If this property (322) holds, A is a ring and is often called an associative algebra over K . It is commutative if, and only if, $\gamma_{ijk} = \gamma_{jik}$ for all indices i, j, k .

It is possible to define various structures of algebras on any vector space, finite- or infinite-dimensional over K , instead of K^n . Some examples are now given.

Quadratic algebras. Here $n = 2$ and e_1 is required to be the unit element of A . Then the multiplication table takes the form of four equations between two elements (see 323).

If one writes $e_1 = 1$ and $e_2 = f$, the habits about the use of the symbol 1 make it unnecessary to write the three first equations, and one writes only that the second power of f is linear in f (see 324).

Commutativity and associativity of the multiplication are readily checked on 1 and f . Thus A is an associative and associative algebra, called a quadratic algebra over K .

If for K the field \mathbb{R} of real numbers is taken and $a = -1$, $\beta = 0$, then $f^2 = -1$. Here f is customarily denoted by i , so that $i^2 = -1$. The algebra A then happens to be a field, and this is the field \mathbb{C} of complex numbers. The invertibility of any nonzero $z = (\lambda + \mu i) \in \mathbb{C}$ comes from the formula for the product of z and its conjugate (see 325); in fact, since the real numbers λ and μ are not both zero, $\lambda^2 + \mu^2$ is greater than 0, hence z is invertible in \mathbb{C} . More generally, the quadratic algebra defined over a field K by $f^2 = a + \beta f$ ($a, \beta \in K$) is a field if, and only if, the equation $x^2 = a + \beta x$ has no root x in K .

Quaternions. Here $n = 4$, and $1, i, j, k$ are the basis elements, the first one being the unit element. The essential part is given in a multiplication table (see 326).

It is an easy, but tedious, exercise to check that this multiplication is associative; it is not commutative in general. The corresponding algebra H is called the algebra of quaternions over K . A simple computation (see 327) proves that if in K a sum of four squares is never 0 unless all its terms vanish, the algebra H is a division ring. This condition is the case if $K = \mathbb{R}$ and H is then the division ring of quaternions, discovered by Hamilton in 1843.

Group algebras. G denotes a finite group with n elements, multiplicatively written. Instead of indexing the components ξ_1, \dots, ξ_n of an n -tuple $x \in K^n$ by the integers $1, 2, \dots, n$, one can index them by the elements of G , so that such an n -tuple is now written $\{\xi_g\}$. The basic n -tuple corresponding to a given $g \in G$ is thus $e_g = \{\delta_{gh}\}$, in which $\delta_{gg} = 1$, $\delta_{gh} = 0$ for $h \neq g$. Hence, $\{\xi_g\}$ for all $g \in G$ equals $\sum_{g \in G} \xi_g e_g$ the summation extending over all $g \in G$. The multiplication table is given by definition (see 328) and the associativity follows from the associativity in G . The corresponding algebra is called the group algebra of G over K , and is denoted by $K[G]$. In view of the multiplication table, it is harmless to write g instead of e_g .

MATRICES; REPRESENTATIONS OF RINGS

Endomorphisms. If V is a vector space over a field K , an endomorphism of V is a mapping u of V into V such that $u(x + y) = u(x) + u(y)$ and $u(dx) = du(x)$ for all x, y in V and d in K . If the addition of two endomorphisms u and v is defined value-wise as $(u + v)(x) = u(x) + v(x)$ and their multiplication as the composition of mappings $(uv)(x) = u \circ v(x)$, the set of all endomorphisms of V becomes a ring. In general, it is noncommutative.

Suppose now that a finite basis (e_1, \dots, e_n) is given on V , then each x in V can be written in a unique way as $x = e_1 a_1 + \dots + e_n a_n$ ($a_i \in K$). An endomorphism u of V is then uniquely determined by the values $u(e_i)$ ($i = 1, \dots, n$); if they are written $u(e_i) = \sum_j a_{ij} e_j$, the sum being on j , it can be seen that u is uniquely determined by the n^2 elements a_{ij} of K . It is customary to arrange these elements in a square (see 329).

The i th column is formed by the components of $u(e_i)$. Such an array is called a square $n \times n$ matrix over K . The matrix is called the matrix of u with respect to the basis (e_1, \dots, e_n) , denoted $M(u)$. Any square $n \times n$ matrix over K is the matrix of some endomorphism u .

Because endomorphisms and matrices are in one-to-

one correspondence, the addition and multiplication of endomorphisms can be translated in terms of matrices. One finds easily that the sum of the matrices (α_{ij}) , (β_{ij}) is the matrix $(\alpha_{ij} + \beta_{ij})$, and that their product [in the order $(\alpha_{ij}) \cdot (\beta_{ij})$] is the matrix (γ_{ij}) in which $\gamma_{ij} = \sum_k \alpha_{ik} \beta_{kj}$ the sum being on k . In this last formula, the row $(\alpha_{i1}, \dots, \alpha_{in})$ is multiplied by the column $(\beta_{1j}, \dots, \beta_{nj})$.

The ring of $n \times n$ matrices over K is denoted by $M_n(K)$. It has no two-sided ideal except itself and 0. It may be viewed as an algebra over K , with n^2 basis elements, namely, the matrices E_{pq} ($1 \leq p, q \leq n$), in which E_{pq} has a 1 at the intersection of the p th row and the q th column, and zeroes elsewhere. In other words, the matrix $M = (\alpha_{ij})$ is $M = \sum_{p,q} \alpha_{pq} E_{pq}$, with summation extending over p and q . The multiplication table can be given (see 330).

$$(330) \quad E_{pq} E_{rs} = 0 \text{ if } q \neq r, \quad E_{pq} E_{qs} = E_{ps} \text{ otherwise}$$

$$(331) \quad \begin{cases} (a+b)x = ax + bx \text{ for all } a, b \in R \text{ and } x \in M \\ a(x+y) = ax + ay \text{ for all } a \in R \text{ and } x, y \in M \\ a(bx) = (ab)x \text{ for all } a, b \in R \text{ and } x \in M \end{cases}$$

$$(332) \quad \frac{a}{b} + \frac{a'}{b'} = \frac{ab' + ba'}{bb'}, \quad \frac{a}{b} \cdot \frac{a'}{b'} = \frac{aa'}{bb'}$$

$$(333) \quad ax = ay, \quad a \neq 0 \quad \text{imply } x = y$$

Representations. Because rings of matrices are rather simple and have a fruitful geometric interpretation, it is important to compare a given ring with rings of matrices. This is the purpose of representation theory. A representation of a ring R is a homomorphism h of R into a ring of matrices $M_n(K)$. Thus, for $x \in R$, $h(x)$ may be viewed as an endomorphism of the vector space K^n . The representation h is called irreducible if no proper subspace of K^n is stable under all the endomorphisms $h(x)$ ($x \in R$). The irreducible representations of rings, and in particular of K -algebras, have been extensively and fruitfully studied.

RINGS AS MODULES

In the same way as a group is often considered as acting on a set—that is, as a group of transformations of this set—it is fruitful to make a ring R act on various commutative groups, then called R -modules. This procedure has the advantage of transforming various algebraic problems into linear ones.

More technically, given a ring R , a left R -module (or a left module over R) is a commutative group M (written additively) endowed with a mapping of $R \times M$ into M satisfying axioms to be listed. This mapping associates to every pair (a, x) formed by an element a of R and an element x of M , a well-defined element of M , denoted by $a \cdot x$ or ax . The axioms are three in number (see 331).

If R is unitary, it is usually required that $1 \cdot x = x$ for all $x \in M$; the module M is then called unitary.

A right module is also defined as the element of M associated to the pair (a, x) and is denoted by xa , and the third axiom (see 331) is replaced by $(xb)a = x(ba)$. This is not a simple change of notation; a right module is not in general a left module. The two notions coincide, however, when R is commutative.

If R is a field, the unitary R -modules are the vector spaces. A module over the ring \mathbb{Z} of ordinary integers is nothing else than a commutative group G written additively (for $n \in \mathbb{Z}$, $n > 0$ and $x \in G$, nx is $x + x + \dots + x$, n times).

If R is a subring of a ring S , S is both a left and a right A -module; for $a \in R$ and $x \in S$, ax (or xa) is defined to be the product of a and x computed in S . In particular, for $S = R$, R is a left module and a right module over itself.

Given a left module M over a ring R , a submodule M' of M is an additive subgroup M' of M such that $a \in R$ and $x \in M'$ imply $ax \in M'$. The submodules of R considered as a left module over itself are called the left ideals of R ; similar definition holds for the right ideals. The two-sided ideals defined in Definition and examples, above, are the

subsets of R that are at the same time left and right ideals.

Given a submodule M' of a left module M over a ring R , the binary relation $(x - y) \in M'$ between elements x, y of M is an equivalence relation called the relation of congruence modulo M' . It is written $x \equiv y \pmod{M'}$. Given elements a of R and x and y of M , the equivalence classes of ax and of $x + y$ depend only on a and on the equivalence classes of x and y . Thus the set of equivalence classes, denoted by M/M' , is endowed with a structure of left R -module and is called the factor module of M by M' . In particular, if I and I' are left ideals of R such that $I' \subset I$, then I/I' is an interesting example of a left R -module. Similar definitions and results hold for right modules.

A representation h of a ring R in a matrix ring $M_n(K)$ endows the space K^n with a structure of left R -module. Thus module theory and representation theory are essentially equivalent.

SPECIAL CLASSES OF RINGS

Domains. It has been shown that a ring may have the unfamiliar feature of zero divisors; that is, nonzero elements a, b such that $ab = 0$. It is thus interesting to define a class of rings closer to computing habits. A commutative ring with unit element $1 \neq 0$ and without zero divisors—i.e., $a \neq 0$ and $b \neq 0$ imply $ab \neq 0$ —is called an integral domain, or a domain or an entire ring. The ring \mathbb{Z} of integers is a domain. A field is a domain; if $a \neq 0$ and if $ab \neq 0$, multiplication by the inverse a^{-1} of a gives $0 = a^{-1}ab = 1b = b$. If R is a domain, so are the polynomial ring $R[X]$ and the power series ring $R[[X]]$. A subring of a domain, and in particular a subring of a field, is a domain provided it contains the unit element.

Conversely, every domain R is a subring of some field. The elements of this field are constructed in the same way as fractions are constructed from integers. The set of all pairs (a, b) is considered in which $a, b \in R$ and $b \neq 0$. The binary relation $ab' = ba'$ between two such pairs (a, b) and (a', b') is an equivalence relation in this set. The equivalence class of (a, b) is denoted by a/b and called a fraction. The operations of addition and multiplication (see 332) are well defined on the set of fractions and make a field K out of this set; it is called the field of fractions of R . The fractions $a/1$, $a \in R$, form a subring of K , isomorphic with R . The field of fractions of the ring \mathbb{Z} of integers is the field \mathbb{Q} of rational numbers. In an integral domain R , the cancellation law holds (see 333).

Rings of integers. It was pointed out earlier that ring theory partly originated from arithmetic. It is thus interesting to study the rings in which important properties of the ring \mathbb{Z} of integers are valid.

In a domain R , the divisibility relation $x \mid y$ (x divides y , x is a divisor of y , y is a multiple of x) is defined to mean that there exists $z \in R$ such that $y = zx$. The set R_x of multiples of x is clearly an ideal in R ; it is called the principal ideal generated by x . The divisibility relation $x \mid y$ is equivalent with the inclusion relation $R_x \supset R_y$. As in \mathbb{Z} , an element d of R is said to be a greatest common divisor, GCD, of x and y if it is a divisor of x and of y , and if it is the greatest in the following sense: every common divisor of x and y divides d . Similarly, a least common multiple, LCM, m of x and y is a common multiple of x and y that divides every other common multiple of x and y . Two elements x, y of R such that $x \mid y$ and $y \mid x$ are called associates; this means that there exists an invertible element u of R such that $y = ux$; whenever divisibility is concerned, associates have the same properties. All the GCD's (or LCM's) of two given elements of R , if they exist, are associates. In an arbitrary domain R , LCM's and GCD's need not exist. To say that the elements x and y of R admit an LCM amounts to saying that the ideal $R_x \cap R_y$ is principal. If any two elements x, y of R admit an LCM, say m , they admit a GCD, say d , and conversely; furthermore, xy and md are associates.

An element $p \neq 0$ of a domain R is called irreducible if it is not invertible and if the only divisors of p are either invertible or associates of p . In \mathbb{Z} , the irreducible elements are the prime numbers and their negatives. In a domain R in which LCM's exist, an irreducible element p enjoys the following property:

Integral domain

Irreducible elements

Purpose of representation theory

(A) If p divides a product ab ($a, b \in R$), it divides one of the factors a, b .

In the ring S formed by the complex numbers including the square root of -5 as a coefficient of one of two elements from Z (see 334), the number 2 is irreducible, but a relation (see 335) shows that (A) does not hold. Thus LCM's do not always exist in S .

$$(334) \quad x + y\sqrt{-5}, \quad x, y \in Z$$

$$(335) \quad (1 + \sqrt{-5})(1 - \sqrt{-5}) = 6 = 2 \cdot 3$$

$$(336) \quad \begin{cases} \phi(n) = |n|, & n \in Z \\ \phi[P(X)] = 1 + \text{degree of } P(X) \text{ and } \phi(0) = 0 \\ P(X) \in K[X], & P(X) \neq 0 \end{cases}$$

$$(337) \quad x^2 - x - \frac{d-1}{4} = 0$$

$$(338) \quad \phi(x + y\sqrt{d}) = |x^2 - dy^2|, \quad x, y \in Q$$

In Z the unique decomposition of an integer into prime factors is well known and quite useful. Thus it is interesting to study the domains R in which every element is a product of irreducible ones in an essentially unique way; i.e., unique up to order and invertible factors. The existence of such a decomposition is usually easy to settle: it is implied by the following property (called by algebraists a finiteness condition):

(B) Any strictly increasing sequence $Ra_1 \subset Ra_2 \subset \cdots \subset Ra_n \subset \cdots$ of principal ideals of R (in which equality between adjacent members of the sequence is excluded) is finite.

When existence is proved, essential uniqueness is implied by property (A).

Gaussian domains

The domains in which the essentially unique decomposition into irreducible elements hold are called Gaussian or factorial domains, or unique factorization domains (UFD). Their definition may be restricted as follows: there exists a subset P of R such that every nonzero element x of R can be uniquely written as: $x = up_1^{n(1)} \cdots p_q^{n(q)}$ with p_1, \dots, p_q distinct elements of P , u invertible and positive integral exponents $n(1), \dots, n(q)$.

The elements of P are irreducible; more precisely, P contains one, and only one, representative of each class of irreducible associates. In Z , the set of positive prime numbers may be taken for P . The divisibility theory of a factorial domain R closely resembles that of Z ; in particular, least common multiples and greatest common denominators exist and can be computed from the decomposition into irreducible factors by the usual rules. The finiteness condition (B) holds. An important theorem, essentially due to Gauss, says that, if a domain R is factorial, so is the polynomial ring $R[X]$; but the power series ring $R[[X]]$ need not be factorial.

An important subclass of factorial domains is formed by the principal domains, or principal ideal domains, PID; i.e., the domains R in which every ideal is principal. In fact, because the ideals $Rx \cap Ry$ are principal, LCM's exist, and the finiteness condition (B) is easy to prove (consider the union of all Ra_i 's, which is an ideal). These PID's are very nice rings: many important facts about their ideals and their modules are known. The ring Z , a polynomial ring $K[X]$ over any field K are PID's, but $Z[X]$ is factorial without being a PID.

These facts about Z and $K[X]$ are usually proved by Euclidean division. More generally, a division algorithm on a domain R is a mapping ϕ of R into the nonnegative integers such that, given any a, b in R , $b \neq 0$, there exist q and r in R with $a = bq + r$ and $\phi(r) < \phi(b)$.

Euclidean domains

If a domain admits a division algorithm, it is called Euclidean. The domains Z and $K[X]$ are Euclidean, the algorithms being easily expressed (see 336). Any Euclidean domain R is a PID: if I is any nonzero ideal in R , take a

nonzero element a in I such that $\phi(a)$ is minimum; then $I = Ra$ is easily proved.

If $d \in Z$ is any squarefree integer (not divisible by the square of any prime) then for $d \equiv 2$ or 3 modulo 4, R_d is defined as the set of complex numbers $a + b\sqrt{d}$ ($a, b \in Z$). For $d \equiv 1$ modulo 4, R_d is defined as the set of

numbers $a + b \frac{1 + \sqrt{d}}{2}$ ($a, b \in Z$). In both cases R_d is a

domain. An interesting problem is to find out whether R_d is principal or Euclidean. It can be proved that R_d is factorial if, and only if, it is principal. For $d \equiv 1$ modulo 4 the seemingly more natural set R'_d of all $a + b\sqrt{d}$ ($a, b \in Z$), a subring of R_d , is never principal, and less interesting for the purpose (the proof uses the fact that the number

$x = \frac{1 + \sqrt{d}}{2}$ is a root of an equation with integer coefficients (see 337).

The above problem is solved for $d < 0$. The domain R_d is Euclidean only for $d = -1, -2, -3, -7$, and -11 ; the proof is technical but not too hard. It is principal without being Euclidean for $d = -19, -43, -67, -163$, and nonprincipal for all other negative values of d ; here the proof is very hard and has been completed only after 1960.

Much less is known for $d > 0$. By explicit computations, the values of d for which R_d is principal have been determined at least for $2 \leq d \leq 499$. No general theorem, however, indicates whether R_d is principal for finitely many or infinitely many values of d . The ring R_d is Euclidean for the corresponding algorithm (see 338) for only 16 explicitly known values of d . For other values, however, it might perhaps be Euclidean for another algorithm; the problem is open.

At any rate, many nonprincipal domains R_d are known; for example, $d = -5, d = -6, d = 10, d = 26$. A similar situation arises in the rings of so-called cyclotomic integers connected with Fermat's equation $x^n + y^n = z^n$. This loss of unique factorization led Kummer and Dedekind to introduce the notion of an ideal and to prove that, in a class of domains now called the Dedekind domains that includes the rings R_d and the PID's, every ideal admits a unique decomposition as a product of prime ideals. A well-developed arithmetical theory of Dedekind domains is available.

Noetherian rings. Algebraic geometry motivated the introduction of a larger class of commutative rings, called Noetherian. They are the rings R that satisfy the equivalent conditions:

(N) Every strictly increasing sequence of ideals of R is finite.

(N') Every nonempty family of ideals of R admits a maximal element (for the inclusion relation).

(N'') Every ideal I of R is finitely generated; that is, there exists a finite number of elements x_1, \dots, x_n of I such that every element y of I can be written as $y = r_1x_1 + \dots + r_nx_n$ with $r_1, \dots, r_n \in R$. It is technically useful to introduce also the Noetherian modules: replace ideal by submodule in (N), (N'), (N''). The class of Noetherian rings is rather large. It includes the Dedekind domains, whence the PID's. Furthermore, it is stable by many ring theoretic operations. For example, the celebrated finite basis theorem of Hilbert states that, if R is Noetherian, so is the polynomial ring $R[X]$; the same holds for power series. By induction it can be shown that a polynomial ring in any finite number of variables over a field is Noetherian, whence the importance of Noetherian rings in algebraic geometry. The theory of Noetherian rings is quite extensive.

Division rings. A nonzero ring in which every nonzero element admits an inverse, it may be recalled, is called a division ring; if it is commutative, it is called a field. Division rings are the simplest noncommutative rings, fields the simplest commutative ones: for example, they have no other ideals than the whole ring and the zero ideal; whence their divisibility theory is trivial (see above *Fields*). Here a few words will be said about division rings.

The simplest example of a noncommutative division ring is the ring H of quaternions. It contains a subfield, formed by the quaternions $a \cdot 1 + 0 \cdot i + 0 \cdot j + 0 \cdot k$, that is

identified with the field \mathfrak{R} of real numbers. For every $a \in \mathfrak{R}$ and every $x \in H$, $ax = xa$.

This introduces the following notion: given a ring S , the set of all elements a of S such that $ax = xa$ for every $x \in S$ is called the centre of S . It contains 0, also 1 if S is unitary, and is a subring of S , necessarily commutative. If S is a division ring, then $a \in Z$, $a \neq 0$ imply $a^{-1} \in Z$, so that the centre Z is a subfield of S . For the ring H of quaternions, the centre is exactly the field of real numbers.

Thus a division ring S is a vector space over its centre Z . The dimension of this vector space may be finite or infinite, the first case being better known than the other. In this case the dimension is the square n^2 of an integer n ; e.g., $4 = 2^2$ for the quaternions. Given a field Z , the set of all division rings D (up to isomorphism) admitting Z as centre and finite-dimensional over Z can be organized by a rather technical process into a commutative group $\text{Br}(Z)$, called the Brauer group of Z . This group is a powerful instrument for studying the field Z . It is trivial for the field of complex numbers and is a two-elements group for the field of real numbers.

A beautiful theorem of the Scottish mathematician Joseph Henry Maclagan Wedderburn says that every finite division ring is commutative; in other words, the Brauer group of a finite field is trivial. Because every element x of a finite division ring D with q elements satisfies $x = x^q$, Wedderburn's theorem is a particular case of the following generalization: if, for every element x of a ring R , there exists an exponent $n(x) \geq 2$ such that $x^{n(x)} = x$, then R is commutative. (P.S.)

Wedderburn's theorem

Categories

Since the mid-1940s mathematicians have found it valuable to formalize the notions of areas of mathematical discourse and interrelations between such areas; the formalization used is the language of categories and functors. A rapidly developing mathematical theory accompanied this formalization so that the theory of categories and functors has become an autonomous part of mathematics. This section deals with the role of this formalization in providing an appropriate language for the expression of mathematical ideas.

The study of mathematics involves certain domains of mathematical discourse, their structural properties, and their interrelations. For example, there is the idea of a set (see SET THEORY) and of functions that are transformations of sets. There is arithmetic, the study of the domain of natural numbers, rational numbers, and integers. Geometry involves subsets of Euclidean space of three dimensions together with the appropriate transformations of such subsets—for example, translations, rotations, and reflections. Algebra is concerned with rational numbers, real numbers, and complex numbers; and abstract algebra involves further mathematical domains such as groups, rings, fields, and lattices. The calculus is again concerned in the first instance with subsets of the real numbers, or of Euclidean space of higher dimension, and with particular transformations of such subsets; e.g., differential operators.

Algebraic topology relates domains of interest in geometry to domains of interest in algebra. Algebraic geometry, on the other hand, goes in the opposite direction, associating, for example, with each commutative ring its spectrum of prime ideals.

Set theory is concerned with a class of objects A, B, C, \dots , called sets, and a class of transformations f, g, h, \dots , called functions. With each function f is associated a domain, which is a set A , and a range or codomain, which is a set B . The notation $f: A \rightarrow B$, or $A \xrightarrow{f} B$, indicates that f is a function from the domain A to the codomain B . There is a strict distinction between the codomain of the function f and the image of the function f , which is simply the set of values taken by the function f . Thus, in particular, two functions can only be identical if not only their domains but also their codomains coincide. They are then, of course, identical if, and only if, they each take the same value at each element of the domain.

Further, functions may be composed under certain conditions. To be precise, the functions $f: A \rightarrow B$ and

$$(339) \quad gf: A \rightarrow C$$

$$(340) \quad h(gf) = (hg)f$$

$$(341) \quad f1_A = f, \quad 1_B g = g$$

$$(342) \quad \mathfrak{F}(A, B)$$

$$(343) \quad \mathfrak{F}(A, B) \times \mathfrak{F}(B, C) \rightarrow \mathfrak{F}(A, C)$$

$$(344) \quad f1_A = f, \quad 1_B g = g$$

$g: B' \rightarrow C$ may be composed to yield a function, written gf or $g \circ f$ (see 339), if, and only if, $B = B'$. Further, the law of composition is associative (see 340), provided, of course, that the relevant compositions are defined. With each set A may be associated its identity function $1_A: A \rightarrow A$. This function 1_A has basic properties (see 341) provided the compositions are defined. Thus, 1_A behaves very much like the integer 1 in the ring of integers, a fact that leads to the habit of dropping the subscript A and simply writing $1: A \rightarrow A$. It is an easy exercise to see that the identity function is entirely characterized by the properties of 1_A (see 341). That is to say, if the function $u: A \rightarrow A$ also satisfies the conditions $fu = f$, $ug = g$ for all appropriate f, g , then indeed $u = 1_A$.

Of course set theory has more structure than this, but if the ideas described above are abstracted from set theory, a model for the notion of a category is obtained.

THE NOTION OF A CATEGORY

A formal definition can be given in the following way: A category \mathfrak{F} consists of three sets of data:

- C1. There is a class of objects A, B, C, \dots
- C2. To each ordered pair of objects A, B in \mathfrak{F} , there is associated a set (see 342) called the set of morphisms, or maps or transformations, from A to B in \mathfrak{F} .
- C3. To each ordered triple of objects A, B, C in \mathfrak{F} , there is associated a law of composition, or composition function (see 343), the image of (f, g) , $f \in \mathfrak{F}(A, B)$, $g \in \mathfrak{F}(B, C)$, under this law of composition being written gf or $g \circ f$, so that gf is a morphism from A to C .

These data satisfy the following three axioms, of which the first is in the nature of a convention, while the remaining two are more substantial:

- C4. $\mathfrak{F}(A_1, B_1)$ and $\mathfrak{F}(A_2, B_2)$ are disjoint unless $A_1 = A_2$, $B_1 = B_2$.
- C5. (Associative Law) $h(gf) = (hg)f$, provided the compositions are defined.
- C6. (Existence of identities). To each object A of \mathfrak{F} there is associated a morphism $1_A \in \mathfrak{F}(A, A)$ such that two equations hold (see 344) provided the compositions are defined.

As a first example, the category \mathfrak{C} is considered, called the category of sets and functions, or simply the category of sets. Precisely, the objects of \mathfrak{C} are sets A, B, C, \dots . A morphism in \mathfrak{C} from the set A to the set B is merely a function with domain A and codomain (range) B . Thus either of two notations (see 345) can be adopted in an arbitrary category as a convenient representation of the statement $f \in \mathfrak{F}(A, B)$. The law of composition in \mathfrak{C} is simply the familiar composition of functions. The axioms are then certainly satisfied. Moreover, this example serves

Category of sets and functions

$$(345) \quad f: A \rightarrow B \quad \text{or} \quad A \xrightarrow{f} B$$

$$(346) \quad A \xrightarrow{f} B \xrightarrow{g} C$$

$$(347) \quad F(fg) = (Ff)(Fg)$$

$$(348) \quad F(1_A) = 1_{FA}$$

Theory of categories and functors

to explain the notation gf for the composition of $f: A \rightarrow B$ with $g: B \rightarrow C$. It is usual to write functions on the left of their arguments, so that the image of $a \in A$ under the composite of f and g appears as $g(f(a))$. A less conservative attitude, defying this tradition and leading to a happier notation, would be to write fg for the composite of f and g , especially in view of the natural notational convention (see 346). In this discussion, however, tradition is not defied.

Just as in the special case of the category \mathcal{C} , the equations relating to the identities (344) entirely determine the morphism 1_A in $\mathcal{F}(A, A)$; 1 is often written for 1_A .

Some further examples of categories follow: finite sets and functions; groups and homomorphisms; Abelian groups and homomorphisms; rings and homomorphisms; subsets of Euclidean space of 3 dimensions and Euclidean movements; subsets of Euclidean space of n dimensions and continuous functions; topological spaces and continuous functions.

The law of composition is not specified explicitly in describing these categories. This is the custom when the objects have underlying set-structure, the morphisms are functions of the underlying sets (transporting the additional structure), and the law of composition is merely ordinary function-composition. Indeed, sometimes even the specification of the morphisms is suppressed if no confusion would arise—thus one speaks of the category of groups.

The examples given suggest a conceptual framework. For example, the concept of group may be regarded as constituting a first-order abstraction or generalization from various concrete, familiar realizations such as the additive group of integers, the multiplicative group of nonzero rationals, groups of permutations, symmetry groups, groups of Euclidean motions, and so on. Then, again, the notion of a category constitutes a second-order abstraction, the concrete realizations of which consist of such first-order abstractions as the category of groups, the category of rings, the category of topological spaces, and so on.

It should not be supposed that, in every category, the objects are sets (probably with additional structure) and that the morphisms are certain preferred functions. One example serves to dispel this misconception. X is a set with a pre-ordering relation \geq . Thus the relation $a \geq b$ holds for certain elements a, b of X and the following axioms are satisfied: $a \geq a$; if $a \geq b$, $b \geq c$, then $a \geq c$. For example, the integers may be ordered by size or they may be pre-ordered by the divisibility condition: $a \mid b$ if a is a factor of b . Then if (X, \geq) is a set with a pre-order, a category \mathcal{C}_X is formed, the objects of which are the elements of X and such that $\mathcal{C}_X(a, b)$ is the single element $a \rightarrow b$ if $a \geq b$ and is empty otherwise. There is evidently a unique law of composition and the category axioms obviously hold.

A morphism $f: A \rightarrow B$ in the category \mathcal{F} is said to be invertible, or a unit, or an equivalence, if there is a morphism $g: B \rightarrow A$ in \mathcal{F} with $gf = 1_A$, $fg = 1_B$. It is easy to prove that g is then invertible and is determined by f (g is the inverse of f , written $g = f^{-1}$), and that if A is isomorphic to B , there existing an invertible $f: A \rightarrow B$, then the relation of isomorphism is an equivalence relation on the objects of \mathcal{F} . Thus every category carries automatically with it a notion of the isomorphism of objects, proper to that category. The concept gives a great gain in universality compared with traditional procedures, which involve the definition, as distinct concepts, of one-one correspondence between sets, isomorphism between groups, isomorphism between rings, homeomorphism between topological spaces, bi-continuous isomorphism between topological groups, order type of ordered sets, and so on. It is particularly offensive, from the categorical point of view, to define an isomorphism of groups $\varphi: G \rightarrow H$ to be a homomorphism that is one-one and onto H ; for an isomorphism of groups should be just an invertible morphism of the category of groups. It is a theorem that, in this category, a morphism that is one-one and onto its codomain is an isomorphism. This theorem is false in the category of topological spaces, so that the definition masks the universality of the concept of isomorphism.

FUNCTORS

The notion of category being established as that which gives precision to the concept of domain of mathematical

discourse, the formalization of the precise notion corresponding to the intuitive idea of the interrelation or connection between different domains is now considered. Within any particular category not only the objects must be specified but also the morphisms. Furthermore, these morphisms are, in the principal examples, required in some sense to transport the structure characteristic of the objects of the category; e.g., group structure, topological structure. In the same way a functor F from the category \mathcal{F} to the category \mathcal{G} is defined as a rule that associates with every object A of \mathcal{F} an object FA of \mathcal{G} , and with every morphism $f: A \rightarrow B$ in \mathcal{F} a morphism $Ff: FA \rightarrow FB$ in \mathcal{G} , subject to the conditions of transport of structure (see 347, 348).

In expressing the relation (347), there is a tacit assumption that the composition fg is defined. This is standard practice, to avoid unnecessarily complicated statements.

A functor F always sends isomorphisms to isomorphisms, a very crucial property. Otherwise expressed, if Ff is not an isomorphism, then f cannot be an isomorphism. This yields a basic methodological procedure; to demonstrate that A and B , two objects of \mathcal{F} , really are different—i.e., non-isomorphic—it may be possible to find a functor F from \mathcal{F} to a category \mathcal{G} in which it is far easier to make the comparison. This procedure may be regarded as a massive generalization of the classical arithmetical test of casting out nines.

Some examples of functors are now given:

(a) For any group G it is possible to render G commutative by adjoining the relations $xy = yx$ for all x, y in G . The resulting group may be written G_{ab} . If $\varphi: G \rightarrow H$ is a homomorphism, it is easy to see that φ induces a uniquely determined homomorphism $\varphi_{ab}: G_{ab} \rightarrow H_{ab}$. Thus there is a functor from the category of groups to the category of Abelian groups. This should be the first functor tried in an attempt to prove two groups nonisomorphic.

(b) For any pointed topological space (X, x) —that is, a topological space X , together with a distinguished point x in X —it is possible to construct the Poincaré fundamental group $\pi(X, x)$. Then π is a functor from the category of pointed topological spaces and pointed continuous functions to the category of groups. Because, for example, the sphere and the torus (a surface in the shape of a doughnut) have non-isomorphic fundamental groups, it follows that they are not homeomorphic.

(c) If X, Y are two pre-ordered sets regarded as categories, as above, then a functor from X to Y is merely an order-preserving function.

(d) There are many important functors, called forgetful or underlying functors, that simply forget part of the structure present in the objects and transported by the morphisms. Thus, the objects in the examples in *The notion of a category* all have underlying set structures and the morphisms are all functions; moreover, the law of composition is simply that of functions. Thus, in all these cases, there is an underlying functor to \mathcal{S} . It is also possible to take a ring, forget the multiplication in it, and thereby obtain an Abelian group; this yields an underlying functor. Underlying functors may seem trivial things; actually, they are fundamental to categorical language.

NATURAL TRANSFORMATIONS

One further basic notion in the theory of categories, or, as it may be said, a basic item of categorical language, will now be introduced. This is the notion of a natural transformation of functors from one category to another. Indeed, the whole language and apparatus of categories and functors were developed initially by the U.S. mathematicians Samuel Eilenberg and Saunders MacLane in order to render precise the intuitive concept of naturality. First an example will be given, the example that may be said to have motivated the definition.

Let V be a vector space over some field K , and let V^* be the dual space of V ; that is, the space of linear functionals on V . There is then a linear transformation $T: V \rightarrow V^{**}$ that is given (see 349). There is an intuitive feeling that the linear transformation T is natural because its description only involves the terms v and φ . Now if V is finite-dimensional, then it is known that T is an isomorphism in

Examples
of functors

Forgetful
functors

$$(349) \quad T(v)(\phi) = \phi(v), \quad v \in V, \quad \phi \in V^*$$

$$(350) \quad e_i^*(e_i) = 1, \quad e_i^*(e_j) = 0, \quad i \neq j$$

$$(351) \quad \begin{array}{ccc} FA & \xrightarrow{T_A} & GA \\ Ff \downarrow & & \downarrow Gf \\ FB & \xrightarrow{T_B} & GB \end{array}$$

$$(352) \quad (T^{-1})_A = T_A^{-1}$$

$$(353) \quad \begin{cases} f^{**}(u^{**})(v^*) = u^{**}(f^*(v^*)) \\ u^{**} \in U^{**}, \quad v^* \in V^* \\ f^*(v^*)(u) = v^*(f(u)), \quad u \in U \end{cases}$$

$$(354) \quad \theta_n: \pi_n(X, x) \rightarrow H_n(X, x)$$

the category of vector spaces over K and linear transformations. One way of proving that T is then an isomorphism is to show that V and V^{**} are isomorphic and then to observe that T is one-one. The usual proof that V and V^{**} are isomorphic would be to proceed by establishing an isomorphism between V and V^* , in the case when V is finite-dimensional. Now if a base (e_1, e_2, \dots, e_n) for V is given, then a basis for V^* may be set up, called the dual basis, by defining e_i^* to be that linear functional on V given by certain rules (see 350). Then the correspondence $e_i \leftrightarrow e_i^*$ sets up an isomorphism between V and V^* .

On the other hand, this isomorphism does not look natural, because it depends on the choice of bases. Of course, the argument above could be generalized to set up a linear transformation from V to V^* even if V is not finite-dimensional over K , but, again, this transformation would not appear to be natural. What is required is a formal and precise expression of the feeling that, for finite-dimensional vector spaces V over the field K , V and V^{**} are naturally isomorphic, while V and V^* are isomorphic in some unnatural way. Eilenberg and MacLane solved this problem in their seminal article, "General Theory of Natural Equivalences," published in 1945, which may be said to have laid the foundation of the theory of categories. The precise definition is:

If $F, G: \mathfrak{F} \rightarrow \mathfrak{G}$ are two functors from the category \mathfrak{F} to the category \mathfrak{G} , then a natural transformation T , from F to G , is a rule assigning to each object A of \mathfrak{F} a morphism T_A in the set $\mathfrak{G}(FA, GA)$, subject to the condition that a diagram (see 351) should be commutative for every $f: A \rightarrow B$ in \mathfrak{F} ; that is, $Gf[\circ]T_A = T_B[\circ]Ff$. Further, if each T_A is invertible, T is said to be a natural equivalence. It is clear that if T is a natural equivalence from F to G , then T^{-1} , given by an equation (see 352), is a natural equivalence from G to F . Thus the term equivalence used here is fully justified. Indeed, the functors from \mathfrak{F} to \mathfrak{G} may be collected into equivalence classes according to the existence of a natural equivalence between them.

This definition can be tested against the example. There are two functors from \mathfrak{B} to \mathfrak{B} , in which \mathfrak{B} is the category of vector spaces over the field K and linear transformations. One functor is the identity functor. The other functor is the double dual functor $**$: $\mathfrak{B} \rightarrow \mathfrak{B}$ that associates with every vector space V its double dual V^{**} and with every linear transformation $f: U \rightarrow V$ in \mathfrak{B} the linear transformation $f^{**}: U^{**} \rightarrow V^{**}$ (see 353). A linear transformation $T: V \rightarrow V^{**}$ was described above. If it is now written as T_V , it is easy to check that T is a natural transformation from the identity functor to the functor $**$. If the subcategory \mathfrak{B}_f of \mathfrak{B} that consists of finite-dimensional vector spaces over K and their linear transformations is considered, then it turns out that the functor $**$ transforms \mathfrak{B}_f into itself; and the natural transformation T , restricted to \mathfrak{B}_f is then a natural equivalence. Further examples of natural transformations of functors can be given:

(a) The category \mathfrak{A} of Abelian groups and homomor-

phisms is considered. With every Abelian group may be associated its torsion subgroup. The torsion subgroup A_t of the Abelian group A consists of those elements of A that are of finite order. A homomorphism from A to B must necessarily send A_t to B_t . Thus a functor F is obtained from \mathfrak{A} to \mathfrak{A} (or to \mathfrak{A}_t , the category of torsion Abelian groups and their homomorphisms), by associating with every Abelian group A the Abelian group $FA = A_t$. Now A_t is a subgroup of A . Thus there is always an embedding i_t of A_t in A . It is easy to see that i is a natural transformation from the torsion functor F to the identity functor. Further, the quotient group $A_f = A/A_t$ may be considered. It is a torsion-free Abelian group. This gives a functor G from \mathfrak{A} to \mathfrak{A} (or from \mathfrak{A} to \mathfrak{A}_f , the category of torsion-free Abelian groups) by associating with the Abelian group A the Abelian group $GA = A_f$. Then the projection of A onto A_f yields a natural transformation from the identity functor to the torsion-free functor G .

(b) With every group may be associated its commutator subgroup. It is then not difficult to see that the embedding of the commutator subgroup in the group is a natural transformation from the commutator subgroup functor to the identity functor. On the other hand, the centre of every group may be associated with the group. Here, however, there is not a functor because a homomorphism from one group to another does not necessarily map the centre of the first group to the centre of the second. On the other hand, if the category of groups and surjective homomorphisms (a surjective homomorphism is one in which the image coincides with the codomain) is considered, then in this category the centre is a functor. It is a functor, however, from the category of groups and surjective homomorphisms to the category of groups and all homomorphisms, because a surjective homomorphism does not necessarily map the centre surjectively. Then the embedding of the centre of a group in the group may be regarded as a natural transformation from the centre functor to the inclusion functor, both of which are functors from the category of groups and surjective homomorphisms to the category of groups and homomorphisms.

(c) In algebraic topology, the singular homology groups and the homotopy groups of a pointed topological space (X, x) are considered. A Hurewicz homomorphism (see 354) exists, from the homotopy groups to the homology groups. Then π_n and H_n , $n \geq 2$, are functors from the category of pointed spaces and pointed continuous functions to the category of Abelian groups, and the Hurewicz homomorphism is a natural transformation of functors.

UNIVERSAL CONSTRUCTIONS

An important procedure that is made possible by the use of categorical language is the relation of apparently distinct concepts in various categories. Here an example is given, but it should be pointed out that the technique described is of extremely broad application.

In the category of sets, the notion of Cartesian product is vital. Its description, however, involves mention of the elements of the sets: the Cartesian product of the sets X and Y consists of the ordered pairs (x, y) , $x \in X$, $y \in Y$. In a definition of the product of two objects in an arbitrary category, this definition cannot be imitated because, in the definition of a category, it is not required that the objects should be sets with elements. Therefore, a property of the Cartesian product $X \times Y$ must be found that characterizes the Cartesian product and that can be expressed in the language of categories. Such a property must be entirely expressible in terms of the data of a category: in terms of objects, morphisms, and composition of morphisms.

For any given set A and functions $f: A \rightarrow X$, $g: A \rightarrow Y$, there is a unique function $h: A \rightarrow X \times Y$ such that equations involving two projections hold (see 355), in which $p_1: X \times Y \rightarrow X$, $p_2: X \times Y \rightarrow Y$ are the projections. This is the clue to the generalization. For two objects X and Y of the category \mathfrak{F} , the triple $(Z; p_1, p_2)$ is taken to be a product of X and Y if $p_1: Z \rightarrow X$ and $p_2: Z \rightarrow Y$ are morphisms of \mathfrak{F} , and if the universal property holds that, given any object A of \mathfrak{F} and morphisms $f: A \rightarrow X$, $g: A \rightarrow Y$, there exists a unique morphism $h: A \rightarrow Z$ such that certain relations hold (see 355).

The
Cartesian
product

$$(355) \quad p_1 h = f, \quad p_2 h = g$$

$$(356) \quad p'_1 \omega = p_1, \quad p'_2 \omega = p_2$$

$$(357) \quad (X_1 \times X_2) \times X_3 \cong X_1 \times (X_2 \times X_3)$$

$$(358) \quad \gcd(\gcd(a, b), c) = \gcd(a, \gcd(b, c))$$

$$(359) \quad \mathfrak{F}^0(A, B) = \mathfrak{F}(B, A)$$

It is easy to prove that the triple $(Z; p_1, p_2)$ is, essentially, uniquely determined by the universal property. This means that if $(Z'; p'_1, p'_2)$ is also a product, then there exists a unique isomorphism $\omega: Z \rightarrow Z'$ in \mathfrak{F} such that two equalities hold (see 356). Therefore, it is permissible to speak of *the* product of X and Y in \mathfrak{F} . Of course, X and Y do not necessarily have a product in \mathfrak{F} . If they do have a product in \mathfrak{F} , in the sense defined above, however, then that product is unique. Now the product may be sought in various other categories. For example, in the category of Abelian groups the product, as defined, characterizes the direct sum; in the category of topological spaces it characterizes the topological product. In any category corresponding to a pre-ordered set, the product characterizes the greatest lower bound. Thus, in particular, in the category corresponding to the natural numbers ordered by divisibility, the product is precisely the GCD. It is possible to prove that the product in any category in which it exists is associative in the following sense. Given three objects X_1, X_2 , and X_3 , then there is an equivalence (see 357). This is, of course, a completely familiar—and trivial—fact for sets: in considering the Cartesian product of three sets, the way in which the sets are to be associated is not relevant. If a proof has been given that is valid in any category, however, it is immediately possible to deduce, for example, that the greatest common divisor satisfies associativity. That is, if a, b, c are any three natural numbers, then a relation involving the GCD holds (see 358). Here there are two points to be made. First, there was no apparent connection between this statement (358) and the statement that the Cartesian product of sets is associative. Second, by proving the statement in sufficient generality—i.e., at the categorical level—it is possible to obtain many more instances of the theorem than could have been obtained by simply being confined to the original category in which the definition of product was carried out; that is, the category of sets.

THE DUALITY PRINCIPLE

For any category \mathfrak{F} a new category \mathfrak{F}^0 can be formed by interchanging the domains and codomains of the morphisms of \mathfrak{F} . More precisely, in the category \mathfrak{F}^0 the objects are simply those of \mathfrak{F} and the effect of interchange of domains is expressed in an equation (see 359). Moreover, the composition in \mathfrak{F}^0 is simply that of \mathfrak{F} , suitably interpreted. \mathfrak{F}^0 is called the category opposite to \mathfrak{F} ; notice that $(\mathfrak{F}^0)^0 = \mathfrak{F}$. This apparently trivial operation leads to highly significant results when specific categories are used. In the general setting it enables any concept in the language of categories to be dualized. For example, the coproduct in \mathfrak{F} is simply the product in \mathfrak{F}^0 . Any theorem that holds in an arbitrary category has a dual form. For example, the theorem asserting that the product in an arbitrary category is associative may be effectively restated as asserting that the coproduct in an arbitrary category is associative. In the special cases, however, the second statement looks very different from the first. For example, in the category of sets, the coproduct becomes the disjoint union; in the category of groups it is the free product; and in a pre-ordered set regarded as a category, the coproduct is the least upper bound. In particular, for the set of natural numbers, ordered by divisibility, the coproduct is the LCM. Thus, the same universal argument that led to the deduction that the GCD is associative also indicates that the LCM is associative. The duality principle has very wide ramifi-

cations indeed. Here it is merely noted that the important concept of a contravariant functor from \mathfrak{F} to \mathfrak{G} may be most simply defined as a functor from \mathfrak{F}^0 to \mathfrak{G} . Thus the association of the dual vector space V^* with V yields a contravariant functor from \mathfrak{B} to \mathfrak{B} .

CONCLUSIONS

Because the concept of a category is so general, it is to be expected that theorems provable for all categories will not usually be very deep. Consequently, many theorems of category theory are stated and proved for particular classes of categories. For example, homological algebra is concerned with Abelian categories, which exhibit features suggested by the category of Abelian groups. In mathematics one seeks generality and depth, but there is a certain conflict between these two aims because the more general the setting, the less likely that the results will be profound. The art of mathematics might be said to be that of finding the best possible compromise between these two aims. Further, a not unimportant purpose of the language of categories and categorical reasoning is to identify within a given argument that part which is trivial and separate it from the part which is deep and proper to the particular context. For example, in the study of the theory of the GCD, the fact that it is essentially unique simply follows from the uniqueness of the product in any category and is thus really trivial. Similarly, as has been demonstrated, the fact that it is associative is trivial. On the other hand, the fact that the GCD of the integers a and b can be expressed as a linear combination of a and b with integer coefficients— $\gcd(a, b) = ma + nb$, m, n integers—is a much deeper fact that is special to the particular situation, or, at least, to a highly restricted class of situations.

Homological algebra

The origins of homological algebra are to be found in algebraic topology. The mathematician W. Hurewicz pointed out in 1936 that if X is a connected polyhedron that is aspherical in all dimensions—that is, any map of sphere S^n into X , $n \geq 2$, is contractible—then the homology groups, $H_n X$, of the space X are entirely determined by $\pi = \pi_1 X$, the fundamental group of X . Indeed, the homotopy type of X is determined by π . More generally, consider the Hurewicz homomorphism (354) from the k th homotopy group of X to the k th homology group. If a condition holds (see 360), π entirely determines the quotient of $H_n X$ by the subgroup $\theta_n \pi_n X$, called the subgroup of spherical cycles. The mathematician H. Hopf investigated the nature of this dependence (see 361) and sought a purely algebraic description. In 1941, he was led in his work on the influence of the curvature of a closed Riemannian manifold on its topology to observe that the phenomenon under consideration could be expressed as a connection between $\pi_1 X$ and $H_2 X$, valid for any connected polyhedron X ; in fact, he produced a description of $H_2 X / \theta_2 \pi_2 X$. For simplicity it is supposed here that X is aspherical in all dimensions; following Eilenberg–MacLane, one writes $X = K(\pi, 1)$, in which $\pi = \pi_1 X$. This notation is justified because the homotopy type of X is determined by π . $K(\pi, 1)$ is called the Eilenberg–MacLane space of type $(\pi, 1)$. Note that a set of conditions holds (see 362). Then Hopf produced a formula for $H_2(K(\pi, 1))$ in terms of a free presentation of the group π . It is presented as the quotient of a free group F by a normal subgroup R ; thus $\pi = F/R$. Writing $H_2 \pi$ for $H_2(K(\pi, 1))$, the Hopf formula takes a specific form (see 363). Here $[F, F]$ is the commutator subgroup of F ; and $[F, R]$ is the (normal) subgroup of F generated by all commutators $f^{-1}r^{-1}fr$, $f \in F$, $r \in R$.

This relation (363) is of considerable intrinsic algebraic interest, apart from the topological significance that it attaches to the group $(R \cap [F, F])/[F, R]$; for it shows that this group actually depends only on π , although it is expressed in terms of an arbitrary free presentation of π . This feature is characteristic of the procedures of homological algebra.

In 1944 Hopf gave his definitive solution of the problem raised by Hurewicz' result. Because World War II had virtually destroyed communication between European

and American mathematicians, further developments of Hopf's theory, by B. Eckmann and H. Freudenthal in Europe and by Eilenberg and MacLane in the U.S., proceeded quite independently.

HOMOLOGY GROUPS OF GROUPS

Hopf's description of the homology groups of $K = K(\pi, 1)$ was based on a geometrical idea. If L is the universal cover of K , then π acts freely as a permutation group on the simplex of L lying above a given simplex of K . It follows that, for each n , the chain group $C_n(L)$, with integer coefficients, is a free π -module. Moreover, the boundary homomorphisms are maps of π -modules. Further, because L is contractible, the homology groups of L are given by a set of equations (see 364) in which Z is the group of integers. Thus it may be said that the chain complex $C(L)$ is π -free and acyclic. If $C(L)_\pi$ arises by killing the π -action, then $C(L)_\pi = C(K)$, so that the homology of K , with any coefficients, may be computed from the chain complex $C(L)_\pi$. Hopf observed that if P is any π -free acyclic chain complex, then P_π is chain equivalent to $C(L)_\pi$ and so could be used to calculate the homology of K . He described such a chain complex P purely in terms of the group π itself.

A particular chain complex $C(\pi)$ will now be described. Let $C_n(\pi)$ be the free Abelian group on $(n+1)$ -tuples (x_0, x_1, \dots, x_n) of elements of π . The Abelian group $C_n(\pi)$ can be turned into a π -module by defining $(x_0, x_1, \dots, x_n)x = (x_0x, x_1x, \dots, x_nx)$, and $C_n(\pi)$ is then plainly a free π -module. A differential $\partial: C_n(\pi) \rightarrow C_{n-1}(\pi)$ can be defined by the usual simplicial boundary formula (see 365), in which x_i^* indicates that x_i is to be omitted. Obviously ∂ is a module map and $\partial\partial = 0$. An augmentation $\varepsilon: C_0(\pi) \rightarrow Z$ is defined by $\varepsilon(x) = 1$ and thus is obtained a chain complex of π -modules (see 366).

It can be shown that this chain complex (366) is acyclic by defining a contracting homotopy $s: C_{n-1}(\pi) \rightarrow C_n(\pi)$, which is a homomorphism of Abelian groups, by a certain rule (see 367).

Thus $C(\pi)$ may be used to replace $C(L)$, so that the homology groups of K are given (see 368) by an equation in which the group on the right is defined entirely in terms of π .

A little more generally, a local system of coefficients on K may be considered; that is, a π -module A of coefficients. Then $C(L) \otimes_\pi A$, the tensor product over π of the (right) π -complex $C(L)$ and the (left) π -module A , is a chain complex yielding $H_n(K; A)$, the homology of K with local coefficients A ; and $C(L) \otimes_\pi A$ is chain equivalent to $C(\pi) \otimes_\pi A$, whence a relation follows (see 369). It is natural to write $H_n(\pi; A)$ for the group on the right of this relation (369), and $H_n(\pi; A)$ is the n th homology group of π with coefficients in the π -module A .

Similarly, as observed by Eckmann and Eilenberg-MacLane, the cochain complex $\text{Hom}_\pi(C(\pi), B)$ may be formed and thus, in cohomology, a similar relation holds (see 370) in which it is natural to write $H^n(\pi; B)$ for the group on the right of (370), so that definitions have been stated for the homology and cohomology groups of the group π (with coefficients in an arbitrary π -module).

It will now be shown how the definitions that have been stated above constitute special cases of the notion of a derived functor, which is basic to homological algebra.

DERIVED FUNCTORS

Let Λ be a fixed unitary ring and consider the category of right Λ -modules, for definiteness. Let F be a functor from this category to the category of Abelian groups that is additive in the sense that, if ϕ, ψ are Λ -module homomorphisms from the module M_1 to the module M_2 , then an equality involving F holds (see 371). For a given module M , let there be given a chain complex of Λ -modules such that each is Λ -free (see 372).

Applying F leads to a chain complex of Abelian groups (see 373), and it may be shown that the homology groups of FP depend only on M and are independent of the choice of P [subject to the conditions described above and in (372)]. P is called a Λ -free resolution of M and a new functor $L_n F$ can be defined because of this independence (see 374). It turns out that $L_n F$ is again an additive functor, called the n th left derived functor of F . For the re-expression of $H_n(FP)$ to be valid, it suffices that each P_n be Λ -projective. This means that if $\eta: R \rightarrow S$ is a surjection of Λ -modules and $\phi: P_n \rightarrow S$ is a Λ -homomorphism, there is a Λ -homomorphism $\psi: P_n \rightarrow R$ that lifts ϕ ; i.e., such

- (374) $H_n(FP) = (L_n F)(M)$
- (375) $FM = M \otimes_\pi A$
- (376) $H_n(\pi; A) = (L_n F)(Z)$
- (377) $GM = \text{Hom}_\pi(M, B)$
- (378) $H^n(\pi; B) = (R_n G)(Z)$
- (379) $\text{Tor}_n^\Lambda(M, N) = (L_n F)(M)$
- (380) $FM = M \otimes_\Lambda N$
- (381) $\text{Ext}_\Lambda^n(M, N) = (R_n G)(M)$
- (382) $GM = \text{Hom}_\Lambda(M, N)$
- (383) $\begin{aligned} \text{Tor}_n^\Lambda(M, N) &= (L_n \bar{F})(N), \quad \bar{F}N = M \otimes_\Lambda N \\ \text{Ext}_n^\Lambda(M, N) &= (R_n \bar{G})(N), \quad \bar{G}N = \text{Hom}_\Lambda(M, N) \end{aligned}$
- (384) $H_n(\pi; A) = \text{Tor}_n^{Z(\pi)}(Z, A)$
- (385) $H^n(\pi; B) = \text{Ext}_{Z(\pi)}^n(Z, B)$
- (386) $H_n(g; A) = \text{Tor}_n^{Ug}(K, A), \quad n \geq 0$
- (387) $H^n(g; B) = \text{Ext}_{Ug}^n(K, B), \quad n \geq 0$
- (388) $A \rightarrow E \twoheadrightarrow \pi$

that $n\varphi = \varphi$. A Λ -free module is certainly Λ -projective. If each P_n is Λ -projective, P is spoken of as a Λ -projective resolution of M .

The special case of the homology of groups is obtained by taking for Λ the integer group ring, $Z(\pi)$, of π , and for M the additive group of integers regarded as a trivial π -module. Then the functor F , given by the tensor product (see 375) in which A is a π -module, is an additive functor to the category of Abelian groups. The complex $C(\pi)$ is then a π -free resolution of Z , the additive group of integers, so that a relation holds (see 376) in which F is given above (see 375).

There are also right derived functors, obtained by taking Λ -injective resolutions, in which injective is dual, in the categorical sense, to projective; and it is possible to consider contravariant functors. The domain and codomain categories of the additive functor F can also be generalized; the essential requirement is that they be Abelian categories. The cohomology groups of the group π are obtained by taking, for a π -module B , the contravariant functor (see 377); GM is the group of π -homomorphisms from M to B ; then, taking right derived functors of G , a relation is obtained (see 378).

The homology and cohomology groups of groups thus arise by taking left derived functors of the tensor product functor and right derived functors of the Hom functor. While there is an extensive general theory of derived functors, the theory of derived functors of these particular functors, but for arbitrary unitary rings Λ , is of particular importance. Thus, generalizing the definitions above (see 375 and 377), two sets of derived functors are defined (see 379 and 381) based on certain functors F , G (see 380 and 382), respectively. These are called the Tor and Ext functors, respectively; they are really bifunctors—that is, functors of two variables—and they enjoy the property of being balanced between their two arguments M , N in a sense that two equations express (see 383). Comparing past results (see 376, 379 and see 378, 381), it can be seen that two further relations hold (see 384, 385).

Tor
and Ext
functors

HOMOLOGY OF LIE ALGEBRAS

Many other homology theories have been found useful in algebra and arise by taking suitable derived functors. Here one will be described in which the derived functors are again Tor and Ext functors.

If g is a Lie algebra over the field K , Ug denotes its universal enveloping algebra. By a g -module, it is understood that A is a K -vector space on which the algebra Ug acts. Definitions are then made (see 386, 387), and these are called the homology groups of g (with coefficients in A) and the cohomology groups of g (with coefficients in B). Just as the (co)homology groups of a group may be interpreted as the (co)homology groups of a suitable space, so may the (co)homology groups of g be interpreted as the (co)homology groups of the underlying topological space of the compact, connected Lie group G the associated Lie algebra of which is g .

APPLICATIONS TO ALGEBRA

The topological significance of the homology theories of groups and Lie algebras has already been explained; these and other homology theories, however, also have important applications in pure algebra. For example, in the homology theory of groups, the group $H^1(\pi; A)$ is isomorphic to the quotient group of the group of derivations from π to A , modulo the inner derivations. The group $H^2(\pi; A)$ is isomorphic to the group $E(\pi; A)$ of equivalence classes of Abelian extensions of the quotient group π by the π -module A ; such an extension can be written (see 388) to show that A is embedded in E and E projects onto π with kernel A . Here the group structure in the set $E(\pi; A)$ is by no means obvious, whereas the group structure in $H^2(\pi; A)$ follows immediately as in any homology or cohomology group. Similar interpretations of H^1 and H^2 are available in the homology theory of Lie algebras.

Many theorems of pure algebra may be proved by homological methods. For example, the homology theory of groups may be used to prove I. Schur's theorem that, if the quotient of a group G by its centre is finite, then the

commutator subgroup of G is finite. It may also be used to prove Maschke's theorem that if the order of the finite group G is not divisible by the characteristic of the field K , then the (finite-dimensional) K -representations of G are completely reducible. Similarly, the homology theory of Lie algebras may be used to prove theorems that make no mention of homology; for example, the Levi-Malcev theorem that every (finite-dimensional) Lie algebra g , over a field K , is the split extension of a semisimple Lie algebra by the radical of g . Hilbert's celebrated chain-of-syzygies theorem may also be proved by homological methods—a notable early triumph for homological algebra; and there is the Auslander-Buchsbaum proof (the first given) that a regular local ring is a unique factorization domain. The claim that homological algebra is a useful tool in mathematics is not invalidated by the fact that these theorems can also be proved without the use of homological methods. For the homological methods are extremely systematic and serve to throw into relief the connections between apparently dissimilar areas of mathematics. (P.J.H./Ed.)

The Lie algebra of a Lie group. Consider now a Lie group G . For each g in G , $T(g)$ denotes the left translation map $x \rightarrow gx$ of G onto G . Then T is an analytic operation of G on G . By Lie's first fundamental theorem, the group $T(G)$ has an infinitesimal generator, and by Lie's second fundamental theorem, the infinitesimal generator is a Lie algebra of infinitesimal transformations; this infinitesimal generator is denoted by \hat{G} and is called the Lie algebra of G . It is readily proved that \hat{G} consists of precisely those infinitesimal transformations on G that are left unchanged by the right translations $x \rightarrow xg$ of G into G . It follows at once that each infinitesimal translation in \hat{G} is uniquely determined by its value at the origin. Thus as a linear space, \hat{G} is equivalent to \hat{G}_e , the tangent space of G at the identity element e . If X is an element of \hat{G}_e , and \bar{X} is the element of G determined by X , then one defines $\exp \bar{X}(e)$. Also, $[X, Y]$ is defined to be the value at e of $[\bar{X}, \bar{Y}]$, in which \bar{X} and \bar{Y} are the elements of G with $\bar{X}(e) = X$ and $\bar{Y}(e) = Y$.

In the special case that G is the group $GL(n)$ of all invertible linear transformations of an n -dimensional linear space V_n over the real numbers, the tangent space to G at the identity element can be identified with the set of all linear transformations of V_n . Then for any $X \in \hat{G}_e$, $\exp X$ coincides with the classical exponential of the transformation X ; that is, $\exp X = \sum X^i/i!$. For any X and Y in \hat{G}_e , $[X, Y] = XY - YX$, in which the multiplication on the right is the usual multiplication of linear transformations.

If the algebraic structure alone is abstracted from \hat{G} , it is seen to be an algebra with Poisson brackets as multiplication. This multiplication is nonassociative, but the structure of such algebras is capable of a virtually exhaustive description. On the other hand, there is a very close connection between the algebraic structure of a Lie group and the algebraic structure of its Lie algebra. Indeed, there is a one-to-one correspondence between the subalgebras of the Lie algebra \hat{G} and the connected Lie subgroups of G , the correspondence being: a connected Lie subgroup H corresponds to the subalgebra of \hat{G} that is determined by the tangent subspace H_e to H at the identity. A connected Lie subgroup H is normal in G if, and only if, the corresponding subalgebra \hat{H} is an ideal in \hat{G} ; that is, $[\hat{G}, \hat{H}]$ is contained in \hat{H} . To the commutator subgroup of G generated by the elements of the form $xyz^{-1}y^{-1}$, there corresponds the derived subalgebra that is generated by the elements $[X, Y]$ with X and Y in \hat{G} . In particular, a connected Lie group G is Abelian if, and only if, $[X, Y] = 0$ for all X and Y in \hat{G} .

The most elementary type of Lie algebra is one wherein the multiplication is trivial; i.e., $[G, G] = 0$. Such a Lie algebra is called Abelian. Next in complexity is a Lie algebra wherein the product of some finite number of any elements is zero; i.e., if setting $G^{(1)} = G$, $G^{(n+1)} = [G^{(n)}, G]$, then $G^{(n)} = 0$ for some n . Such a G is called nilpotent. One step more complex are Lie algebras G that have a decreasing sequence of ideals, $G \supset G_1 \supset \dots \supset G_n \supset \dots$ with the quotient algebra G_i/G_{i+1} Abelian and $G_n = 0$ for some n ; such a Lie algebra is called solvable. The maximum

Uses of
homo-
logical
algebra

Theorems describing the structure of Lie algebras

solvable ideal of a Lie algebra is called its radical. If G is a Lie algebra and R denotes its radical, then G/R has no nonzero radical; such a Lie algebra is called semisimple. If a Lie algebra has no nonzero properly smaller ideal, it is called simple. The basic theorems describing the structure of Lie algebras over any field of characteristic zero areas may be stated as follows:

Any Lie algebra is a semi-direct sum of its radical and a semisimple subalgebra.

Any semisimple Lie algebra is a direct sum of simple Lie algebras.

Any simple Lie algebra over the field of complex numbers is one of the following type:

A_n : the Lie algebra of the group of all $n+1$ by $n+1$ complex-valued matrices of determinant-1.

B_n : the Lie subalgebra of A_{2n} that annihilates the quadratic form composed of a sum of squares of $\{x_k\}$ (see 389).

C_n : the Lie subalgebra of A_{2n-1} that annihilates the alternating bilinear form (see 390).

D_n : the Lie subalgebra of A_{2n-1} that annihilates the quadratic form composed to a sum of squares of $\{x_k\}$ (see 391).

$$(389) \quad x_1^2 + x_2^2 + \cdots + x_{2n+1}^2$$

$$(390) \quad x_1 y_{n+1} - y_1 x_{n+1} + x_2 y_{n+2} - y_2 x_{n+2} + \cdots + x_n y_{2n} - y_n x_{2n}$$

$$(391) \quad x_1^2 + \cdots + x_{2n}^2$$

The five exceptional simple Lie algebras G_2, F_4, E_6, E_7, E_8 discovered by the mathematician W. Killing are of dimensions 14, 52, 78, 133, 248, respectively. This remarkable classification is achieved by a study of the so-called root diagram of the Lie algebra.

Although each Lie group has a unique Lie algebra, a Lie algebra in the abstract (*i.e.*, divorced from its presentation as the infinitesimal generator of a Lie group) may arise from inequivalent or nonisomorphic groups. For example, the one-dimension Abelian Lie algebra over the field of real numbers is the Lie algebra of both example G1 and example G2 above. The problem of determining the relation between the various connected Lie groups having abstractly isomorphic Lie algebras was solved by the mathematician Otto Schreier.

The situation may be described in this way: to each abstract Lie algebra g (over the field of real numbers) there corresponds a unique (up to isomorphism) simply connected Lie group G —that is, a connected Lie group in which every closed curve can be deformed continuously to a point; any other Lie group G_1 the Lie algebra of which is isomorphic to g is obtained from G by a homomorphism with a discrete kernel. Thus G_1 is evenly covered by G , and all connected Lie groups the Lie algebras of which are isomorphic to G have the same simply connected covering group. The spin representation of physics provides another example of this phenomenon.

It should be emphasized, however, that in a neighbourhood of the identity, any two Lie groups having isomorphic Lie algebras are isomorphic. This can be seen from the Baker–Campbell–Hausdorff formula (see 392) that identi-

$$(392) \quad (\exp X)(\exp Y) = \exp(X + Y - \frac{1}{2}[X, Y] + \cdots)$$

Complexification

fies the product of exponentials with the exponential of an algebraic form involving an infinite sum of terms built from X and Y with Poisson brackets. By a process known as complexification it can be proved that the classification of complex simple Lie algebras also applies to compact Lie groups.

The topological structure of Lie groups. It has been shown above that to a given abstract Lie algebra there may correspond Lie groups that are not topologically equivalent. Therefore, it cannot be expected that the ab-

stract Lie algebra \hat{G} of a Lie group G will determine the topological structure of G completely. One of the greatest contributions of Cartan to mathematics, however, was his demonstration that the Lie algebra G determines the important topological invariants called Betti numbers of the group G in the very important case that the Lie group G is compact and connected.

Cartan's researches on this problem led him to invent his theory of exterior differential forms and to conjecture the celebrated de Rham theorems, which were proved by his student Georges de Rham.

(G.D.M.)

OTHER ASPECTS OF HOMOLOGICAL ALGEBRA

The scope of homological algebra is extremely broad. Only two homology theories (groups, Lie algebras) have been described from among many. There are also, however, aspects of homological algebra in which homological ideas are further refined and developed or in which homological techniques lead to new algebraic constructs. Two examples are now described.

Attention may be given to the category of Abelian groups that may well be graded by the integers, or even bigraded by pairs of integers. If A is such an Abelian group it is said to be differential if it is equipped with an endomorphism $d: A \rightarrow A$, called the boundary, or differential, such that $d^2 = 0$. Notice, however, that a chain complex of Abelian groups may be thought of as a differential graded Abelian group, in which d is the boundary homomorphism and so of degree -1 ; whenever A is (bi)-graded a degree is supposed for d . If A is differential, the group $ZA = \ker d$ may be defined, and ZA is called the cycle group of A ; one writes $BA = \text{im } d$, and calls BA the boundary group of A . Because $d^2 = 0$, it follows that $BA \subset ZA$; HA is written for ZA/BA and HA is called the homology group of A . This is, of course, familiar from topology. A spectral sequence of differential Abelian groups is a sequence (E_n, d_n) , $n \geq 0$, in which E_n is an Abelian group with differential d_n and $HE_n = E_{n+1}$.

Associated with every spectral sequence there is a limit term, which may be described as follows. If $z \in ZE_n$, then its homology class $\{z\}$ belongs to E_{n+1} and the boundary d_{n+1} may be applied to $\{z\}$. It is convenient to talk of applying d_{n+1} to z itself in this case. Thus one may talk

$$(393) \quad E_0^* \rightarrow E_1^* \rightarrow \cdots \rightarrow E_n^* \rightarrow E_{n+1}^* \rightarrow \cdots$$

$$(394) \quad \cdots \subseteq F_{p-1} G \subseteq F_p G \subseteq \cdots \subseteq G$$

$$(395) \quad Gr(G)_p = \frac{F_p G}{F_{p-1} G}$$

$$(396) \quad E_2^{pq} = H_p(B; H_q(F; G))$$

$$(397) \quad E_n^{pq} = E_{n+1}^{pq} = \cdots = E_\infty^{pq}$$

$$(398) \quad N \rightarrow G \twoheadrightarrow Q$$

$$(399) \quad E_2^{pq} = H_p(Q; H_q(N; A))$$

$$(400) \quad L_0 G(FP) = GFP, \quad L_n G(FP) = 0, \quad n \geq 1$$

$$(401) \quad E_2^{pq} = (L_p G)(L_q F)(A)$$

$$(402) \quad \mu^*: H^*(M; Q) \rightarrow H^*(M \times M; Q) \\ = H^*(M; Q) \otimes_q H^*(M; Q)$$

$$(403) \quad \psi: A \rightarrow A \otimes_q A$$

$$(404) \quad (1 \otimes \eta)\psi = (\eta \otimes 1)\psi = 1: A \rightarrow A$$

$$(405) \quad (1 \otimes \theta)\psi = \psi(1 \otimes \theta) = \eta$$

of successively applying the differentials d_n, d_{n+1}, \dots to an element c of E_n , each differential becoming applicable when its predecessor produces the value 0. In particular E_n^* may be defined as the subgroup of E_n consisting of those elements of E_n that are cycles for all $d_r, r \geq n$. Now the passage from cycle to homology class plainly induces a surjection of E_n^* onto E_{n+1}^* and E_∞ , the limit of the spectral sequence, is defined to be the direct limit of the resulting sequence (see 393). Thus E_∞ is the quotient of E_0^* by those cycles that eventually become boundaries; i.e., that go to zero in some E_n^* . It is also said that the spectral sequence converges to E_∞ .

Often in applications of spectral sequence theory the terms E_n are graded (or bigraded), and an early term of the spectral sequence is known and the limit term E_∞ is related to an Abelian group to be calculated, or, at least, about which information is sought. The relation of E_∞ to this group is frequently that of the graded group associated to a filtration of that group. A filtration (strictly, an increasing filtration) of the Abelian group G is a sequence of subgroups (see 394) and the associated graded group $\text{Gr}(G)$ is the graded group, the p th component of which is given (see 395).

It is plain that if the filtration (see 394) is to be such that $\text{Gr}(G)$ yields useful information about G , it must have certain properties. Usually it is asked that $F_p G = 0$ for p less than or equal to some p_0 , and that $\cup_p F_p G = G$. Then every nonzero element of G appears as a nonzero element in precisely one component of $\text{Gr}(G)$. From the given knowledge of E_2 , say, conclusions can be drawn about E_∞ by passing through the spectral sequence and then inferences made about the filtered group G of which E_∞ is the associated graded group; sometimes this procedure is reversed.

The concept of a spectral sequence was invented by the French mathematician Jean Leray. Topologists first became generally aware of its importance, however, when the French mathematician Jean-Pierre Serre applied it to the study of the relations between the homology groups of fibre, total space, and base space in a fibration, in 1951. He was thus able to obtain deep relations between the homology groups and homotopy groups of a space. Precisely, Serre showed the following (his result is not stated here in its fullest generality): If F is the fibre, E the total space, B the base space, all spaces being connected, B simply-connected, and if G is an Abelian coefficient group, then there is a spectral sequence of bigraded Abelian groups (E_n, d_n) with specific properties (see 396) and E_∞ is the graded group associated with $H_*(E; G)$, suitably filtered. Moreover, the filtration has the good properties mentioned earlier; and the convergence to the limit is finite in the sense that, given any (p, q) , there exists n such that a sequence of equations holds (see 397). The differential d_n on E_n has degree $(-n, n-1)$. Thus knowledge of the homology groups of B and F makes it possible to draw conclusions about the homology groups of E ; indeed, knowledge of the homology groups of any two of F, E, B leads to information about the third.

Serre's theorem revolutionized homotopy theory; but spectral sequences then began to appear all over algebraic topology and homological algebra. For example, in the homology theory of groups, let a short exact sequence of groups be given (see 398); G is a group with normal subgroup N , such that $G/N \cong Q$. Let A be a G -module. There is then a Lyndon-Hochschild-Serre spectral sequence such that an equation holds (see 399), which converges to the graded group associated with $H_*(G; A)$, suitably filtered. There is a similar sequence in the homology theory of Lie algebras. Indeed, all the sequences described are special cases of a procedure due to the French mathematician Alexandre Grothendieck. Additive functors $F: \mathfrak{A} \rightarrow \mathfrak{B}, G: \mathfrak{B} \rightarrow \mathfrak{C}$ of suitable Abelian categories (for example, categories of modules) may be considered. Suppose that, for every projective object P of \mathfrak{A} , FP is (left) G -acyclic, that is to say, the left derived functors of G , evaluated on FP , give a set of equations (see 400). Then, for each A in \mathfrak{A} , there is a spectral sequence such that a relation holds (see 401) and it converges to the graded group associated with $L_*(GF)(A)$, suitably filtered.

Even this formulation by no means exhausts the scope of useful generalization.

Turning now to another topic of homological algebra, namely, that of Hopf algebras, again the source lies in algebraic topology. Suppose there is given a connected Lie group M ; for example, the rotation group of Euclidean n -space. The cohomology ring $H^*(M; Q)$ of the underlying space of M with coefficients in the ring Q of rational numbers may then be formed; this is a graded commutative Q -algebra. Moreover, the multiplication map $\mu: M \times M \rightarrow M$ induces an algebra map (see 402). Further, the fact that there is a two-sided unity for μ shows that if μ^* is followed by either projection onto $H^*(M; Q)$, the composite is the identity. This leads to a study of graded Q -algebras $A = \bigoplus_{n \geq 0} A_n$ admitting a diagonal map ψ , which

is a map of Q -algebras (see 403), and a co-unit $\eta: A \rightarrow Q$ such that a consequence follows (see 404). (Note that $A \otimes_Q Q \cong A \cong Q \otimes_Q A$ so that $1 \otimes \eta$ and $\eta \otimes 1$ correspond to the projections mentioned above.) This is now called a graded Hopf algebra. Of course, the example $A = H^*(M; Q)$ has other properties that may qualify the Hopf algebra. It is commutative; it is connected in the sense that $A_0 = Q$ and η is simply the obvious projection onto A_0 ; it is co-associative in the sense that ψ is associative; and it admits an involution $\theta: A \rightarrow A$ such that equations result (see 405).

In a pioneer work published in 1941, Hopf proved that, in the terminology introduced above, if A is a commutative graded connected Hopf algebra over Q , then it is, as an algebra, an exterior algebra on odd-dimensional generators; moreover, if it is co-associative, then these generators are primitive, meaning that $\psi(x) = x \otimes 1 + 1 \otimes x$. Hopf thus explained a phenomenon relating to the four main series of simple Lie groups that had been observed by geometers, algebraists, and topologists in the 1930s. Because Hopf's theorem only required that M admit a continuous multiplication with two-sided unity, it encompassed a broader class of topological space than that defined by the Lie groups. The true breadth of this class is now beginning to be glimpsed, as more and more Hopf manifolds are being discovered.

The study of Hopf algebras is now a part of algebra; moreover, there is a theory of differential Hopf algebras that is securely placed in the domain of homological algebra. Hopf's is seen as the first of many structure theorems that have proved of great value in both algebra and topology. A particularly interesting connection between the theory of Hopf algebras and what has gone before is provided by the group ring KG , of a (finite) group G , over the field K . The diagonal map $\Delta: G \rightarrow G \times G$, yields a diagonal map $\psi: KG \rightarrow KG \otimes KG$ and so makes of KG a co-associative, co-commutative Hopf algebra over K with involution.

(P.J.H.)

Universal algebra

Algebra began as the manipulation of numbers, using the four operations of arithmetic: addition, subtraction, multiplication and division. As the subject developed, the operations have changed very little, if at all, but the notion of number has been progressively enlarged. It was already recognized by the school of Pythagoras that rational numbers do not suffice to describe the diagonal of a unit square (i.e., $\sqrt{2}$). In order to take account of such irrational numbers as $\sqrt{2}$, a geometric theory of proportion was developed during the 4th century BC by Eudoxus of Cnidus; this theory forms the substance of Book V of Euclid's *Elements*.

In the 16th century, when it was found that square roots of negative numbers may be needed to solve cubic equations, even when all their roots are real numbers, complex numbers were introduced. For a long time these numbers were known as impossible or imaginary, and their use was put on a firm basis only at the end of the 18th century, by Gauss.

The 19th century saw a series of discoveries, resulting in the creation of modern function theory. Some extensions of the complex number system were also made. Although

Hopf
algebras

Serre's
theorem

Historical
back-
ground

these did not rival the complex numbers in importance, they formed a beginning of the more abstract outlook adopted today.

The first of these generalized number systems was Hamilton's quaternions. They were intended to describe points in space just as complex numbers describe points in the plane, and in fact Hamilton had mainly geometric applications in mind. From a somewhat different point of view, Grassmann, in his calculus of extension, treated geometric entities as objects of an algebraic system with addition and multiplication. The ideas of Hamilton and Grassmann gave rise, at the hands of Heaviside and Gibbs, to the modern development of vector analysis, not of concern here, except in so far as both the quaternions and Grassmann algebra may be regarded as an algebraic system with vectors instead of numbers, or a linear associative algebra. A system of quite a different sort, but still formally fitting into the framework of linear associative algebras, was described by Boole, who defined certain operations on statements: If two statements A , B are combined by conjunction (i.e., the new statement " A and B ") is formed), disjunction (forming " A or B ") and negation (forming "not A "), a system satisfying many of the rules of the ordinary number system is obtained.

Another branch of algebra that began to take shape in the early days of the 19th century was the theory of groups, first as groups of permutations by Abel and Galois and later more generally as groups of transformations by Lie and Klein. The mere existence of all these different types of algebraic systems suggested a comparative study. Such a study was begun by the English mathematician Alfred North Whitehead, who in his 'Universal Algebra' I, described the systems of Boole, Hamilton, and Grassmann, as a preparation to a comparative study, which was to form volume II, but was never written. The name 'Universal Algebra,' according to Whitehead, was taken from a paper by the British mathematician James Joseph Sylvester: "Lectures on the Principles of Universal Algebra," published in the *American Journal of Mathematics*, vol. 6, 1884.

One of the characteristics of 20th-century mathematics has been the development of axiomatic foundations. Instead of referring new developments back to some part of the subject regarded as known, one would base everything on a small set of axioms. The method was used especially in algebra; the whole of group theory could be built up on three or four simple axioms. It also helped to crystallize such general notions as linear associative algebra and ring. Emmy Noether showed how the notion of group with operators allowed a number of different notions, such as group, vector space, representation module, to be treated by the same method. From here it was only a small step to drop the group structure. Universal algebra is nowadays understood to be the study of such general algebraic systems, by methods uniformly applicable to all of them.

BASIC NOTIONS OF UNIVERSAL ALGEBRA

An operation on a set A is a mapping or function defined on A with values in A . For example, if A is mankind, then "mother of x " is an operation in one argument, or a unary operation (here the fact that the mapping is undefined for Adam and Eve is ignored). On the set of integers, the operation of taking the sum of the numbers x and y , written $x + y$, is a binary operation, because it depends on two arguments: x and y . In the plane, the operation of taking the centroid of a triangle ABC is a ternary operation, depending on three arguments, A , B , C . Most operations depend on a finite number of arguments; that is, they are said to be finitary. If an operation depends on n arguments, in which n may be 1, or 2, or any positive integer, then the operation is said to be n -ary, and the number n is called its arity. Occasionally, 0-ary operations are used; such an operation depends on no arguments at all; it simply picks out a particular element of the set. For this reason it is also called a constant operator. For example, in a group the neutral element may be regarded as the value of a 0-ary operation.

An algebraic structure on a set A consists in specifying a number of operations on A ; these operations are not re-

stricted in any way except that the arity of each is usually a preassigned integer. In this way A becomes an algebraic system, or simply an algebra. For example, groups may be regarded as algebras with a binary operation, multiplication: xy ; a unary operation, the inverse: x^{-1} ; and a 0-ary operation, the neutral: e , together with certain laws (such as the associative law). As an example of an algebra with infinitely many operations, a real vector space is considered. This has the group operations (because it is an additive group) as well as a unary operation for each real number λ : scalar multiplication by λ . To facilitate the comparison of different algebras, a set Ω is usually chosen as operator set; with each member ω of Ω an integer $n(\omega)$ is associated, to indicate the arity of the resulting operation, and an Ω -algebra structure is obtained by prescribing for each ω in Ω an operation $\omega(x_1, \dots, x_{n(\omega)})$ of arity $n = n(\omega)$.

The notion of a subgroup of a group or a subspace of a vector space is generalized by defining a subalgebra of an algebra A as a subset admitting all the operations of A . The result is an algebraic structure of the same kind as A , just as every subgroup of a group is a group in its own right. To give an example, the complex numbers form a real vector space, with the real numbers as subspace. But the complex numbers may also be regarded as a complex vector space, and now the real numbers do not form a subspace because they do not allow multiplication by $\sqrt{-1}$. This illustrates the need to specify the operations as well as the sets in describing algebras.

If in an algebra A a subset X is taken, it will in general not be a subalgebra; i.e., by applying the algebra operations to elements of X new elements are generally obtained that do not lie in X . $\langle X \rangle$ denotes the set of all elements obtainable from X by repeated application of the algebra operations. When any of these operations is applied to elements of $\langle X \rangle$, again an element of $\langle X \rangle$ is obtained; in other words, $\langle X \rangle$ admits all the algebra operations and so is a subalgebra of A . It is actually the least subalgebra containing X and is usually called the subalgebra generated by X .

The notion of a quotient group can be generalized as follows: If an Ω -algebra A is partitioned into classes, it is possible to define an operation ω of A on the set of classes, provided that varying the arguments of ω within a given class does not change the class in which the result lies; that is, if x_1, x'_1 lie in the same class and likewise x_2, x'_2 , etc., then $\omega(x_1, \dots, x_n)$ and $\omega(x'_1, \dots, x'_n)$ must lie in the same class. When this condition holds for all ω in Ω , the given partition is called a congruence, and denoting it by q say, A/q is written for the set of classes. The above condition ensures that each ω in Ω can be defined unambiguously as an operation on A/q . In this way A/q is turned into an Ω -algebra, called the quotient algebra of A by q . For example, if \mathbf{Z} is the ring of integers and \mathbf{Z} is partitioned into classes by putting two numbers in the same class precisely when their difference is divisible by 7, then there are just 7 classes, described by their least remainders after division by 7. If two numbers a, a' leave the same remainder and b, b' do likewise, then so do their respective sums $a + b$ and $a' + b'$; similarly for the other ring operations (subtraction and multiplication), and therefore a congruence is obtained and the residue classes form a quotient ring.

A mapping f from one Ω -algebra, A , to another, B , is called a homomorphism and is written as $f: A \rightarrow B$ if it preserves the Ω -algebra structure in the sense that the result of applying f to the value of an operation ω is the same as applying f to the arguments and then taking ω :

$$f(\omega(x_1, \dots, x_n)) = \omega(f(x_1), \dots, f(x_n)).$$

For example, if q is a congruence on an algebra A , then there is a natural mapping φ that associates with each element of A the class of q in which it lies; now the condition for q to be a congruence ensures that φ is a homomorphism. A homomorphism from A to B that is a one-one correspondence (bijection) between these algebras is called an isomorphism between A and B , and A is then said to be isomorphic to B .

Given two Ω -algebras A and B , a new Ω -algebra $A \times B$

Develop-
ment of

Quotient
groups

can be defined, called their direct product, by taking the set of all pairs with the first component a member of A and the second a member of B , and performing the operations of Ω componentwise. More generally, such a direct product can be formed from any collection (even infinite) of Ω -algebras.

These notions of subalgebra, quotient algebra, homomorphism, and direct product arose by generalizing the familiar situation in group theory. There the notion of a quotient group looks simpler than in the general case because the classes of a congruence on a group are just the cosets of a subgroup. For other algebraic systems having no underlying group structure, such as lattices or semi-groups, the situation is more involved; nevertheless the notion of congruence has been useful there too, in analyzing homomorphisms. Thus with each homomorphism $f: A \rightarrow B$ between Ω -algebras, there can be associated a quotient algebra A/q of A and a subalgebra B' of B , together with an isomorphism $f_1: A/q \rightarrow B'$ such that the original homomorphism f is obtained by taking in turn the natural mapping $A \rightarrow A/q$, the isomorphism f_1 , and the inclusion mapping $B' \rightarrow B$, which leaves each element of B' fixed but considers it as an element of B . The congruence q of A that arises in this way is called the kernel of the mapping f , and it has the following interpretation: two elements of A are mapped to the same element of B by f precisely when they belong to the same class of the kernel of f . The set of values of f , namely B' , is also called the image of A under the mapping f , and the above analysis of homomorphisms shows that the images of an algebra under homomorphisms are precisely its quotient algebras. For this reason the quotient algebras of an algebra are also called its homomorphic images.

Now the usual isomorphism theorems of group theory, which allow a comparison of subgroups of quotients, and of quotients of quotients, to be made, can be taken over with hardly any change. One can also prove, under suitable hypotheses, an analogue of the Jordan-Hölder-Schreier theorem, which compares different chains of factor algebras; *i.e.*, quotients of subalgebras. There is a close connection with lattices here: as already observed, the results can be applied to lattices, as particular algebraic systems. At the same time the subalgebras of an algebra form a lattice, as do the congruences on an algebra, and in this way the results of lattice theory can be used in a general analysis of algebraic systems.

THE CONNECTION WITH MATHEMATICAL LOGIC

The results described in the last section are quite general in scope, and apply even to systems with infinitary operations; that is, operations depending on infinitely many arguments. There is, however, another group of results for which finitariness of the operations is essential; these results are often regarded as characteristic of algebraic systems. The basic property is the following algebraicity condition: if A is any algebra and X a subset of A , then an element of A lies in $\langle X \rangle$, the subalgebra generated by X , precisely when it lies in the subalgebra generated by some finite subset of X . This is so because any member of $\langle X \rangle$ is obtained by applying the algebra operations repeatedly to elements of X , and, because all operations are finitary, the total number of arguments needed is also finite. This principle forms the basis for the application of Zorn's lemma (an algebraic formulation of the axiom of choice in set theory). It applies not only to algebraic systems—that is, sets with operations—but also to relational systems; that is, sets with operations and relations defined on them, such as ordered groups. It also has a remarkable connection with logic: any mathematical theory may be regarded as an algebraic system the elements of which are the theorems (the provable statements in the theory) and the operations of which are the usual rules of deduction in logic (modus ponens and the rule of substitution); therefore it satisfies the algebraicity condition mentioned earlier. Now a basic theorem of logic due to the logician Gödel, the completeness theorem, states that any theory (composed of statements of the lower predicate calculus) admitting the rules of deduction and not including a contradictory statement has a model. On the other hand one

can show, by purely algebraic means, that the theories that have models satisfy the algebraicity condition. The practical consequence is often stated as the compactness theorem: A set of statements within a theory (of the lower predicate calculus) is consistent whenever every finite subset of statements is consistent.

A typical application of this result to the algebraic theory of fields states that a sentence holds in every field of characteristic zero, provided that it holds in every field of sufficiently high characteristic. This follows because fields of characteristic greater than a given number n can be defined by the conjunction of the sentences E_2, E_3, \dots, E_n , in which E_2 is: "for each $x \neq 0, x + x \neq 0$ "; *i.e.*, no nonzero element when added to itself gives zero (to exclude fields of characteristic 2), E_3 is: "for each $x \neq 0, x + x + x \neq 0$," and so on, while fields of characteristic zero are defined by the conjunction of all the sentences E_2, E_3, \dots . If a sentence holds for all fields of characteristic exceeding some fixed number N , then it must be consistent with any finite subset of the collection E_2, E_3, \dots , and hence (by the compactness theorem) with all of them; *i.e.*, it holds in characteristic zero.

Besides being a field of application of universal algebra, mathematical logic is also an important tool. Thus to study a particular class of algebraic systems, it is not enough to specify the operations. It is also necessary to lay down which algebras are to be admitted. This is usually done by means of sentences formed from such basic statements as $x + y = z$, in accordance with the rules prescribed by logic; for example, if the system to be specified has a multiplication that is to have an inverse, a sentence is required of the form: For all x, y , there exists u such that $xu = y$. The sentences needed to define a class of algebras can be classified according to logical principles, and conclusions can then be drawn about the class of algebras defined. Thus, if the sentences defining the class of algebras contain only universal quantifiers ("For all...") and no existential quantifiers ("There exist..."), in other words, if they are universal sentences, then the class of algebras so defined is closed under subalgebras: with an algebra, all its subalgebras belong to the class. This is fairly easy to prove; more difficult (and more interesting) is a result in the opposite direction: A class of algebras that is closed under subalgebras and that is definable by axioms can be defined by universal sentences. The condition of being definable by axioms can also be expressed in terms of explicit conditions on the algebras of the class, but is a little more complicated to state and so is omitted here.

As an example, the class of all groups is considered. This can be defined by the following laws: (a) the associative law: $x(yz) = (xy)z$; (b) the law expressing that e is neutral: $xe = ex = x$; and (c) the law expressing that x^{-1} is inverse to x : $xx^{-1} = x^{-1}x = e$. These laws are understood to hold for all group elements x, y, z , and so they are universal sentences, and in fact any subalgebra, within the general sense of the word (that is, any subgroup), of a group is again a group. The same is true if a sentence such as "for all $x, x^3 = e$ " is added. This picks out the class of groups in which the cube of any element is the neutral element, and any subgroup of such a group has the same property. Next consider the class of periodic groups; *i.e.*, groups in which every element has some power equal to e : $x_n = e$, in which the value of the exponent n depends generally on x . Any subgroup of a periodic group is periodic, but the class of periodic groups cannot be defined by axioms. If one attempts this, one finds oneself having to say that for each x , either $x^2 = e$ or $x^3 = e$ or $x^4 = e$ or \dots , a sentence of infinite length that is not admitted. It might seem as if periodic groups could be defined by the finite sentence: For every x there exists a positive integer n such that $x^n = e$. This is not, however, allowed by the rules of the game, which permit only sentences of the lower predicate calculus, because a quantifier has been applied to an integer (\dots there exists a positive integer $n \dots$). Next examine the class of all groups that are not periodic; it is easy to find a group that is not periodic but that has a periodic subgroup. So this class cannot be expected to be defined by universal sentences. Finally, the class of aperiodic groups is considered; that is, groups in which no

The compactness theorem

Classes of algebraic systems

element other than e has any positive power equal to e . This class is closed under subgroups and can in fact be defined by universal sentences, expressing the fact that no power of an element other than e can be e : For all x , if $x \neq e$, then $x^2 \neq e$; for all x , if $x \neq e$, then $x^3 \neq e$ These sentences form the multiplicative analogue of the sentences E_2, E_3, \dots used earlier to define fields of characteristic zero.

VARIETIES OF ALGEBRAS

Many important classes of algebras can be defined entirely by identities; that is, equations that hold for all values of the arguments. Thus groups were defined by the identities expressing the associative law and the properties of neutral and inverse elements. Such a class is called a variety. Groups form a variety, likewise Abelian groups, but not all finite groups, because any law satisfied by all finite groups is also satisfied by all infinite groups. Testing for varieties is facilitated by the following criterion due to Garrett Birkhoff: A class of algebras is a variety if, and only if, it is closed under taking subalgebras, homomorphic images, and direct products. Using this test it is easy to check that finite groups do not form a variety: a direct product of finite groups, with infinitely many factors, is no longer finite. In the same way one finds that periodic groups do not form a variety; nor do the aperiodic groups; the groups satisfying $x^3 = e$, however, do form a variety.

Varieties have several properties that make them more amenable to treatment. A useful property, actually characteristic of varieties, is the following: For each integer n , there is an algebra F_n the quotients of which constitute precisely the algebras in the variety that can be generated by n elements; a corresponding algebra exists when n is replaced by an infinite cardinal number. This algebra F_n is called the free algebra of the variety, on n free generators; it is rather like the algebra of polynomials. In elementary algebra a polynomial in n variables x_1, \dots, x_n with real coefficients has the property that any substitution of real numbers for the variables x_1, \dots, x_n gives a real number. Moreover, these polynomials can be added, subtracted and multiplied; *i.e.*, they form a ring, the polynomial ring in the variables x_1, \dots, x_n over the real numbers, and it is not hard to see that any substitution of real numbers for the x 's preserves the ring operations; *i.e.*, it is a homomorphism. In the same way group elements can be formed in n variables x_1, \dots, x_n using only the general group laws to simplify the expressions. Thus a variable that is followed or preceded by its formal inverse can always be omitted: $xyy^{-1}z = xz$, $ux^{-1}xu = u^2$, but no other simplification is possible. For example, one may not replace xy by yx because the commutative law $xy = yx$ does not hold in all groups. In this way the free group on x_1, \dots, x_n is obtained; its elements are all products in x_1, \dots, x_n and their inverses; that is, all group words in these variables. By the associative law all parentheses can be omitted, and two group words represent the same group element if it is possible to pass from one to the other by inserting or omitting occurrences of a variable together with its inverse. Given any group G , any elements of G can be substituted for the variables in words of the free group. Thus x_1 can be replaced by a_1 , x_2 by a_2 , etc., taking care to replace x_i^{-1} by a_i^{-1} , etc. In this way each word corresponds to an element of G , and words representing the same element of the free group will certainly correspond to the same element of G . Therefore, a mapping is obtained from the free group into G , and this mapping can easily be shown to be a homomorphism. By taking enough variables (infinitely many if necessary) any group can be expressed in this way as a homomorphic image of a free group. A similar construction applies in any variety of algebras, such as the variety of Abelian groups, or the variety of lattices, or of semigroups with a neutral element.

Algebraic systems often arise in a concrete way; for example, groups may arise as groups of transformations. There is another important method of defining algebras within a given variety, however, which consists in writing down a set of generators and defining relations. This means that a set of symbols is written as the generating set, and a set of relations is written that are to hold between these symbols,

such that all other relations can be deduced from them. Such an algebra then consists of all expressions formed from these symbols by the algebraic operations, in which two expressions are to represent the same element whenever it is possible to pass from one to the other using only the given relations and the defining laws of the variety. To give a simple example, the group of complex cube roots of unity has the following presentation: All expressions obtained by applying group operations to a single group variable x are taken; *i.e.*, all group words in x , namely $e, x, x^2, x^3, \dots, x^{-1}, x^{-2}, \dots$. Two of them are declared equal if and only if it is possible to pass from one to the other using the relation expressing that the cube of x is the neutral element: $x^3 = e$. This is abbreviated by writing the group as $gp(x \mid x^3 = e)$, called a presentation of the group. In this particular case it is easy to see the structure of the group: two powers of the generator x^m and x^n , say, represent the same element of the group if, and only if, the difference of their exponents $m - n$ is divisible by 3; so there are just three elements, represented by the words e, x, x^2 . Of course, few groups have a presentation as simple as this one, and for more complicated presentations it may be quite difficult to decide when two words represent the same group element. This problem is known as the word problem for groups; a given presentation of a group is said to have a soluble word problem if there exists a method enabling one to decide for each pair of words in a finite number of steps whether or not they represent the same element. The word problem has been solved for some simple classes of groups, but more interestingly, it has been shown to be insoluble in general. Group representations have been found that have an insoluble word problem. Similarly, presentations can be obtained for the algebras in any variety, and it will be necessary to solve the word problem. For many algebras encountered in practice, a presentation can be found with soluble word problems, but generally there will also be algebras with insoluble word problems in all but the simplest varieties.

The notion of a free algebra is useful in many ways. If it is required to establish a property of groups that is preserved by homomorphisms, the first step is to check whether the free group has it. If so, then the desired conclusion follows because every group is a homomorphic image of a free group; if the free group does not have the property, it is a counter-example. This method is particularly effective for groups (as well as for semigroups and rings) because the word problem for free groups (and semigroups and rings) is rather easy to solve. This means that the elements of free groups can be represented in a very perspicuous form. It is no longer true of such varieties as alternative algebras or Jordan algebras, and as a consequence some apparently quite simple problems—such as the existence of zero-divisors in free Jordan algebras (nonzero elements the product of which is zero)—are still open.

Free algebras (in different varieties) have been the subject of intensive investigation, partly as an end in itself and partly on account of applications. Thus in commutative ring theory, the free algebras are polynomial rings, and the theorem that every commutative ring is the homomorphic image of a free commutative ring is the algebraic counterpart of the geometric fact that every geometric figure lies in n -dimensional space (for a suitable integer n). This accounts for the importance of polynomial rings in the study of algebraic geometry.

A free semigroup in the variables x_1, \dots, x_n may be realized as the set of all finite sequences of letters from x_1, \dots, x_n , allowing repetitions; that is, all words in the alphabet x_1, \dots, x_n . The study of such words has led to applications in coding theory as well as in the algebraic theory of languages, which has provided much of the impetus for studying free semigroups. As an example, the free semigroup on x, y, z and a set of words is sought such that no spaces or commas are needed to divide any message into its constituent words (this is known as a comma-free code). The set of words x, xy, z, yz clearly will not do, for the expression xyz can be parsed in two ways: as $x \cdot yz$ or $xy \cdot z$. But there is an infinite set of words with the required property: x, xy, xy^2, xy^3, \dots . From the algebraic point of view a comma-free code is

Testing

and
relations

a set that forms a free generating set for a free subsemigroup, and such sets have been characterized by simple criteria. Another application is to elementary arithmetic: the positive integers may be regarded as the free semigroup on one free generator. Now the basic property, that every mapping of the single free generator defines a unique homomorphism, is just another way of expressing the principle of induction.

Besides applications in algebra itself, free algebras have many uses in algebraic geometry and topology, automata theory, and the statistical theory of queues.

UNIVERSAL ALGEBRA AND CATEGORY THEORY

There are close links between universal algebra and category theory. Although the precise degree of useful interaction is still open to discussion, it is widely agreed that category theory provides a convenient language for stating many of the results of universal algebra. Often there are several ways of expressing the same phenomenon; thus the characteristic property of free algebras is a particular instance of a universal construction, which appears in many different contexts. It may also be described as the left adjoint of the forgetful functor (which passes from an algebra to its underlying set and so forgets the algebra structure).

The definition of an Ω -algebra involved prescribing, for each member of Ω , an operation of the right arity. If n elements of the algebra are taken and m n -ary operations are performed on them, m elements are obtained on which an m -ary operation can be performed. In this way an n -ary operation is obtained by composition. There are also the identity operations, which pick out the first argument, or the second, or any other of the n arguments. Any collection of operations on a set, closed under the composition described above and containing all the identity operations (one unary, two binary ones, three ternary ones, etc.) is called a clone, and in studying a particular Ω -algebra the operations corresponding to members of Ω may be replaced by the clone they generate. Now it is possible to define clones abstractly, and to define algebraic systems one may take a particular abstract clone C and define C -algebras as sets on which the clone C is realized by operations. This definition is due to P. Hall, and is very close to the categorical definition, due to Lawvere. The latter defines a category as a category \mathfrak{T} the objects of which are nonnegative integers, in which the number n is regarded as the coproduct of n copies of the number 1. Any contravariant functor from \mathfrak{T} to the category of sets and mappings, in which coproducts map to products, is called a \mathfrak{T} -algebra. If A is the set corresponding to the number 1, then n corresponds to the n th direct power A^n , and the various morphisms in \mathfrak{T} from 1 to n correspond to mappings from A^n to A ; i.e., n -ary operations on A . Any morphism in \mathfrak{T} from m to n corresponds to m morphisms from 1 to n ; this means that the mappings from A^n to A^m each correspond to m n -ary operations on A . In other words, the \mathfrak{T} -algebra structure so defined amounts to picking out a clone of operations on A .

Although many of the results of universal algebra can be proved within the framework of category theory, they can be proved just as easily directly. The most significant progress in universal algebra has been in the areas adjacent to logic, and there category theory has been of little help. On the other hand, in applications to other parts of mathematics (especially in algebraic geometry) category theory has to some extent replaced universal algebra.

BIBLIOGRAPHY

Elementary algebra: For the history of algebra, see ERIC T. BELL, *The Development of Mathematics*, 2nd ed. (1945); and DIRK J. STRUIK, *A Concise History of Mathematics*, 3rd rev. ed., 2 vol. (1967). There are many textbooks on elementary algebra, such as MORRIS S. KNEBELMAN and TRACY Y. THOMAS, *Principles of College Algebra* (1942). Somewhat more advanced are the books on the theory of equations: LEONARD E. DICKSON, *New First Course in the Theory of Equations* (1939); JAMES V. USPENSKY, *Theory of Equations* (1948); and LOIS W. GRIFFITHS, *Introduction to the Theory of Equations*, 2nd ed. (1947). Also more advanced are textbooks on abstract algebra, such as GARRETT BIRKHOFF and SAUNDERS MACLANE, *A Survey of Modern Algebra*, 3rd ed. (1965). See also JOHN R. DURBIN, *College*

Algebra (1982); MARSHALL D. HESTENES and RICHARD O. HILL, *College Algebra with Calculators* (1982); JOHN D. LIPSON, *Elements of Algebra and Algebraic Computing* (1981); MUSTAFA A. MUNEM and DAVID J. FOULIS, *Algebra and Trigonometry with Applications* (1982); M.L. KEEDY and MARVIN L. BITTINGER, *Algebra and Trigonometry: A Functional Approach*, 3rd ed. (1982); and ROBERT C. FISHER and ALLEN D. ZIEBUR, *Integrated Algebra, Trigonometry, and Analytic Geometry*, 4th ed. (1982).

(Ed.)

Linear and multilinear algebra: W.H. GREUB, *Linear Algebra*, 3rd ed. (1967), a standard textbook, advanced level; and *Multilinear Algebra* (1967), a standard modern treatment of multilinear algebra that fully exploits universal mapping properties; P.R. HALMOS, *Finite-Dimensional Vector Spaces*, 2nd ed. (1958), a standard textbook, advanced level, which emphasizes methods that can be carried over to infinite-dimensional spaces, particularly to Hilbert space; SIR WILLIAM ROWAN HAMILTON, *Lectures on Quaternions* (1853), mainly of historical interest; K. HOFFMAN and RAY KUNZE, *Linear Algebra*, 2nd ed. (1971), a standard textbook, intermediate level; N. JACOBSON, *Lectures in Abstract Algebra*, vol. 2, *Linear Algebra* (1953), a standard textbook, advanced level; MARVIN MARCUS and HENDRYK MINC, *Introduction to Linear Algebra* (1965), a standard textbook, elementary level; and *A Survey of Matrix Theory and Matrix Inequalities* (1964), a very concise account, omitting standard proofs, of the main facts of matrix algebra, with many references to original sources; DAVID C. MURDOCH, *Linear Algebra* (1970), a standard textbook, elementary level; ROBERT C. THOMPSON and ADIL YAQUB, *Introduction to Linear Algebra* (1970), a standard textbook, at the elementary level. A later, well-motivated work is JAMES W. DANIEL, *Elementary Linear Algebra and Its Applications* (1981).

(Ed.)

Lattice theory: JOHN E. WHITESITT, *Boolean Algebra and Its Applications* (1961), gives a very elementary introduction to Boolean algebra, with some applications to logic and switching circuits; GARRETT BIRKHOFF and THOMAS C. BARTREE, *Modern Applied Algebra* (1970), gives a more comprehensive and more recent discussion from a similar standpoint. JAMES C. ABBOTT, *Sets, Lattices and Boolean Algebras* (1969), is a very readable introductory text on sets and lattices from a purely mathematical standpoint; *Trends in Lattice Theory*, ed. by Abbott (1970), discusses informally some recent trends. GARRETT BIRKHOFF, *Lattice Theory*, 3rd ed. (1967), is the standard treatise on the subject. PAUL R. HALMOS, *Algebraic Logic* (1962), discusses in depth some of the Boolean algebras arising in logic; JOHN B. ROSSER, *Simplified Independence Proofs* (1969), shows how these have been recently applied to prove fundamental theorems in set theory and logic. Relevant later monographs include A.G. HAMILTON, *Numbers, Sets, and Axioms: The Apparatus of Mathematics* (1982); WILLIAM S. HATCHER, *The Logical Foundations of Mathematics* (1982); PETER T. JOHNSTONE, *Stone Spaces* (1983).

Groups: CAMILLE JORDAN, *Traité des substitutions et des équations algébriques* (1870); and WILLIAM BURNSIDE, *Theory of Groups of Finite Order*, 2nd ed. (1911, reprinted 1955), are the great classical works on group theory. For a period the subject was relatively dormant, but in the 1930s a revival began signaled by PHILIP HALL's celebrated paper "A Contribution to the Theory of Groups of Prime Power Orders," *Proc. Lond. Math. Soc.*, Second Series, 36:29-95 (1932). In 1923 there appeared the first edition of ANDREAS SPEISER, *Die Theorie der Gruppen von endlicher Ordnung*, 4th ed. (1956); HANS ZASSENHAUS, *Lehrbuch der Gruppen theorie* (1937; Eng. trans., *The Theory of Groups*, 2nd ed., 1958); B.L. VAN DER WAERDEN, *Gruppen von linearen Transformationen* (1935); and ALEXANDER G. KUROSCHE, *The Theory of Groups*, 2 vol. (1955-56; orig. pub. in Russian, 1953), which developed the theory of free groups and free products extensively. IRVING KAPLANSKY, *Infinite Abelian Groups*, rev. ed. (1969), treats a theory that is now a major subject in its own right. The importance of group theory in physics is recognized by VOLKER HEINE, *Group Theory in Quantum Mechanics* (1960); and G.Y. LYUBARSKII, *The Application of Group Theory in Physics* (1960; orig. pub. in Russian, 1957). A turning point was the new approach in the paper by PHILIP HALL and GRAHAM HIGMAN, "On the p-Length of p-Soluble Groups and Reduction Theorems for Burnside's Problem," *Proc. Lond. Math. Soc.*, Third Series, 6:1-42 (1956). This more modern approach and the revival of representation theory, omitted by Kurosch and Zassenhaus, is shown in MARSHALL HALL, JR., *The Theory of Groups* (1959); and WILLIAM R. SCOTT, *Group Theory* (1964). GILBERT DE BEAUREGARD ROBINSON, *Representation Theory of the Symmetric Groups* (1961), deals with a special but important topic. WILLIAM MAGNUS, ABRAHAM KARRASS, and DONALD SOLITAR, *Combinatorial Group Theory* (1966), deals mostly with generators and relations. The book-length paper by WALTER FEIT and JOHN THOMPSON, *Solvability of Groups of Odd Order* (1962), brought activity to its present

Clone

high pitch; and the development and extension of this theory is the subject of the advanced treatise by DANIEL GORENSTEIN, *Finite Groups* (1968). BERTRAM HUPPERT, *Endliche Gruppen I* (1967), is the first volume of an encyclopaedic reference work. DANIEL GORENSTEIN, *Finite Simple Groups: An Introduction to Their Classification* (1982), and *The Classification of Finite Simple Groups: Groups of Noncharacteristic 2 Type* (1983), present detailed outlines of the problem as it stood in the early 1980s; DANIEL SEGAL, *Polycyclic Groups* (1983), illustrates algebraic number theory, algebraic groups, linear groups, and other mathematical areas involved.

Fields: Many works on algebra contain material on fields. Of these, GARRETT BIRKHOFF and SAUNDERS MACLANE, *A Survey of Modern Algebra*, 3rd ed. (1965); SOLOMON FEFERMAN, *The Number Systems: Foundations of Algebra and Analysis* (1964); I.N. HERSTEIN, *Topics in Algebra* (1964); and CYRUS C. MACDUFFEE, *An Introduction to Abstract Algebra*, ch. 1–6, (1940), are four standard undergraduate works.

Rings: Most treatises on algebra have chapters on rings—e.g., BIRKHOFF-MACLANE (*op. cit.*); and SERGE LANG, *Algebra*, ch. 2–6 and 17 (1965). A deeper study of commutative rings may be found in OSCAR ZARISKI and PIERRE SAMUEL, *Commutative Algebra*, 2 vol. (1958–60); MASAYOSHI NAGATA, *Local Rings* (1962); IRVING KAPLANSKY, *Commutative Rings* (1970); and MICHAEL F. ATIYAH and I.G. MACDONALD, *Introduction to Commutative Algebra* (1969). For noncommutative rings, see NATHAN JACOBSON, *The Theory of Rings* (1943, reprinted 1966); and I.N. HERSTEIN, *Noncommutative Rings* (1968). Applications of ring theory to arithmetic may be found in PIERRE SAMUEL, *Théorie algébriques des nombres* (1967; Eng. trans., *Algebraic Theory of Numbers*, 1970). See also R.B.J.T. ALLENBY, *Rings, Fields, and Groups: An Introduction to Abstract Algebra* (1983); ALEC FISHER, *Formal Number Theory and Computability* (1982); and HAROLD N. SHAPIRO, *Introduction to the Theory of Numbers* (1983).

Categories: Standard texts on the theory of categories include BARRY MITCHELL, *Theory of Categories* (1965); and BODO PAREIGIS, *Categories and Functors* (1970). ION BUCUR and ARISTIDE DELEANU, *Introduction to the Theory of Categories and Functors* (1968), is an excellent account of the theory of categories and functors with special reference to its applications in algebraic topology. SAUNDERS MACLANE, *Categories for the Working Mathematician* (1971), is a recent work in which the author, a distinguished categorist, sets out his view of the material of category theory basic to the professional mathematician. PETER J. FREYD, *Abelian Categories* (1964), is devoted to a special and very important class of categories. The first mention of the notions of category and functor in their explicit form is contained in the paper by SAMUEL EILENBERG and SAUNDERS MACLANE, "General Theory of Natural Equivalences," *Trans. Am. Math. Soc.*, 58:231–294 (1945).

Homological algebra: The classic text in homological algebra

is HENRI CARTAN and SAMUEL EILENBERG, *Homological Algebra* (1956). More recent texts are SAUNDERS MACLANE, *Homology* (1963); and PETER J. HILTON and U. STAMMBACH, *A Course in Homological Algebra* (1971)—an abbreviated version of this work may be found in Hilton's *Lectures in Homological Algebra* (1971). A natural context for homological algebra is described in PETER J. FREYD, *Abelian Categories* (1964). The role played by homological algebra in algebraic topology may be inferred from PETER J. HILTON and SHAUN WYLIE, *Homology Theory* (1960); and EDWIN H. SPANIER, *Algebraic Topology* (1966). Particular aspects of homological algebra are to be found in JOHN W. MILNOR and JOHN C. MOORE, "On the Structure of Hopf Algebras," *Ann. Math.*, 81:211–264 (1965); and EDWIN WEISS, *Cohomology of Groups* (1969). The background for the study of homological algebra in the theory of Lie groups and Lie algebras is contained in GERHARD P. HOCHSCHILD, *The Structure of Lie Groups* (1965); and NATHAN JACOBSON, *Lie Algebras* (1962). The pioneer work of Hopf that led to the emergence of homological algebra as a separate discipline is contained in the papers of HEINZ HOPF: "Fundamentalgruppe und zweite Bettische Gruppe," *Comment. math. helvet.*, 14:257–313 (1941–42); and "Über die Bettischen Gruppen die zu einer beliebigen Gruppe gehören," *ibid.*, 17:39–79 (1944–45). His work on Lie groups that led to a Hopf algebra is described in "Über die Topologie der Gruppen-Mannigfaltigkeiten und ihrer Verallgemeinerungen," *Ann. Math.*, 42:22–52 (1941). CZES KOSNIOWSKI, *A First Course in Algebraic Topology* (1980), is a work suitable for independent study.

Universal algebra: Some works on universal algebra are: ALFRED NORTH WHITEHEAD, *A Treatise on Universal Algebra, with Applications*, vol. 1 (1898, reprinted 1960), a description of the algebras of Boole, Hamilton, and Grassmann, with emphasis on geometrical applications; ABRAHAM ROBINSON, *Introduction to Model Theory and the Metamathematics of Algebra* (1963), a treatment of model theory with many applications to algebra; PAUL M. COHN, *Universal Algebra* (1965), a general introduction to the subject, stressing the connections with logic and giving applications to algebra; GEORGE GRATZER, *Universal Algebra* (1968), a comprehensive treatment of the subject, including much current research in the field; J.F.C. KINGMAN, "On the Algebra of Queues," *Methuen's Review Series in Applied Probability*, vol. 6, pp. 1–44 (1966), a description of the algebraic background to the problem of queues (waiting lines) with a single server; GIAN-CARLO ROTA, "Baxter Algebras and Combinatorial Identities I, II," *Bull. Am. Math. Soc.*, 75:325–334 (1969), in which an operator identity from probability theory is proved by first solving the word problem for a class of algebras; and GARRETT BIRKHOFF, (*op. cit.*), which has a long chapter on universal algebra. Relevant information can be found in J. CONRAD CROWN and MARVIN L. BITTINGER, *Finite Mathematics: A Modelling Approach*, 2nd ed. (1981), and their *Mathematics: A Modelling Approach* (1982).

American Indians

The American Indians had their origins in Asia and, despite superficial variation, are basically Mongoloid in physical type. The date of man's first arrival in North America has not been accurately established, but it is assumed to have occurred sometime during the last glacial period, about 20,000 to 35,000 years ago (though some authorities have argued for an even earlier date, some 50,000 years ago or more). The site of entry into North America is assumed to have been a land (or ice) bridge where the Bering Strait now divides Asia and America. By the time Europeans arrived in the 15th century, the descendants of these and later waves of migrants had spread over the Americas and developed a variety of cultures adjusted to various ecological conditions.

This article begins with a survey of the indigenous peoples and cultures of North, Middle, and South America, with an emphasis on traditional ways of life and the changes wrought by contact with European civilization. The second major section deals with the characteristic art forms of the North, Middle, and South American peoples and with those of the groups commonly known as the Eskimo (the traditional culture of Eskimo peoples is treated in the article ARCTIC, THE). The arts are discussed in relation to the cultures of these peoples and to Western standards of aesthetics.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 511, and the *Index*. This article is divided into the following sections:

NORTH AMERICAN PEOPLES AND CULTURES

The North American continent into which the Asian migrants descended is divided roughly into three major physiographic landforms: the high Cordilleras in the west, the relatively lower Appalachian Highlands and Piedmont in the east, and, between them, the Great Plains, which spearhead from the Arctic Ocean to the Gulf of Mexico in a great triangle. The Western Cordilleras are a series of parallel north-south ranges cutting from Alaska to Central America; in the area of Canada and the United States they enclose, from north to south, a large plateau of grasslands and forests, an even broader, arid plateau known as the Great Basin, and a desert plain and range area of Arizona and New Mexico (as well as northwestern Mexico). The Cordilleras along the Pacific Coast separate a plethora of basins and plateaus from the coastlands. The central Great Plains, in the extreme north, consists of subarctic land that is swampy and coniferous and similar to the taiga and tundra of Siberia; to the south, the great Mississippi drainage system divides the relatively drier high plains to the west from the low, well-watered prairies and rolling hills to the east. The Appalachian Highlands and Piedmont contain, to the north, the great eastern woodlands and, to the south, a series of highlands and foothills descending to lowlands on the coast of the Atlantic and the Gulf of Mexico.

At the time of European contact there were perhaps as many as 240 different tribal entities in North America. Groups of these tribes, however, have been classified by anthropologists into a more convenient limited number of culture areas, determined very much by physiographic or environmental differences: the subarctic, the Northwest Coast, California, the western Plateau, the western Great Basin, the Southwest, the Plains, the Eastern Woodlands, and the Southeast. This section, in dealing with the major culture areas of North America, excludes the Arctic Eskimo and Aleuts. The peoples of Mexico, other parts of Middle America, and the peoples of South America are treated in separate sections below.

THE PEOPLE

Physical types. Although American Indians are fundamentally Mongoloid, considerable variation is found. The generally uniform physical features are these: the hair is usually straight, coarse, and uniformly black; the skin is reddish brown, the eyes dark, and the body hair scant; the cheekbones are prominent; and the facial size is generally large. Such features as cephalic index, nasal form, and stature, however, are extremely variable.

The uniform features are definitely Mongoloid; the variable features are more difficult to assess. Some scholars believe that the early migrant populations were essentially Mongoloid and that the variations came about through adjustment to American environments. Other scholars argue that the New World was peopled by a variety of physical types, with later mixtures but some marginal survival in isolated regions.

Archaeologically, the earlier populations were generally long headed (dolichocephalic) and showed fewer Mongoloid characteristics. These early peoples were slight in build with well-developed brow ridges, and many represent either a proto-Mongoloid type or an unspecialized early Caucasoid form related to the Ainu of Japan.

Detailed study of the distribution of blood groups among the American Indians may eventually aid in solving the problem of their origins. Thus, for example, it has been found that blood type B is generally absent in the aboriginal population of the Americas (though its incidence is high among Asian Mongoloids), and type A is found mainly in North American Indians.

Modern genetic theory would explain much of the variation found in terms of such factors as mutation, selection, admixture, and random genetic drift. In the small-scale groups involved in the early peopling of the New World, relatively rapid changes were possible and could account for all of the variation found.

Population and languages. Estimates of the aboriginal population are based on information supplied by explorers, traders, missionaries, and other early reporters and are only as good as the reporters' observations were trustworthy. A more serious impediment to an accurate count is that some tribes, by the time they were visited, had already been depopulated by European diseases and weapons. The estimates in the Table, it should be noted, are given an approximate dating.

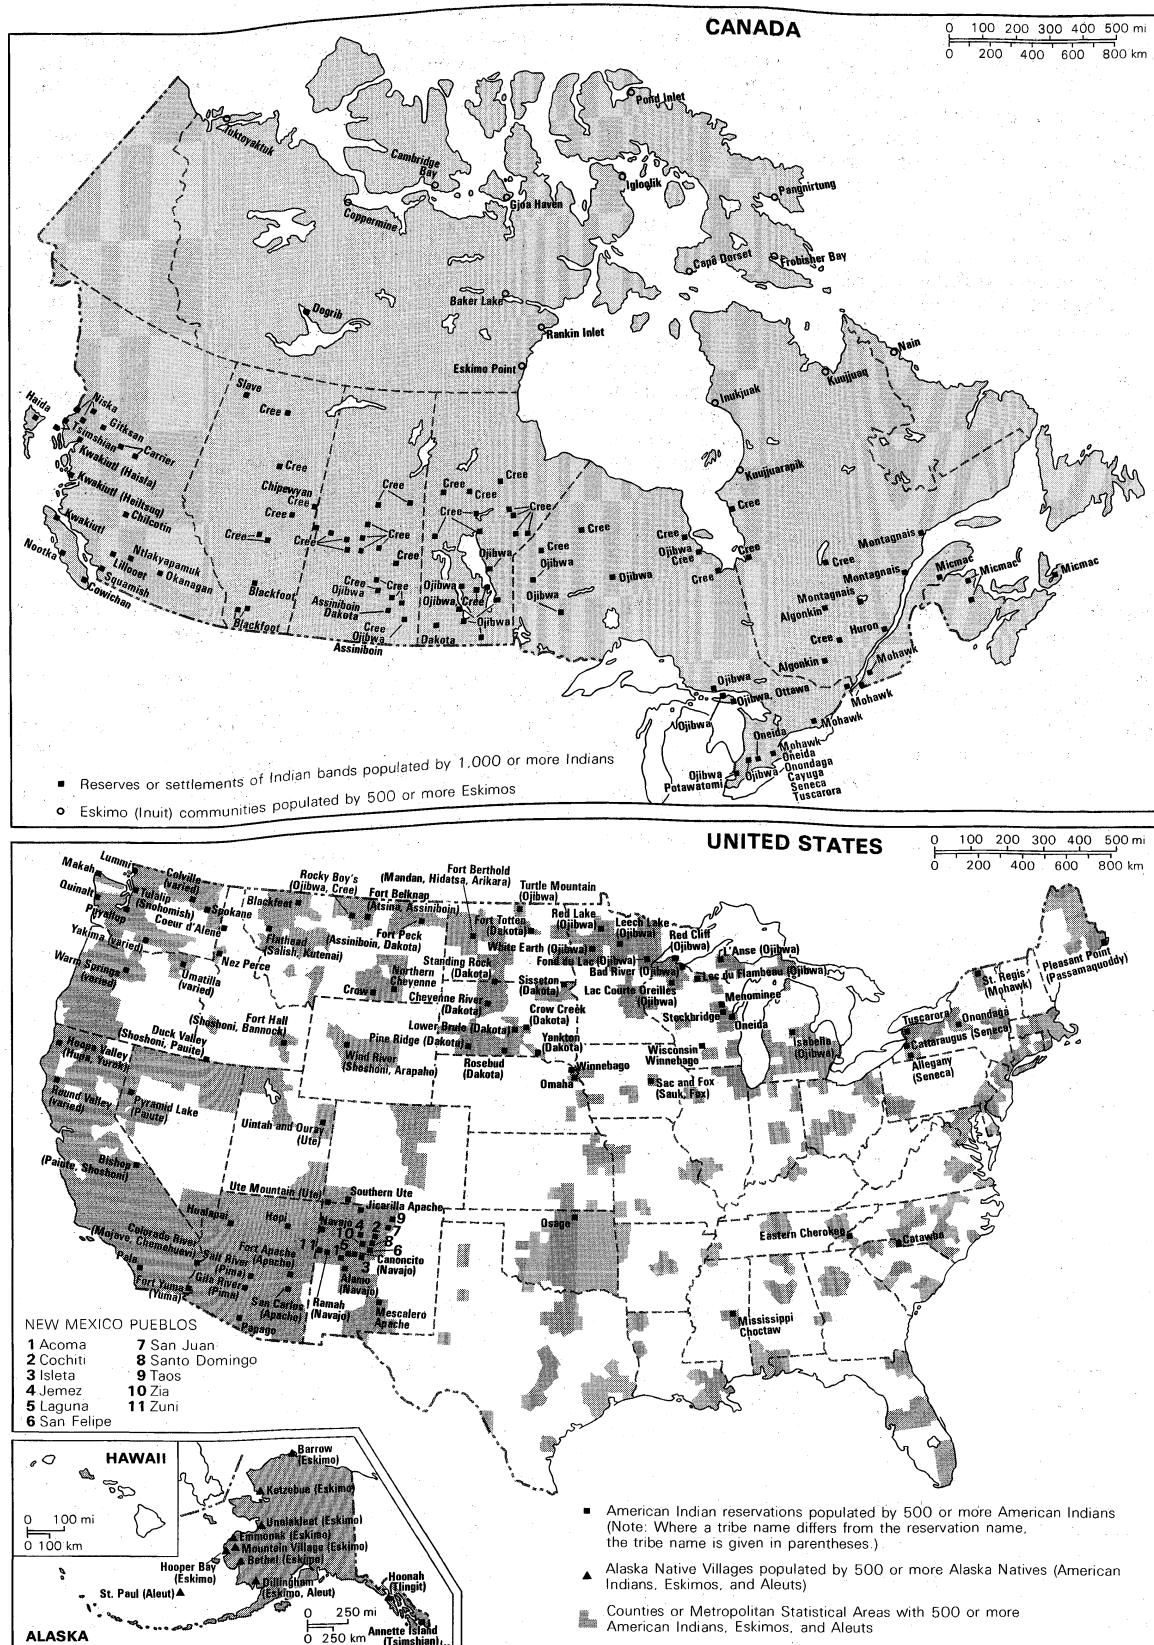

The American anthropologist Alfred Louis Kroeber submitted a population total for the area north of Mexico almost identical to that given in the Table, since he used the same figures except for California. He subgrouped the material, however, to accord with subsistence areas rather than geographical boundaries. In addition, he ranked the areas according to population densities, expressed in numbers of persons per square kilometre: California area, 43.40; northwest Pacific Coast, 28.30; southwestern United States, 10.70; Columbia-Fraser rivers area, 7.15; eastern area, 6.95; Arctic coast, 4.02; Great Basin, 2.47; and northern area, 1.35. Although agricultural areas of the east and southwest contained the greater population (about 405,000 in all), Kroeber believed that the predominantly fishing economy of the Pacific Coast (Bering Strait to southern California) had greater relative density of population. His estimates were Pacific Coast, 25.2 persons per square kilometre; agricultural areas, 10.1; remaining area north of Mexico, 2.2.

The population of a little over 1,000,000 for North America north of Mexico contrasts with the estimated 5,000,000 for Mexico and Central America and with the estimated 25,000,000 for the Western Hemisphere as a whole. (These uncertifiable estimates must, however, be approached with caution.)

The outstanding characteristic of American Indian languages is their diversity. There were more than 60 language families in North America, comprising over 500 languages, but these have been reduced to a smaller num-

Aboriginal Indian Population North of Mexico		
	date	estimated population
North Atlantic		
New England, New York, New Jersey, Pennsylvania	1600	55,600
South Atlantic

Mongoloid characteristics of American Indians

Distribution of North American peoples and cultures (top) in Canada and (bottom) in the United States.

Diversity of languages

ber of superstocks by modern linguists. The American linguist and anthropologist Edward Sapir, for instance, proposed six linguistic groups for North America (including the Arctic): Eskimo-Aleut, Algonkian-Wakashan, Na-Dené, Penutian, Hokan-Siouan, and Aztec-Tanoan (see LANGUAGES OF THE WORLD). No American language has

any genetic relationship to any language group in the Old World that has yet been fully demonstrated. It may be concluded from this that the ancestors of the Indians left the Old World so long ago that any relationship was lost through linguistic change.

Culture areas. *Subarctic.* The population of the Amer-

ican subarctic was always relatively small, given the vast area from Alaska to Labrador. The various tribes—Algonkian speakers in the east and Athabascan speakers in the west—were hunters, fishers, and gatherers of wild plant foods; and social organization tended to be simple and territorially very limited. The largest cohesive group tended to be a small kinship group or no more than a band or village of related families.

Northwest Coast. The peoples of the Northwest Pacific Coast depended for their livelihood almost entirely on salmon, which was, however, supplemented by other fish, sea mammals, shellfish, birds, and some food plants; they also took advantage of the woods of the forests for constructing homes and canoes and developed the use of bark fibres and mountain-goat wool to make clothing and blankets. So rich were their available resources and so intensively were the resources exploited that the density of population, as calculated by Kroeber, was greater on the Northwest Coast than in most places in North America north of Mexico. Although social organization centred on the village rather than a larger tribe, it tended to be fairly sophisticated and highly stratified.

California. From very early times until European contact, California was marked by a great complexity of tribal groups and languages. In some instances a group of not more than 500 individuals, speaking a distinct language, would live near another group of similar size that spoke a different language, and neither seemed to impinge on the other. The diversity is partly attributable to the complex of mountains and valleys and coastlands. In spite of the great complexity of linguistic and demographic factors, however, the California culture area presented no striking deviations. Agriculture was not practiced except along the Colorado River, since throughout the vast central portion and southward along the coast a method of leaching acorn pulp and converting it into flour supplied abundant and constant food. Elsewhere, fishing and hunting were equally productive.

Plateau. The northern plateau area, bounded by the Rocky Mountains and the Coast and Cascade ranges, was a land of vast rolling treeless areas, dense forests, and snow-covered mountains. Because the area is drained largely by two great river systems, the Fraser and the Columbia, most of the peoples of the area depended primarily on fishing for salmon, though other fish, game, and wild plants were also taken. Although the material accomplishments of the Plateau Indians were modest, their political achievements were sometimes impressive. The primary political unit was the village, but a sense of larger tribal and cultural unities led sometimes to the creation of forms of representative government, with village hierarchies, tribal chieftainships, and even confederations.

Great Basin. The Great Basin, a large area centring on the modern states of Nevada and Utah, was perhaps fertile during and just after the great Ice Age, but it has become arid and impoverished in modern times. Before the beginning of European contact, the Shoshonean-speaking inhabitants were divided into loosely affiliated family units that subsisted on wild seeds, small mammals, and insects. Each family was independently nomadic during most of the year and joined other families only briefly for certain hunts or dancing. Some groups acquired horses in the 18th and early 19th centuries, however, and formed bands of mounted hunters and warriors and adopted many cultural characteristics of the Plains Indians.

Southwest. The Southwest, centring on Arizona and New Mexico, but including parts of Utah, Colorado, Texas, and Mexico, has at various periods been the territory of a number of agricultural and hunting and gathering peoples. Best known among the former are the Pueblo Indians, from the Zuni and Hopi on the west to the Rio Grande groups on the east, who built architecturally remarkable multiple apartment houses of adobe and stone masonry and developed to a high state agriculture, arts, and crafts. Their ancestors occupied the Southwest thousands of years ago, and their high cultural development began during the 1st millennium AD with the arrival of influences from Mexico. Two other major groups, the Athabascan-speaking Navajo and the Apache, undoubtedly

came from the far Canadian north and probably did not initially reach the Southwest until AD 1000 or later. The Navajo borrowed extensively from the Pueblo Indians—notably in agriculture, weaving, and arts—but the Apache remained basically hunters and gatherers; only a few Apache groups engaged in supplementary cultivation of maize (corn) and other vegetables.

Plains. Until the late 16th century the Great Plains were occupied only sparsely or intermittently. Toward the year 1600, however, Spanish horses were introduced and spread northward from the region of New Mexico, reaching almost the entire Plains area by 1750. Horses revolutionized the hunting of bison, making it much more profitable, and not only improved the conditions of resident peoples but also seem to have drawn peoples from surrounding areas into the plains to develop a new way of life. Thus, most tribes thought by Europeans to be typical nomadic horse Indians—such as the Cheyenne, Arapaho, and Dakota (Sioux)—were actually newcomers to the area and had been farmers and village dwellers not many generations before their first European contacts. In any event, the Plains Indians, with their bands organized into assemblages of tribes, their buffalo hunts and tepee villages, and their elaboration of warfare and raiding (much facilitated by the horse), became, through various media of popular culture, the tribes of North America often regarded now as “typical” American Indians.

Eastern Woodlands. The peoples of the eastern woodlands, largely Iroquoian and Algonkian speakers, were semi-sedentary, living in villages and cultivating maize, beans, and squash. The forests provided much of their material cultures—their wigwams and longhouses made of coverings of bark sheets, their dugout and bark canoes, and their clothing made of wild animal skins—and added game and fish to their diet. A village band of a few hundred persons was the social and economic unit, though several bands might be loosely organized into tribes. The honour of warfare was engrained in most of the Eastern Woodlands Indians.

Southeast. The southeastern Indians, most of them Muskogean speakers, were primarily agricultural, planting maize, pumpkins, beans, cane millet, tobacco, and other crops; they also gathered wild nuts and fruits and hunted deer or, in the west, bison. Their settlements were straggling; the “town” contained a square, on which were public and religious buildings; “villages” were often outlying. The towns were autonomous and essentially constituted tribes. They might unite into confederacies, such as those of the Creek and Choctaw, directed by councils; such confederacies might break up and recombine. In contrast to the fairly well organized political institutions, economic life was rather unsophisticated; there was little property, almost no stored wealth, and limited trade before the coming of Europeans.

THE PREHISTORIC PERIOD

The earliest records of the peopling of North America are scanty, and it is difficult to characterize their culture beyond calling it a hunting and gathering economy. The first settlers seem to have crossed the Bering Strait region from Asia during the expansion of the glacial sheets of the Ice Age (or Pleistocene Epoch). As the great ice sheets developed and expanded, they not only covered major land areas in the Northern Hemisphere but also brought considerable areas of the continental shelves above sea level. In the Arctic this provided a tundra coastal plain across which man could move from Asia to North America. The amount of the Earth's moisture incorporated into the ice probably lowered the sea level hundreds of feet. Asia and America were thus not separated again by the melting of the glaciers and the consequent gradual rise of the sea until about 9,000 or 10,000 years ago; likely sites of the earliest migrants are now below sea level.

The Americas were the last major land mass, with the possible exception of Australia, to be occupied by prehistoric man, who, in order to spread over the vast area of the two continents, first had to develop the cultural equipment to exist in the Arctic area. Once this adjustment was made, he was able to move by way of ice-free,

from Asia

open-land routes into the Mackenzie Basin and down into climatically less rigorous and ecologically richer and more accommodating central North America. In addition to the Mackenzie route southward, at a later time the Yukon River valley also offered an ice-free route, and still later (8,000–10,000 years ago) the Liard and Peace river systems were available for intramontane travel. The Pacific Coast slope was probably available for travel at about the same time. Some migrations may also have occurred by way of the Aleutian Islands, but this would have taken place at a considerably later date.

Early cultures. The earliest well-defined cultures in the New World have been placed by radiocarbon dating at about 10,000 to 8000 bc. At this period, two distinct traditions in North America are known: the Paleo-Indian big-game hunters of the West, the Great Plains, and eastern North America; and the Desert culture peoples of the western Basin-Range region.

Paleo-Indian hunting cultures. In spite of regional differences in detail, there was a remarkable similarity in the economic complex of the hunters. They lived in a variety of environments, from mountain passes and valleys in the west to the then better watered grasslands of the Plains and the varied forest and parkland environment of the eastern woodlands. The variety of their bone tools indicates that one of their major food supplies came from animals, the hides of which provided clothing. In the western Plains and the Southwest they hunted such extinct North American animals as the camel, ground sloth, tapir, mammoth, and horse.

In the Great Lakes area of the eastern woodlands they may have hunted mastodon, but other commoner animals, such as the elk and deer, presumably formed the bulk of their meat diet. Some of their bone and wooden tools were probably used for working and ornamentation. These early hunters had temporary shelters and moved about as small bands in search of game. Their physical type is not clearly known, but it was related to that of an eastern Asian Early Stone Age population and is less Mongoloid than many groups of American Indians of the historic period.

Archaeologically, the oldest remains of the Paleo-Indian tradition are found on kill sites, where large Pleistocene mammals were killed and butchered. The most distinctive artifact type of this horizon is the Clovis Fluted projectile point (named after the site of first discovery, near Clovis, New Mexico); this was a lance-shaped point of chipped stone that had had one or more longitudinal flakes struck from the base of each flat face. These points are accompanied by side scrapers and, in one instance, by long cylindrical shafts of ivory. They are most frequently associated with mammoth. A second Paleo-Indian horizon, which seems in part to be contemporary with the Clovis material and partially to postdate it, is the Folsom phase of the central High Plains (Folsom, New Mexico, being the site of initial discovery). It is characterized by lance-shaped points of more careful manufacture (including broader fluted surfaces) than Clovis, associated with the remains of extinct *Bison antiquus*. The Lindenmeier site, a Folsom campsite in northeastern Colorado, has yielded a wide variety of end and side scrapers, graters, and miscellaneous bone artifacts. Clovis sites have been dated at about 9000 bc and Folsom sites at about 500 to 1,000 years later.

The Desert culture. In the western United States, over a region extending from Oregon to northern Mexico and from the Pacific coast to the eastern foothills of the Rocky Mountains, there was a distinctive cultural adaptation to the dry, relatively impoverished upland environment. There, in the relative absence of large game resources, vegetation was exploited to a great extent, with the development of grinding tools and related equipment. The Cochise Desert culture (named from Cochise County in southern Arizona, where it was discovered) ran from about 8000 bc through several stages, persisting down to the historic period in some areas.

The Desert culture people lived as small bands of wandering seasonal food gatherers, collectors, and hunters. They ate a wide variety of animal and plant foods and

developed techniques for small-seed harvesting and processing; an essential feature of Desert assemblages was the milling stone, for use in grinding wild seeds. Their best known habitations were caves and rock shelters, and they had twined basketry, nets, mats, cordage, fur cloaks, sandals, wooden clubs, and digging sticks. They also had the spear thrower, with darts of pointed hardwood or with points of flint and later of obsidian. Their rough stone implements were shaped by percussion, and consequently many of their choppers and scrapers had an Earlier Stone Age appearance. Their projectile points, however, showed excellent craftsmanship and followed continent-wide styles. The domesticated dog, another migrant from Asia, was known by about 4000 bc in the Desert culture (though by this time the dog was also known elsewhere in North America).

The far west. On the far west coast in California, the marked variety of geographical situations encouraged the development of a number of diverse regional complexes dependent upon intensive exploitation of the local resources. None of these cultures was agricultural. In the southern desert area the people subsisted upon plant seeds and small game and used crude flint tools, grinding stones, and (later) arrowheads. In the mountainous areas and in the better watered central areas, larger game animals such as the elk and deer, supplemented by acorns, fish, and birds, constituted the major items in the food supply. By at least 2000 bc, in this central area, the utilization of the local resources plus cultural intrusions from the north resulted in full adaptation to the area. The coastal groups from north to south depended upon the sea for their food supply, some subsisting mainly on shellfish, some on sea mammals, others on fish, and still others on a mixture of all three.

In the north Pacific part of the United States and in western British Columbia, some of the early sites of the hunters have yielded fluted blades, crude choppers, and cutting tools. Between 9000 and 7000 bc there were varied economic activities but with an emphasis on hunting. By about 8000 bc there was a strong orientation toward salmon fishing, particularly during the salmon runs, and the peoples tended to emphasize the use of bone and antler tools. The burin, a chisel-like bone working tool, has been found in such sites, along with prepared cores and blades. During the postglacial warming period that culminated between 3000 and 2000 bc, the inhabitants of the drier areas without permanent streams took on more of the traits of the Desert culture to the south, while others turned toward riverine fishing and marsh resources or to food from the sea. In the 1st millennium bc, the so-called Marpole complex, a distinctive ground slate complex, was known in the Fraser River area, with basic resemblances to the northwest coast historic culture in maritime emphasis, woodworking, large houses, and substantial villages. The emphasis on ground slate and woodworking tools is like that in the Eastern Woodlands Archaic (see below) and recalls similar emphasis in certain northwestern Siberian cultures. In most of the areas of the Northwest Coast, clear indications of the beginnings of the historic cultures were not known until about ad 1300.

The Archaic cultures. *The Eastern Archaic.* With the retreat of the ice sheets in the north, beginning about 10,000 years ago, the cool, moist climate gradually became hot and dry in the Great Plains and Great Basin regions, with consequent extinction or migration of Pleistocene animal life. The High Plains were largely deserted by man for a considerable period. In the eastern woodlands area, partly as a result of the variety of forest environments, climatic differences, and physiographic features, there developed a series of regional readaptations to changed local food supplies. The change from the primarily hunting economy of the early American hunters was gradual and is clearly seen in the slowly evolving form of the projectile point and other implement changes. The pattern of life became one of mixed hunting and collecting, with some groups developing by 6000 bc a taste for riverine and coastal living in order to exploit abundant fish and mollusk resources to supplement such vegetational products as acorns, seeds, berries, and tubers.

During the long Eastern Archaic, from 8000 to 1500 BC, regional social and economic diversification was developed, and it was during the Archaic that significant early linguistic differentiation also probably occurred and during which varieties of physical types developed.

The typical Archaic house was a small circular structure with wooden posts for the wall and roof supports; the covering was probably bark. Cooking was done in the open by boiling in containers of wood, bark, or hides or by baking in pits or by roasting and grilling. Lists of mammal, fish, and bird bones from Archaic sites read like a listing of the early historic fauna. Game-gathering devices, including nets, traps, and pitfalls, were used along with the spear and dart thrower. Fishhooks, gorges, and net sinkers were known, and in some areas fish weirs were built. River, lake, and ocean mollusks were consumed, and probably a great many native roots, berries, fruits, and tubers known in the early historic period were incorporated into the diet during the Archaic. The extensive lists of plant medicines recorded by the early colonists were probably a part of the primitive Archaic pharmacopoeia.

developing
ade and
chnology

The large variety of chipped-flint projectiles, knives, scrapers, perforators, drills, and adzes reflect regional styles and changes during the long Archaic period. The late Archaic was distinguished by the gradual development of ground and polished, grooved stone axes, pestles, gouges, adzes, plummets, and forms attached to the spear thrower. This was a reflection of a growing versatility in the technology and economy. Trade and exchange are also known from the distribution of native copper implements from the Michigan-Wisconsin area to as far south as Louisiana and Florida and the finds of southeastern marine shells as far north as the upper Mississippi-Great Lakes area. An extensive system of trails and water routes was probably in existence during the Late Archaic.

The great boreal forest zone of spruce, fir, and pine that now runs from New England and the maritime provinces of Canada westward to the Canadian plains and the Mackenzie Valley gradually acquired its present distribution following the retreat and melting of the Arctic ice cap. Its present distribution was reached by about 2500 BC. The forest cover and climate had a limiting effect on the cultural development and on the general pattern of hunting and fishing. These efforts were supplemented by some use of plant material.

In the upper Great Lakes area there was an Old Copper culture, which has special interest because copper implements and weapons were made from the native copper of the Lake Superior basin. This culture appeared about 3000 BC and lasted about 2,000 years. It was a northern expression of the Late Archaic. Its tools and weapons, particularly in the adzes, gouges, and axes, clearly indicate an adaptation to the forest environment. In the area south of James Bay to the upper St. Lawrence about 2000 BC, there was a regional variant called the Laurentian Boreal Archaic and, in the extreme east, the Maritime Boreal Archaic. In this eastern area, slate was shaped into points and knives of forms similar to those of the copper implements to the west. Trade between the eastern and western areas has been recognized, and this evidence, along with general similarities of the culture, suggests that water transportation by canoe was known at this time.

Along the southern border of the central and eastern boreal forest zone between 1500 and 500 BC, there developed a distinctive burial complex, reflecting an increased attention to burial ceremonialism. These burials, many including cremations, were often accompanied by red ochre, caches of triangular blanks, fire-making kits of iron pyrites and flint strikers, copper needles and awls, and polished stone forms. The triangular points of this complex may have represented the introduction of the bow and arrow from the pre-Eskimo cultures east of Hudson Bay. The earliest Woodland pottery appeared in the Great Lakes area about 1000 BC. It is another of the culture traits derived from northeastern Asia and across northern Alaska to northwestern Canada. The route by which it reached the Great Lakes is not known.

The Plains Archaic. In the western Plains from about 8000 to 3000 BC the fluted blade points were no longer

made, and many styles or types were produced that have been identified by such local names as Plainview, Angostura, Milnesand, Agate Basin, and Scottsbluff. These minor varieties of dart and spear point and their primarily hunting culture may be included in the term Plano. The Plano complex or culture type was a direct descendant from the fluted-blade early American hunters. Their primary game animal was the bison, for the larger animals of the preceding period had died out or were exterminated.

Plano
culture

The stone complex associated with the Plano hunters was markedly similar from site to site over a considerable period of time during which the climate became increasingly warmer and until the major warm period was reached, about 3000 to 2000 BC. As the climate moderated, peoples of the Late Plano complex moved north into Saskatchewan and Alberta with the grazing game animals and, by 3000 BC, had reached the Arctic tundra zone in the Northwest Territories of Canada at Grant and Dismal lakes and Great Bear River. Important elements of this culture also moved east in the Mississippi valley and western Great Lakes area. Many of the sites of this culture type were kill sites with abundant bison bones that accounted for the number of implements and tools associated with hunting and leatherworking. In the tundra zone the major game animal was the caribou. Choppers, pounders, and milling stones have been found there.

Early agriculturalists. Early southwestern planters. Primitive agricultural practices began in Mexico by 6000 to 4000 BC and by approximately 2000 BC were known on the northern fringe of the Middle American culture area. Maize was not the only crop plant, for gourds, squash, peppers, cotton, and varieties of beans were also domesticated. Maize was grown in the southwestern United States by 2000 to 1000 BC, but most of the other domesticates did not arrive until just before and after AD 1. The early introduction of maize in the Southwest had no marked effect on cultural development, and the existence of pottery, storage pits, and domestic houses with semi-subterranean floors and lateral entryways was not known until about AD 1. These houses had wood uprights for walls, central roof supports, radiating beams, and wattle-and-daub plastered walls. The small settlements of the early Puebloan, or Basket Maker, people of the Four Corners area (namely northwestern New Mexico, southwestern Colorado, southeastern Utah, and northeastern Arizona) were among the first village agricultural societies in the Southwest.

Ohio Valley cultures. In eastern North America one of the Early Woodland phases preceding the introduction of maize agriculture is the Adena culture, which occupied the middle Ohio River Valley by about 500 BC (Adena takes its name from an estate near Chillicothe, Ohio, the site of a large burial mound). The Adena were hunters and gatherers but apparently provided the stimulus that brought about the spectacular Hopewell culture in the Illinois and Ohio valleys. (Hopewell is similarly named after a farmsite in Ohio). The success of the Hopewell peoples, particularly from 100 BC to AD 200, seems to have been due largely to their combining elements of the preceding Archaic cultures with elements of Adena and other Early Woodland cultures, and perhaps with some features of a local cultivating tradition, since some corn and squash has been found. It is evident that the Hopewell culture included a well-organized village-based society in which surplus resources were used in the construction of elaborate earthworks and were concentrated as wealth by a restricted group of individuals. The most outstanding feature of Hopewell culture is a burial complex that called for the deposition of concentrations of wealth in tombs of one or several deceased individuals. The interment procedure was elaborate and involved the construction of a large log tomb, later burned and covered by an earth mound. Artifacts found within these burial mounds indicate that the Hopewell were able to obtain goods from widespread localities in North America. Obsidian and grizzly bear teeth were apparently derived from the Rocky Mountain region; copper from the northern Great Lakes; and conch shells and other exotic objects from the southeast and along the coast of the Gulf of Mexico. Ohio, particularly, served as a distributing centre for

Adena and
Hopewell
cultures

ceremonial goods and special products over a wide area in the eastern United States. The ceramics of the Hopewell appear to be based in two major traditions: one derived from an Ohio Valley development which began about 1000 BC, stimulated by the early fibre-tempered pottery of the Southeast, and the other from a pottery with complex decorations, which probably developed in the Illinois area around AD 1. In less favourable areas of eastern North America, a "generalized Woodland" culture paralleled the Hopewell in time, probably based more on collecting than on cultivation for subsistence.

There is a clear evidence of cultural regression between AD 200 and 700 in the north central United States following the Hopewell expansion and florescence. This is attributed to a number of changes in their activities which are not well understood as yet. Although there was concurrent change in the south, this did not take the form of a lowering of the cultural level.

The
Mississippian
culture
complex

Mississippi Valley and peripheral woodlands. The last major cultural development in the eastern United States is called Mississippian because its primary centre was in the valleys of the Mississippi River and its major tributaries and in the southeast. This predominantly agricultural complex was a marked cultural advance over earlier stages in the east. Its initial growth and expansion was at approximately the same period (AD 700–1200) as that of the southwestern Puebloan complex. The initial growth was along the Mississippi between modern St. Louis and Vicksburg. It was stimulated by the introduction of concepts, religious practices, and improved agricultural procedures from northern Mexico, plus local developments, which resulted in a sedentary societal organization. By AD 1000, large villages were in existence with subsidiary villages and farming communities nearby. Regional specialized production in pottery, projectile points, house types, and other utilitarian products reflected the tribal groupings of the period. An outstanding feature of this culture type was the earthen temple mound, which served as a raised platform on which the major community buildings were placed. These council houses and temples served as the political and ceremonial centres. The platform mounds were placed on the sides of a central plaza that served as a ceremonial centre for the tribal community during important recurrent functions or during times of crisis. The more permanent buildings, both family and community, were of wattle-and-daub construction, usually rectangular in floor plan. In some areas large, circular charnel houses received the remains of the dead, but burial was normally made in large cemeteries or in the floors of dwellings. The size of the ceremonial tribal centres varied from 10 to 100 acres (four to 40 hectares). Important household industries involved the production of mats, baskets, clothing, and a variety of vessel forms for specialized uses. Food surplus was kept in ground storage pits and in storage cribs above the ground.

One of the more striking developments was the production of ceremonial costumes and ornaments, for use in the religious ceremonies that were conducted by an organized priesthood with a well-established ritual. The religious symbolism spread throughout the Mississippian complex, and a number of centres of production of specialized ceremonial items are known. Other innovations were walled fortifications with timber palisades and bastions surrounding the village, which reflected an increase in intergroup aggression and a tendency, continuing into the historic period, toward the development of confederacies. The intergroup conflicts apparently were primarily quests for prestige and revenge instead of a means of territorial expansion or economic control.

Spread of
Woodland
culture

Along the eastern and northern periphery, some tribes, while retaining the older Woodland complex, were somewhat influenced by the Mississippian culture. The extent of this influence seems to have depended on their nearness to the more advanced cultural complex and on their ability to maintain an agricultural economy along with hunting and gathering. There was a spread of Woodland culture from about 200 BC to AD 200 into the eastern part of the Plains from Oklahoma to North Dakota, with some sites, particularly in eastern Kansas, clearly forming

a part of the Hopewellian complex. In the Plains there was evidence of corn and bean cultivation during this period, and later there was cultivation of gourds and squash, but between about AD 300–400 and 800 there was little occupation of the western part of the Plains by agricultural people because of the relative aridity.

After 800, however, Late Woodland populations had spread west to the eastern slopes of the Rockies and were in contact with eastward-moving Puebloan people. A favourable agricultural period was indicated by the marked increase in village size and in population density for the next 400 years, during which hospitable areas along major streams were occupied by various interrelated cultural groups collectively known as the Plains Mississippian cultures. Part of this complex was connected to the developing Mississippi complexes to the east by diffusion and, to some degree, by a migration of such groups as the Omaha and Ponca from the St. Louis area by about AD 1000.

Between AD 1500 and 1700 the High Plains from New Mexico to Wyoming and in eastern Oklahoma, Kansas, and Nebraska were pre-empted by horse-using, semi-agricultural peoples of the plains—the Apache and Comanche. Prehistoric village agriculturalists of a plains Mississippian tradition came into the historic period as the Pawnee, Arikara, Mandan, Hidatsa, Crow, and Wichita.

Southwestern village farmers. *Anasazi, Mogollon, and Hohokam cultures.* The southwestern village farmers were distributed from eastern Utah and southern Colorado through most of New Mexico and Arizona. The effective agricultural area varied with fluctuations in climate that profoundly affected the ability of the Indians to occupy marginal regions. Although corn and some other agricultural plants were introduced from Mexico between 2000 BC and AD 1, the first village complexes, with five to 15 pit or surface houses, ceremonial buildings, refuse pits, and pottery, did not appear until shortly before AD 1 in southern Arizona and New Mexico. Two of the major farming complexes began at this time: Mogollon was located in the mountainous belt of west central New Mexico and east central Arizona, while Hohokam was located in the desert area of the Gila basin of southern Arizona. The latter group depended upon irrigation for its crops, whereas Mogollon depended upon rainfall and stream diversion over floodplains. Mogollon became the pattern of agriculture that later was developed in the Anasazi or Puebloan culture, the third major farming complex of the Southwest.

Pre-Pueblo
cultures

The geographical expansion, population growth, and striking development of permanent villages with multi-room and multilevel buildings came during the period from AD 700 to 1200, which coincided with a minor climatic period of favourable distribution of rainfall for plant growth over the entire Southwest. For the same climatic reasons, there was an expansion of population and cultural movement from central and western Mexico into northwestern Mexico. Trade and cultural stimuli then moved from northwestern Mexico into the American Southwest at a time when the climate in both areas was most favourable for population and cultural growth. Indicating such cultural movement, cast copper bells, parrots, ball courts, shell trumpets, and pottery vessel shapes and designs have been found; they clearly reflect the transmission of religious beliefs and ceremonies. These southern influences were blended into local and regional complexes.

The Anasazi village agricultural complex had expanded by AD 900 to occupy northeastern Arizona, southwestern Colorado, and northwestern New Mexico. By AD 1100, expansion had taken place into the Virgin River valley of southeastern Nevada, north as far as the Great Salt Lake and northwestern Colorado, to the east into southeastern Colorado and to the Pecos and upper Canadian river valleys of New Mexico. During this period there was probably a development of priestly offices and of rituals and ceremonialism. The increasing population concentration in large pueblos was apparently organized into households according to lineage. Control of the agricultural activities was presumably in the hands of clan leaders, who were also the priests who officiated in the rain-producing ceremonies. During this period some of the larger village populations ranged from 300 to more than 1,000 people.

Primarily because of increasing aridity there was a marked retraction of Anasazi culture between 1100 and 1300. As a result, a concentration of the pueblos took place in northeastern Arizona, along the Rio Grande and its immediate tributaries, and in the present Zuni area of western New Mexico. The Anasazi groups maintained their societies by sand-dune farming with floodwater and some canal irrigation. The increased importance and elaboration of religious rain-producing ceremonies between 1300 and 1540 is deduced from paintings on walls and from symbolic pottery decoration.

Mogollon
and
Hohokam
cultures

The Mogollon complex in its early phases, from 200 BC to AD 700, consisted of relatively small villages of pit houses grouped near a large ceremonial structure. No organization of the village structures into a pattern is apparent, however, and trash disposal was random. Although the initial impetus for sedentary village life appeared early in the Mogollon area, there was a period of apparent cultural quiescence about AD 400 to 600. With the growth and spread of the Anasazi complex in the period after 700, the main flow of culture was from that area, and Mogollon villages from AD 900 to 1100 were a blend of local development strongly influenced from Anasazi. During the climatic deterioration after AD 1200, much of the Mogollon territory in southwestern New Mexico was abandoned.

The Hohokam culture of southeastern Arizona was primarily limited to main river valleys. Agriculture was made possible by extensive irrigation canals that required cooperation between villages. The people lived in villages of scattered pit houses made of brush and mud that were dispersed along the streams and canals. Their main settlements and major culture growth took place also during the period AD 700–1200. Following this for 200 years, there was a blend with Anasazi and Mexican elements and a tendency toward the construction of more compact settlements surrounded by compound walls with a few massive multiroom and two-story buildings. There is relatively little evidence of trade and influences from northwestern Mexico. Such historic groups as the Pima and Papago are descended from the Hohokam people.

Pueblo culture. Best known of the prehistoric and historic southwestern peoples are the Pueblo Indians proper, whose ancestors built great cliff villages now seen in ruins and equally remarkable multiple apartment houses of adobe and stone masonry. Some of the latter are still occupied, and the Pueblo Indian inhabitants speak languages and observe ceremonies that are at least pre-Spanish in origin.

Pueblo
culture
periods

The beginnings of Pueblo culture, in the 1st millennium AD, are obscure. The traditional type of aboveground, straight-line, or crescent-shaped multiple house continued to be built, two rooms wide; stone masonry, however, began to replace the earlier pole-and-mud and adobe construction. Agriculture, including several varieties of corn, may have been augmented at that time by the cultivation of a native long-staple cotton. Pottery was not much changed, but it included a greater variety of shapes and decoration. Basketry was much less common. These early phases of Pueblo culture are termed Developmental Pueblo.

The great Classic Pueblo period followed in about AD 1050–1300, a period most popularly associated with the term Pueblo. It was the time of the great cliff houses, such as Mesa Verde, and the large apartment-like structures in Chaco Canyon (Pueblo Bonito) and elsewhere. An actual shrinking in area took place as inhabitants of the outer fringes moved in to build the large dwelling units. Also, because a number of outstanding structures were built in quite inaccessible canyons and mesa walls, there is the possibility that hostile strangers had reached the outlying districts. The most notable advance over previous periods was in architecture and pottery. Masonry walls were greatly thickened, dressed stones being used in many localities to bear the greater weight of massive structures. These community structures had from 20 to as many as 1,000 rooms and from one to four stories. Each of the larger houses was in effect a single village. Windows and doors were quite small, and usually no openings were made in the lowest rooms, which were entered by ladder through

the roof. Floors were terraced or set back, and the terraces were much used as outdoor living space. Roofs were constructed to carry great weights by laying heavy beams covered with a mat of smaller poles and brush, then laying on a coat of adobe six to eight inches thick. Some semi-subterranean ceremonial chambers, known as kivas, were enlarged to as much as 80 feet (25 metres) in diameter. Craftsmanship in pottery reached a high level, and specialization became so pronounced in the different centres, as in Chaco canyon, Mesa Verde, Kayenta, and a number of others, that the style of each can be recognized easily. To the earlier black-on-white and red-on-white designs were added polychromes of three or more colours applied more lavishly. Cotton cloth, blankets, and bags were woven, and yucca fibre also entered into various articles of clothing and such utility objects as mats. Feather-cloth robes were worn in cold weather.

Abandonment of the cliff houses and large community buildings marked the close of the great Pueblo period. In part this may have resulted from incursion into the northern part of the territory by nomadic Athabascans (Navajo and Apache) and a prolonged drought that occurred in the late 13th century. It is also possible that lack of central leadership led to internal dissensions.

The next period (AD 1300–1700), called Regressive Pueblo, was characterized by a general movement southward and eastward, and new villages, some larger than those of Classic Pueblo, were built on the Little Colorado, Puerco, Verde, San Francisco, Rio Grande, Pecos, upper Gila, and Salt rivers. Pottery showed new developments; geometric patterns were largely replaced by naturalistic representations of birds, animals, insects, and the human figure; glazing was frequently used. The modern Pueblo period is usually dated from the beginning of permanent Spanish settlement at the close of the 17th century. From 1540 on, when the Spaniards first entered the Pueblo country, the number of Pueblo settlements declined considerably, though much of the culture and many of the skills in agriculture and crafts continued down to present times.

EVOLUTION OF CONTEMPORARY CULTURES

The great diversity that marked Indian cultures also persisted into modern times. After the arrival of the Europeans, some tribes disappeared by amalgamation with others or by wars and epidemics, and some languages perished. The process of adaptation to white encroachments and of acculturation to European ways worked at varying rates within the various Indian societies, transforming and devaluing segments of custom and practice. Nevertheless, many Indian populations north of Mexico continued to manifest an unexpected viability, and Indian attitudes, customs, and values persisted.

Colonial policies. The formulation of public policy toward the Indians was of concern to the major European colonizing powers. The Spanish tried assiduously to Christianize the natives and to remake their living patterns. Orders were issued to congregate scattered Indian villages in orderly, well-placed centres, assuring the Indians at the same time that by moving to such centres they would not lose their outlying lands. This was the first attempt to create Indian reservations. The promise failed to protect Indian land, according to the Franciscan monk and historian of Mexico, Juan Torquemada, who reported about 1599 that there was hardly “a palm of land” that the Spaniards had not taken. Many Indians who did not join the congregations for fear of losing what they owned fled to mountain places and lost their lands anyway.

The Russians never seriously undertook colonization in the New World. When Peter I the Great sent Vitus Jonassen Bering into the northern sea that bears his name, interest was in scientific discovery, not overseas territory. Later, when the problem of protecting and perhaps expanding Russian occupation was placed before Catherine II the Great, she declared (1769):

It is for traders to traffic where they please. I will furnish neither men, nor ships, nor money, and I renounce forever all lands and possessions in the East Indies and in America.

The Swedish and Dutch attempts at colonization were so brief that neither left a strong imprint on New World

Early
Spanish
policies

practices. The Dutch government, however, was probably the first (1645) of the European powers to enter into a formal treaty with an Indian tribe, the Mohawk. Thus began a relationship, inherited by the British, that contributed to the ascendancy of the English over the French in North America.

France handicapped its colonial venture by transporting to the New World a modified feudal system of land tenure that discouraged permanent settlement. Throughout the period of French occupation, emphasis was on trade rather than on land acquisition and development, and thus French administrators, in dealing with the various tribes, tried primarily only to establish trade relations with them. The French instituted the custom of inviting the headmen of all tribes with which they carried on trade to come once a year to Montreal, where the governor of Canada gave out presents and talked of friendship. The governor of Louisiana met southern Indians at Mobile. The English, reluctantly, found themselves competing on the same basis with annual gifts. Still later, United States peace commissioners were to offer permanent annuities in exchange for tribal concessions of land or other interests.

Early
English
policies

In contrast to the French, the English were primarily interested in land and permanent settlements; beginning quite early in their occupation, they felt an obligation to bargain with the Indians and to conclude formal agreements with compensation to presumed Indian landowners. The Plymouth settlers, coming without royal sanction, thought it incumbent upon them to make terms with the Massachusetts Indians. Cecilus Calvert (the 2nd Baron Baltimore) and William Penn, while possessing royal grants in Maryland and Pennsylvania respectively, nevertheless took pains to purchase occupancy rights from the Indians. It became the practice of most of the colonies to prohibit indiscriminate and unauthorized appropriation of Indian land. The usual requirement was that purchases could be consummated only by agreement with the tribal headman, followed by approval of the governor or other official of the colony. At an early date also, specific areas were set aside for exclusive Indian use. Virginia in 1656 and commissioners for the United Colonies of New England in 1658 agreed to the creation of such reserved areas. Plymouth Colony in 1685 designated for individual Indians separate tracts that could not be alienated without their consent.

In spite of these official efforts to protect Indian lands, unauthorized entry and use caused constant friction through the colonial period. Rivalry with the French, who lost no opportunity to point out to the Indians how their lands were being encroached upon by the English; the activity of land speculators, who succeeded in obtaining large grants beyond the settled frontiers; and, finally, the startling success of the Ottawa chief Pontiac in capturing English strongholds in the old Northwest (the Great Lakes region) as a protest against this westward movement, together prompted King George III's ministers to issue a proclamation (1763) that formalized the concept of Indian land titles for the first time in the history of European colonization in the New World. The document prohibited issuance of patents to any lands claimed by a tribe unless the Indian title had first been extinguished by purchase or treaty. The proclamation reserved for the use of the tribes "all the Lands and Territories lying to the Westward of the sources of the Rivers which fall into the Sea from the West and Northwest." Land west of the Appalachians might not be purchased or entered upon by private persons, but purchases might be made in the name of the king or one of the colonies at a council meeting of the Indians.

This policy continued up to the termination of British rule and was adopted by the United States. The Appalachian barrier was soon passed—thousands of settlers crossed the mountains during the American Revolution—but both the Articles of Confederation and the federal Constitution reserved either to the president or to Congress sole authority in Indian affairs, including authority to extinguish Indian title by treaty. When French dominion in Canada capitulated in 1760, the English announced that "the Savages or Indian Allies of his most Christian Majesty, shall be maintained in the lands they inhabit, if they choose

to remain there." Thereafter, the proclamation of 1763 applied in Canada and was embodied in the practices of the dominion government. (The British North America Act of 1867, which created modern Canada, provided that the parliament of Canada should have exclusive legislative authority with respect to "Indians, and lands reserved for the Indians." Thus, both North American countries made control over Indian matters a national concern.)

United States policy. The first full declaration of U.S. policy was embodied in the Northwest Ordinance (1787):

The utmost good faith shall always be observed toward the Indians, their lands and property shall never be taken from them without their consent; and in their property, rights, and liberty, they shall never be invaded or disturbed, unless in just and lawful wars authorized by congress; but laws founded in justice and humanity shall from time to time be made, for preventing wrongs being done to them, and for preserving peace and friendship with them.

This doctrine was embodied in the act of August 7, 1789, as one of the first declarations of the U.S. Congress under the Constitution.

The final shaping of the legal and political rights of the Indian tribes is found in the opinions of Chief Justice John Marshall, notably in decision in the case of *Worcester v. Georgia*:

The Indian nations had always been considered as distinct, independent, political communities, retaining their original natural rights, as the undisputed possessors of the land, from time immemorial. . . . The settled doctrine of the law of nations is, that a weaker power does not surrender its independence—its right to self-government—by associating with a stronger, and taking its protection. A weak state, in order to provide for its safety, may place itself under the protection of one more powerful, without stripping itself of the right of government, and ceasing to be a state.

The first major departure from the policy of respecting Indian rights came with the Indian Removal Act of 1830. For the first time the United States resorted to coercion, particularly in the cases of the Cherokee and Seminole tribes, as a means of securing compliance. The Removal Act was not in itself coercive, since it authorized the president only to negotiate with tribes east of the Mississippi on a basis of payment for their lands; it called for improvements in the east and a grant of land west of the river, to which perpetual title would be attached. In carrying out the law, however, resistance was met with military force. In the decade following, almost the entire population of perhaps 100,000 Indians was moved westward. The episode moved Alexis de Tocqueville to remark in 1831:

The Europeans continued to surround [the Indians] on every side, and to confine them within narrower limits . . . and the Indians have been ruined by a competition which they had not the means of sustaining. They were isolated in their own country, and their race only constituted a little colony of troublesome strangers in the midst of a numerous and dominant people.

The territory west of the Mississippi, it turned out, was not so remote as had been supposed. The discovery of gold in California (1848) started a new sequence of treaties, designed to extinguish Indian title to lands lying in the path of the overland routes to the Pacific. The sudden surge of thousands of wagon trains through the last of the Indian country and the consequent slaughtering of prairie and mountain game that provided subsistence for the Indians brought on the most serious Indian wars the country had experienced. For three decades, beginning in the 1850s, raids and sporadic pitched fighting took place up and down the western Plains, highlighted by such incidents as the Custer massacre by Sioux and Cheyenne Indians (1876), the Nez Percé chief Joseph's running battle in 1877 against superior U.S. army forces, and the Chiricahua Geronimo's long duel with authorities in the Southwest, resulting in his capture and imprisonment in 1886.

Toward the close of that period, the Ghost Dance religion, arising out of the dream revelations of a young Paiute Indian, Wovoka, promised the Indians a return to the old life and reunion with their departed kinsmen. The songs and ceremonies born of this revelation swept across the northern Plains. The movement came to an abrupt end December 29, 1890, at Wounded Knee Creek, South

Indian
Removal
Act of
1830

Indian
wars

Dakota. Believing that the Ghost Dance was disturbing an uneasy peace, government agents moved to arrest ring-leaders. Sitting Bull was killed (December 15) while being taken into custody, and two weeks later units of the U.S. 7th Cavalry at Wounded Knee shot down more than 200 men, women, and children who had already agreed to return to their homes.

A further major shift of policy had occurred in 1871 after congressional discussions lasting several years. U.S. presidents, with the advice and consent of the Senate, had continued to make treaties with the Indian tribes and to commit the United States to the payment of sums of money. The House of Representatives protested, since a number of congressmen had come to the view that treaties with Indian tribes were an absurdity (a view earlier held by Andrew Jackson). The Senate yielded, and the act of March 3, 1871, declared that "hereafter no Indian nation or tribe" would be recognized "as an independent power with whom the United States may contract by treaty." Indian affairs were brought under the legislative control of the Congress to an extent that had not been attempted previously. Tribal authority with respect to criminal offenses committed by members within the tribe was reduced to the extent that murder and other major crimes were placed under the jurisdiction of the federal courts.

The most radical undertaking of the new legislative policy was the Dawes General Allotment Act of 1887. By that time the Indian tribes had been moved out of the mainstreams of traffic and were settled on lands that they had chosen out of the larger areas that they had formerly occupied. Their choice in most cases had been confirmed by treaty, agreement, act of Congress, or executive order of the president. The tribes that lived by hunting over wide areas found reservation confinement a threat to their existence. Generally, they had insisted on annuity payments or rations, or both, and the U.S. peace commissioners had been willing to offer such a price in return for important land cessions. In time the view came to be held that reservation life fostered indolence and perpetuated customs and attitudes that held Indians back from assimilation. The strategy offered by proponents of this theory was the Allotment Act authorizing the president to divide the reservations into individual parcels and to give every Indian, whether he wanted it or not, a particular piece of the tribally owned land. In order not to make the transition too abrupt, the land would be held in trust for a period of 25 years, after which ownership would devolve upon the individual. With it would go all the rights and duties of citizenship. Reservation land remaining after all living members of the tribes had been provided with allotments was declared surplus, and the president was authorized to open it for entry by non-Indian homesteaders, the Indians being paid the homestead price.

A total of 118 reservations was allotted in this manner, but the result was not what had been anticipated. Through the alienation of surplus lands (making no allowance for children yet unborn) and through patenting of individual holdings, the Indians lost 86,000,000 acres (35,000,000 hectares), or 62 percent, of a total of 138,000,000 acres in Indian ownership prior to 1887. A generation of landless Indians resulted, with no vocational training to relieve them of dependence upon land. The strategy also failed in that ownership of land did not effect an automatic acculturation in those Indians who received individual parcels. Through scattering of individuals and families, moreover, social cohesiveness tended to break down. The result was a weakening of native institutions and cultural practices with nothing offered in substitution. What was intended as transition proved to be a blind alley.

Indian population had been dwindling through the decades after mid-19th century. The California Indians alone, it was estimated, dropped from 100,000 in 1853 to not more than 30,000 in 1864 and 19,000 in 1906. Cholera in the central Plains in 1849 struck the Pawnee. As late as 1870-71 an epidemic of smallpox brought disaster to the Blackfeet, Assiniboin, and Cree. These events gave currency to the concept of the Indian as "the vanishing American." The decision of 1871 to discontinue treaty making and the passage of the Allotment Act of 1887

were both founded in the belief that the Indians would not survive, and hence it did not much matter whether their views were sought in advance of legislation or whether lands were provided for coming generations. When it became obvious after about 1920 that the Indians, whose numbers had remained static for several years, were surely increasing, the United States was without a policy for advancing the interests of a living people.

A survey in 1926 brought into clear focus the failings of the previous 40 years. The investigators found most Indians "extremely poor," in bad health, without education, and lacking adjustment to the dominant culture around them. Under the impetus of these findings and other pressures for reform, Congress adopted the Indian Reorganization Act of 1934, which contemplated an orderly decrease of federal control and a concomitant increase of Indian self-government and responsibility. The essentials of the new law were as follows: (1) allotment of tribal lands was prohibited in the future, but tribes might assign use rights to individuals; (2) so-called surplus lands not pre-empted by homesteaders might be returned to the tribes; (3) tribes might adopt written constitutions and charters of incorporation embodying their continuing inherent powers to manage internal affairs; and (4) funds were authorized for the establishment of a revolving credit program, for land purchases, for educational assistance, and for aiding the tribes in forming organizations. Moreover, the act could be rejected on any reservation by referendum.

The response to the 1934 act was indicative of the Indians' ability to rise above adversity. About 160 tribes, bands, and Alaska villages adopted written constitutions, some of which combined traditional practices with modern parliamentary methods. The revolving credit fund helped Indians build up their herds and improve their economic position in other ways. Borrowers from the fund were tribal corporations, credit associations, and cooperatives that loaned to individual Indians and to group enterprises on a multimillion-dollar scale. Educational and health services were also improved through federal aid.

Originally, the United States exercised no guardianship over the person of the Indian; after 1871, when internal tribal matters became the subject of national legislation, the number and variety of regulatory measures multiplied rapidly. In the same year that the Indian Reorganization Act was passed, Congress significantly repealed 12 statutes that had made it possible to hold Indians virtual prisoners on their reservations. Indians were then able to come and go as freely as all other persons. The Snyder Act of 1924, extending citizenship to all Indians born in the United States, opened the door to full participation. Few Indians took advantage of the law, and because of their lack of interest a number of states excluded Indians from the franchise. Organization of tribal governments following the Reorganization Act, however, seemed to awaken an interest in civic affairs beyond tribal boundaries, and when Indians asked for the franchise, they were generally able to secure it eventually, though not until 1948 in Arizona and New Mexico, after a lengthy court action.

The federal courts consistently upheld the treaties made with Indian tribes and also held that property may not be taken from Indians, whether or not a treaty exists, "except in fair trade." The latter contention was offered by the Hualapai Indians against the Santa Fe Railway. The company was required by the courts in 1944 to relinquish about 500,000 acres it thought had been granted to it by the U.S. The lands had been occupied since prehistory by the Indians, without benefit of treaty recognition, and the Supreme Court held that, if the occupancy could be proved, as it subsequently was, the Indians were entitled to have their lands restored. In 1950 the Ute Indians were awarded a judgment against the United States of \$31,750,000 for lands taken without adequate compensation. A special Indian Claims Commission, created by act of Congress on August 13, 1946, received many petitions for land claims against the United States and awarded, for example, about \$14,789,000 to the Cherokee nation, \$10,242,000 to the Crow tribe, \$3,650,000 to the Snake-Paiute of Oregon, \$3,000,000 to the Nez Percé, and \$12,300,000 to the Seminole.

policies

The period from the early 1950s to the 1970s was one of increasing federal attempts to seek new policies regarding the Indians, and it was also a period in which Indians themselves became increasingly vocal in their quest for a better measure of human rights and the correction of past wrongs. The first major shift in policy came in 1954, when the Department of the Interior began terminating federal control over those Indians and reservations deemed able to look after their own affairs. From 1954 to 1960, support to 61 tribes and other Indian groups was ended by the withdrawal of federal services or trust supervision. The results, however, were unhappy. Some Indian groups, in extreme poverty, lost more acreage in deals for the private exploitation of Indian land and water resources. Indians in certain states became subject exclusively to state laws that were less liberal or sympathetic than federal laws. Finally, the protests of Indians, anthropologists, and other interested groups became so insistent that the program was decelerated in 1960. In 1961 a trained anthropologist was sworn in as commissioner of Indian Affairs, the first anthropologist ever to hold that position. Federal aid expanded greatly, and in the ensuing decade Indians were specifically brought into various federal programs for equal economic opportunity. Indian unemployment remained severe, however.

American Indians came more and more into public attention in the 1970s and 1980s as they sought (along with other minorities) to achieve a better life. Following the example set by black civil-rights activists of the 1960s, Indian groups drew attention to their cause through mass demonstrations and protests. Perhaps the most publicized of these actions were the 19-month seizure (1970-71) of Alcatraz (California) by members of the militant American Indian Movement (AIM) and the February 1973 occupation of a settlement at the Oglala Sioux Pine Ridge (South Dakota) reservation, the latter incident becoming known as the second Battle of Wounded Knee. Representing an attempt to gain a more traditional political power base was the establishment in 1971 of the National Tribal Chairman's Association, which eventually grew to include more than 100 tribes.

Indian leaders also expanded their sphere of influence into the courts; fishing, mineral, forest, and other rights

involving tribal lands became the subject of litigation by the Puyallup (Washington state), the Northern Cheyenne (Montana), and the Penobscot and the Passamaquoddy (Maine), among others. Although control of economic resources was the focus of most such cases, some groups sought to regain sovereignty over ancient tribal lands of primarily ceremonial and religious significance. (Ed.)

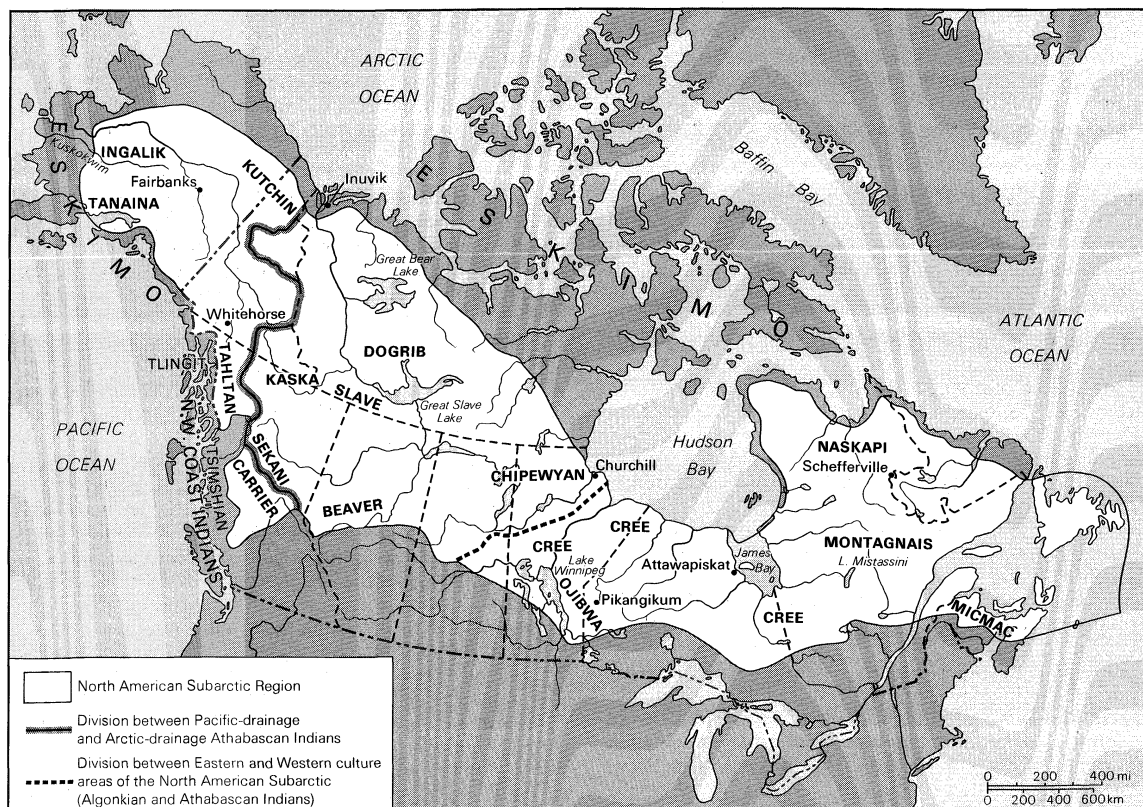

American subarctic cultures

The subarctic, or the physiographic zone called the taiga, is a land of coniferous forest covered with sphagnum moss and traversed by many waterways. Its main natural resources utilized by the Indians include wood, of which spruce, tamarack, and alder have been especially important for manufactures; game animals, such as moose, caribou, and beaver, whose meat is used for food and whose skins are used for blankets and clothing; berries; fish, usually the most abundant and therefore the staple food; and coloured earths converted into paints. Cold winters, when the ground is covered with snow and the waterways are frozen, are reflected in many technological adaptations, including the use of fur garments, toboggans, ice chisels, and snowshoes.

Since the 17th century, traders have been attracted to the region by its wealth in fur-bearing animals. Together with missionaries, they decisively influenced the native Indians' history. Many old beliefs, hunting customs, kinship relations, and so on, however, persisted throughout the fur-trade years in this marginal area and are only now beginning to vanish.

The subarctic contains two relatively distinct culture areas. The eastern subarctic is inhabited by Algonkian-speaking Indians, including the Naskapi of northern Quebec; the far-flung Cree; and an intrusive wedge of Ojibwa, who, after the beginning of the fur trade, displaced the Cree from west central Ontario and eastern Manitoba. The western subarctic belongs largely to Athabaskan speakers, who extend from Canada into Alaska. Cultural differences among the Athabascans justify the delineation of two subareas. The first subarea, drained mostly by the northward-flowing Mackenzie River system, is inhabited by Chipewyan, Beaver, Slave, and Kaska Indians. Their

Resources
and
populations

Distribution of American subarctic cultures.

culture was generally simpler and less sedentary than that of the second subarea, whose salmon streams drain into the Pacific Ocean. Its groups include the Carrier, part of the Kutchin, the Tanaina, and Ingalik Indians.

Northward the Algonkians and Athabascans border on the Eskimo; to the west the Canadian Athabascans encounter the Tlingit, Tsimshian, and other Northwest Coast tribes, while the Alaskan groups again abut on the Eskimo. (For a discussion of the cultures of the Northwest Coast, see below. Eskimo groups are treated in the article ARCTIC.)

TRADITIONAL CULTURE PATTERNS

Ethos. In most of the region east of Alaska, the uncomplex nature of subsistence and manufacturing technology is reflected in the Indians' elemental social structure, based on the family and the small local band, and in their individualistic relationship to the supernatural. Both features of the culture pattern are linked in turn with characteristic personality features, such as the high value placed on personal autonomy; the generalized conception of the world as dangerous; the emphasis on concrete, current realities rather than on future possibilities; and self-reliance, manifested, for example, in bearing up stoically to deprivation. Psychological homogeneity in the subarctic extends to other personal traits such as reticence, nondemonstrative emotionality, deference to other people, and strong individual control of aggressive impulses. Hostility is not absent, but it is only indirectly revealed through such outlets as sorcery, fear of sorcery, or malicious gossip.

Territorial organization. At the time of first white contact with the Indians, social structure tended to be extremely simple. The Indians had no stable, territorial political systems, no special offices charged with the task of coordinating groups, no formal social stratification, and no occupational specialization except as related to age and sex. Temporary leadership emerged when one group raided another or fought with the Eskimo or when there were other tasks requiring cooperation beyond the family.

The Indians were territorially grouped in informal regional bands without chiefs. These units took their identity from some geographical feature of the land that members exploited—hence such appellations as “mountain people,” or “Marten Lake people.” A smaller kind of group east of the Pacific drainage culture area was the local band. It usually consisted of a few related families who travelled together for a time. Several local bands coalesced seasonally at a good fishing lake or near rich hunting grounds for periods that were as intensely sociable as they were abundantly provided with fish or game. In the eastern subarctic, where local bands have been called hunting groups, they averaged about 20 individuals.

The fur-trade period created a new type of territorial group: the trading-post band, named from the settlement in which its members traded. The new bands amalgamated local groups and notably expanded the population in which marriage occurred. In some places the Canadian government concluded treaties with such groups and arranged for the election of chiefs and councillors.

In the Pacific drainage area, sedentary villages took the place of local bands. On the lower Yukon and upper Kuskokwim rivers, Ingalik village life centred on the *kashim*, or men's house, where a council of old men met to hear trouble cases and where elaborate seasonal ceremonies were performed.

Authority in bands and villages derived primarily from the combination of a man's eloquence, wisdom based on experience, healing or magical power, generosity, and capacity for hard work. Aided by the latter quality, he would normally be well supplied with food and thereby able to help others.

Family and kinship relations. Within the local band, the simple family of husband, wife, and children, frequently including adopted children, constituted the nucleus of economic activity and emotional security. The intense importance of the family, especially in a young person's life, is revealed in stories about the unhappy lot of cruelly treated orphans and is further suggested by the reported eagerness with which widowers sought to remarry.

The prevailing modes of obtaining a wife required bride service rendered to the wife's father or transfer of a sister of the groom in exchange for a bride. Although households were primarily monogamous, a man occasionally had two wives. This could happen, for example, when by custom a man espoused his dead brother's widow. Cross-cousin marriage (that is, a man's marriage with his mother's brother's daughter or his father's sister's daughter) is known to have been practiced, perhaps by preference, among some groups. Elsewhere it can be inferred from several features in kinship terminology. For example, a man uses the same term for his female cross-cousins and for his wife's sister. The custom declined when it was opposed by missionaries, who condemned it as incest, and when marriageable populations expanded around trading posts and missions.

Kin relations among the Kaska included teasing between grandparents and grandchildren, initiated by the youngsters. Siblings of the opposite sex who had reached puberty conducted themselves circumspectly in each other's presence and even tended to practice polite avoidance, as a father and a grown daughter also did. Parallel cousins (mother's sisters' children and father's brothers' children) were treated as siblings, both being called by the same kinship term. Ceremonial avoidance also governed the relationship of a man and his mother-in-law, contrasting with the camaraderie linking brothers-in-law, which was one of the warmest of all relationships between grown men. A Kaska man could joke freely with his wife's sister and brother's wife, sexual ribaldry not being barred from their conversation.

Socialization of children. Pregnancy taboos and postnatal observances served to ensure the well-being of mother and child. Birth took place in the dwelling, in a special birth hut, or, according to early travellers among the eastern seaboard Micmac, in the woods. One or more knowledgeable women assisted the mother in giving birth and in caring for the delivered child. Swaddled babies were diapered with moss and carried on the mother's back in an ornamented skin bag or a cradleboard.

Family members and other relatives played the major role in the informal process of childhood education. A child had considerable scope to learn through copying the unself-conscious example of models. Thus a Kaska Indian parent might say “Make tea!” and a small girl would try to reconstruct what she had often observed her mother and older sisters doing but what she had never been formally instructed to do. Parents did not neglect disciplining and even chastising a disobedient child for such offenses as stealing and rebelliousness. More important for the formation of personalities suited to a life of food gathering is the fact that parental treatment subtly but firmly encouraged children to become independent and self-reliant.

Several “firsts,” including the first tooth, the first game killed by a boy, and the first menstruation (menarche), were ceremonially recognized, sometimes by a small feast or, in the case of menarche, by an elaborate series of taboos. Athabaskan Indians paid the greatest ritual attention to menarche, the Kutchin girl going to live for up to a year in a special shelter constructed some distance from the family camp. Here she wore a pointed hood that forced her to look down toward the ground. Other precautions for her own good included a rattle of bone that was supposed to prevent her from hearing anything; a special stick to use if she wanted to scratch her head, and a special cup that should not touch her lips. Subsequent menstruation required only a short period of seclusion.

When a boy approached adolescence, he went alone into the forest to seek a vision. In Kaska Indian terms the vision came from “dreaming of animals in a lonely place” or from hearing “somebody sing,” perhaps a moose in the guise of a person. Success in the vision quest supernaturally enhanced the youth's ability, bestowing on him the power of the animal helpers. Dreams also notified an individual of impending events and might advise him on when and where to hunt or how to behave on other occasions in order to achieve success or avoid misfortune.

Social stratification. The maximum of social stratification was reached among the Ingalik, who informally

Marriage,
friendship,
and
avoidance

bands and
villages

Education
and
initiation

recognized three classes of families. Three-quarters of the village comprised common people. Rich families, so called because they accumulated surplus food thanks to members' industry or superior hunting and fishing abilities, constituted about 5 percent of the community. They took the lead in the community's ceremonial life. The rest of the people did "nothing" and lived off the others; consequently, they enjoyed so little respect that they had a hard time finding spouses.

Seasonal
migration

Settlement and housing. In pursuit of a livelihood, families and local bands shifted their location as the seasons changed. In northwest Canada groups scattered in early winter to hunt caribou in the mountains; elsewhere, autumn drew people to shorelines of lakes and bays where large numbers of ducks and geese could be taken for the winter larder. At other times people gathered around fish lakes. Ingalik Indians in late winter quit the village and headed for spring camps, as much for a change as for the good fishing. As dependence on fur trapping became heavier, the Cree, Slave, Kaska, and many other Indians adopted a two-part annual cycle. In winter the family lived on its trapline. Then, with summer, it brought its furs to the trading post where people camped until fall, enjoying a rest from work and abundant sociability. The warm months with their long daylight became a time for dances (the steps and fiddle music being copied from early European types), for marriages, and for visits of the Anglican or Roman Catholic bishop.

Despite much movement, shelters were not always portable. The Ingalik spent winters in houses excavated in the soil, roofed with beams and poles, hung with mats, and provided with an entry. Other groups, such as the Cree and Ojibwa, built conical winter lodges durably roofed with boughs, earth, and snow. On the trail, however, people put up skin or brush shelters, sometimes only a simple lean-to, or camped in the open facing a fire.

Production and technology. Everywhere in the subarctic, fish and game, augmented by berries and a slight quantity of other vegetable products, provided the food supply. Meat was boiled with the aid of hot stones in containers of bark or woven spruce roots. A large, varied set of weapons, traps, and other ingenious appliances played a vital role in providing subsistence. Important devices included the bow and arrow, with stone or bone tips for different kinds of game; lances; the spear thrower and spear; weirs and basket traps for fish; nets of willow bark and of other substances; snares for such small game as rabbits; deadfalls (traps with logs or other weights that fall on game and kill them); pit traps; and decoys for birds. No less vital for people who depended heavily on mobility for survival were vehicles, such as bark canoes or snow toboggans of hardwood, and travel aids, such as large sinew-netted snowshoes to run down large game, a smaller variety to break trail for the toboggan, and snow goggles to use against the glare of the spring sun. Dogs large or numerous enough to pull toboggans were unavailable until the fur-trade period.

Techniques and
skills

In addition to the Indians' technical resourcefulness and skill, magic and divination aided hunting. A noteworthy form of divination used in locating game required heating a large animal's shoulder blade over fire until it cracked. Hunters then went in the direction of the crack. The random element in the method increased the chances that they would go to a fresh, relatively undisturbed piece of ground.

An idea of the extent to which people depended on game and of the labour involved in food getting can be gained from food-consumption figures obtained in the mid-20th century. In the relatively poor country west of James Bay, 400 Cree men, women, and children in the course of a fall, winter, and spring (nine months) consumed about 128,000 pounds (58,000 kilograms) of meat and fish in addition to staples from the store, especially flour, lard, and sugar.

Across the subarctic, people preserved meat by drying and pounding it together with fat and berries to make pemmican. The Pacific-drainage Athabascans also preserved salmon by smoking. Other widely distributed, basic technical skills included complicated chemical processes, using animal brains or human urine, to tan caribou and

moose skins; these were then sewn into garments with the help of bone needles and animal sinew. Women also plaited rabbit skins into ropes and wove roots to form watertight baskets.

Property. Land and water, the sources of food, were not considered to be either individual or group property, yet nobody would usurp the privilege of a group that was currently exploiting a berry patch, beaver creek, or hunting range. Clothing, the contents of food caches, and other portable goods had individual owners. Legally inalienable family trapping territories came into being with the fur trade and in many places have been registered by the government. Sharing game was always important economically, while gifts other than food were bestowed primarily ceremoniously.

Religious beliefs. Two important concepts of the Naskapi and other Algonkian groups were Manitou and the "big man." Manitou represents a pervasive power in the world that individuals can learn to use in their own behalf. The term Great Manitou, designating a personal god, probably represents a missionary-inspired adaptation of the Indians' older idea. Among the Naskapi and Rupert House Cree, a person's big man is a spirit intimately associated with him. It confers wisdom, competence, skill, and strength in the food quest as well as in other areas of life, including magic. Maintaining this spirit requires ethically good conduct. Spirit "bosses" who control the supply of caribou, fish, and other creatures are another traditional belief shared by Algonkian and certain Athabaskan groups.

Among many subarctic Indians, success in the vision quest augmented personal competence by allying the individual with animal helpers. There was also a widespread belief that if one wanted to continue to hunt game successfully, the dead animals and their remains must be treated with reverence. This required disposing of their bones carefully so that dogs could not chew them. Respect was particularly evident in the use of polite circumlocutions to refer to bears. Quebec Indians undertook several ceremonial observances in bear hunting, including a purifying sweat bath before departing on the hunt and an offer of tobacco to a bear that had been killed. Afterward the people feasted and danced in its honour.

Three of the most popular characters in Algonkian folklore are Wiitiko (Windigo), a terrifying cannibalistic giant apt to be encountered in the forest; Tcikapis, a kindly, powerful young hero and the subject of many myths; and Wiskijan, an amusing, prankful trickster. Wiitiko psychosis refers to a condition in which an Indian would be seized by the obsessive idea that he was turning into a cannibal with a compulsive craving for human flesh.

The shaman, the sole religious functionary, served subarctic people as a part-time specialist curer and diviner. Occasionally he also behaved malignantly. Shamanistic ability came to an individual from dreaming of animals who taught the dreamer to work with their aid; such ability had to be validated through successful performance.

The Ingalik conceived of man as comprising body, soul, and "speech," the latter an element surviving after death but not, like the soul, reincarnated. Hazards to life came from the soul always being menaced by various supernatural figures that were the primary enemies of human survival, and by the souls of powerful evil shamans acting on behalf of these supernatural figures. The animal and berry people supported life. Animal "songs" and amulets created good relations with helpful animal people; and elaborate ceremonies in the men's house, to which animals were invited, protected the food supply.

magic,
and spirit
relations

MODERN DEVELOPMENTS

One view of culture change in the subarctic is that, during the fur-trade and missionary period, the Indians lost vital cultural traits faster than satisfactory replacements were absorbed. An opposite view holds that the fur-trapping era enriched Indian culture. Life came to be organized around the trading post; an emotionally satisfying belief system came to be centred in the Christian Church; and trapping offered new opportunities for prestige. Formal education and modern health care began during fur-trade times, the churches choosing a few localities to institute

boarding schools and hospitals that in time received government subsidies.

After World War II the fur-trade era was succeeded by a new period characterized by planned social change, incipient urbanization, and intensified modernization. The growing unprofitability of trapping, chronic illness (especially tuberculosis), and high infant-mortality rates aroused the conscience of Canada and introduced the welfare state into the Canadian subarctic. Local schools and health stations replaced distant boarding schools and hospitals. Other government-sponsored programs brought about modern housing, large-scale fur farming, and vocational training. The fishing industry in Alaska, military and other construction, and iron mining in Quebec gave Indians the opportunity to work for wages in place of trapping. A slow trend of migration began to draw native families to established northern cities, such as Fairbanks (Alaska), Whitehorse (Yukon Territory), and Churchill (Manitoba), as well as to new towns, such as Schefferville (Quebec) and Inuvik (Northwest Territories). At the same time expanding jobs in health care, education, mining, defense, and administration stimulated an influx of white families from southern Canada to the north who settled in the northern towns.

own life

Town life for some Indian migrants means a squatter's cabin, welfare, and occasional odd jobs; but many men and women have regular employment at open-pit mining, as janitors and hospital aides, in construction and domestic service, or as equipment operators. Indian townsmen restrict hunting and fishing, of which they are still very fond, to holidays and weekends. If the coming of the fur trade and missions widened the intellectual horizons beyond what they were in aboriginal times, then town life with its grade school, high school, library, movies, television, church groups, civic groups, and other associations increases awareness much more and provides many added chances to enact new, modern roles. Subarctic Indians of all ages are adapting successfully to urban economic and social opportunities, but the ease with which people take to jobs and adjust to new conditions varies in the same town, and some families are experiencing difficulties. Indians are not modernizing as rapidly as Eskimos, who live under similar conditions and sometimes in the same town.

Many Indians remain attached to small, isolated trading-post settlements and to a way of life that revolves around the forest, at least for the men. Even among the non-townspeople, one perceives a heightened awareness of native identity, together with growing objectivity about their "traditional" Indian cultural heritage. Their awareness is believed to stem from the knowledge that a different identity and way of life are possible. For the time being, however, they prefer to be cautious about changing the life that they know for one fraught with new challenges.

(J.J.Ho./Ed.)

Northwest Coast Indians

The most sharply delimited culture area of native North America was the Northwest Coast. It covered a long narrow arc of Pacific coast and offshore islands from Yakutat Bay in the northeast Gulf of Alaska south to Cape Mendocino in modern California. Its eastern limits were the crest of the Coast Ranges from the north down to Puget Sound, the Cascades south to the Columbia, and the coastal hills of Oregon and northwest California. The Kuroshio (Pacific Ocean current) offshore warms the coast and deluges it with rain. The northern Coast Range, cresting at heights of 5,000 feet and more, rises steeply from the sea and is cut by a myriad of narrow channels and fjords. The shores of Puget Sound, southwest Washington, and the Oregon coast hills are lower and less rugged.

Coastal forests are dense and predominantly coniferous with spruces, Douglas fir, hemlock, red and yellow cedar, and, in the south, coast redwood. These forests support an abundant fauna. Most important from the cultural point of view was the aquatic fauna, for it was on this that the areal culture depended primarily. Five species of salmon; herring; oil-rich "candlefish," or eulachon; smelt; cod; halibut; and mollusks abounded.

The peoples of the Northwest Coast linguistically consisted of a series of units related to widespread "stocks" of native North America (see LANGUAGES OF THE WORLD). From north to south the following linguistic divisions occurred: Tlingit; Haida; Tsimshian; northern Kwakiutl, or Heiltsuk; Bella Coola; southern Kwakiutl; Nootka; Coast Salish; Quileute-Chimakum; Kwalhioqua; Chinook. Then along the Oregon Coast and northwest California a series of small divisions occurred: Tillamook, Alsea, Siuslaw, Umpqua, Coos, Tututni-Tolowa, Yurok, Wiyot, Karok, and Hupa.

Major
Indian
groups

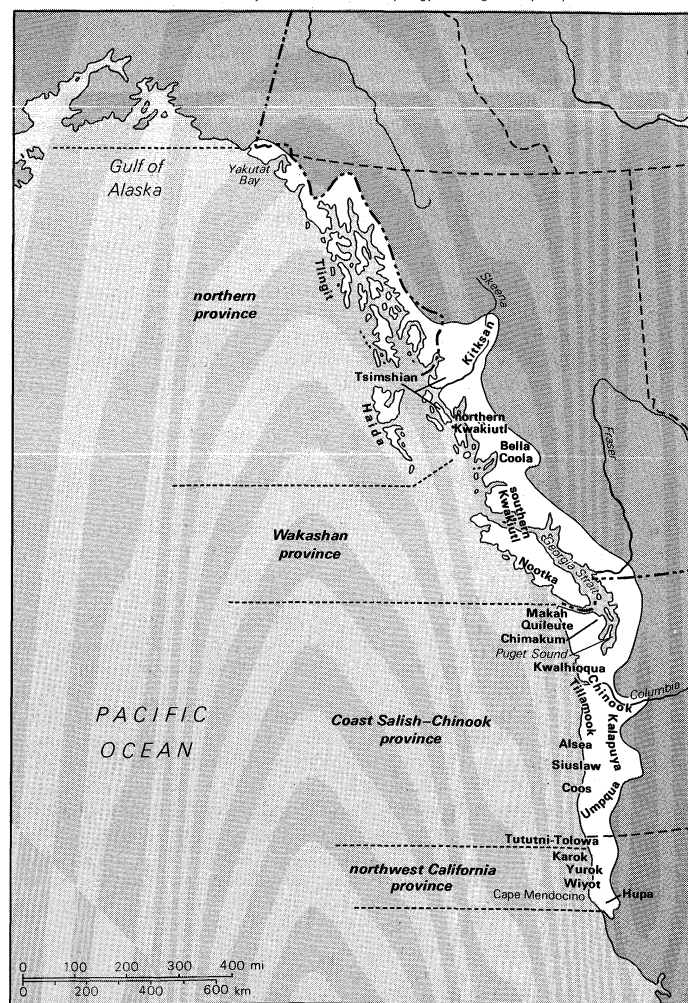

Culturally, Northwest Coast groups can be classified into four subareal units, or "provinces": the northern one, including speakers of Tlingit, Haida, Tsimshian, and the Tsimshian-influenced Haisla (northernmost Heiltsuk or Kwakiutl); the Wakashan province, including all other Kwakiutl, the Bella Coola, and the Nootka; the Coast Salish-Chinook province, which included various enclaves of other speech down to the central coast of Oregon; and the northwest California province plus the Athabaskan-speaking Tututni-Tolowa.

The Northwest Coast was densely populated. Estimates of density in terms of persons per square mile mean little in a region where long stretches of coast consisted of uninhabitable cliffs rising from the sea. But early historic sources indicate that many villages had hundreds of inhabitants. One conservative population estimate of 129,000 persons on the coast at the dawn of the historic period must represent nearly the maximum that the area could support without improvement of the already complex technology.

TRADITIONAL CULTURE PATTERNS

Social structure. The Northwest Coast was the outstand-

ing exception to the anthropological truism that "hunting-and-gathering" (in this case "fishing-and-gathering") cultures are characterized by simple technologies, sparse possessions, and egalitarian, loosely organized societies consisting of small bands comprising small total populations. In this area, complex patterns of culture were the rule.

Familial
and group
organiza-
tion

The nuclear family—a man, his wife or wives, their children or, in the northern provinces, the man's sisters' sons—was the basic production unit. In the native view, the significant social unit was the local group—that is, a group of men who considered themselves related and who formed a corporate entity holding title to fishing places, berry-picking and hunting grounds, habitation sites, and a host of incorporeal rights, such as names, songs, dances, and, especially in the north, totemic representations called "crests." Members of each group were graded in an integrated sequence from high to low, according to closeness to the direct line of descent from the group ancestor. The highest in rank, invariably holder of a special title that in each language translated into English as "chief," was administrator of the group's properties. It was he who set the time for the move to the salmon-fishing station, decided when the weirs and traps should be built, when the first catch should be made and the rite propitiating the first salmon of the season celebrated, when other groups should be invited to feasts, and so on. He had many prerogatives and sumptuary privileges, but he was expected to administer efficiently and to tend to social and ritual affairs for the general welfare of his group.

From Tlingit country in the north at least as far south as Puget Sound and perhaps farther, several such local groups assembled at a site in some sheltered cove protected from winter winds to pass the winter. Food-gathering activities were limited by weather but were unimportant; the stores of salmon dried in the fall were adequate. Practice of arts and crafts, jollity, and feasts and ceremonials were the order of the day. These assemblages of several local groups at winter village sites are often called "tribes," but it must be noted that such units were not politically integrated, for each of the component local groups retained its economic and political autonomy. For ceremonial purposes, though, the local groups were ranked in series from highest to next highest, and so on.

Individual
social
ranking

Stratification. A signal feature of Northwest Coast society was the emphasis on each individual's hereditary social rank. His position within his local group depended on his genealogical closeness to the legendary group ancestor. When several groups assembled at a common winter site to form a "tribe," the relative rank of the individual's group also was another factor important for ranking purposes.

Indian informants tend to oversimplify the situation in casual conversation, describing their former society as a class-structured one with a class of "chiefs," a class of commoners, and below these two a class of slaves. It is true that slaves (*i.e.*, war captives) formed a special social division, but the division into two great classes of "chiefs" and "commoners" is an inadequate explanation. The fact is that each person had his particular hereditarily acquired status, which placed him within his group as though he stood on a step of a long staircase of statuses, with the eldest of the senior line on the highest step, the most remotely related at the bottom. Strictly speaking, each person was in a class by himself.

Nominally, those of high rank were said to have had vast authoritarian powers, and group members of low degree have been described as serflike. In actual fact, mature persons of the latter sort voiced their opinions on group affairs, for they held interest in group properties. The chief refrained from abusing them because they were his kin and also because he was aware that he needed their assistance. Many strong arms and sturdy backs were needed to obtain, assemble, and position the heavy materials needed to build or repair a house, to construct fish weirs and traps, and to launch and paddle the chief's huge dugout canoe. Many singers, dancers, and attendants were necessary to stage an important ceremonial properly. Many bold warriors were needed to defend the group's wealth against foemen. There was enough flexibility in the

social structure so that those of low rank could abandon an abusive chief and reside with kindred elsewhere who would welcome them.

Slaves usually were persons captured in childhood and taken or traded so far from their original homes that they had little hope of finding their way back. They were mere chattels, who might be treated well or ill, traded off, slain, or freed at their owner's whim.

The statuses of group members were hereditary, but they were not automatically assumed at birth. They had to be formally and publicly assumed at a "potlatch," a performance given by all coast groups north of the Columbia River. The term comes from a widespread trade jargon and means "to give." A potlatch always involved invitation of another group or groups, who were received as guests with great formality; they served as witnesses to the announcements by the host chief at the assumption or bestowal of prerogatives, such as noble titles, crests, or ceremonial rights, and then were given gifts. The previously assumed statuses of the guests were recognized in the gift-giving, for distribution was made in the order of their rank sequence, and the more splendid gifts were given to guests of highest status. Not only were titles and other honours announced for the host chief or his heir and for his close kin of high position but children of low-rank group members were awarded names from the group stock and, at times, minor prerogatives. Participation of all members in major or minor roles in the proceedings also served to identify them with the social unit. There were some regional variations: in the northern province, a major potlatch was part of the cycle of mortuary observances after the death of a chief, at which his heir formally assumed his rights; in the Wakashan and Salish regions a chief gave such affairs to bestow rights on an heir apparent before his own demise.

Potlatch

Some early anthropologists, and a few modern ones, considered potlatch to be an economic enterprise in which the giver expected to recover a profit on the goods he distributed when his various guests potlatched in their turn. This actually was an impossibility because only a few guests of highest rank would ever stage such affairs and invite their former hosts; those of intermediate and low rank never did so, yet the total amount of gifts bestowed on them was considerable. Indeed, before white traders came and made great quantities of trade goods available, potlatches were few, whereas feasts, though also formal but not occasions for bestowing titles and gifts, were very frequent.

Socialization and education. An interesting aspect of Northwest Coast culture was the emphasis on teaching children etiquette, moral standards, and other traditions of social import. Every society has processes by which children are taught the behaviour proper to their future roles, but often such teaching is not overtly a deliberate process. On the Northwest Coast, particularly northward of the Columbia, children were instructed formally. This instruction began at an age when modern educators would consider children too young to learn effectively—while they were still in their cradles. Children born to high statuses were given formal instruction throughout childhood and adolescence. They had to learn not only routine etiquette but also the lengthy traditions by which the rank and privileges of their particular group were validated and many rituals including songs and formulaic prayers. It was not only the parents (or, in some groups, the mother's brother) who taught children. All elder relatives, particularly grandparents, participated. The educative procedure did not consist of dry, barebones moral lectures. Some of it was given in the form of folktales, amusing and entertaining but with pointed morals: the troubles of the anti-hero, Raven, in the tales were obviously the result of his dissolute way of life, his laziness, his gormandizing, and his lechery.

Early
training of
youth

Other socialization processes, those that involved public recognition of the attainment of new status, were usual among Northwest Coast groups. One variety included ritual observances considered necessary at each critical stage in a person's lifetime. At the birth of an infant, at a girl's attainment of puberty (there were no boys' puberty rites in the area), and at death, it was considered that persons involved might be in danger or might be dangerous to

the society at large. A newborn infant was believed to be in danger from supernatural causes; the infant's parents were both in danger and dangerous. A girl at puberty was similarly viewed, as were the close kin of a deceased person and those who actually participated in preparing and disposing of the body. Such perils were avoided by isolating the persons involved, either within a boarded-off cubicle in the house or in a makeshift hut out in the woods, and by limiting his or her diet to old dried fish and water. At the conclusion of the isolation period some sort of formal ritual purification was carried out, such as ceremonial bathing. The intensity of the restrictions varied considerably, not only in different parts of the coast but within individual groups. Often the pubescent daughter of a chief, for example, was secluded for many months, whereas her low-ranking kinswoman might have to observe only a few days of confinement.

Over most of the coast there was a very great fear of the dead. A body was removed from the house through some makeshift aperture other than the door, to be disposed of as rapidly as possible. Only in the northern region were bodies of chiefs set up in state for several days while the clan dirges were sung. Disposal of the dead varied. In the northern province cremation was practiced (anciently, interment was customary). In the Wakashan and part of the Coast Salish areas large wooden boxes suspended from branches of tall trees or placed in rock shelters served as coffins. Other Coast Salish deposited their dead in canoes set up on stakes. In southwest Oregon and northwest California interment in the ground was preferred.

Economic systems. Of the various distinctive attributes of Northwest Coast culture, one of the most important was the highly efficient exploitation of natural resources. The resources, particularly the fisheries, were very bountiful; but they were scattered and not equally easy to exploit. Certain species of salmon, for example, ran in certain rivers at various times of the year. The important species for preservation for winter stores were the pink and the chum salmon. Because these species ceased to feed for some time before entering freshwater and their flesh thus had less fat content, they could be smoked and dried and kept for a long period of time. Other species, such as sockeye, coho, and the flavorful chinook or king salmon, could be utilized immediately or dried and kept for a short period but could not be preserved the whole winter through. Therefore, the principal fishing sites were those along rivers and streams in which pink or chum salmon ran in the fall. In the spring of the year other sorts of fish became available in tremendous schools: herring, which came in to spawn in coves; "candlefish" (eulachon), which entered certain rivers; and, farther south, "smelt," which spawned on sandy beaches in summer. Elsewhere, in the summer months, bottom fishing for such species as halibut was a profitable enterprise on shallow offshore banks.

To exploit the total resources of the region it was most efficient for the people to have various bases of operation. In the winter months when storm winds blew and heavy seas slammed against the coasts, shelter behind some point of land that broke the force of the sea was highly desirable. The Northwest Coast adaptation to this pattern was shifting residence. The people moved from one site to another, according to the season and according to the resources about to become available. This was not nomadism. The Indians moved systematically in certain seasons from one fixed site to another for convenient access to seasonal resources. Typically at these seasonal stations there were either permanent houses or permanent houseframes that could be covered over with planks brought along for the purpose. Occasionally, when the weather permitted or only a short stay was planned, makeshift shelters were erected.

Aboriginal Northwest Coast economy may be viewed as a system comprised of several mutually supporting subsystems. The first of these subsystems is the efficient techniques for taking fish and other marine resources and for preserving them. The second subsystem consisted in the construction of large rectangular plank houses that made possible the smoking and drying of fish during the torrential rains of autumn. Such houses also provided storage space for the bulky preserved foods. The third sub-

system consisted of the water-transport complex. Canoes, both large and small, provided access to fishing grounds and the means of transporting preserved foodstuffs to other habitation areas. It was the combination of these subsystems that made the exploitation of local resources so efficient that the people were able to live with a wide margin of plenty.

Northwest Coast houses shared a few significant traits. All were rectangular in floor plan with plank walls and plank roof, and all but those of northwestern California were large structures designed for multifamily use. At the northern and southern extremes of the area deep central pits were dug within the house. In the north, houses were built on a nearly square plan—averaging about 50 feet wide by 55 feet long—and had gabled roofs; walls and framework were intermeshed to form a permanent structural unit. In the Wakashan province, on the other hand, the houses were rectangular—40 feet by 60 to 100 feet. Huge cedar posts with side beams and ridgepoles comprised the permanent framework, and to these were attached wall planks and roof planks that could be taken down, loaded onto canoes, and transported from one site to another. Some Coast Salish similarly built houses of permanent frameworks with detachable siding and roofing; their houses, however, had "shed-roofs," that is, a roof with only one slope instead of the two of the Wakashan house. Some Coast Salish houses were tremendously long, housing many people. Along the lower Columbia the typical house had a deep large rectangular pit, lined with planks, capped with a gabled roof. Only roof and gable ends showed above ground. The northwestern California house type was designed for single family only. Each house had low side walls of redwood planks and a three-pitch roof. Living space was the plank-lined central pit. Northwestern California also added a specialized structure: the men's combined clubhouse and sweat house, a common native Californian institution.

Water transport was highly important in the area. All groups made efficient dugout canoes. Northern groups, as well as the Kwakiutl and Salish down to Puget Sound, made dugouts with projecting bow and stern pieces, vertical "cutwaters," rounded sterns, and rounded hulls. The Nootka and some of their neighbours made vessels with projecting bow pieces, curving cutwaters, vertical sterns, and angular flat bottoms. Northwest Californian dugouts had upturned rounded ends, rounded hull, a carved seat and foot braces for the steersman. All types were made in different proportions for different purposes: large, beamy ones for moving people and cargo; shorter, narrow ones with racy lines for sea mammal hunting, and so on.

Northwest Coast woodworking was facilitated by the natural abundance of easily worked timbers, especially the red cedar and the redwood. Trunks of these trees could be split into planks or they could be hollowed out into canoes, containers, or other useful objects. Along the Northwest Coast as far south as the Columbia, wooden boxes were made of red-cedar boards that were "kerfed"—cut nearly through transversely. The wood was steamed at these points until it was flexible enough to bend into the form of a box. Dishes often were hollowed out of pieces of wood, sometimes plain, sometimes in the form of animals and monsters. Also of wood were spoons and ladles (some were of horn), canoe bailers, trinket boxes, chamber pots, and masks used in ceremonials and rattles for musical accompaniment. A special character of Northwest Coast woodworking was the emphasis on symmetry, neatness of finish, and frequent decoration of the surfaces, with relief carving or with relief carving and painting. All of this woodworking was accomplished with rather limited tools, the principal ones being the adz, mauls and wedges, chisels, drills, curved knives, abrasive stones and sharkskin for polishing. Mountain-goat horn, mountain-sheep horn traded from the interior, and, in the south, elk horn were carved by essentially the same methods as wood.

Another highly developed craft was weaving. The inner bark of red cedar was stripped long and ribbonlike to be woven into mats and baskets in a checkerwork technique. The same bark was shredded into finely divided flexible hanks, which were twined together to make a slip-on rain

eliance
fishing

atterns of
roduction
nd
chnology

Crafts

cape shaped like a truncated cone. The softer inner bark of yellow cedar was made into robes. Persons of high status wore such robes edged with strips of sea-otter fur and a few strands of yarn made of mountain-goat wool. Salish of the Georgia Strait wove robes of mountain-goat wool and also of wool from a special breed of shaggy little dog. The Chilkat, a Tlingit group, wove robes of mountain-goat wool that was twilled like basketry. Chilkat blankets bore representations of crests in blue, yellow, black, and white.

Twined basketry made from long, flexible splints split from spruce roots was made with great technical skill in several regions. Baskets so tightly woven as to be waterproof were made for cooking in the northern and northwestern Californian regions. Storage containers, receptacles for valuables large and small, and rainhats (Californians' hats were snug and caplike, worn only by women) also were woven. The Coast Salish specialty was coiled basketry.

Clothes

Dress patterns of the area were simple. Only the northernmost Tlingit and the Kitsan of the upper Skeena wore tailored buckskin clothing: breechclouts, leggings, and shirts for men; long gowns for women. Elsewhere, men wore robes of yellow cedar bark or of crudely tanned pelts in cold weather, rain capes in downpours, and nothing but ornaments on the infrequent bright sunny days. Ornaments, such as necklaces, earrings, bracelets, and anklets, were made of various materials, mostly shells, copper, wood, and fur. Some groups practiced tattooing.

Head-flattening was considered a beautifying process from the northern Kwakiutl region to the central Oregon coast. A newborn infant in its cradle had its head bound in such a way as to produce a long subconical form, a strong slope from the eyebrows back, or a distinctive wedge shape in which the back of the skull was flattened.

Belief and the aesthetic systems. *Religion.* Among no group or groups on the Northwest Coast did religion consist of an organized coherent body of beliefs in and attitudes toward the supernatural. Rather, there were several quite unrelated concepts that provided the widespread bases for various kinds of religious activity.

Fish spirits

One concept was that salmon were supernatural beings who voluntarily assumed piscine form to sacrifice themselves annually for the benefit of mankind. On being taken, the spirits of the fish returned to their home beneath the sea, where they were reincarnated if their bones were returned to the water. If offended, however, the salmon-beings would refuse to return to the river. Hence, there were numerous specific prohibitions on acts believed to offend them and observances designed to propitiate them, chief of which was the first salmon ceremony. This rite varied in detail along the coast but invariably involved honouring the first salmon of the main fishing season by sprinkling them with eagle down, red ocher, or some other sacred substance, welcoming them in a formal speech, cooking them and distributing their flesh, or morsels of it, communion-fashion, to all the members of the local group and any guests. The maximal elaboration of this rite was found in northwestern California, combined there with first fruits observances, and dances in which lineage wealth was displayed, in what have been called world-renewal ceremonies. Elsewhere the first salmon rituals were less elaborate but still important (except among the Tlingit, who did not perform them).

Another concept was that of acquiring personal power by seeking contact with a spirit—as through prayer and a vision. Among Coast Salish all success in life—whether hunting, woodworking, accumulating wealth, military ventures, or magic—was bestowed by spirits encountered in the spirit quest. From his spirit or spirits each person acquired songs, special regalia, and dances. Collectively, the dances comprised the major ceremonials of these people; known as the Spirit Dances, they were performed during the winter months. In the Wakashan province and the northern one it was believed that remote ancestors on spirit quests had been rewarded with totemic symbols called “crests.” Displaying these hereditary crests and recounting their traditional acquisition formed an important part of the potlatches. In the Wakashan area certain ceremonial cycles called for the dramatization of the whole tale of the supernatural encounter, including the spirit’s

possession of the seeker and the eventual exorcism of the spirit; such dramas were performed by what were called “dancing societies.”

Shamanism differed from other acquisitions of supernatural power only in the nature of the power obtained; that is, power to heal the sick through extraction of disease objects or recovery of a strayed soul. It was commonly believed that some shamans, or medicine men, had power to cause these infirmities as well as to cure them. Witchcraft, to kill or make ill, was also believed to be carried out by malicious persons who knew secret rituals for that purpose.

Art. The Northwest Coast is noted for its art styles. In the northern province low-relief carving accented by painting was essentially an applied art. The motifs were the hereditary crests of the clans or parts of the crests, applied to the magnificent memorial poles and interior house-posts, painted on house-fronts and screens, wrapped around carved wooden boxes and dishes, painted on basketry hats, woven into Chilkat robes, and carved on the handles of ladles and spoons, on halibut hooks, and even on the triggers of animal traps. There were differences within this style. Haida art tended to be massive, of highly conventionalized balanced elements, and slightly static. In Tsimshian carving and painting there was an effort to leave no open space in or between the conventionalized motifs: filler elements such as eye-designs and miniature figures were used intensively. Tlingit art was slightly less conventionalized, more vigorous by modern standards, with relatively little use of filler elements.

Wakashan representative art was more frankly sculptural than applied, and it was impressionistic and bold. There was a limited amount of simple geometric design on such things as whalebone clubs and whaling harpoon barbs. Their Coast Salish neighbours used some, but less, representative art, similar if cruder in style. On Puget Sound there was little if any representative art; the formless painted designs on the canoe boards were unlike anything else on the Coast. All that is known of Chinook art is represented by a few angular figures incised on mountain sheephorn bowls. In northwestern California art was limited to geometric patterns incised on elkhorn objects and shells. (See also below *Arts of the American Indian peoples.*)

MODERN DEVELOPMENTS

The impact of white man’s culture on that of the Northwest Coast varied at different periods and in different regions. Maritime traders, searching for precious sea-otter pelts, purveyed Euro-American manufactures to the Indians; but the material objects affected native culture only slightly. The Indians picked and chose the articles that had meaning to them—those that could fit well into their existing culture patterns. They acquired steel blades, for example, that could be fitted to their adzes to cut more efficiently than the aboriginal stone or shell blades; they spurned axe and hatchet blades that required a drastic change in motor habits and coordination patterns. In other words, the Indians accepted what they wanted; they were under no compulsion to change their way of life. Contagious diseases—smallpox, venereal infections, and the rest, introduced incidentally—had more effect on native society. The abnormal rate of deaths forced unusual distributions of roles and status positions, involving frequent adoptions, allocation of various titles to the same person, and other makeshift compromises to maintain the social system despite rapid population decline.

The establishment of white trading posts had somewhat more effect; and the great pressures started when white settlers began streaming into western Washington, Oregon, Vancouver Island, and the lower Fraser River Valley about the middle of the 19th century. This foreign occupation was accompanied by removal of the Indians to small reservations in Washington and Oregon under the provisions of formal treaties. In the area that became British Columbia there were no treaties extinguishing Indian title to the land; land transfers were private affairs.

In the closing decades of the 19th century, the Indians were in dire straits. Divested of most of their lands and at the same time more and more dependent upon white

Economic problems

American and British-Canadian manufactured goods, the Indians had to develop new economic patterns. The fur trade was inconsequential; logging and mining were still underdeveloped, requiring skills that the Indians did not have. Northwest Coast concepts of wealth differed from the Euro-American ones, but there were enough general similarities so that the Indians could perceive and accept certain equivalences. Northwest Coast Indians thus came to be more disposed to enter the new economic system, working for wages in a dull day-after-day routine, something that most other North American Indians refused to do. There was at first, however, little hired work available—guiding prospectors, back-packing cargo over mountain passes, cutting cordwood for coastal steamers—until the canned salmon industry developed, principally from the Fraser River northward. It was this industry that most effectively deprived the Indians of their fishing economy by monopolizing salmon streams, while at the same time offering them entrée into the new economy. Indian labour was cheaper than Oriental because it did not have to be imported.

The Indians also knew more about the habits of the salmon than anyone else. Of great importance was the fact that the commercial salmon fishery began with a very simple technology. The Indians themselves had long used canoes, spears, and weirs and other trapping devices. As motive power changed from paddles and oars to two-cycle gasoline engines, to high-speed gasoline engines, to diesel engines; as harvesting changed from gill nets and crude “beach seines” to huge purse seines handled with power gear; and as navigation changed from eyeball piloting to navigation using tide tables, compasses, and charts, the Indians could learn the new skills along with white and Oriental fishermen. The problem now is that the Indians are largely committed to a short-season industry, which ties up capital in expensive boats and nets. When the salmon run is over, there is no significant source of income until the next year.

Effective missionary activity began in various parts of the coast at about the same time that administrative controls were established. Missionaries on the Northwest Coast as elsewhere have been very successful at directed culture change, teaching not only Christian precepts but also etiquette, values of work and sobriety, household hygiene, and a host of other things that the Indian needed to know in order to participate in modern culture. Formal schooling of Indian children was in the hands of missionaries on much of the coast for many decades.

The aggressive and warlike Northwest Coast Indians never mounted a major war against the whites. There were only a few isolated local conflicts. This pacific pattern was not due to cowardice but to a realistic appraisal of the vulnerability of their coastal villages to naval gunfire.

There were some nativistic movements—that is, attempts to preserve or resuscitate former valued concepts or activities: for instance, the southern Kwakiutl tried to revive potlatch on a splendid scale, despite administrative prohibitions; and the Canadian Coast Salish tried to continue their Spirit Dances. But there is a distinction between these limited efforts of the Northwest Coast Indians and the “revitalization” movements of the Great Plains Indians, who, with their Ghost Dance, sought by supernatural means to evict the oppressor culture and return completely to the “good old days.”

In southeast Alaska and later on in coastal British Columbia a different type of organization was created, the “Native Brotherhoods,” whose purpose is to foster cultural change. The accomplishments of the Alaska Native Brotherhood have surpassed those of the Canadian organization, but both have been effective in creating a sense of Indian unity and community of interest. The organizations also provide valuable training in modern political processes and negotiations. The Alaskan organization has been partially superseded by the Tlingit-Haida Association, which handles matters related to the successfully prosecuted land claims of those people. Leaders of the British Columbia Brotherhood also have been effective in legal suits for compensation for lands.

(P.Dr.)

Californian Indians

Native peoples found in California were only generally circumscribed by the present state boundaries. Some of the peoples within these boundaries were culturally intimate with other areas neighbouring California. The Colorado River groups, such as the Mojave (Mohave) and Yuma, shared traditions with both the Southwest (Arizona and New Mexico) and southern California, whereas the peoples of the Sierra Nevada, such as the Washo, shared traditions with the Great Basin peoples. In northern California were to be found native traditions of the Northwest Coast; the remaining native groups occupied the greater part of California, and they represented indigenous cultural developments.

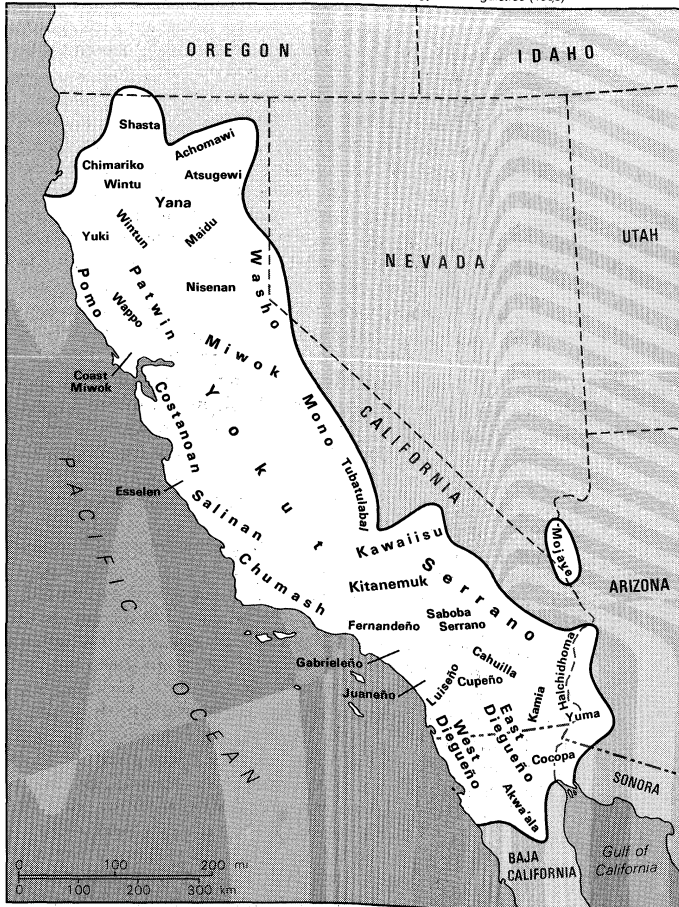

A conservative estimate of the pre-Spanish population of California is 275,000, making it one of the most populous culture areas of native North America. Various ecologic features—seacoasts, tidelands, river and lake areas, valleys, deserts, and foothills—and various historical traditions contributed to great cultural diversity. Thus there existed a seemingly endless variety of local environmental niches, each contributing advantages and disadvantages to human adaptation.

The peoples of California were politically stable, sedentary, and conservative and less in conflict with one another than was usually the case in other areas of North America; and neighbouring groups often developed elaborate systems of economic exchange of goods and services. The Californian Indians reached peaks of cultural attainment rarely seen among peoples depending almost wholly for subsistence on hunting, fishing, and the gathering of wild plant foods.

TRADITIONAL CULTURE PATTERNS

Local and territorial organization. California was occupied by a large number of cultural groups that have been described as ethnic nationalities—that is, groups of

From H. Driver et al., *Indiana University Publications in Anthropology and Linguistics* (1953)

Distribution of Californian Indians.

"Tribelet"
organiza-
tion

people sharing common linguistic, social, and cultural traditions and recognizing themselves as part of a single culture distinct from that of other groups. Except for the Colorado River peoples (Mojave and Yuma) and perhaps some Chumash groups, these ethnic nationalities had no centralized governmental structures; instead, each group comprised independent territorial and political units that may be termed tribelets, tightly organized polities that were smaller than the average groupings in most other parts of North America. Populations in these tribelets ranged from a hundred to a few thousand people, depending on the richness of locally available resources; tribelet territories ranged in size from about 50 to 1,000 square miles (150 to 3,000 square kilometres).

Within each tribelet there might be only one principal village in which all the people lived and from which some of them ranged for short periods of time to collect food, hunt, or visit other tribelets for ritual or economic purposes. In some tribelets there was a principal village surrounded by settlements of people who came to the principal village for ritual, social, economic, and political occasions. In other tribelets there were two or more villages, each having various satellite settlements and one serving as a "capital" or central village. Here a principal chief would usually reside, and major rituals and political and economic affairs would be held.

Community organization of tribelet villages was varied, but basic patterns are discernible. Among the Miwok and the peoples south of them, village ownership was usually based on clan arrangements, whereas in northern California land ownership was based more on territorial principles than on kinship ties. Bilateral or nonlineal descent organization usually occurred where village land ownership was not clan based, as in the case of the southeastern desert-dwelling peoples, although exceptions to this occurred in the far northern part of the state.

Kinship and status patterns. Marriage was almost always a matter arranged by the families because it created long-range economic and social bonds between families. Generally the families exchanged goods at the time of the marriage, the bulk of goods coming from the husband's family. In most cases the wife resided with the husband's family and was taught the ways of the husband's group by the mother-in-law. Levirate (widow marriage to the brother of the deceased) and sororate (widower marriage to the sister of the deceased) were widely observed, maintaining relationships between already connected families and stabilizing child-care conditions. Men could often have more than one wife; this was particularly true of chiefs and shamans (medicine men) because heavy social responsibilities were required of their offices and because political ties between groups could thereby be established.

The aged served as the teachers and advisers. Young adults were active in subsistence, and the elders prepared the children for adulthood. The aged made most of the decisions concerning legal disputes and economic crises.

Role of
the chief

The role of chief was generally an inherited position providing political stability to the group (though in northern California no formal chief appears to have existed). Women in some groups, such as the Pomo, were chosen as chiefs or "little chiefs." The chief was an economic administrator whose instructions to his people ranged from general admonitions to specific directions for particular tasks, such as indicating where food was available and how many people it would require to collect it. He redistributed the economic resources of his community and, through donations from village members, maintained resources from which emergency needs of individuals could be met. He was the major decision maker and the final authority in most villages, but he had the aid of a council consisting of such persons as heads of extended families, ritualists, assistant chiefs, and shamans. In some areas the chief functioned as a priest, maintaining the ceremonial house and ritual artifacts. The chief was generally a conspicuous person, wealthier, more elaborately dressed, and often displaying the symbols of his office. He was treated with great respect. Chiefs' families formed a superstratum of the community elites, especially in areas in which lineage development was present.

Shamans served not only as physical and mental healers and diviners but also as artists and poets. They defined and described the world of the sacred and regulated the fortune of souls before and after death, thereby serving as mediators between the profane and sacred worlds. Most tribelets in California had one or more shamans, usually men. Shamans were active in political life, working with other leaders and placing their powers at the disposal of the community.

Shamans
and
ritualists

Alongside chiefs and shamans in native California there were ritualists—dancers, singers, fire tenders—who were carefully trained in their crafts, and they functioned intimately within the political, economic, and religious spheres of their communities. They were men or women who acquired considerable respect and often wealth because of their skills and placement in the social structure. In effect, they were members of the power elite. When performing, ritualists were usually costumed in headdresses, dance skirts, wands, jewelry, and other items.

Socialization and education. Formal learning was a continuous process in native California life. Older persons instructed children through elaborate tales containing lessons concerning behaviour and values. Constant supervision—provided by adults, older siblings, or other relatives—instructed and reminded the child about how things should be done.

The dramatic time of the educational process occurred during rites of passage, when individuals attained new status and responsibility. The girls' puberty ceremony, for example, generally consisted of a time of isolation because the female was considered dangerous (or especially empowered) at menarche. During this time, which varied from several days to several weeks, an older woman would care for the girl and instruct her in her role as an adult. Ceremonies for boys' initiation were less common and, when carried out, were usually less formal, involving instruction in manly occupations and behaviour and prediction of the boys' future religious, economic, or political careers.

Rites of
passage

Sometimes education was quite institutionalized. Young Chumash men, for instance, purchased positions from guildlike associations of specialists in order to receive apprenticeship as professional artisans of some kind, while young Pomo men were charged a fee to be trained as apprentices by recognized professional craftsmen.

Leaders and specialists continued their training on a less formal level throughout their lifetimes. A man destined to become chief received his learning from others (such as ritualists and shamans) and continued to receive such instruction even after assumption of office.

Economic systems. *Settlement patterns.* In most of California the villages were occupied the year round, with small groups moving out only for short periods of time to hunt or collect food. In areas poor in economic resources, people moved more frequently, only temporarily gathering together in large groups for such activities as antelope drives and piñon-nut harvests. Riverine and coastal peoples as a rule enjoyed more stable settlements than those living in the desert and foothills.

House types varied throughout California from permanent, carefully constructed houses occupied for a lifetime or more to the most temporary type of structure, such as a brush shelter, as dictated by circumstances. Types of houses ranged from wood-framed (northern California), earth-covered (various areas), semi-subterranean (Sacramento area), and brush (desert areas) to thatched palm (southern California). Communal and ceremonial houses were found throughout the region and were often large enough to hold several hundred people for rituals or festivals. Domestic houses ranged in size from five or six feet (almost two metres) in diameter to apartment-style houses in which several families lived together in adjoining units. Another common type of housing consisted of the sweat-houses, earth-covered permanent structures that were used by most Californians (the Colorado River groups and the northern Paiute, on the margins of California, were exceptions); sweating was usually a daily activity for men.

Housing

Patterns of production and technology. Food production in native California centred on hunting, fishing,

and collecting wild plant foods. Men usually hunted and fished while women collected plant foods and small game. Hunting and fishing equipment such as bows and arrows, throwing sticks, fishing gear, snares, and traps were made by men; women manufactured clothing, nets, baskets, pots, and other cooking utensils. Older people commonly made the productive equipment used in the harder labours of production by younger adults.

For coastal Californians, shellfish, deep-sea fish, surf fish, acorns, and game were the main subsistence staples; peoples in the riverine and lake areas relied on fish, acorns, tule, game, and waterfowl. Native groups of the foothills, valleys, and plains depended on acorns, tule, game, and fish; and those living in the desert regions sought piñon nuts, mesquite, and game (especially antelope and rabbit) and practiced some marginal agriculture.

There were also various special technological devices. The Chumash of southern coastal California made large seagoing plank canoes, which allowed them to hunt large sea mammals. Peoples living on the bays and lakes used tule balsas or rafts, while riverine groups had flat-bottom dugouts (canoes made by hollowing out large logs). Techniques of food preservation included drying, hermetic sealing, and leaching of some foods high in acid content. Milling and grinding equipment was common.

Property and exchange systems. Concepts of property tended to vary in degree rather than kind throughout California. Everywhere, property was owned by individuals, family groups, lineages, communities, or larger political groups such as clans. In general, socially defined groups (such as clans and villages) owned the land and protected it against infringement from other groups. Individuals, lineages, or extended families usually owned exclusive rights only to certain food-collecting, fishing, and hunting areas. Such resources as obsidian mines or areas where medicinal plants grew might be owned by either groups or individuals. Individual articles could be acquired by manufacture, inheritance, purchase, or gift.

Goods and foodstuffs were distributed through two main institutions—reciprocal exchange between kin and “trade fairs,” often ritualized. Both operated similarly in that they served as a redistribution and banking system for spoilable foodstuffs; a group with a surplus of foods, that is, would bring it to another group and exchange it for goods (such as shells), which could be used in the future to acquire foodstuffs in return.

There were professional traders in most California groups who travelled long distances among many ethnic nationalities. Goods from as far away as Arizona and New Mexico were exchanged by coastal peoples. Generally, shells from the coastal areas were valued and exchanged for products of the inland areas, such as obsidian or food. Medicines, manufactured goods such as baskets, and other objects were also commonly exchanged in these systems.

Religion. Throughout native California religious institutions were intensely and intimately associated with all other institutions—political, economic, social, and legal. In all the groups there were shamans, religious leaders who served as intermediaries between the supernatural world and the world of man. Priests and other ritualists were common in many groups.

Two religious systems—the Kuksu and the Toloache—were associated with social organizations into which initiates were formally indoctrinated. In the Kuksu religion common to northern California (as among the Pomo, Yuki, Maidu, Wintun), members “impersonated” spiritual beings and engaged in colourful and dramatic rituals requiring special costumes and equipment; these events usually were conducted in large public communal houses. Within the Toloache religion of southern California (as among the Luiseño and Diegueño), initiates performed while drinking a hallucinogenic decoction made of the plant *Datura meteloides*, which put them in a trance and provided them with supernatural knowledge about their future life and role as members of the sacred societies. In both religions special instruction was a significant factor in the recruitment of members into the ritual society. Members exercised considerable economic, political, and social influence.

Religions on the Colorado River differed slightly because they were not concerned with developing formal organizations and recruitment procedures. Individuals received religious information through dreams; and members recited long narrative texts, explaining the creation of the world, the travel of culture heroes, and the adventures of historic figures.

In the northwest there was another informally structured religious system. It was associated with rituals concerned with world renewal (as in the white-deerskin dance), in which privately owned myths were recited. One communal need served by these ceremonies was that of restructuring relationships in societies lacking the rigid social ordering found in many other native California groups. The display of costumes and valuable possessions (such as white deerskins or delicately chipped obsidian blades) reaffirmed social ranking, and the success of the ritual reaffirmed the orderly relationship of man to the supernatural.

The use of supernatural power to control events or transform reality was basic to every California group. Generally, magic was used in attempts to control the weather, increase the harvest of crops, and foretell the future. Magic was deemed not only the cause of sickness and death but also the principal means of curing many diseases. Magic was considered also as an agent to protect oneself, to punish wrongdoers, or to satisfy personal ends.

Arts and crafts. Oral literature was the art form for which native California was most renowned—especially esoteric and elaborate creation tales and epic poems. There were also songs with accompanying narratives, tales of victory, recollections of recent events or daily activities, and airs of love. Songs were usually short but could, in narrative form, last for days. Singing was accompanied by rattles, whistles, or drums.

Visual art forms ranged from decoration on items of daily use (such as baskets and tools) to elaborate rock paintings and rock engravings. California natives are generally most remembered for their exquisite basketwork, though pottery in the eastern desert was shaped and decorated handsomely. Costuming, particularly in relation to the Kuksu religion, involved the creation of elaborate head-dresses, skirts, feathered costumes, and so on, which were often symbolic of supernatural beings. Body painting was also popular.

Incising or pecking designs into rock was practiced in various parts of the area, and rock paintings were widespread. They were associated probably with individual and group rituals and hunting and gathering activities on the one hand and served as simple trail markers or indicators of food or water on the other.

MODERN DEVELOPMENTS

Contemporary native Californians are rural peoples residing mainly on reservations or rancherias. There is, however, a long-established pattern of individuals moving to urban areas to find work when necessary but considering their reservation or rancheria as “home,” as a place where they will be welcomed upon return. In this manner many native Californians may live away from their lands for the better part of a lifetime and yet come back at last to a way of life compatible with their cultural ideals and involving their family and friends. Many individuals come and go sporadically, depending upon economic conditions; some live only seasonally on the reservations. Native Californians move from depressed areas to towns, villages, and cities, however, not only to find employment but also to arrange for schooling for their children and to find the amenities of life that are often totally lacking in the more remote Indian lands.

In the late 20th century, as industries moved into some rural areas, the nearby reservations became more attractive, offering some prospects of local employment. In many areas, the permanent populations of reservations were expanding, particularly with more young people with children. In other more remote rural areas, the economic situation remained bleak.

Since the United States government withdrew most federal responsibility for native Californians in 1955, reservations have become relatively autonomous. Each reserva-

tion or rancheria has an elected body of officials, known variously as a business committee or tribal council, which acts as a liaison between the people and such outside interests as the U.S. Bureau of Indian Affairs, business corporations desiring the purchase or lease of reservation lands, public utilities concerned with seeking rights-of-way across lands, and individuals having some form of business with the group. The council acts with the advice and consent of the people in dispersing tribally owned assets such as the lands or funds, and it also acts as the receiving agent for grants from various economic-development or relief organizations of the government. It is often involved in litigation with the government or other agencies concerning tribal grievances, and today it almost invariably participates directly in planning economic and social development programs for the future protection of the group's assets.

Generally speaking, native Californians have adopted much of the ways of contemporary society. In clothing, housing, transportation, education, and often religion, they are not significantly distinguishable from other people residing in California. In more subtle ways, however, native culture, attitudes, ritual, and psychology are still viable throughout the state from north to south. Wherever there are native populations, one finds ceremonial houses, ritual, and the continued use and manufacture of ritual materials, as well as occasional use of native foods. Many arts and crafts, especially basket weaving, have been maintained. The Indian languages, though spoken less and less as first languages, are being maintained and revived for cultural and nostalgic reasons. On some reservations there are cultural centres and museums helping to preserve the culture and languages, and on other reservations and in some local school districts classes in native languages and culture are being offered to both children and adults. Various organizations of native Californians, such as the American Indian Historical Society and the California Indian Education Association, are aggressively examining, criticizing, and providing new teaching materials for schoolteachers who deal with native Californians in the classrooms.

On the other hand, few if any traces of traditional cultures remain in some areas of California. These areas generally coincide with what have become the major population centres of California, from San Francisco and Oakland south to San Diego. A new form of native American cultural development is under way, however, as Indians from all over the United States, not only from rural California but also from reservations in the central great plains of the United States and the Southwest, gravitate to these major urban areas, bringing with them diverse tribal and cultural backgrounds that add up to a new measure of cultural diversity in urban life. Many of these people came in large numbers during World War II, often to work in defense industries, while others came in large numbers after the war as part of the aggressive planning and development of the Bureau of Indian Affairs in the 1950s. These moves led to serious problems among some of the relocatees because Bureau of Indian Affairs coordination was ineptly carried out, with the result that many native American groups have had to develop their own self-help organizations to care for their people in the cities. A pattern of replicating the institutions of the cultural groups they came from is apparent throughout the state. Recreational groups as well as educational and political groups have developed generally along lines of cultural similarity.

(Lo.J.B.)

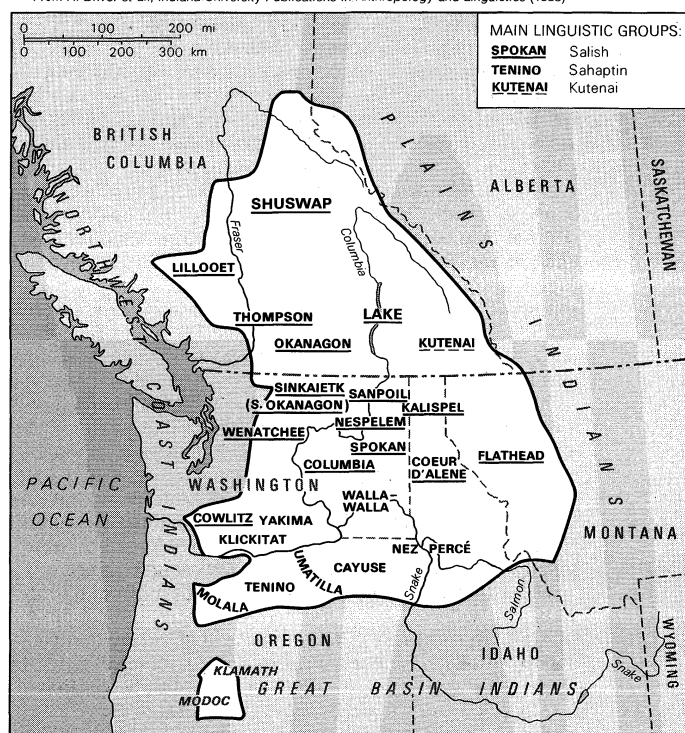

North American Plateau Indians

The North American Plateau is both a complex physiographic unit and a native cultural area. It is bounded on the west by the Canadian Coast Mountains and the Cascade Range, on the south by the Blue Mountains and the Salmon River (excepting a narrow corridor to California), on the east by the Rocky Mountains and the Lewis Range, and on the north by low extensions of the Rocky Mountains, such as the Cariboo Mountains. It may be defined as the drainage territory of the Columbia and Fraser

ivers and as the high plateau between the main range of the Rocky Mountains and the coastal mountain system. In the south the natural area of the Plateau gradually merges with the Great Basin natural area: the boundaries between the corresponding culture areas are indeed also very imprecise. Previously, anthropologists included both culture areas as one, the Plateau.

The climate is a harsh, continental type. Temperatures range from -30°F (-34°C) in winter to 100°F (38°C) in summer. Precipitation is low, except in the mountainous areas, and forms a snow cover during the winter. There are three different provinces of vegetation, which correspond to three subcultures: the Middle Columbia area, a steppe of sagebrush and bunchgrass fringed by yellow pine on higher levels, is the territory of the Sahaptin groups and some Salish; the Upper Columbia area, a mainly wooded area with grassland in river valleys, is the home country of such Salish groups as the Okanagon and Flathead, and of the Kutenai; and the Fraser area, with a semi-open coniferous forest interspersed with dry grassland and a partly maritime flora, is the tribal ground of the northern Salish groups. The fauna is not rich, but there are deer and elk in the mountains and salmon and trout in the rivers.

From H. Driver et al., *Indiana University Publications in Anthropology and Linguistics* (1953)

Distribution of North American Plateau Indians.

The Indians of the Plateau belong mainly to four linguistic families: Salish, Kutenai, Sahaptin, and Klamath-Modoc (Lutuami). The majority of Plateau groups speak Salishan and Sahaptian. The Salish may be conveniently divided into Northern Plateau and Interior Salish (there are also Coast Salish on the Northwest Coast). To the Northern Plateau group belong the Shuswap, Lillooet, and Thompson (Ntlakyapamuk) Indians; to the Interior group belong (mostly in the Upper Columbia area) the Okanagon (with Sinkaietk), the Lake (Senijextee), the Wenatchee, Sanpoil and Nespelem, the Spokane, Kalispel (with Pend d'Oreille), Coeur d'Alene, and Flathead. Some early works term all Salish "Flathead." The Sahaptin may be subdivided into three main groups: the Nez Percé, the Cayuse-Molala, and the Central Sahaptin (Umatilla, Yakima, Wallawalla, Tenino, and others).

TRADITIONAL CULTURE PATTERNS

The main characteristics of the Plateau cultures are best discernible against a historical background, for the Plateau cultural pattern was not stable. Opinion is divided as to

Classic
Plateau
Culture

whether its origins lay with the "desert culture" of arid Western North America, a primitive, seed-gathering culture, or with the "old Cordilleran culture" of the Plateau and North Pacific Coast, a culture with hunting, fishing, and gathering activities. It is certain, however, that the latter subsistence pattern predominated after 1500–1000 BC. By AD 1200–1300 the "classic" Plateau culture, characterized by permanent winter villages with semi-subterranean earth lodges along the main rivers and by summer camps with mat-covered conical lodges on the meadows, had emerged. There is evidence that the Plateau culture expanded as far south as the Snake River, including for some time Shoshoni groups in Idaho. During the centuries that followed, the Plateau area was influenced by cultural elements from the highly specialized Northwest Coast culture. Thus, mat and plank houses, carving in wood and bone with animal motifs, and cremation and scaffold burial appeared. Part of this diffusion was possibly brought about by a Chinook group, the Wishram, who migrated from the coast into the Cascade Mountains.

During the 18th century there were influences from the east. The Shoshoni had acquired horses by this time and furnished their closest neighbours on the Plains and the Plateau with horses. White traders, from the beginning of the 19th century, testified that tribes such as the Nez Percé, Cayuse, Wallawalla, and Flathead had more horses than the tribes of the northern Plains.

Other elements of Plains culture came with the horse, particularly in the Middle Columbia area. Sahaptin Indians, for example, soon appeared in Plains beaded dresses and warbonnets and started to use tipis. Similar innovations occurred on the eastern periphery, in particular among the Flathead and the Kutenai. The northwestern Salishan groups, however, retained their original Plateau culture. Due to pressure from the Blackfoot, the Flathead and Kutenai had to withdraw from their home quarters on the plains of western Montana about 1800. They resettled in the intermontane valleys of the Rockies and from there made occasional buffalo hunts on the Plains in the company of other Plateau tribes, such as the Coeur d'Alene and Nez Percé.

The kind of military ethos found among the Plains Indians was not found uniformly among the Plateau Indians. The Thompson and Shuswap groups, and also the Sahaptin and Klamath further south, did make occasional war raids, dressed in elk hide or wooden slat armour and armed with bows and clubs. Other groups remained peaceful; the Flatheads, in particular, were well regarded by white settlers for courtesy, hospitality, honesty, and courage.

Social structures. Before the introduction of Plains culture, the village always formed the sociopolitical unit. The Thompson Indians, for example, had informal village meetings for decision making, and in matters of general interest the consent of all the villagers had to be obtained. The Sanpoil, on the other hand, had a more formal political structure: the village had a chief, a subchief, and a general assembly in which every adult had a vote (except for young men who were not married). The Nez Percé had a similar organization until the buffalo hunts on the Plains started. Each village had a chief whose office was hereditary, except in the case of poorly qualified sons. Sometimes groups from several villages came together at certain fishing sites or camas (edible lily) meadows, and on these occasions the leading men of the villages constituted an informal council. Early in the 19th century this organization was overruled when families from different villages joined to form bands for the autumn hunts on the Plains. The authority of the village chiefs lapsed as good hunters and fighters became band chiefs. As a result of pressure from missionary and governmental agencies, a tribal head chief was appointed in the 1840s, but he was unable to win any influence over the people. A truly tribal political organization existed among the Flathead, who had a head chief of great power and band chiefs under him. The head chief decided on matters of peace and war and was not bound by the recommendations of his council.

In many Plateau societies chiefs played a more prominent role than in Plains Indian culture, and they were also to a greater extent hereditary. But, although Sahaptin

chiefs could exert their authority through whipping (perhaps a Spanish trait), social control was as a rule achieved through social pressure and public opinion. Nobody was coerced into following the advice of a chief or the decisions of a council meeting, and those who did not want to conform could move to another village or another band.

The simple, bilateral-descent system prevailed in typical Plateau groups. The average Plateau kin group consisted of the nuclear family and the closest relatives on the father's as well as the mother's side. This is the case among, for instance, the Tenino. Their kinship terminology reveals the close connection between family relatives of the same generation on both paternal and maternal sides, so that all female cousins are called by the same terms as those used for sisters. Marriages do not occur among first cousins (in distinction to the custom in clan-organized societies), and newly wedded couples may put up their residence with the father's or the mother's group. The Tenino also show a patterned kinship behaviour that has possibly existed in other Plateau groups, such as a "joking relationship" between a father's sister's husband and his wife's brother's child, and permitted sexual license between a man and his sister-in-law. All over the Plateau, marriages between one man and several wives (polygyny) were practiced, although they were not common.

It has been observed that kin term distinctions and ranked status distinctions tend to counteract each other: the Coast Salish have a ranked society with reduction of kinship terminology, whereas the majority of Plateau Salish have prevalence of descriptive kin terms and few status distinctions. Among the Sinkaietk or Southern Okanagon, chiefs were hereditary and the most important persons in the tribe in regard to moral influence, for the chief and his family were supposed to exemplify the virtues of the group. He was, on the other hand, not necessarily the wealthiest man in his group, although he was economically supported by his people. The chief had a female relative among his advisers. Such highly respected women also existed in other groups, such as the Coeur d'Alene, and bear witness of the independence of women in Plateau society (excepting the Plains-influenced Kutenai and Flathead). Although marked off as hereditary in his office, the Plateau chief did not separate himself from his group. The general spirit was one of equality and personal autonomy, particularly among the Interior Salish. The Northern Plateau Salish, however, and several other groups kept slaves, as did the Indians on the Northwest Coast, and traded them between each other. The tribes on the eastern fringe who shared the Plains values had a rank of honoured warriors and war chiefs.

The life cycle of the individual was marked by fixed ritual acts that opened the gateway to the different social roles he had to enact. One could say that it started before birth. Among the Sinkaietk, for example, a pregnant woman was not supposed to give birth to her child in her regular home but in a menstrual lodge or another separate lodge. The newborn baby spent its day strapped in a cradle of the flat board type. At the age of one the child was ceremonially conferred a name from the wealth of names in the family. The training of the child was left to the mother and grandmother, but even as a small boy a Sinkaietk could accompany his father on fishing and small-game hunting trips, while the little girls helped their mothers about the house and gathered roots in the fields. Grandparents saw to it that the child was hardened by such practices as bathing in cold streams. Disobedience was rare but could sometimes result in the child being whipped.

At puberty the boy was sent out to spend some days fasting on a mountain top and probably to receive a blessing vision from some spirit. Upon returning to the community, he took his place among the adult men. The girl who had her first menstruation was secluded in a menstrual lodge some distance from the village. Her hair was bound up in rolls, and she was only allowed to touch it with a small comb. Her face was painted red or yellow, and she wore undecorated clothing. She was not allowed to drink directly from a well but had to use a drinking tube, and she cleansed herself after the flow in a sweathouse. After a time—one or several months—she finished her seclusion

Kinship
patterns

Puberty
rites

with prayers in the evening on a hill. Then she returned to the village, a full-grown woman.

Marriage was an entirely informal affair, as was divorce; a woman who was tired of her husband or had been expelled by him returned to her parents if they were alive. She could then remarry if she wished.

Two forms of burial predominated in the Plateau area, pit burials and rockslide burials. The pit burials took place in sand or gravel near the river banks and were often marked with piles of boulders. The rockslide burials were also located close to the river flats, with a cedar stake as a marker. Some cremation burials occurred in the Yakima Valley and at The Dalles and also in the Lillooet-Thompson area. The bereaved had to observe certain taboos, and a widow was supposed to dress poorly and wail at the grave, sometimes for as long a period as a year. There are reports that the house where the death occurred was torn down so that the dead person would not reappear there.

Economic life. The Plateau villages were generally located on waterways and particularly at rapids and other places where fish were abundant during the winter season. Each village had an upland for hunting; in contradistinction to the fishing localities, these uplands were mostly open for people from other villages as well. There were also permanent or semipermanent summer camps for hunting and root gathering in mountain valleys. River villages were permanent winter quarters and could at least temporarily lodge several hundred people. A Kalispel village, for example, numbered 300–400 and a Yakima village as many as 2,000.

Winter dwellings were of two main types, the semi-subterranean earth lodge and the mat-covered surface house. The latter was apparently more recent and existed only in the southern Plateau, where it had replaced an older earth lodge. It was replaced in its turn by the Plains Indian tepee. The average earth lodge was circular, with a pit 4–6 feet (1–2 metres) deep and a diameter of 10–40 feet (3–12 metres). The roof was conical or flat and was supported by leaning poles fastened to some central posts. The smoke hole in the top was also the entrance, the floor being reached by an inside ladder or notched log. The other type of dwelling was formed of two walls of varying length leaning together and covered with tule mats. It was a “longhouse” with a series of hearths in the middle, each one of them shared by two families, one on each side. During the summer people housed in conical mat lodges of small size or in simple windbreaks.

Food-gathering techniques

Fishing was the most important source of food. The Plateau Indians used one- or three-pronged fish spears, traps, and nets when taking their staple fish—eels, suckers, trout, and especially salmon. Large quantities of fish were dried on elevated wooden racks or kept in storage pits and preserved for winter consumption. Roots were dug with digging sticks provided with cross handles of antler or wood. The main root was the camas bulb (*Camassia esculenta*), but bitterroot, onions, wild carrots, and parsnips were also gathered. They were then cooked in earth ovens heated by hot stones. Berries—serviceberries, huckleberries, blueberries—were harvested as well. Hunting occasionally played an important role, even in the winter. Equipped with bow and arrows and perhaps a short spear, the Indian hunted deer first of all but also bear and caribou. In the winter he wore long and narrow snowshoes to track animals; in the summer he could use a canoe—a dugout in the southern Plateau, a dugout or a bark canoe in the northern Plateau.

In historical times all Plateau peoples used tailored skin garments of the type well-known from the Plains. In prehistoric days both sexes wore a bark breechclout or apron and a twined bark poncho falling a little below the waist. During the cold season men wrapped their legs with fur, and women had leggings of hemp. Rabbit-fur robes or other skin robes were worn in winter. Sahaptin women had twined basket hats, whereas men everywhere had headbands; caps of fur and feathered headdresses appeared with the Plains influences. Both sexes braided their hair. The Chinook practiced flattening of the infant's head as sign of free birth. Curiously, the Flathead never shared this custom.

The village community owned the land, in particular the fishing sites. Household tools, weapons, traps and snares, and similar items were the property of individuals, except for larger weirs that were communal property. Food resources were in most places distributed according to needs. A more restricted system prevailed on the northern Plateau, where gift-giving ceremonies occurred, reminiscent of the potlatches of the Northwest Coast Indians: after some days of games and contests, gifts were distributed to the guests, who in their turn reciprocally handed over presents to their hosts. Although possessions were valued in many parts of the Plateau, the Klamath paid greater attention to them than any other group and held wealthy persons in great esteem. This value orientation, most probably derived from the Northwest Coast, contrasted with the general Plateau pattern of equality and sharing of necessities.

Belief and aesthetic systems. Religion was, like the rest of the culture, closely intertwined with Plateau ecology. In many ways religious beliefs echoed North American religions in general: there was a “great spirit,” among the Okanagon conceived of as a bearded white man, and there were spirits of the atmosphere (winds, thunder, etc.) and a host of zoomorphic lesser spirits serving as personal guardian spirits.

The main rituals were the guardian-spirit quest, the firstling rites, and the winter dance. The guardian-spirit quest was compulsory for boys and recommended for girls and was usually performed in connection with the puberty ceremony. The spirits who granted their blessings in lonely places were very specialized. Some made their clients into hunters, others into warriors or medicine men (shamans). Both boys and girls, but preferably the former, could become medicine men. Medicine men were much feared and sometimes very wealthy. They cured diseases by extracting the bad spirit that had entered the patient's body, and on the Northern Plateau they brought back souls that had been stolen by the dead, describing their feats in a dramatic pantomime.

Religious rituals

The firstling rites concentrated on the first salmon or berries (roots, fruits) that had been caught or gathered during the summer season. The first salmon ceremony celebrated the arrival of the salmon run with the ritual cutting and eating of the first fish and the ritual throwing of the bones back into the water, in this way ensuring a good return next year. Some Salish had a “salmon chief” who surveyed the rituals. The Okanagon, Thompson, and Lillooet had similar rites for the first berries, which were eaten ceremonially, whereas they lacked the salmon ritual.

The winter or spirit dance, finally, was a ceremonial meeting at which participants personified their respective guardian spirits. The dramatic performances and the songs were, among the Nez Percé, thought to bring warm weather, plentiful game, and successful hunts.

Plateau mythology and folklore revolved around the culture hero and transformer, mostly the Coyote but in some places the Bluejay or another mythical personage. He is a beloved character in the stories, creator and trickster at the same time. The Coyote cycle is well-known from adjacent areas as well.

There is nothing distinctive about Plateau art. On the contrary, most art historians divide it into a western branch, peripheral to the Northwest Coast, and an eastern branch, peripheral to the Plains. Plastic art is on the whole very rare, except in the vicinity of the Northwest Coast. Decorative art consisted of pictographic designs with a symbolic content, referring to supernatural beings and cosmic things. The same division between east and west characterizes musical styles.

MODERN DEVELOPMENTS

The preceding description of traditional Plateau culture demonstrates that the culture was neither static nor unitary but changed with time and place. The most dynamic development was introduced when the first impulses from white civilization penetrated the area: the coming of the horse in the beginning of the 18th century, the appearance of epidemics from 1780 onward, and the arrival of eschatological ideas, adapted in the Prophet Dance from

perhaps the same time. The latter, which was the origin of the famous Ghost Dance, was a mixture of aboriginal and Christian elements: by dancing like the dead in the other world the Indians thought they could hasten the renewal of the world and the return of the dead. The Prophet Dance seems to have been a reaction against the increasing disruption of traditional culture through the new influences.

Early in the 19th century the fur trade brought Indian and white trappers from the east into the country, particularly to the northern Plateau. Roman Catholic Iroquois trappers propagated Christian ideas among the Flathead, who thereafter visited St. Louis to call on missionaries. The great invasion of white settlers and gold seekers in the 1850s and 1860s and the ensuing Indian wars (of which the Nez Percé War of 1877 is the most famous) resulted in the reduction of Indian territories, the creation of a series of small reservations, and the isolation and deprivation of the Indians in "white" surroundings.

In the 20th century, the blending of aboriginal and white cultures accelerated continuously and produced a variety of mixed cultures on the reservations, some more conservative, others more Europeanized. The Kutenai, for instance, have turned into ranchers or ranch hands during the warm season but use their fishing traps during the winter, a seasonal pattern that in a way conforms with the old culture. The Nez Percé, on the other hand, have at least partly become farmers. Their cultural assimilation has been furthered by political and religious factionalism. Summarily, it may be said that the Plateau Indians have retained their group feelings, part of their old economics, and in places much of their religion, whereas technology and material culture have long been characteristic of white poverty levels.

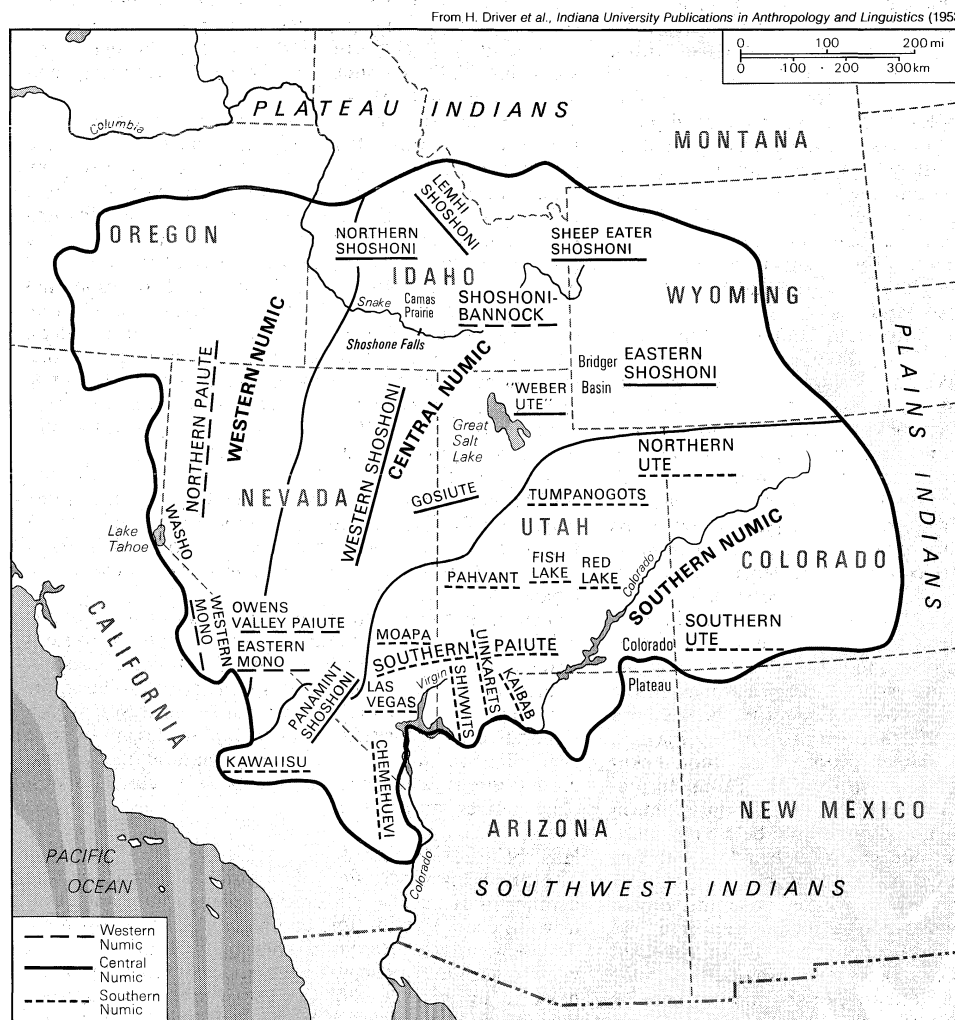

(A.G.B.H.)

North American Great Basin Indians

The Great Basin Indians in aboriginal times occupied a 398,000-square-mile (1,031,000-square-kilometre) area of interior western North America. Aboriginal population density was sparse, ranging from 0.8 to 11.7 persons per 100 square miles. The area includes the physiographic Great Basin—the interior mountain and basin region of present-day southeastern California, Nevada, southeastern Oregon, and western Utah—and the Snake River Plain of Idaho, the mountains to the northeast, the Bridger Basin of southwestern Wyoming, the Colorado Plateau area of Utah and Colorado, and the mountains of central and southern Colorado. The entire region is arid to semi-arid, annual average precipitation being four inches in the lowlands to 20–25 inches in the mountains. The precipitation falls primarily in the form of winter snow. Ecologically, the area is characterized by a vertical succession of life zones, each with a dominant xerophytic (desert-type) flora and related fauna.

The languages spoken by the Indians are of two widely divergent language families. The Washo, whose territory centred on Lake Tahoe, speak a Hokan language related to languages spoken in parts of California, Arizona, and Baja California. The remainder of the Great Basin culture area was occupied by speakers of Numic languages. Numic, formerly called Plateau Shoshonean, is a division of the Uto-Aztecan language family, a group of related languages widely distributed in the western United States and Mexico. Linguists distinguish three Numic branches, Western, Central, and Southern, each branch having a pair of languages. Western Numic languages are Mono, spoken by the Eastern Mono and Owens Valley Paiute of California, and Northern Paiute, spoken by the several

Peoples
and
languages

Distribution of Numic languages and major groups of Great Basin area Indians.

Northern Paiute groups of northeastern California, western Nevada (Paviotso), and southern Oregon and by the Bannock of southern Idaho. Central Numic languages are Panamint, spoken by the Koso, or Panamint Shoshoni, near Death Valley, California; and Shoshone, spoken by the Western Shoshoni of Nevada, the Gosiute of western Utah, the now extinct "Weber Ute" of northern Utah, the Northern Shoshoni of Idaho, the Lemhi and Sheep Eater (Tukuarika) Shoshoni of the northeastern Idaho mountains, the Eastern (or Wind River) Shoshoni of western Wyoming, and the Comanche of the southern Plains. The Comanche separated from the Eastern Shoshoni in late prehistoric times, moved southward through the Rocky Mountains, and became Plains Indians culturally.

Southern Numic languages are Kawaiisu, spoken by the Kawaiisu band of southern California, and Ute, spoken by the several Southern Paiute bands, including the Chemehuevi of southeastern California and the Las Vegas, Moapa, Kaibab, Shivwits, and Uinkarets bands of southern Nevada, southern Utah, and northern Arizona. Ute is also spoken by the several Ute bands, the Fish Lake, Red Lake, Pahvant, and Tumpanogots of central Utah, the various Northern Ute bands of eastern Utah and the several Southern Ute bands of southern Colorado. The distinction between Southern Paiute and Ute is cultural rather than linguistic: Ute speakers who had horses in the early historic period are regarded as Ute; those without horses were Southern Paiute. The Numic peoples called themselves "Numa" or "Numu," meaning "people" or "human beings." The Washo called themselves "Washoe," meaning "Washo people" as distinguished from people of other tribes.

Linguistic and archaeological evidence indicates that the Washo had long been separated from other California Hokan-speaking groups, possibly for several millennia. Similar evidence indicates that the Numic-speaking peoples spread across the Great Basin from southeastern California sometime after the year 1000.

TRADITIONAL CULTURE PATTERNS

Social and cultural patterns. Great Basin Indians of the early historic period (1800–50) were divided into horse-using and non-horse-using groups. Horse-using groups generally occupied the northern and eastern sections of the Great Basin culture area. The Southern Ute and Eastern Shoshoni were among the first Indians north of the Spanish settlements of New Mexico to obtain horses, perhaps as early as 1680. There is some evidence that these bands acted as middlemen in the transmission of horses and horse culture from New Mexico to the northern Plains in the 1700s. As the Northern Shoshoni of Idaho obtained horses in the 18th century, they were joined by Northern Paiute speakers from eastern Oregon and northern Nevada to form the Shoshoni-Bannock bands of historic times. By 1800, the Southern and Northern Ute, the Ute of central Utah, the Eastern Shoshoni, the Lemhi Shoshoni, and the Shoshoni-Bannock were well equipped with horses, lived in skin tipis, and were oriented toward the Great Plains, the pursuit of bison, and warfare with other tribes. To the south and west in the Great Basin proper and on the western Colorado Plateau, the people did not take up the use of horses until 1850–60. The Washo did not use horses prior to white settlement, and rarely used them thereafter.

The basic Great Basin social and cultural patterns were those of the nonhorse bands. The people were closely adapted to their arid environment. Small family bands moved through an annual cycle, exploiting available food resources in the various ecological zones of a particular valley and adjacent mountains. The exigencies of the food quest structured Great Basin society and culture. Food supplies were seldom adequate to permit groups of any size to remain together for more than a few days. Consequently, social organization was fluid and atomistic. For most of the year the people lived in small local groups, coming together into larger aggregates only for certain brief periods—during rabbit drives or when fish were spawning, as the Washo did at Lake Tahoe in the spring, or during the piñon nut season in the autumn. But despite periodic gatherings, there was no sustained sense of political cohe-

sion or "tribalness," as that term is understood for other American Indian groups.

The same fluidity of social organization was characteristic of the horse-using bands. Possession of horses permitted larger numbers of people to remain together for much of the year, but such aggregation did not lead to the development of formal tribal organizations. Among both horse- and non-horse-using groups, a particular leader was followed as long as he was successful in leading people to food, or in war. If he failed, people would leave to join other bands, or to form their own bands.

Kinship, marriage, and rites. The basic local social unit usually was one or more "kin cliques," consisting of a nuclear family (parents and their dependent children) or two brothers and their families, in addition to assorted other individuals related by blood or by marriage to someone in the core group.

Kin ties were reckoned bilaterally through both the mother's and the father's sides and were widely extended to distant relatives. Such extension permitted people to invoke kin ties and move from one group to another if circumstances warranted.

Marriage practices varied, with a tendency among some groups to marry true cross-cousins (mother's brother's or father's sister's child), or pseudo cross-cousins (mother's brother's or father's sister's stepchild). Both the sororate (compulsory marriage of a man to his dead wife's sister) and the levirate (compulsory marriage of a widow to her dead husband's brother), were practiced, as were their logical extensions, sororal polygyny and fraternal polyandry. Usually the latter was not formalized, consisting only of a man extending sex privileges with his wife to a brother for a time. Marriages were brittle and divorce frequent. Yet to survive, it was necessary to be married, as most men and women were throughout their adult lives. There was no set pattern of postmarital residence. A newly married couple might live with the bride's family for the first few years until children were born, but the availability of food supplies was the determining residence factor.

Children began to learn about and participate in the food quest as soon as they were old enough. There was little emphasis on puberty rites except among the Washo, who held a special dance and put a girl through various tests at the time of menarche.

Death rites were minimal. An individual was buried with his possessions or they were destroyed. The Washo abandoned or burned a dwelling in which a death occurred. Occasionally, old people who could not keep up with the group or who could no longer produce their share of the food supply were abandoned.

Technology and economy. The Numic people and the Washo built two types of shelters; semicircular brush windbreaks in the summers, and domed brush, bark-slab, grass, or reed-mat dwellings in the winter. The horse-using groups used Plains-style tipis but sometimes built grass or brush houses. Winter villages were sited along the edge of valley floors, near water, food caches, and firewood. Summer encampments were near food areas and were shifted as necessary. Horse-using groups camped along wooded stream bottoms near firewood and forage areas for their horses.

Tools were simple and portable: the bow and arrow, stone knife, rabbit stick, digging stick, several types of baskets and nets, and flat seed-grinding slab and handstone. Some Western Shoshoni and Southern Paiute groups made a coarse brown-ware pottery; some Northern Shoshoni made steatite jars and cups. In fishing areas, lines and hooks, harpoons, nets, and willow fish weirs were used. The Northern Paiute used duck decoys made of tule reeds covered with duck skins. Rodents were taken with snares and traps or pulled from burrows with long, hooked sticks. Rabbits were driven into nets and clubbed, or they were shot with bow and arrows. Antelope were driven into corrals and traps. Waterfowl were netted, trapped, or shot with bunt arrows (arrows with rounded heads, intended simply to stun). Deer, elk, and mountain sheep were taken by individual hunters with bow and arrows.

The people followed an annual round, exploiting plant and animal resources as they became available in the

Basic social
organiza-
tion

Tools
and food-
gathering

several ecological zones. Well over 70 percent of the food supply was vegetal. Over 200 species of plants were named and used, principally seed and root plants. Piñon pine groves were found in upland areas of Nevada and central Utah, and large quantities of piñon nuts were collected in the autumn and cached for winter use. Rabbit drives were also held in the autumn. The drives provided an occasion for larger numbers of people to come together for gambling, dancing, and courting. Winter was spent in small villages, living on cached foods and such game as might be taken. Early spring was a poor time; stored resources were often exhausted, and the people were forced to seek early greens and roots for food. Late spring and summer were devoted to collecting seeds, roots, insects, fishing where possible, and continued hunting.

Some Southern Paiute bands practiced limited horticulture along the Colorado and Virgin rivers. Some bands of Mono and Northern Paiute reportedly irrigated patches of wild seed plants to increase the yield.

The horse-using groups also followed an annual round but ranged over a much larger area. In some years, they ventured onto the Northern Plains for bison in the autumn, returning to the Bridger Basin, the Snake River area, or the Colorado Mountains for the winter. In the spring and summer, Shoshoni and Shoshoni-Bannock obtained roots from the Camas Prairie in Idaho and salmon from the Snake River, below Shoshone Falls. Deer, elk, and mountain sheep were taken when possible. Seed and root foods were collected as they became available.

Clothing consisted of sage bark aprons and breechclouts and rabbit-skin robes in the winter. The horse-using peoples wore Plains-style, tailored skin garments. Artwork was largely confined to basketry decoration. Among the horse-using bands, quill and beadwork decorated clothing and rawhide shields, and bags and containers were painted.

Trade was minimal among western Great Basin groups, although there is some evidence of the use of strings of shells as a medium of exchange in aboriginal times. Horse-using groups were more active, trading among themselves and with other tribes. The Eastern Shoshoni and some Ute bands participated in the fur trade between 1810 and 1840. Between about 1800 and 1850, mounted Ute and Navaho bands preyed on Southern Paiute, Western Shoshoni, and Gosiute bands for slaves, capturing and sometimes trading women and children to be sold in the Spanish settlements of New Mexico and southern California.

Religious concepts. Religious concepts derived from a mythical cosmogony, beliefs in "power" beings, and a belief in a dualistic soul. Mythology provided a cosmogony and cosmography of the world. Mythical animals, notably wolf, coyote, rabbit, bear, and mountain lion, were believed to be the progenitors of the modern animals. They lived prior to Indian life but were anthropomorphic, speaking and acting as people do in the present world. They created the world and were responsible for present-day topography, ecology, food resources, seasons of the year, and the distribution of Indian tribes. They set the nature of social relations—that is, defined how various classes of kinsmen should behave toward each other—and set the customs surrounding birth, marriage, puberty and death. Their actions in the mythic realm set moral and ethical precepts and determined the physical and behavioral characteristics of the modern animals. Most of the motifs and tale plots of Great Basin mythology are found widely throughout North America.

Power beings were animals, birds, or natural phenomena, each attributed with a specific natural power according to an observed characteristic. Some such beings were thought to be benevolent, or at least neutral, toward men. Others, such as Water Babies—small, long-haired creatures who lured men to their deaths in springs or lakes and who ate children—were malevolent and feared. There were conceptions of various other vague beings, such as the Southern Paiute *unupits*, mischievous spirits who caused illness.

Shamans, or curers, were prominent in all Great Basin groups. Both men and women might become shamans. Shamans received their powers to cure disease, foretell the future, and, sometimes, to practice sorcery from a power being who came unsought to a prospective shaman. It

was considered dangerous to resist being given a shaman's power, for those who did sometimes died. The being became a tutelary spirit, instructing an individual in curing and sources of power. Some shamans had several tutelary spirits, each providing instruction for specific types of treatment. Among Northern Paiute and Washo and probably elsewhere, a man who had received power apprenticed himself to an older, practicing shaman and from him learned rituals, cures, and feats of legerdemain associated with curing performances. Curing ceremonies were performed with family members and others present and might last several days. The widespread American Indian practice of sucking an object said to cause the disease from the patient's body was often employed. Shamans who lost too many patients were sometimes killed.

In the western Basin, some men had powers to charm antelope and led communal antelope drives. Beliefs that some men were arrow-proof (and after the introduction of guns, bulletproof) are reported for the Northern Paiute and Gosiute but were probably general throughout the area.

Among the Eastern Shoshoni, young men sought power beings through a visionary experience. The active seeking of power beings through visions is a practice the Eastern Shoshoni probably learned from their Plains neighbours, although the characteristics of the beings sought were those common to Great Basin beliefs.

There was a concept of soul-dualism among most, if not all, Numic groups. One soul, or soul aspect, represented vitality or life; the other was the individual as he was in a dream or vision state. During dreams or visions, the latter soul left the body and moved in the spirit realm. At death, both souls left the body.

MODERN DEVELOPMENTS

Contact with white civilization drastically altered Great Basin societies and cultures. The Southern Ute were in sustained contact with the Spanish in New Mexico as early as the 1600s, but other Great Basin groups had no direct or continued contact with whites until after 1800. The fur trade, between 1810 and 1840, brought new tools and implements to the eastern bands. Settlement began in the 1840s, as did the surge of emigrants through the area on their way to Oregon and California. Mining, ranching, and farming activities destroyed or closed off traditional Indian food-gathering areas. Piñon groves were cut for firewood, fence posts, and mining timbers. The Indians attempted to resist white encroachment. Mounted bands of Ute, Shoshoni, Shoshoni-Bannock, and Northern Paiute preyed on ranches and wagon trains and tried to drive the intruders away. The struggle culminated in several local "wars" and "massacres" in the 1850s and 1860s. After 1870, Indians were forced onto reservations or into small groups on the edges of white settlements, thus reducing their land base to a small fraction of its former size. This forced the abandonment of aboriginal subsistence patterns in favour of limited agriculture or stock raising, where possible, and wage work, especially as farm and ranch hands.

In 1870 and again in 1890, so-called Ghost Dance movements started among the Northern Paiute of western Nevada. The dances were millenarian in character. Prophets foretold that if the Indians danced and prayed, the whites would go away and the "old days" would be restored. The 1870 dance, led by a man named Wodziwob, centred in Nevada and California. The 1890 dance, led by Wovoka, or Jack Wilson, of Smith Valley, Nevada, spread to many Indian tribes in the western United States.

A Peyote Cult was introduced to the Ute and Eastern Shoshoni in the early 1900s by Oklahoma Indians. It later spread to other Great Basin peoples. Most peyote groups became members of the Native American Church, a nationally recognized organization. Great Basin peyote rituals are a mixture of aboriginal and Christian elements. Ceremonies are led by "road chiefs"; that is, those who lead believers down the Peyote Road or Way. A ceremony, which lasts all night, includes singing, praying, and eating peyote buttons or drinking a concoction made therefrom, producing a mild hallucinogenic experience. The tenets of the Native American Church stress moral and ethical precepts and behaviour.

In postreservation times, the Eastern Shoshoni and Ute adopted the sun dance from the Plains Indians. The four-day dance is performed yearly to achieve health and valour for the participants, and partly as a tourist attraction.

The Indian Reorganization Act of 1934 led to the establishment of local elected "tribal councils" for the various reservations and colonies. Councils have sought to develop various economic activities including ranching, light industry, and tourism.

Indian children were sent to federal day schools and boarding schools beginning in the 1880s. These federal schools were phased out and Indian children began to attend local schools and universities.

Great Basin Indian peoples have retained some of their traditional culture in crafts, dances, and visiting patterns. Older people speak the native languages, but many of the younger people have neither learned nor used them. Many people remain on the reservations, but others have moved to towns and cities.

(D.D.F./C.S.F.)

Southwest American Indians

More than one-third of the rapidly growing population of American Indians live in the southwestern United States, mainly in or bordering Arizona and New Mexico. In this predominantly arid and climatically unstable region, located between the Rocky Mountains and the Mexican Sierra Madre, the Continental Divide separates the watersheds of two great river systems: the Colorado-Gila-San Juan, in the west, and the Rio Grande-Pecos, in the east.

From the viewpoint of human habitation, the region's main geographic features are the two river systems, cyclical droughts, and arid lands, some low and hot, others high and cold. The hot deserts have sparse and irregularly occurring rainfall. Their long growing season supports a great variety of plant and animal communities adapted to desert conditions—creosote, sage, tarbush, and numerous cactus species, as well as such small, nocturnal, burrowing animals as the kangaroo rat. Along the river flood plains grow cottonwood, willow, mesquite, and sycamore. Basin and range landscape, from about 1,000 to 4,000 feet (300 to 1,200 metres) in elevation, predominates.

Despite its low moisture content, coarse texture, and occasional salty patches, the soil of most of the Southwest is relatively fertile.

The cold semideserts include the Colorado and other plateaus of northern Arizona. The frost-free growing season is relatively short. Much of this plateau area is covered with scrub or with piñon-juniper woodland, where rattlesnakes, rabbits, coyote, bobcat, and mule deer are found. Antelope, American elk, and mountain sheep were once plentiful. Bordering the plateau country are sheer cliffs, deep canyons, and forested mountains. Ponderosa pine, Douglas fir, blue spruce, and alpine meadows shelter weasel, deer mouse, porcupine, squirrel, and chipmunk, as well as the larger animals of the region.

In the past century most of the wild mammals have disappeared from the region. Domesticated species brought to America from Europe by the Spaniards during the 16th and 17th centuries, such as cattle, sheep, goats, horses, and burros, have multiplied and destroyed delicate ecological balances, critically accelerating natural erosion processes, especially on the Colorado Plateau and in the basin and range country.

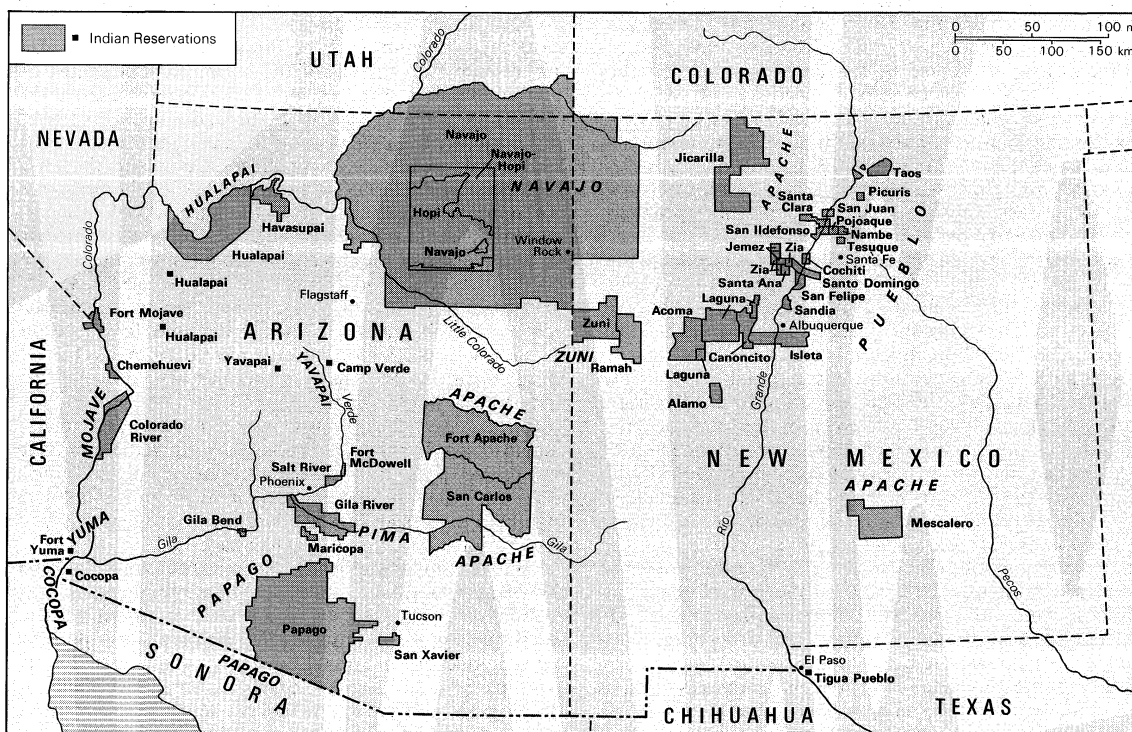

The Indian tribes that have gained a foothold in the Southwest are highly diversified culturally, linguistically, and psychologically. From a comparative viewpoint, however, they fall roughly into four groupings, each of which is characterized by living patterns designed to cope with the practical problems of communities attempting to survive and prosper in the diverse geographical zones of the region.

The ancient Yuman tribes inhabit the floodplains on both sides of the Lower Colorado River (Yuma, Mojave [Mohave]) and the Middle Colorado highlands (Havasupai, Hualapai [Walapai]), as well as the lower Gila (Cocopa, Maricopa) and the Rio Verde (Yavapai). The Pima and Papago, constituting the second group, live along the middle Gila River and in the basin and range country west of the Santa Cruz River, as well as in Sonora across the Mexican border.

The Colorado Plateau and the Middle Rio Grande, with its tributaries, have long been the home of the third group, the Pueblo (village-dwelling) Indians, who, although highly diverse linguistically, share many basic cultural traits. These form three subgroups: the western Pueblos (Hopi, Hano, Zuni, Acoma, and Laguna); the central Pueblos (Jemez, Santa Ana, Zia, Cochiti, Santo Domingo, and San Felipe); and the eastern Pueblos (San Juan, Santa Clara, San Ildefonso, Nambe, Tesuque, Taos, Picuris, Isleta, and Sandia).

The peoples

Environment of the area

Distribution of Southwest American Indians and their reservations and lands.

Finally, also on the Colorado Plateau, completely surrounding the Hopi villages and Hano and separating them from the other Pueblos, dwell the fast-growing Navajo, a branch of the Athabascan-speaking Apache who are relative late comers to the Southwest. Their nearest linguistic relatives are found in parts of California, Canada, and Alaska. The Apache, inhabiting the mountains of the plateau rim, form a wedge between ancient Pueblo inhabitants of the region and the Pima-Papago. The major Apache tribes are the Western Apache, the Chiricahua, the Mescalero, the Jicarilla, the Lipan, and the Kiowa Apache.

TRADITIONAL CULTURE PATTERNS

Differences among the four native groupings

General characteristics: ethos. Even though the four native groupings share some patterns of behaviour, they also evidence considerable variety in the ways in which they adapt to life and perceive life. Moreover, all of the distinctively Indian points of view differ radically from Euro-American patterns of thought. For example, River Yuman tribes, who combined collecting edible fruits and seeds with farming rich bottomland, were relatively free of the food anxiety common to most desert dwellers. Yuma tended to focus attention on the acquisition of supernatural power by means of singing songs acquired through dreaming and illustrative of myth sequences. The individual's success in life, including leadership in warfare and curing rites, was considered to be entirely dependent on this unusual form of solitary dreaming.

On the other hand, the desert-dwelling Papago tempered their reliance on magical power achieved through singing, vision seeking, and intoxication, with concentration on such practical living problems as the defense of village communities dependent on flood farming, hunting, and collecting wild foods. Their wary approach toward any sort of personal commitment and their preference for perceiving the world in terms of flexible wholes and a continuous range of inductions, rather than the two-sided options characteristic of Euro-Americans, directly reflected a long-range, successful adjustment to an exceptionally inhospitable environment.

The Hopi Indians expressed an extreme variation of Pueblo culture developed in response to their unusually dry niche of the high, semiarid Colorado Plateau. The Hopi tribe's solution to the well-nigh insoluble living problem of village farmers without a permanent water supply was embodied in a flexibly balanced social system that stressed not only group self-defense, sobriety, and peaceful relations but also dry and arroyo flood-farming techniques developed to a high degree of skill. Their technological expertise was supplemented by formal ceremonial activities and reinforced by their conception of the world, which required active collaboration of each individual Hopi, with superhuman powers embodied in deities, animals, and plants. Consequently, a Hopi tended to develop a special type of planning mentality with a complex approach that took into consideration well-formulated whole problems with their effective parts in balance.

Another version of the Pueblo culture was found at Zuni, which differed from Hopi land in having an adequate water supply. From the time of its European discovery (1539-40), Zuni was under strong pressures from Spanish explorers, soldiers, Franciscan missionaries, and governors to repudiate its indigenous customs, especially its religious beliefs and activities. The Zuni's solution to this persistent cultural harassment was figuratively to draw a magic circle around their innermost beliefs and ceremonies in order to keep them hidden from prying foreigners. Outside this sacred core they allowed certain changes to occur in behaviour and attitudes. Thus, the famous dances of kachina (masked impersonators of deities) functioned as a screen for the perpetuation of ancient rites. When the wholeness of their culture was destroyed by the intrusion of outside influences, the Zuni became preoccupied with a rote-perfect rendition of detailed ceremonial procedures, each fraught with magical efficacy. Zuni tended to perceive and emphasize tiny details rather than complex wholes, as among the Hopi, or global wholes, as among the Papago, but this tendency is giving way to a more integrated approach toward the external world.

In contrast to the Pueblos, the Navajo, who entered the southwestern region more recently than other Indian tribes and settled there by expropriating crops, herds, and rangelands, expressed an aggressive, mobile way of life. Their culture pattern, bolstered by an animistic conception of the world, fostered in the individual a matter-of-fact mental approach that singled out for attention large, discrete details with little interest in relationships between them. Such an approach relied both on adjusting to new situations by adapting segments from other cultures and on avoiding long-range planning. The Navajo were well able to make and carry out complex planning projects, however, if they believed such activities would enhance their welfare.

Social structures and economic systems. The most favourable habitation sites of the region, from the indigenous viewpoint, were probably the basins of permanent rivers, especially the floodplains of the Lower Colorado. Toward the end of the 18th century, the most desirable patches of bottomland were densely settled by village-dwelling Yuma Indians. Each village comprised a relatively stable and autonomous band composed of a number of large families living in brush shelters or rectangular, sand-covered houses. The male head of each family participated in an informal village council that settled disputes (often over land ownership) and made decisions on community problems. The wisest, ablest, and most powerful senior member of the band was its acknowledged leader. A number of bands constituted the loosely organized but strongly identified tribe, which fostered friendly relations and trade with neighbouring tribes (Mojave, Yavapai, Papago) and maintained a state of hostility or open warfare with others (Cocopa, Maricopa).

Unlike most other southwestern tribes, the Yuma did not suffer from a water problem, despite a minimum of rainfall and a hot desert climate. Although they collected edible fruits and seeds, fished, and hunted small game, the river was their lifeline. In small, irregular fields that were flooded and silted in spring when the Colorado overflowed its banks, they cultivated, with simple hand tools, several varieties of rapidly maturing maize, as well as beans, pumpkins, melons, and grasses (later, wheat and cowpeas acquired from the Spaniards). Such fields were privately owned and were inherited in the male line. Abundant harvests, supplemented by gathering and storage of food in large baskets, coupled with a simple inventory of material possessions, allowed the Yuma to concentrate on a rich world of dream and fantasy.

Although the culture of the Pima-Papago showed a certain resemblance to that of the Yuma, it represented an alternate version of the ancient Southwestern desert tradition. In the Pima-Papago case this tradition was modified and enriched by a prehistoric influx of immigrants who built canals to irrigate larger areas of cropland than had been possible by flash flooding alone. After the first summer rains, fast-growing varieties of maize, as well as tepary and lima beans, pumpkins, and cotton, were planted to take advantage of the moisture before it evaporated. During this time (July and August) the Papago lived in several (perhaps 50 or 60) scattered rancheria villages near their fields. After the harvest, when water and food became scarce, each village community moved from its "fields" village to its "wells" village in the hills, where fresh water and game were obtainable.

Each Papago village was composed of several related extended families living in widely spaced wattle-and-daub houses and led by the oldest active man. A village council, attended by all the adult men of the community, met nightly to discuss and resolve local problems, such as land distribution and defense. Each village had its "keeper of the smoke," a religious leader (shaman) who presided over the village roundhouse and led its communal ceremonies. A number of villages formed a dialect group, and six or seven such groups constituted the tribe—a nonpolitical entity united by traditional, linguistic, and genetic bonds.

Compared to the Pima-Papago and Yuman tribes, the Pueblo villages were more independent as well as more sedentary, spatially compact, and highly structured both socially and ceremonially. Although they shared a com-

mon theocratic life-style based on complex interweaving ties between kinship and religious groups and also a similar pattern of perceiving the world of nature, they differed considerably, both in language and in the way the members of each village organized themselves to cope with the vicissitudes of their particular environment. Life for the western group of Pueblo farmers on the high, semiarid Colorado Plateau was particularly hazardous and nowhere more so than on the mesas of the Hopi lands. Here the well-being, even the survival, of whole communities long depended on what seemed to the casual observer to be minute, even insignificant variations in climate and topography—especially in the amount and seasonal rhythm of precipitation, the configuration of floodplains and erosion of ephemeral stream beds, the presence and flow of freshwater springs, even the piling of sand into fixed dunes that conserved moisture.

In all of the western Pueblos the key social grouping was the maternal family line, or lineage. This was a kinship group centred in a core of blood-related women but conceived as timeless, extending backwards into the remote past and forward through generations yet unborn. Several related lineages formed a corporate clan with descent through the female line.

Among the Hopi, sets of linked clans, considered to be ceremonial "partners," formed what have been called phratries. Under this system a person was not allowed to marry into the lineage of his mother, his father, his mother's father, or into his own phratry or set of clans. The Hopi clan owned croplands and ritual paraphernalia, and its oldest active woman functioned as its "real" head, while her brother assumed the responsibilities of ceremonial leader. Although the ceremonial leader supervised the annual reenactment of various ceremonies, the performance of a major ceremony was the responsibility not of a single clan but rather of a voluntary secret society that drew its predominantly male initiates from the entire pueblo. In each pueblo were several such societies. Their elaborate ritual activities were centred in a number of kivas (underground ceremonial chambers).

The kinship system was extended symbolically beyond the human community into the world of nature, linking clans with certain kinds of animals and plants as well as with other classes of natural and supernatural phenomena into a supersociety that included all aspects of the Pueblo world considered important to its well-being.

The basic local unit in the social organization of the western Pueblos was the extended family. This was a female-centred group occupying a common household of two or more adjoining rooms in a three-storied terraced communal structure. It was built of stone, faced the sun, and partially surrounded a central dance plaza. A household normally consisted of a core of women related through the female line, together with their husbands and unmarried sons (and unattached male relatives of the women), as well as their daughters, sons-in-law, and maternal grandchildren. Among the Hopi the women of the household cared for the children, cultivated spring-irrigated gardens, produced baskets and pottery, and had charge of the cooking and storage of food as well as of certain clan fetishes. On the other hand, the men of the household raised field and dune crops of corn, squash, beans, and cotton (later apricots and peaches) and wove clothing. They were also the sheep herders. They "belonged ceremonially" to their mothers' households, however, to which they returned frequently to fulfill religious responsibilities.

The Hopi fired their painted clay pots and warmed their ceremonial chambers and homes with soft coal, which they mined by hand methods from open veins near their villages. Coal mining (the Hopi were the only American Indians to have discovered it) helped to create favourable wintertime conditions for building a surplus of skillfully fabricated craft goods—baskets, pottery, cloth woven of cotton (later of wool), and ceremonial paraphernalia. Such goods formed the basis of a trade network that supplied food and other necessities to the mesas.

Except for Acoma and Laguna, the Keresan-speaking central Pueblos are located on the banks of the Rio Grande and its tributaries, with a permanent and depend-

able water supply that is used for household purposes and irrigation. In contrast to the pueblos in the west, the Keresans and their eastern-Pueblo neighbours inhabited adobe, rather than stone, houses and built circular, rather than rectangular, kivas. These villages also cooperated in inter-pueblo ceremonies, but each formed an economic unit engaged in agriculture, gathering, and hunting.

Except for the Tewa, knowledge of the social structure of the central and eastern Pueblos is incomplete and often conflicting, partly because, in reaction to the Spanish system of administration, they tended to disguise their native rites and beliefs (while still holding on to them strongly). It is known, however, that the Tewa-speaking eastern Pueblos exhibited a unique type of dual organization of social and ceremonial life—one division associated with summer and the other with winter and each, on the basis of solar observations, regulating various seasonal activities and interpersonal village rivalries. In general, they divided communal responsibilities.

The most aggressive Southwestern tribes were its most recent (about the 11th century) Indian settlers—the Athabascan-speaking Apache and Navajo. (The Navajo are generally believed to be descendants of a band of hunters and gatherers closely related to the Apache.) By the beginning of the 17th century the Navajo on the Colorado Plateau achieved a relatively settled way of life. From the neighbouring Pueblos, they had learned to grow corn, to weave, and to care for livestock. Toward the end of the 17th century, however, when the Spaniards and Pueblo Indians attempted to reestablish themselves in the area, the Navajo developed their propensity to spread into and prey upon settled communities to acquire food, sheep, horses, and cattle. The movement of Navajo groups westward into and around Hopi lands seriously threatened the precarious economic situation of that tribe.

The basic socioeconomic unit of the Navajo was the extended family, which consisted of one or more related women, their husbands and unmarried sons, their daughters, sons-in-law, and grandchildren. Certain other unattached relatives might also reside with the group. Each "nuclear" family of husband, wife, and children—or each wife and her children, if a man had more than one wife—occupied a separate hogan (circular, earth-covered lodge), but the entire extended family cooperated in activities such as farming, sheepherding, and family ceremonies. Navajo extended families were grouped into about 60 clans, with descent reckoned through the female line; and marriage within one's clan was considered incestuous. Neighbouring extended families cooperated in solving land-use problems, such as range management, farmland development, and water use, under the direction of a noncoercive type of headman chosen for his leadership qualities. Such a community (which might occupy 12,000–80,000 acres [5,000–30,000 hectares]) was called an outfit. All the outfits together constituted the Navajo tribe, which was not a political unit but was unified by traditional, linguistic, and cultural bonds.

The Apache were probably the least understood of Southwestern Indians. Their culture ranged from that of the Western Apache group, who resembled Pueblos and Navajo in the practice of agriculture, in clan organization, and in the elaboration of mythology, to that of the Chiricahua Apache, who retained their mobile, war-gear organization and their hunting economy until the late 19th century. The Chiricahua consisted of three bands, which were associated respectively with the northern, central, and southern parts of their vast semiarid tribal territory ranging from the Rio Grande to southwestern Arizona and from northern Mexico to Zuni and Acoma. Within each band's hunting grounds, sites favourable for defense, hunting, and food collecting were used as temporary encampments and rallying points for smaller local groups the members of which cooperated in such undertakings as war and important ceremonies. Each local group consisted of a number of widely scattered extended families similar to the families of the Navajo, except that descent was reckoned through both parents. The Chiricahua family, however, was more mobile than that of the Navajo.

As among the Navajo, the family in all the Apache groups

patterns

was centred in related women who cared for the children; gathered and processed edible seeds and other wild plants, such as yucca fruit and mescal; collected firewood and water; produced buckskin clothing, baskets, and pottery; and constructed the dome-shaped, branch-covered shelters that housed the group. The men of the family, on the other hand, hunted, fought, raided, and made weapons, such as arrows, slings, and shields. The most persuasive, strong, and successful family heads became Apache leaders whose authority depended primarily on their personal charisma and success in warfare.

Socialization and education. In all the Southwestern tribes, child training was a serious adult responsibility. The Indians were conscious of a maturation process, which was regarded in several tribes as a "path" along which the individual made his "journey through life."

Without exception in these tribes, a child was treated with warmth and permissiveness during the period of infancy (which might last from one to three or four years). He was given the breast whenever he cried. Weaning was gradual, and training in cleanliness was delayed until a child could walk or even longer. Care was taken not to agitate him unduly, and he was protected from harm (often by means of magical prophylactics) and accepted as an integral part of the family. In some tribes the infant spent much of his time laced onto a cradle board which, among the Navajo at least, was hung up in the hogan so that his head was level with the other members of a seated family circle. The effect of this treatment was apparently to augment the child's physical safety and to enhance his feeling of security. Among the Hopi the use of the cradle was viewed as an early conditioning to the restrictions of the difficult Hopi way.

After the infancy period, tribal socialization patterns began to diverge. From the beginning of childhood there was a strict sexual division of labour. Little boys were given chores appropriate to developing strength, such as collecting firewood or tending animals, while little girls early began to learn food processing and child care. But the child soon learned that every individual in the group was expected to pull his own weight, at every age grade, according to his sex, strength, and capacities.

When they were between five and seven years old, the boys in all the tribes began to associate almost exclusively with the men of their households, who from then on directed their education into masculine tasks and lore, while the girls remained with their mothers and aunts, taking on increasing responsibilities for the exacting tasks of the household. Among the warrior tribes the physical strength, stoicism, and skill needed for the warpath were stressed, and warrior training intensified as the youth grew to young manhood. Even among the peace-oriented Pueblos, however, boys learned agility, endurance, and speed in running. Racing was important ceremonially because it was considered to possess magical efficacy in helping plants, animals, and human beings to grow.

Among the Papago-Pima a child early learned the fundamental principles of family life: the precedence of males over females; seniority and respect for age, regardless of sex; solidarity among all family members under the leadership of the oldest active male; and respect for the role, function, and opinion of every member of the group. Within these limitations the Papago child, male or female, was allowed more freedom of action than was customary elsewhere among the Southwestern tribes.

By contrast, the Pueblo child, after infancy, was probably the most restricted, the degree of harshness in his training apparently depending on the severity of the living problem that the particular Pueblo community had to resolve. The transition from each phase of the Pueblo life cycle to the succeeding one was marked with a major ceremony. Any child who failed to move along the path of life at the culturally designated pace was pulled or pushed in formalized ways to meet the standard. For example, during the secret kachina ceremony, which marked the initiation of all Hopi children into the tribe at about seven years of age and their introduction to the Hopi gods (impersonated as masked dancers), it is reported that all the novices were ceremonially whipped to exorcise evil influ-

ences. "Bad" boys, however, were whipped more severely than the others.

Whereas the Pueblos stressed life-crisis ceremonies that offered symbolic solutions to the major problems faced by the entire community of humans, animals, and plants, the warrior groups in this region emphasized rites by which an individual might ward off sickness and acquire magical power for personal success in war and the hunt. In still another manner, the Papago youth was expected to go alone into the desert in quest of a power-giving vision to help him through life.

Belief and aesthetic systems. The life-crisis rites reflected the religious belief systems of the several tribal groups. The spectacular, communally centred Pueblo ceremonies for rain and growth reflected a conception of the universe in which every person, animal, plant, and supernatural being considered significant to the Pueblo lifestyle had its place and role. Without the active participation of every individual in the group, it was believed that the life-giving sun would not return from his "winter house" after the solstice; the rain would not fall nor could the crops grow. In fact, without human help in an annual cycle of ceremonies, the cosmic order would be in danger of breaking down.

To the Yuma, on the other hand, the universe was pervaded by a single animating principle that was the source of all supernatural power. There was only one medium, namely dreaming, for the personal acquisition of power that was considered necessary for success in life. Sequences of traditional myths acquired through dreaming were converted into songs and acted out in ceremonies. So great was Yuman interest in this kind of dreaming and the power that it could bring to an individual religious or war leader that all other activities—farming, food collecting, and even hunting—were of secondary concern.

The religion of the Papago seems to reflect their position between the Yuman tribes and the Pueblos. Not only did they "sing for power" and go on individual vision quests, but they also held regular communal ceremonies to "bring down the clouds" and keep the world in order.

By contrast, the Apache conceived of the universe as composed of a great many different kinds of power entities, such as animals, plants, witches, superhuman beings, rocks, and mountains. Each power source could exert force in the world for good or ill, and each had to be separately propitiated. Each was personalized, talked to, sung to, scolded, or praised. Apache ceremonies were concerned mainly with the magical coercion of these power entities for the curing of disease and the acquisition of personal success in hunting and warfare.

Navajo ceremonial was apparently based on an elaboration of a similarly animistic view of the universe, with the power sources both diffused and specified. Power was localized in a great many autonomous personal beings who were dangerous and unpredictable. These were of two classes: Earth Surface People (human beings, ghosts, and witches) and Holy People (supernaturals who could aid or harm Earth Surface People by sending sickness).

With the acquisition of techniques of farming, herding, weaving, and silversmithing, and the abandonment of hunting and warfare, the Navajo turned their attention to elaborate and colourful ceremonies (called "sings") that aimed, by means of compulsive magic, to cure sickness and bring an individual into harmony with his family group, nature, and the supernatural.

MODERN DEVELOPMENTS

Heritage of integrating and disintegrating factors. Each local community tried to maintain a delicate balance between population and natural resources. If the population outgrew the capacities of its base within the limitations of the group's technology, a segment or faction might split off and form a colony in a favourable habitat resembling that of its parent group. Under normal conditions the daughter colony was so constituted to reproduce as far as possible the parent culture even in its most esoteric aspects. If prolonged drought (as in 1272-99) dried up springs needed by Hopi villages for drinking water, an entire community might migrate.

Importance of rites and ceremonies

Adolescence

Traditional adaptations to change

By contrast, human pressures from without, such as raids by marauding bands or aggressive missionary activity, caused some pueblos to consolidate or to move to less vulnerable mesa sites. In 1680, for instance, all the Pueblos united to kill or drive out the Spaniards (who, however, eventually reestablished Roman Catholic missions in all the pueblos except those of the Hopi). Papago settlements consolidated into large compact villages for defense against the Apache, but they spread out again after the raids ceased.

Religious reactions

Constant or intermittent efforts by missionaries, educators, and administrators to undermine native ceremonies and to change indigenous beliefs were resisted in various ways. The mobile Navajo-Apache tribes rejected all efforts of the Spaniards to reduce or convert them. The more accessible sedentary Pueblos employed various devices, under cover of practicing the outer forms of Catholicism, to hide their sacred religious paraphernalia and to perpetuate their essential beliefs and ceremonies. The Papago produced their own Christian sect, a blend of native and mission practices known as Sonoran Catholicism.

Unless totally destroyed, a pueblo of the western type, which was relatively decentralized, did not surrender structurally to foreign control. In fact, pueblo organization was characterized by a permanence and continuity that would not accommodate externally imposed social change. Alterations in sociopolitical or ceremonial patterns due to foreign intervention occurred only at superficial levels, while basic religious beliefs and practices tended to persist (even to the present day).

By contrast, pueblos of the eastern type, with more centralized control, proved more vulnerable to attack at both the sociopolitical and the ceremonial levels. If not utterly destroyed, most of them incorporated aspects of the foreign system into their own structures so that the result was a blend of the two.

The Navajo and the Western Apache adapted their mobile hunting cultures by borrowing from the Pueblos whole complexes of traits, such as agriculture, herding, weaving, and sand painting, and later from their industrialized neighbours, such traits as lumbering, mining, and commercial enterprises.

In virtually all the Southwestern tribes, however, the native languages are still spoken in the family groups, which continue to organize themselves according to traditional principles and values. Native ceremonies are still practiced, often secretly, in all the tribal groups, even those considered to be at least nominally Christian.

Effects of modernization

Current cultural conditions. Although the seeds of "modernization" probably were sown earlier, the process did not get under way until the end of the 19th century and the beginning of the 20th. The isolation of many of the tribes, the vastness, aridity, and poor natural endowment of many of their lands, and, of course, the ferocity of the Athabascans all played a part in delaying modernization of the Southwestern tribes. Indeed, military defeat, the loss of traditional lands, and missionary efforts to change their religious beliefs and practices left a heritage of rejection and bitterness among these Indians.

Under the administration of the United States, many changes have been made on the reservations in the interests of Indian welfare. Tribal government has been developed and empowered with legal authority. Schools and hospitals have been constructed. Irrigation systems have been built and crops increased in quantity and quality. Roads and highways have been improved and communications by telephone and radio, bus and airplane inaugurated.

Indian incomes, however, remain generally low compared to those of the rest of the American population, especially among the Papago, Hopi, Fort Apache, and some of the highland Yuman tribes. Unemployment is high among Indians both on and off the reservations.

Biculturalism

In the opinion of some authorities, however, the Indian problem in this region is not poverty or lack of industriousness or even apathy. The primary problem rather is biculturalism. In the late 20th century the tribal reservations served as the physical and spiritual homes of the several Indian groups, although some 50 percent of the members resided outside their boundaries. All except a

few who have identified with the surrounding American culture periodically returned to their family households on the reservations for ceremonies and for deep religious and social nourishment.

(L.Th./Ed.)

North American Plains Indians

The Indians of the North American Plains are popularly regarded as the typical American Indians. They were essentially big-game hunters, the buffalo being a primary source of food and equally important as a source of materials for clothing, shelter, and tools. Until supplanted by the white man from the 16th century onward, they occupied the area between the Mississippi River and the Rocky Mountains, which includes portions of both the United States and Canada. It is a vast grassland stretching from northern Alberta and Saskatchewan in Canada to the Rio Grande border of Texas.

The climate is in general a continental one, with a wide seasonal range. Temperatures in winter may go below 0° F (-18° C) and in summer as high as 110° F (43° C). The plant cover varies with the amount of moisture, the tall grass of the prairies in the east giving way at about the 100th meridian to the shorter grass of the High Plains in the west. The area is drained principally by the Missouri-Mississippi river system.

The peoples of the Plains are designated by the languages they speak. It is permissible to call them "tribes" or "nations," bearing in mind, however, that in some cases, for example the Dakota (popularly known as Sioux), the designation covers several completely autonomous political divisions. The northern and southern divisions of the Cheyenne retained their unity as a tribe, while the Pawnee on the other hand comprised at least four independent groups. Many of the tribes of the Plains, such as the Cheyenne, migrated into them from the prairies and woodlands of the east. In addition, some of the tribes to the west of the area—the Ute and Jicarilla Apache, for instance—were influenced to a degree by the Plains culture and can be regarded as marginal to the area.

Peoples and languages

Six distinct language families or stocks were represented in the Plains area, although none of them was confined to it. The speakers of the several languages within a stock might or might not be geographically contiguous. Some of the languages, moreover, were more closely related to each other than to others within the same stock. Thus languages belonging to the Algonkian stock included the Blackfoot (Piegan-Blood-Northern Blackfoot), Arapaho-Atsina (Gros Ventre), Plains Cree, and Plains Ojibwa, all in the Northern Plains, while Cheyenne, also an Algonkian language, was in the central part of the area. The Siouan language stock embraced Mandan, Hidatsa, Crow, Dakota-Assiniboin, Omaha-Ponca-Osage-Kansa, and Iowa-Oto-Missouri. The Pawnee-Arikara and Wichita were Caddoan languages, whereas Wind River Shoshoni and Comanche were of the Uto-Aztecan stock. The Athabaskan (Na-Dené) stock was represented by the Sarcee (Sarsi) in the northern part of the area and by the Kiowa-Apache in the southern. Finally the Kiowa-Tanoan stock was represented in the area by one language, Kiowa.

Sign language provided a common, if limited, means of communication among tribes speaking different languages. This was a system of fixed hand and finger positions symbolizing ideas, the meanings of which were known to the majority of the tribes of the area.

TRADITIONAL CULTURE PATTERNS

In aboriginal times the only domestic animal was the dog, which served some tribes for food but was in general use as a pack animal. Dogs were also made to draw the travois, a vehicle consisting of two poles in the shape of a V, the point of the V dragging on the ground; the ends were attached to the animal, and a platform was put across to carry the burden. The Spaniards introduced the horse in the 16th century, in the southwest, and its use gradually spread northward. By the middle of the 18th century or earlier, all of the Plains Indians were equestrian. There was also a flowering of what one authority has termed luxury

General cultural characteristics

developments—"showy clothing, embroidered footgear, medicine-bundle purchases, elaborate rituals [culminating in the sun dance], [and especially] gratuitous and time-consuming warfare." The fighting seldom involved major tribal forces; it was carried out mainly by raiding parties of a few warriors, to avenge a death, to steal horses, and especially to gain glory. Touching an enemy's body was considered among many groups of greater moment than killing or scalping him.

In many of its aspects, Plains culture emphasized intense individualism and aggression, placing a high valuation on violent experience. Rivalry and hostility between men were part of the pattern, so much so that military organizations had to be established to maintain order at tribal assemblies. Nevertheless, a man who became eminent in war could enhance his status by showing generosity to the poor, sharing his goods with relatives, engaging in lavish hospitality, and behaving cooperatively with others.

The tribes who were marginal to the Plains generally borrowed only the external traits of Plains culture and not the religious, ceremonial, or social customs. On the other hand, the southern tribes of the Siouan language family, along with the Pawnee, Mandan, Hidatsa, and Arikara, while possessing most of the typical Plains Indian cultural traits, had a number of others, such as horticulture, pottery, and residence in fixed villages for part of the year; they may be said to constitute a subculture within the Plains Indians.

Social organization. *Local and territorial units.* Among the nomadic tribes the local units were bands—i.e., groups of people wandering together in search of food. The size and composition of the bands varied. Comanche bands were loosely organized, each centring its activities in a

vaguely defined area within the tribal territory. Only the larger bands received permanent recognition and a name. The bands did not fight one another, but neither did they act in concert as a tribe. The Teton Dakota tribe comprised seven independent bands, the largest being the Oglala. The Cheyenne, however, were more highly organized than the Teton; their ten bands sent representatives to a council of 44 peace chiefs, whose decrees were binding on all the bands. Only in late spring and summer, as a rule, did the nomadic band or tribe come together as a unit on the open Plains, when they engaged in the communal hunt and held major ceremonies. During the remainder of the year, the members dispersed in small groups to more sheltered areas.

The semi-sedentary prairie dwellers lived in villages. The three Hidatsa villages were each independent of the others, whereas the Skidi Pawnee villages were united. The seasonal round of the village peoples may be illustrated by the Arikara, who spent the period between planting their crops and harvesting them on the summer hunt living as nomads. After the harvest small groups went to the Plains for another hunt, returning not to their permanent villages but to protected areas in the bottomlands, going back to the permanent villages to plant their crops in the spring.

Family and kinship units. Each local band or village was composed of families and wider kinship units. Every group had regulations governing the mating of kin. Some, such as the Atsina and Blackfoot, did not tolerate marriage between consanguineal relatives, no matter how distant the tie, and others proscribed marriage within varying degrees of relationship. On the other hand, marriage between those who were already relatives by marriage was often prescribed or preferred; the custom of a man marrying the widow of his deceased brother was widespread, as was also the replacement of a deceased wife by her sister. Most marriages were monogamous, but a man might have several wives, sisters being preferred.

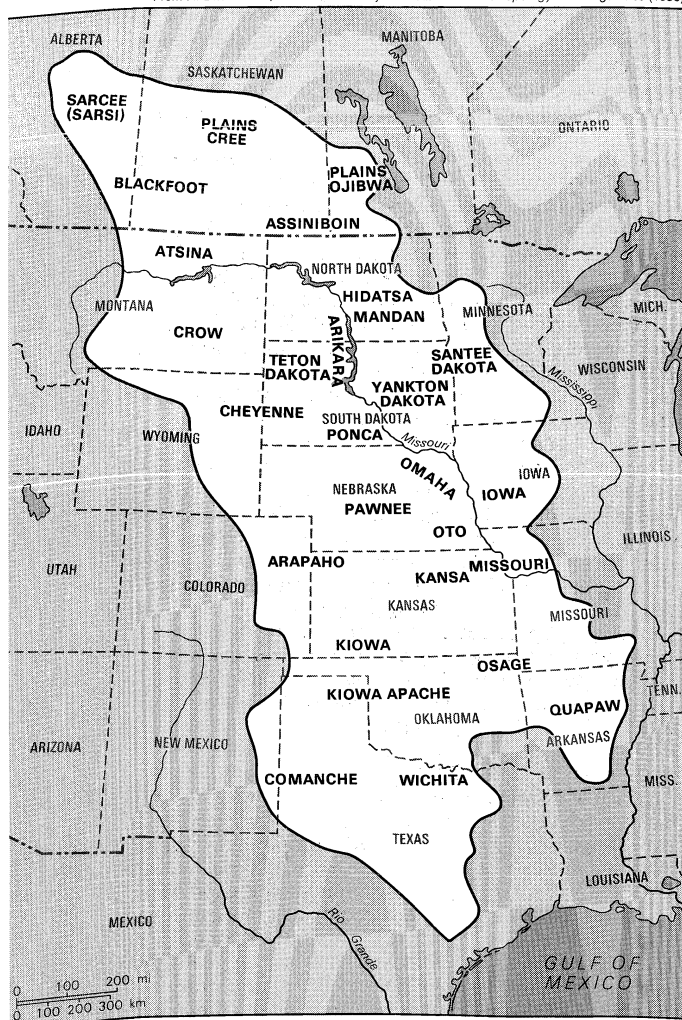

Ideally, marriages were arranged between the families of the bride and groom, the latter usually paying a bride-price; sometimes, as among the Mandan, each side provided exactly equivalent gifts. Virginity was highly prized among most of the tribes, particularly the Cheyenne. Among the Blackfoot, women known to be chaste were selected for roles in important ceremonies. The double standard prevailed, however, and men in all of the tribes were expected to make sexual conquests. A husband who had evidence of his wife's infidelity might disfigure her by cutting off her nose or demand compensation from her lover. Romantic love and elopement were not unknown, but attitudes varied; the Teton tolerated the couple on their return, while the Cheyenne considered the girl disgraced forever.

Most Plains tribes had definite rules governing conduct between in-laws, such as the widespread "mother-in-law taboo" in which a man and his wife's mother showed their mutual respect by not speaking to, or in some cases not even looking at, each other. In some tribes, as among the Arapaho, the taboo was extended to include a woman and her father-in-law. The Atsina and a few other tribes required brothers-in-law to be very circumspect in their speech, avoiding any reference to sex no matter how indirect. Yet many of the tribes adhering strictly to this respect taboo permitted the greatest freedom between a man and his sister-in-law. Among the Crow they were expected to romp with each other and to talk to each other in vile language; the Atsina encouraged mutual practical joking and teasing; the Blackfoot allowed the same freedom as between man and wife. It is notable that, according to marriage rules on the Plains, the parties to this joking relationship were potential mates.

While some of the Plains societies reckoned descent bilaterally—that is, equally in both the male and female lines—others reckoned descent exclusively in either the male or female line. This did not mean that there was no recognition of the other parent and his or her relatives. The Hidatsa had a matrilineal clan system (i.e., they traced their descent through females back to a common ancestress), yet there were important relationships to the father and his clansmen; they were always treated with

Villagers

Distribution of North American Plains Indians.

Family
lines

respect and often presented with gifts; before battle a man would ask his clan father to paint his face; the clan father would give personal names to a clansman's son; and ceremonially the father's clan folk played an important part in performances such as the sun dance.

The Mandan and Crow also had matrilineal clan systems. The Oto and Missouri are reported to have had them as well, but there is little information on these groups. The patrilineal clan system was characteristic of the Iowa, Kansa, Omaha, Osage, and Ponca. There is some question as to whether or not the Blackfoot and Atsina had clans, since there was a tendency for the child to be a member of his father's subdivision, and marriage within this subdivision was frowned upon. The organization of the eastern Dakota and the Assiniboin is likewise in doubt.

Among some groups certain clans regarded themselves as more closely related to each other than to other clans. Among the Kansa the 16 clans were grouped into seven larger units. Often the larger units, or phratries, had no important function, although presumably in some cases they regulated marriage. Occasionally there was a further, higher grouping of phratries into two complementary units, or "moieties," as anthropologists call them. The Ponca moieties were composed of two phratries, each consisting of two clans. A similar dual division also existed among societies lacking clans and phratries. The Pawnee, for instance, were divided into the Summer People and the Winter People.

Social rank and warfare. There were no hereditary social classes, but there was ranking of individuals. A poor man, with the help of supernatural power, could win wealth and standing, mainly through prowess at war; but the son of a wealthy family would have an advantage over an orphan.

Most tribes ranked war exploits, but they did not all evaluate particular deeds alike. The taking of scalps was common, but many tribes considered scalping of lesser merit than counting coups—touching one's enemy. Stealing a valuable horse that had been picketed at its owner's lodge was considered a feat.

Most tribes had a number of clubs or associations, religious and secular. Among the latter were the military societies that often functioned as police for the tribal hunt. Some organizations were rivals. Among the Crow, for example, there were two outstanding societies, the Lumpwoods and the Foxes, that were of equal rank but competed violently in feats of war. The Arapaho, Atsina, Blackfoot, Mandan, and Hidatsa differed from the other Plains tribes in that their military societies were ranked in an ordered series. Distinctive regalia and membership privileges in each society were purchased collectively by one group of roughly the same age from an older group. Then the sellers as a group bought from the next older group, the exchange continuing until the oldest group sold out completely and retired from the system. The number of societies varied. The Hidatsa at one time had as many as ten military societies.

Women participated in many of the associations, often playing important roles. Among the Mandan and Hidatsa, women's societies existed similar to the men's graded societies.

Socialization and education. Training began early for Plains children, as part of their play. A very small boy would be given a bow and blunt arrows; as he grew stronger, he would receive larger, heavier bows and be shown how to stalk small game and to hit moving targets. Groups of boys engaged in shooting matches and sham battles, the winners receiving acclaim from their elders; the losers were praised if they had fought bravely. Competition marked almost all of the boys' games.

Girls were taught domestic skills. A father might make toy scraping tools for a girl, which her mother would teach her to use. She would learn to sew by making clothes for her doll and be given a toy tepee to put up while her mother was erecting the big one. In general the line between work and play was not sharply drawn.

The young were encouraged to behave in desired ways by praise and reward, special attention being given in many of the tribes to the first success. Thus an Oto father

publicly gave away property to honour his son when the boy first walked, when he brought in his first small game, when he killed his first deer, and when he returned from his first war party. When a Crow boy killed his first big game animal, he was given public recognition; a song celebrating the achievement was sung at a ceremony similar to that which would mark his return from a first war party. Progress toward maturity was generally rewarded by removing restrictions and granting special privileges. Blackfoot boys who won shooting matches were allowed to wear feathers in their hair. As soon as he went on his first war party, the Cheyenne boy was relieved from the duty of herding horses and also from the necessity of listening to long lectures on proper behaviour.

Relatives helped to train children. Grandparents were often consultants and advisers. In a number of tribes, the mother's brother and the father's sister played important roles as mentors and disciplinarians. Among the matrilineal Hidatsa, the maternal uncle was responsible for the direction and supervision of his nephews; he guided them and punished them, but also praised them. Arapaho parents relied on the father's sister to instruct a girl in proper behaviour and to reprimand her when necessary. Physical punishment was seldom employed. Praise and reward for achievement seem to have been generally emphasized more than ridicule and admonishment for failure.

Though the quest for supernatural power through a vision or dream was important among all of the Plains tribes, the experience was not sought primarily at puberty, as was the case in other areas. Again, while fear of menstrual blood was universal, only a few tribes, including the Cree, marked the occurrence of the girl's first menses with an adolescent rite.

Economic systems. The nomadic tribes lived throughout the year in portable dwellings, while the semi-sedentary peoples used them only seasonally. The tent, or tepee, was conical in shape, the foundation being either three or four poles with other poles placed around them to form a circular base. The cover was made from dressed buffalo skins carefully fitted and sewn together. Since the fireplace was in the centre, a smoke hole was left at the top that could be closed in bad weather.

When the whole tribe assembled, a camp circle was usually formed, leaving the space in the centre for ceremonial structures. Among some peoples, such as the Cheyenne and Atsina, each subgroup had a defined place in the circle. Among many tribes, too, the orientation of the lodges and the opening of the circle was toward the rising sun.

The earth lodge of the semi-sedentary peoples was a permanent structure much larger than a tepee; it was dome shaped, roofed with earth, and entered by a covered passage. The Pawnee, the Mandan, and some other tribes excavated the floor so that their dwellings were partly subterranean. The Osage and Wichita houses differed from those of the other horticultural tribes; the dwellings of the Osage were oval in ground plan, composed of upright poles arched over on top, interlaced with horizontal withes, and covered with mats or skins, while the Wichita houses were conical in shape and thatched with grass.

The nomads depended for subsistence primarily on big game: buffalo, antelope, deer, and elk. These were also important in the diet of the semi-sedentary tribes. While the animals could be hunted by individuals, the usual methods involved the whole tribe in driving the game down a cliff or into a corral or encircling it by fire. The introduction of the horse increased hunting efficiency, allowing larger numbers of game animals to be killed more quickly. The mounted hunter continued to prefer the bow and arrow over guns.

The semi-sedentary tribes practicing horticulture raised principally maize (corn), but also beans, squashes, and sunflowers. The plots were cultivated by the women, using only a rake, a digging stick, and a hoe made from the shoulder blade of an elk or a buffalo.

Animal skins were used for clothing. On the Northern Plains, men wore a shirt, leggings reaching to the hips, moccasins, and a buffalo robe—the robe being painted to depict the war deeds of the owner. Women's clothing consisted of a long dress, leggings to the knee, and moccasins.

Tech-
nology

Among the villagers and some southern nomads, men traditionally left the upper part of the body bare. Clothes were decorated with porcupine-quill embroidery, fringe, and, in later times, beadwork. Ordinarily the head was not covered, the feathered warbonnet and other elaborate headgear being reserved for ceremonial occasions.

Receptacles of various kinds were made from rawhide and leather. Traditional tools were of bone, horn, antler, and stone—before the introduction of metal by Europeans. Pipes were usually of stone. Basketry and pottery were characteristic products of the villagers; some of the nomads, including the Cheyenne, Comanche, and Arapaho, were said to have made flat coiled gambling trays, while the Atsina, Blackfoot, and Cree, among others, had traditions of having once made earthenware.

Some anthropologists have argued that Indians could not have lived on the Plains before the introduction of the horse. Others, pointing to the fact that Francisco Vázquez de Coronado's expedition in 1541 encountered fully nomadic buffalo-hunting tribes on the Southern Plains who lacked horses and depended on dogs for transport, claim that the acquisition of the horse produced only minor changes. One consequence of the horse was the creation of great differences in wealth. Horse stealing became a major motive for warfare. The man who had horses to give away or to offer as bride-price was at a distinct advantage in social prestige.

There was very little intratribal trade in material goods, although there was much exchange of intangibles. The transfer of war medicine and of curing rites brought high prices in horses and other goods among practically all of the tribes. For the spiritual benefit believed to accrue from viewing the contents of a sacred pipe bundle (*i.e.*, a pack containing various sacred objects) of the Mandan, the individual had to pay, in the 1830s, the equivalent of what was then \$100. Among the Hidatsa a person wishing to learn to chip flint and make arrows had to buy the rights and receive the instructions from those with ceremonial rights who possessed bundles carrying arrow-making songs.

Intertribal trade was fairly common, one form being that between nomads and villagers; *e.g.*, the exchange of skin robes for grain. The Cheyenne were middlemen in the trade of horses between the Indians of the Southern Plains and those of the north central Plains. Guns and other materials such as blankets, beads, cloth, and kettles, introduced into the northeast by the British and French, were highly valued by the Comanche, Kiowa, and other groups, who were willing to give horses in exchange for them.

Belief systems. The Plains Indians did not distinguish sharply between the sacred and the secular nor between religion and magic. They attached much importance to visions. Success in life was believed to depend in large measure on the intervention of friendly spirits. The usual procedure for obtaining spirit help was to go to some lonely spot to fast, mortify the flesh, and beg for aid. If the suppliant was successful, the spirit would appear to him or be audible to him and would give him detailed instructions to follow to win immunity in battle, ability to cure illness, or various other kinds of power. The spirit might assume the form of an animal or a bird. Not everyone was successful in this quest, and, among the Crow and some other tribes, those with power were permitted to transfer it to others less fortunate. Among the Atsina and Teton Dakota, women might be vouchsafed visions, although they did not usually seek the experience.

All of the tribes had medicine men, or shamans, who had received supernatural powers. Arapaho, Atsina, and Cheyenne medicine men would walk on fire as a proof of their powers. More important was the ability of the shaman to cure illness. While, in most of the groups, ordinary illnesses such as dysentery or headaches would be treated with herbal remedies, a shaman was called in to diagnose and treat more serious illnesses. It was widely believed that illness was caused by intrusion of a foreign substance in the body and that the medicine man could cure the patient by extracting the object. If the medicine man failed, the reason was that there had been some unwitting infraction of the rules as laid down by his supernatural sponsor.

He was not required to take every case; among the Teton Dakota he could refuse after examining a patient. Other services a medicine man might render included locating enemies and game animals and even finding lost objects.

In some tribes it is difficult to distinguish the role of medicine man, who had direct contact with the supernatural, from that of the priest who obtained his knowledge from other practitioners. The Cheyenne medicine man is thought to have been more of a priest than a shaman, since his main road to supernatural power was through acquisition of ritual knowledge from one who was already a priest, although some did seek power through visions. The same individual may have acted in some situations as a shaman and in others as a priest.

Among the tribes having a clear belief in a spirit superior to all other spirits were the Cheyenne, the Atsina, and the Pawnee. The Cheyenne, for instance, held that "the Wise One above" knew better than all other creatures; long ago he had left the Earth and retired to the sky. In smoking ceremonies the first offering of the pipe was always made to him. Some of the other tribes, such as the Crow, are not known to have believed in such a supreme deity.

Ceremonial and ritual were well developed on the Plains. They ranged from very simple rites to complicated proceedings requiring weeks of preparation, the final performance lasting for days. A number of common ritual elements were used alone or combined in various ways by the several tribes. Medicine bundles figured prominently in rituals throughout the area. In some cases the bundle was a personal one, the contents of which had been suggested to the individual by a supernatural sponsor, while in others it was a tribal property originating in the mythological past. It was handled reverently and opened according to definite rules. The opening of the Cheyenne sacred arrow bundle, for instance, was the focus of an elaborate tribal rite extending over four days.

The sacred number for most tribes was four, entering into the rituals in many ways. A less common number was seven. Many rituals centred on a kind of altar, a specially prepared space in a ceremonial structure for arranging sacred objects or smoking them with incense. The dimensions of the altar and the symbols that were used varied with the ceremony. Ritual purification in a sweat lodge was a widespread practice, required in connection with many ceremonies.

One important ceremony found among about 20 tribes is known inaccurately in English as the sun dance. The native terms varied: the Cheyenne phrase may be translated as "New Life Lodge"; the Atsina term means "Sacrifice Lodge." While the central features were the same among all the tribes, there were many differences in detail. The sun dance was always held in summer, when the whole tribe gathered, and was usually performed in fulfillment of a vow by someone who had promised it if he were relieved of some grave difficulty. The ceremony was an annual event among the Teton Dakota but occurred at quite irregular intervals among the Crow. The pledger was instructed by a priest or medicine man, and some weeks were needed for gathering food and other preparations. A ceremonial structure was built in the centre of the camp circle, and, before it was erected, offerings were placed in the fork of the central log. Within the structure was an altar upon which buffalo skulls were laid. The pledger and other participants fasted and danced for several days, praying for power. A widespread, though not universal, feature of the ceremony was self-torture by some of the participants. The skin of the breast or back was pierced, and a wooden skewer inserted. One end of a rope was tied to the skewer, the other end being attached to the centre pole. The dancer leaned back until the line was taut and he strained until he tore himself loose. The Teton elaborated on this torture by dragging around buffalo skulls attached to skewers on the dancers' legs.

MODERN DEVELOPMENTS

With the coming of the white man, the Plains Indians began to acquire manufactured articles such as guns, metal utensils, axes, knives, blankets, and cloth. This led to a decline of the native arts and crafts. Paradoxically,

Cultural
changes

however, some aspects of social life were intensified as a result of the fur trade. Since women dressed the hides, the successful hunters secured more and more wives to do the dressing for them, and therefore polygyny increased on the Northern Plains. Religion was affected insofar as wealth brought by the fur trade encouraged more frequent transfer of medicine bundles, at higher prices.

With the coming of immigrant wagons, the building of railroads across the Plains, and the encroachment of white settlements, warfare became a unifying force. During the latter half of the 19th century, tribes that had formerly been hostile to one another often united against the intruders. Not infrequently the Indians were successful, although in the end they were overwhelmed. Eventually the buffalo disappeared, the system of status and rank collapsed, and the tribes were placed on reservations. The culture of the Indians was radically changed.

The United States government hoped to make the Indians into literate farmers, but the agents sent to teach them encountered many obstacles. The nomadic groups were loath to settle down, looking upon cattle as a poor substitute for buffalo. The reservation land was often unsuitable for agriculture. The semi-settled village peoples, among whom digging-stick cultivation was traditionally considered women's work, resisted the change in division of labour brought by the plow. Much confusion resulted when officials insisted on listing families by surnames, which Indians did not possess. Many misunderstandings arose among the matrilineal tribes when inheritance rules were changed so that land passed from father to son.

Schools were established on and off the reservation. Boarding schools had the advantage of facilitating the learning of the white man's language and customs. While some individual Indians adapted to the new conditions and were able to make their way among whites, those who returned from school to the reservations often found themselves in a difficult and marginal position.

Many Indians were Christianized. A new religious movement known as peyotism, combining pagan and Christian elements, spread among the Plains Indians in the latter part of the 19th century. It centred on a species of cactus

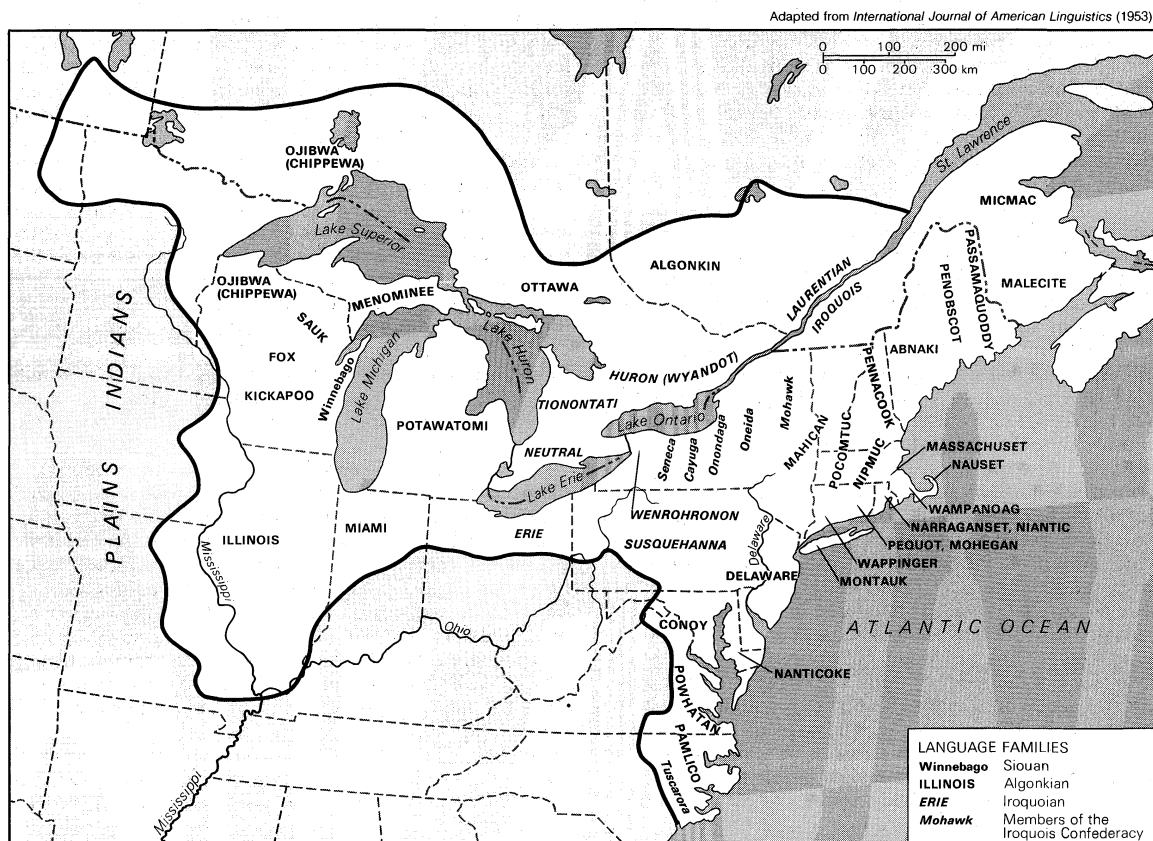

that when eaten or imbibed caused hallucinations. Since it was considered dangerous by the government as well as by the missionaries, efforts were made to suppress it. But groups practicing the peyote religion were incorporated in 1918 as the Native American Church. (R.F.-He.)

Eastern Woodlands Indians

At the time of the European discovery of North America, the area stretching from Lake Superior to the Atlantic coast was occupied by many different Indian groups speaking languages that belong to three distinct language families: Iroquoian, Algonkian, and Siouan. The major speakers of northern Iroquoian languages include the Iroquois confederacy (Mohawk, Oneida, Onondaga, Cayuga, Seneca, and, later, Tuscarora), the Huron confederacy, Tionontati (Petun or Tobacco Nation), Wyandot (a group of Hurons and Tionontati), Neutral, Wenrotronon, Erie, Susquehanna (Conestoga), and Laurentian Iroquois. The major speakers of Algonkian languages include the Passamaquoddy, Malecite, Abnaki, Penobscot, Pennacook, Massachusetts, Nauset, Wampanoag, Narraganset, Niantic, Pequot, Mohegan, Nipmuc, Pocumtuc, Mahican, Wappinger, Montauk, Delaware (Lenni Lenape), Powhatan, Ojibwa (Chippewa), Menominee, Sauk (Sac), Kickapoo, Miami, and Illinois. The Winnebago, who also lived in the eastern woodlands, spoke a Siouan language.

Although the area generally was a wooded one, it was in the open spaces in the forests that many of the best natural resources were to be found. In consequence, the heaviest population concentrations were near or along the seacoast, lakes, ponds, marshes, creeks, and rivers. There animals could be hunted, fish caught, birds taken, leaves, seeds, and roots of wild plants gathered, shellfish collected, and crops grown. Certain areas were favoured with resources not found elsewhere in the region. In certain parts of the upper Great Lakes area, wild rice (*Zizania aquatica*) grew in abundance, and the Menominee especially depended on it. Buffalo (bison) roamed the plains-prairie area, and such groups as the Sauk, Fox, Illinois, and Miami, who lived near the prairie, hunted them. On

the Atlantic coast, shellfish were plentiful and played an important part in the diet.

TRADITIONAL CULTURE PATTERNS

Economic systems. *Food production and consumption.* Except in the northern part of the upper Great Lakes area and the northern part of the Eastern Seaboard—areas that do not have a growing season long enough for corn (maize) to mature—some agriculture was practiced. The three principal plants cultivated were corn, beans, and squash, plants the Iroquois termed the three sisters because they were to be found like sisters together in the fields. Generally, it was the women who cultivated the fields, planting the seed, weeding, and harvesting the crops. Men, however, usually aided in clearing the land preparatory to planting. The type of agriculture practiced is often termed horticulture, as domesticated draft animals were not used. The implements used in planting were the hoe and the digging stick (dibble stick), a wooden stick pointed at one end that was used to make a hole in the ground into which the seeds could be dropped and then covered.

Of all the groups in the area, the Iroquoian tribes were probably the most dependent on agriculture, but even they did not rely wholly on it. The population of the area was never great enough to have exhausted the supply of wild plants and animals, and as a result the Indians living there did not have to expend the time and effort necessary for intensive agriculture. They also could avoid a dull and monotonous, though balanced, diet confined to corn, beans, and squash and could enjoy a rich and varied diet merely by travelling to the proper places at the proper times of the year to collect food. Leaves of wild plants were gathered in the spring and cooked as greens. Later in the year, berries and other seeds were gathered. Fish were caught in the spring, summer, and fall—different species being plentiful at different times of the year. Birds were taken, and in certain areas the spring roosting places of pigeon provided virtually unlimited amounts of squab. In early spring, the maple trees were tapped for their sap. Fall was the best time for hunting, and numbers of families went into the forests at this season of the year to hunt. The seasonal round of activities was, then, a varied one and one that, contrary to common opinion, afforded a great deal of leisure time, for the Indians did not wander aimlessly around, barely avoiding starvation by collecting what few eatable foods were available. They relied, instead, on their knowledge of the country to provide them with a diverse diet and diverse experiences in obtaining it.

Some cooking was accomplished by roasting over the fire or baking in the ashes, but the most popular method was boiling. The typical meal included soup cooked in a pottery or bark vessel. Dishes, however, were made not of pottery but of bark or of carved wood, as were the spoons used in eating. Each individual had his own bowl and spoon, and so an invitation to a feast was likely to include the invitation to "Come, and bring your bowl and spoon." Corn was generally prepared by pounding it with a wooden pestle in a wooden mortar hollowed out of a tree trunk. Before pounding, the corn was usually soaked in ashes to make removal of the hull easier. Occasionally, however, the corn was ground between two flat stones.

Housing, transportation, and weapons. As the land provided the Indian with food, so also it provided him with other necessities of life. The culture of 19th-century white American farmers has been labelled a "wood culture," and the earlier Indian cultures of the area may also be so characterized: the forest provided the Indian with many of the raw materials that he used to make his houses (as well as the food implements described above). Two types of houses were built: the wigwam by the upper Great Lakes and Eastern Seaboard Algonkians and the longhouse by the Iroquoians. The wigwam was made by driving a number of pointed poles into the ground to make a circular or oval floor plan. These poles were tied together with strips of bark and reinforced with other poles tied horizontally to make a dome-shaped framework that was covered with bark, reeds, or woven mats, the type of covering depending on the availability of materials in the

area. A fire in the centre provided heat for cooking and for warmth. Although the Iroquoian longhouse, like the wigwam, was made of a framework of poles covered with bark sheets, it was arbor-shaped rather than dome-shaped, having straight sides and an arched roof. After European contact, the roof shape often was of the gable type. Rather than being circular or oval, the longhouse was rectangular in floor plan and had a door at either end. A longhouse was approximately 20 feet wide and ranged from less than 50 feet to more than 200 feet in length, depending on the number of families living in it. Down the middle of the house were the fires, two families on either side sharing the fire in the middle. The average longhouse probably had five fires and ten families.

The forest also provided materials for the dugouts and bark canoes commonly used for transport in this area of many lakes and streams, the birchbark of the northern portions of the area making the best canoes. The forest also provided materials for the frames of the snowshoes, which made travel in the winter easier and which were essential in the north (a man on snowshoes could outrun a moose or other large animal in the snow and take him with an ease that was not possible in more clement seasons). The bows and arrows and the spears used in hunting and warring were also made of wood provided by the forest. Points for the arrows and spears were chipped from flint or other suitable stone, as were the knives and other sharp-edged implements.

Clothing. Animals of the forest provided the skins from which the women made clothing. The basic item of men's dress was the breechclout, a strip of skin drawn between the legs and held in place by looping it over a belt at the waist. For protection from the cold or while travelling in the forest, leggings (basically, two tubes of skin also attached to the waist belt) were added. A cape or robe of skin or fur was also worn in cold weather. The basic item of women's dress was a skirt, to which might be added leggings tied at the knee and a cape or robe. Both men and women wore moccasins, the soft-soled and heelless shoe adapted, among other things, for use with the snowshoe. The clothing of both sexes might be decorated with painting, porcupine-quill embroidery, shells, or shell beads. For special occasions, such as feasts and war expeditions, the body might also be decorated with paint and jewelry. (The face might also be tattooed.) Long hair was admired and might be greased to give added lustre. A number of men plucked out some hair and cut the remainder to form roaches or other distinctive styles.

Social organization. The relatively small numbers of Indians who lived in the area and their particular manner of obtaining the essentials of life—food, clothing, and shelter—did not require an elaborate social organization to coordinate their activities. Rather, it was a way of life that tended to foster individual self-reliance. Division of labour was simple: women took care of the children, did the cooking and other household tasks, made the clothing and basketry containers, and did much of the agricultural work; and the men hunted, fished, traded, warred, and made the houses and the implements that they used. Beyond this division of labour by sex, there was little specialization.

Bands, tribes, and confederations. An important unit of social organization was the band, a loosely organized collection of people who occupied a particular tract of land and who recognized a common identity, including a name for themselves. A number of names now known locally as Indian tribal names were band names. Several bands comprised a tribe, which, like the band, was loosely organized and which in many parts of the area was not so much a political unit as a cultural one—a group of people who spoke a common language and had similar customs. (It is the names of tribes rather than of bands that are listed at the beginning of this article.)

Although chieftainships often were inherited, personal ability was the basis for the influence that was exercised by a chief (sometimes termed sachem, especially in the eastern part of this area). The man who had the requisite abilities was chosen to succeed. Particularly important to a chief was his ability to persuade. As one result, oratory

Leaders
and
councils

Wigwams
and
longhouses

was highly valued and developed into a fine art; even in English, the power of Indian oratory is evident. Typically, the councils of the Indians involved the making of speeches, but the intent of this oratory was not to impress others with mere rhetoric but to find a solution to the issue at hand that all could agree to. If unanimity was not achieved, no action could be taken. The dissidents would either continue to express their opposition or withdraw; in either case, the effectiveness of the group would be weakened. Speech making, then, served as a means of ascertaining the diversity of opinion within the group and the manner in which consensus could be reached, for commonly each speaker summarized the opinions previously expressed before offering his own. Councils often were lengthy affairs.

Councils (including some religious councils—the Indians typically did not draw a sharp distinction between sacred and secular affairs) normally opened with the smoking of a pipe. In the Midwest, this practice was elaborated into the calumet ceremony used to greet foreigners and on other occasions. It is from this custom that the phrase “smoke the peace pipe” is derived.

League
of the
Iroquois

The most elaborate and powerful political organization developed in this area was that of the League of the Iroquois, but even this league rested on the political principles to be found elsewhere. Unanimity was required (the failure to achieve this unanimity being one of the reasons for the Iroquois defeat at the hands of the Revolutionists during the Revolutionary War), and oratory was highly regarded. Tradition has it that the league was formed as a result of the efforts of Dekanawida and Hiawatha probably sometime in the 15th or 16th century. The intent of the league was to establish peace among the five tribes of the Iroquois (the sixth member of the league, the Tuscarora, was to join it in the early part of the 18th century); and thus one of the most important parts of the constitution of the league established the price for murder: ten strings of wampum (shell beads) for the life of a man and 20 strings of wampum for the life of a woman, to be paid to the kinsmen of the murdered person. (If a man murdered another man, the total paid by the relatives of the murderer was 20 strings of wampum—ten for the murdered man's life and ten for the murderer's life, which had been forfeited by the act of murder; the total for murder of a woman by a man was 30 strings of wampum, and so on.) Before the establishment of the league, tribes might go to war if the compensation was not considered just, a common custom in the area. (Witchcraft, not murder, was the most serious crime among Indians and evoked capital punishment.) The fixing of the price prevented war from occurring between members of the league, although not between members of the league and other tribes.

If the League of the Iroquois was a league of peace to its members, it was not to other Indian groups. In the 17th century, beaver had become scarce in Iroquois territory. They began a series of wars with their neighbours, defeating and dispersing the Hurons and Tionontati in 1649–50 (a number of Hurons and Tionontati were to join forces to become the Wyandot), the Neutrals in 1651, the Erie in 1656, and the Susquehanna in 1675. Earlier, about 1638, the Wenrohonons had joined the Hurons in consequence of Iroquois attacks on them. The Iroquois then took on still more distant Indian peoples.

The founding of the League of the Iroquois has been dated variously from about 1460 to about 1600, but, regardless of whether the date is pre- or post-Columbian, it seems likely that its strength and effectiveness increased as a consequence of European influence on the continent. Somewhat similarly, loose confederacies of various Indian bands were established along the Eastern Seaboard after European contact, in part to counter the force of the whites. Later, diverse groups of Indians living in the upper Great Lakes area banded together in a like manner, under the leadership of particularly influential chiefs, in order to affect events in that region.

Warfare

It seems likely that warfare among Indians increased in the years following European settlement and the establishment of trading posts. War parties were, typically, groups of men gotten together for the purpose of raiding for loot

or for captives. For example, if compensation for murder had not been agreed on, a war party might be raised to avenge the murder and might include the taking of a captive to replace the murdered person. Before setting out, there might be a ceremony in which the men would boast of previous exploits, both to gain recruits and to rouse feelings to the proper pitch.

Among the Iroquoian, captives taken during war might be killed or brought back to the village, where they were either tortured to death or adopted into the tribe. If the captive was taken to compensate for a previous murder, he was often given to the family of the murdered person, and that family decided whether the captive was to be tortured to death or adopted as a member of the family. If the decision was for torture, members of the community tried to excel each other in the invention of tortures. The captive tried to accept these tortures without crying out—a practice that has contributed to the white stereotype of the stoic Indian. A captive who was killed might be scalped. Scalping may have been introduced by the Europeans, but the evidence is not conclusive. It may have been merely an elaboration of the old Indian custom to take a piece of hair or clothing of the killed person as a trophy of the event.

Clans. An important kind of social group in the area, particularly in the more southerly parts, where agriculture was relatively more important and population density higher, was the clan (sometimes now termed sib). The division of a tribe into clans served both to divide the community into smaller cooperating units and to provide a means of uniting it with others. Members of the same clan had certain obligations toward one another, regardless of tribal or community affiliations. They were expected to provide hospitality to visitors of the same clan, for example. Loyalty to clan often overshadowed that to the nuclear family, but the marriage tie among Indians often was a relatively unstable one and frequently was marked by little or no ceremony. In contrast, clan affiliation continued for life. On occasion, clan membership was as important as tribal, band, or village membership.

Clans often have names that refer to an animal. The Seneca clans, for example, are Turtle, Bear, Beaver, Wolf, Snipe, Hawk, Deer, and Heron. The animal, or totem (a word adopted into English from the Algonkian word meaning “kinsmen”), had a special relationship to the clan. Members of a clan considered themselves to be related, whether an actual genealogical relationship could be traced or not. Partly because of this view, the members of a clan were not permitted to marry within the clan (that is, clans were exogamous).

Among the Iroquoians and the Delawares, a child automatically belonged to the clan of his mother (that is, the clans were matrilineal). Among the Winnebago and many other upper Great Lakes (Central) Algonkians, a child belonged to the clan of his father (that is, the clans were patrilineal—such patrilineal clans sometimes being termed gentes; singular, gens). Thus, for example, an Iroquois child of a father who belonged to the Wolf clan and a mother who belonged to the Turtle clan was a member of the Turtle clan, the clan of his mother. Further, he could not marry (without being accused of committing incest) a girl who also belonged to the Turtle clan. And if he married a girl, say, of the Bear clan, she did not become a member of the Turtle clan but remained a member of her own clan, the Bear clan, because clan membership was for life. (In a few instances, an individual might be adopted into another clan, but this had nothing to do with marriage.) In tribes that had clans, everyone in the tribe belonged to a clan; and, if a captive or other person was adopted into the tribe, he was also adopted into a clan of that tribe.

Commonly in this area, each clan owned a number of names, and a newborn child was given one of the clan's names that was not currently in use (that is, a name belonging to someone then deceased or a name that had been given up for a new name by someone still living). Certain names carried special responsibilities, such as those belonging to the 50 chiefs of the Iroquois League. When a chief died, the women of his clan decided on a successor,

Names
and rela-
tionships

who was a member of the same clan. If the successor was approved by the other chiefs, he was given the name of the deceased chief in the condolence ceremony, in which the chief was "raised up" and resuscitated by giving his name to his successor.

Among many upper Great Lakes tribes, the clan owned a bundle of sacred objects, with which there was associated a ritual that was performed periodically by members of the clan. At least in recent times, the Iroquois had no comparable clan ceremonies; rather, a significant part of their ritual life centred on ceremonies in recognition of foods as they matured. These rituals included the maple, strawberry, bean, green corn, and harvest festivals, as well as the midwinter ceremony.

In some groups, such as the Winnebago and the Iroquois, the clans were grouped into two sides or moieties ("halves"), which had reciprocal obligations. Among the Iroquois, for example, members of a moiety buried the dead of the opposite moiety. Traditionally, the moieties were exogamous, and thus, in a sense, they provided wives for each other.

Medicine societies. Also often important in Indian religion are the medicine societies, so termed because one of their important functions was curing and because their membership consisted of individuals who had undergone such cures. The most famous medicine society among the upper Great Lakes Indians was the Mide Society (Midewiwin, or Grand Medicine Society), a society that held elaborate annual or semi-annual meetings during which various magical feats were performed. Of the various Iroquois medicine societies, the False Face Society is most familiar to whites because the carved wooden masks worn by members of this society during their rituals often are to be found exhibited in museums and pictured in books on Indian art.

Belief systems. Not all curing was performed by members of medicine societies. Certain individuals (often termed medicine men or shamans in anthropological literatures or powwows in the literature on New England Indians) had the power to cure, a power that was often indicated in a vision or dream. Dreams were especially important, because, generally among the people of this area, dreams indicated not only the causes of illness and an individual's power to cure but also the means of maintaining good fortune in various aspects of life. So much attention was paid to dreams that, among some Indians, a mother customarily asked her children in the morning if they had dreamed, for dreams were to be cultivated and attended to. Dreams could also influence the decisions of councils; as some early writers said, "The dream is the God of the country." Although the vision had some importance and although boys in the various tribes might seek a vision experience (particularly about the time of puberty), the vision quest (and the concomitant acquisition of a guardian spirit) was not as important in the area as a whole as it was among the Plains Indians.

The reliance on dreams, on the other hand, should not be interpreted as meaning that these Indians lived in a fantasy world. In these societies in which great emphasis was placed on self-reliance and on individual competence, attention to the content of dreams provided a means of understanding oneself and of bringing to consciousness knowledge stored in the unconscious, including knowledge as to where one's greatest abilities lay; for dreams and visions might indicate whether one had special ability in warfare, hunting, and the like.

Indians, moreover, did not lack real knowledge of herbal medicine. Indeed, it was the reputed success of their medicine that added credibility to the value of bottles of "Indian oil" and other medicines sold by the touring "Indian shows." Certain other practices, such as the sweat baths taken in small structures built for the purpose, also were beneficial in the treatment of others. The Indian practice of soliciting the aid of medicine societies and shamans to cure illnesses not cured by "natural" means is not unlike the modern-day treatment of psychosomatic illnesses.

More difficult for a member of Western civilization to comprehend is the "spirit world" of the Indian, for it appears to the outsider as if the Indian world was populated

by a number of spirits, including spirits of such natural objects as the sun, the moon, thunder, and the trees. Some anthropologists have interpreted these beliefs as meaning that the Indians believed in pure supernatural power—that is, a force in the universe that, like electricity, could attach itself to certain persons and things. The Algonkian word *manito*, the Siouan word *wakan*, and the Iroquoian word *orenda* have been interpreted as referring to such supernatural power. There is some recent evidence, however, suggesting that this difference between Western and Indian thought rests on a different classification of the animate and inanimate worlds. The Indians classed as animate such things as the sun and the moon. And even those things that they regarded as inanimate they treated as "beings"—to be feasted as human beings are, to be called by kinship terms as human beings are, and in general to be paid attention to. Their exploits, like those of human beings, are reported in tales and myths.

MODERN DEVELOPMENTS

When the whites arrived on the North American continent, they brought manufactured goods that the Indians wanted and new diseases that they did not. Certain of the new diseases proved particularly virulent among Indians because they did not have the immunity that the whites had developed through centuries of exposure. At one time or another, all the Indian tribes were decimated by epidemics. In one notable instance, an epidemic swept over New England, killing many Indians in 1616–17, just a few years before the Pilgrims landed at Plymouth, a catastrophe that the Pilgrims saw as a sign of God's favour. (One reason that the Indian Squanto was so friendly to the Pilgrims was that he had been taken as a captive to Europe, spent some time in England, and had returned after the epidemic.)

The extensive trade that developed between the Indians and the Europeans (French, English, and Dutch) rested on the European desire for furs, particularly for beaver fur (beaver fur makes a fine felt, and beaver hats were the rage in Europe), and on the Indian desire for European-manufactured objects, particularly guns, kettles, needles, fishhooks, other metallic objects, and beads.

The Europeans soon discovered the Indians' desire for wampum (tubular beads made of shell) and thus established "wampum factories" in New Jersey and on Long Island. The Indians used wampum for jewelry and for gifts or signs to mark significant occasions. Important messages, for instance, were accompanied by strings of wampum; the making of treaties involved the exchange of wampum belts to confirm the sincerity of the parties and to serve as reminders of the agreement. They also were used on other political and religious occasions and kept as reminders of the occasions. Because it was valuable, wampum became a medium of exchange not only between Indians and white traders but also among the colonists. Because the coinage in common use in the colonies was already various, including Spanish, Portuguese, French, and Dutch coins as well as English ones, the adoption of wampum as another medium of exchange was an easy matter. Wampum, however, was not used as money before European contact.

The initial European settlement clung to the Atlantic coast—the sea providing the lifeline to the European homeland that the colonists needed—and thus the Eastern Seaboard Indians were first affected by the newcomers' desire for land. They were ill equipped to counter the invasion. Not only were their numbers relatively small and made even smaller by the epidemics, but their political organization was not of the kind that easily led to unified action of numbers of men. Friction between Indians and colonists did occasionally erupt, however, as in the Pequot War (1637) and King Philip's War (1675–76). Such resistance could not be maintained long, and these eastern Indians, as other Indians after them, began to adopt European ways as a means of survival. Such adoption often involved the acceptance and practice of Christianity as well as other features of European life. Some missionaries were especially influential. John Eliot, for example, accomplished the monumental task of translating the Bible into Algonkian and publishing it. There remain in New

England and on Long Island some few reservations on which the Indians still are to be found. Further south, however, the Delawares gradually sold their land in the 18th century and began to drift west, becoming involved in the affairs of the country there.

The Iroquois fared somewhat better than the coastal Algonkians. In the 17th century and in the 18th century, they lived too far inland for European settlement, and only parts of their eastern territory were settled by whites. Also, the Europeans wished to maintain their trading relations with them and, through them, with Indians living farther west. The Iroquois themselves took advantage of this situation, engaging in war and diplomacy to maintain their position of power in the Northeast. Their power was finally broken in the American Revolution when George Washington, aware of the alliance of a number of Iroquois with the British, sent a punitive expedition into what is now upstate New York. After the Revolution, a number of Iroquois moved to Canada, though many remained in New York state. With the exception of many Oneida who moved to Wisconsin, those who remained in New York successfully resisted 19th-century efforts to move them (along with other eastern Indians) west of the Mississippi, and a number of them still live on the six Iroquois reservations in the state.

Like the Indians farther east, those of the upper Great Lakes area were greatly affected by the fur trade. The French established a series of trading posts, and the English challenged them for control of the area. Indians from the east, such as the Delawares, Wyandots, Ottawas, and Shawnee, drifted into the area seeking furs and land. The result was a series of wars and skirmishes between the English and the French and the Indians. Among the Indians, there emerged a series of prophets who attempted to revitalize Indian society and a series of chiefs who attempted to unite the Indians for the purposes of war. Notable among these were the Delaware Prophet, the Ottawa Pontiac, the Miami Little Turtle, the Shawnee Tecumseh and his half brother, the Shawnee Prophet (Tenskwatawa), and the Sauk Keokuk and Black Hawk. The upper Great Lakes Indians responded to various pressures put on them by whites, and many of them moved west. They are now to be found on reservations and other settlements of the more western states, though some still live in the upper Great Lakes area.

If there is any single thread that runs through the complex history of Indian-white relations, it is probably that of ambivalence. The Indians had certain resources that the whites wanted, and the whites had certain items that the Indians wanted. At times, these interests could be pursued to the benefit of all involved, but too often the interests of the various groups were in conflict. Emotionally, too, the attitudes have often been those of ambivalence: the Indians both wanting acceptance by whites and wanting their own separate identity and the whites both wanting to be rid of the Indians and admiring them. This ambivalence is likely to continue, for their histories and cultures are now so entwined that it is impossible to separate them.

(E.To.)

Southeast American Indians

The Southeastern American culture area is bounded on the east and south by the Atlantic Ocean and the Gulf of Mexico (though some scholars would place the southern portion of aboriginal Florida within the orbit of the circum-Caribbean culture area). To the west, the Southeastern area merges with the southern Plains and the extreme easternmost part of the Southwestern culture area. To the north, the Southeast blends into the northeastern woodlands area with no discernible break in cultural tradition (see also above *North American Plains Indians* and *Eastern Woodlands Indians*.)

Physiographically, the Southeast is characterized first by a coastal lowland belt broadly encompassing the subtropical zone of southern Florida; the scrub forest, sandy soil, and savannah grassland of the Atlantic and Gulf coastal plains; and the alluvial floodplains of the Mississippi drainage. Second, there is the piedmont of the midland interior,

where the landscape changes to rolling hills, crisscrossed by several major river systems and covered predominantly with oak-hickory forest. Third, there is the southern Appalachian Mountains area of eastern Tennessee and the western Carolinas, a land of high peaks and deeply etched valleys, containing hardwood forests and, at high elevations, flora and fauna typical of more northerly regions.

The Southeast was one of the more densely populated areas of native North America, having an aboriginal population conservatively estimated at 120,000. The bulk of this population resided inland, where advantage could be taken of extensive game resources, wild plant foods, and an abundance of arable land. Only the non-horticultural peoples of south Florida appear to have satisfactorily adjusted to a basically maritime way of life.

Population was distributed among a large number of separate groups—-independent villages, autonomous village clusters, and “tribelets.” Most of those tribelets disappeared soon after white contact and left only faint traces in recorded history. They perished through the lethal combination of newly introduced diseases, removal into slavery, and direct warfare with white invaders or intertribal conflicts generated by white pressure. The survivors, if any, were assimilated into such larger, more powerful tribes as the Choctaw and Cherokee and various member tribes of the Creek Confederacy. These latter tribes persist to the present as distinctive peoples possessing a rich history and viable cultural heritage. Other intermediate-sized groups, such as the Houma, Catawba, and Chickasaw, survive as marginal enclaves but have lost much of their historic Indian identity. Such groups as the Seminoles (a branch of the Creek that migrated to Florida in the 18th century) and the Lumbee (a large group of Indians in Robeson County, North Carolina, whose precise Indian ancestry is unknown) appear to be entering an active phase of retribalization in which their Indian identification is being reasserted.

Muskogean-speaking peoples constituted the major linguistic family in the aboriginal Southeast. The Muskogean family included the following five main subdivisions: (1) Choctaw and Chickasaw, two different dialects of a single language, found in Mississippi and western Tennessee; (2) Apalachee, a long extinct language of northwestern Florida; (3) Alabama and Koasati, two closely related languages spoken in the central Southeast; (4) Hitchiti and Mikasuki, two related dialects, formerly spoken in Georgia; and (5) Creek and Seminole, also closely related dialects, spoken in eastern Georgia and later in Florida.

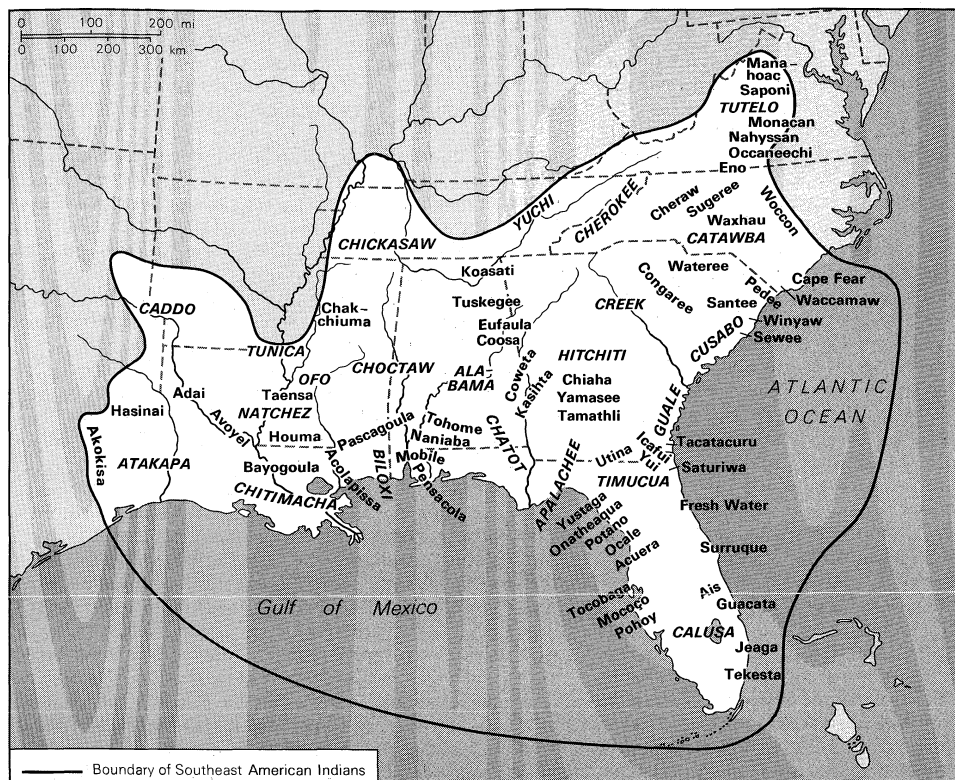

Four Lower Mississippi Valley languages, namely Natchez, Tunica, Chitimacha, and Atakapa, are thought to have distant affinity to Muskogean, but they show sufficient divergence both from the main Muskogean languages and from each other to warrant semi-independent status as linguistic isolates. Timucua, the major language of aboriginal north Florida, was once thought to be related to Muskogean, but its present status is problematic. One linguist believes it may be related to a language spoken in Venezuela, while others feel it may bear ultimate relationship to Siouan.

There are four definite representatives of the Siouan family in the Southeast: Tutelo, Biloxi, Ofo (Mosopelea), and Catawba. These tribes were widely scattered and, with the exception of Biloxi and Ofo, show little relationship to one another and probably represent different prehistoric penetrations of Siouan speakers into the Southeast. Yuchi, the language of a major tribal group once residing in eastern Tennessee and later in Georgia, also demonstrates distant affinities to Siouan but is sufficiently distinctive to be classified as an isolate. Many small piedmont tribes were probably Siouan speaking, but surviving data are insufficient to make definite identifications.

The Cherokee represent the sole member of the Iroquoian family in the presently demarcated Southeast, though the Iroquoian-speaking Tuscarora, Nottaway, and Meherin, residing on the margin of the area, are included in the Southeast in some culture area maps. The Caddoan speakers on the western boundary of the Southeast belong to a distinctive language family that shows distant relationships to the Siouan and Iroquoian families. The

affiliations of many of the smaller coastal and piedmont tribes are unknown. Mention should also be made of Mobilian, an important trade language containing many Choctaw components, which served as a lingua franca in the Mississippi Valley.

TRADITIONAL CULTURE PATTERNS

It is difficult to describe the Southeast in terms of a total cultural pattern or dominant ethos. The environment provided possibilities for such different ecological adaptations as the dependence on maritime resources and the wild zamia root by the Calusa of south Florida and the seasonal buffalo hunts of the horticultural Caddoan tribes. Besides the internal diversity, the external relations of the Southeast are also complex. The lack of geographic barriers to the north and west allowed significant cultural interchange between the Southeast and adjacent areas. There is evidence of overseas cultural connections with the Antilles; however, the dominant thrust of this diffusion seems to have been from the mainland to the islands. Such individual culture traits as the cane blowgun, double-weave basketry, fibre-tempered pottery, and miscellaneous musical, ritual, and mythological details suggest at least limited contact with northern South America. More definite is prehistoric cultural contact with Meso-America. Not only did such basic cultivated plants as maize, beans, and squash ultimately derive from Meso-America, but numerous symbolic motifs in Southeast religious art have close analogues in ancient Mexico.

The picture of the Southeast that emerges at the time of first European contact is one of intensive cultural change. One senses a period of cultural levelling marked by considerable population movement, warfare, and the formation of confederacies, all of which was accompanied by large-scale technological and ideological diffusion. A distinctive Southeastern cultural tradition or style was in the process of being forged, but this fusion was far from complete on the eve of European contact.

The village or town

Social organization. *Settlement patterns.* The basic political unit for most Southeastern tribes was the local village or town. This basic unit varied in size and configuration depending on differences in local ecological potential and cultural preference. Some towns attained

populations of over 1,000 individuals, but the more typical Southeastern village numbered less than 500 people. Settlement patterns conformed to two basic types: (1) dispersed hamlets, with households strung out for several miles, usually following valley bottoms or streams, and (2) tightly nucleated settlements often surrounded with protective timber palisades. The heart of the local town was a ceremonial centre consisting of a central council house or temple, which in the interior region might be semisubterranean or located on a pre-existing mound; a central plaza or square, which, among the Muskogean-speakers, was usually surrounded by three or four benches or harbours oriented in the cardinal directions; a ball pole or scalp post sometimes culminating in a carved animal emblem; the residences of the chief and other important local dignitaries; and sometimes storage structures for communal produce.

Considerable variation in house types existed. In much of the area, the Indians constructed circular, conical-roofed winter "hot houses," sealed tight, except for an entryway and smoke hole. Summer dwellings tended to be rectangular, gabled structures made from a framework of upright poles, lashed together and covered with lath, grass, cane matting, or bark and plastered with clay. To the south, housing tended to be more flimsy, with raised floors, palmetto thatched roofs, and, often, open sides. To the west, the Caddoans lived in domed "grass houses." A homestead might contain auxiliary storage buildings and a special cookhouse.

Each town or village was fairly autonomous. Superordinate control at the tribal level tended to be weakly developed, although pressure for tribal consolidation and even the formation of intertribal confederacies was greatly increased with the coming of Europeans. A village might be linked to other villages in the same area by ties of kinship, language, and shared cultural traditions; nevertheless, each village claimed sovereignty over its local area and was governed by its own chiefs and war leaders.

Stratification. Over most of the Southeast, chieftainship tended to be hereditary within certain lineages. The degree of chiefly power and authority varied, however, from the almost divine kingship of the Great Sun among the theocratic Natchez to the self-effacing status of the peace-

Chiefs and other leaders

making, consensus-seeking *micos* and *ukus* among the more egalitarian Choctaws, Creeks, and Cherokees. War leaders normally achieved their positions on the basis of past accomplishment. War chiefs tended to be active and assertive personalities and younger, by about a generation, than the peace chiefs.

The alternation between peace and war or the occurrence of such competitive activities between alien groups as ball games, communal hunts, and trading expeditions helped to imbue much of Southeastern social structure with a characteristic dualism. The peace chief held sway in the domestic village, whereas the war chief was ascendant in areas external to the village, except when the village was under threat of imminent attack. Young men in the village alternately adjusted to roles appropriate to war and peace, often symbolically represented as red and white activities, and these transformations were usually effected through extensive ritual. This dualistic emphasis was also frequently expressed in the organization of clans, subtribes, and villages into complementary social divisions.

Social stratification was highly developed in some parts of the Southeast, while its significance in other subareas was minimal. Although much has been written about the supposed caste systems among the tribes of the Lower Mississippi, the Chitimacha appear to have been the only society to have possessed true castes in the sense of ranked groups that practiced strict endogamy (marriage within the group).

The elaborate rank system of the Natchez consisted of four groups: three upper classes, composed hierarchically of the suns, the nobles, and the honoured people, and a lower class of commoners (or stinkards, as they are referred to in the early French sources). Upper class individuals were required to marry into the lower class of commoners, and many commoners also married other commoners. Offspring of males in the upper classes would assume a rank one step below that of their fathers (thus, the child of a sun father and commoner mother would become a member of the noble class). The progeny of upper class females, however, would retain the rank of their mothers rather than descend to a lower station. The system, as described, would be unstable, since the supply of available commoner women would soon be depleted after several generations. Many explanations have been advanced to explain this so-called "Natchez paradox," but the difficulties probably reside in the inaccuracies or incompleteness of the original French sources.

Social stratification also was highly elaborated among the aboriginal inhabitants of Florida. Among the Timucua, for instance, the "king" enjoyed an elevated status considerably above that of his followers and was sometimes carried about in a litter. In many other Southeastern societies there was a trend toward the ranking of towns or clans. Member towns of the Creek Confederacy were sometimes ranked in terms of their tribal affiliations or on the basis of outcomes of inter-town ballgames. The Caddo were said to have ranked their clans on the basis of the reputed strength of the totemic animal ancestor in a kind of natural "pecking order." In other tribes, such as the Cherokee, stratification was only weakly developed, though certain clans might possess special ceremonial prerogatives and recruitment to certain offices might be determined on the basis of clan.

Kinship and marriage. In the Southeast, descent was almost universally reckoned in the female line, though not all societies possessed matrilineal clans. Clans, where they existed, were apparently not restricted to nor localized within specific villages. The resulting dispersal of clan members throughout a tribe or nation thus served as a kind of social adhesive binding together the larger body politic. Certain ceremonial knowledge and privileges might also be passed down along clan lines, and clans were also important as mechanisms of social control, since vengeance for serious crimes was frequently a clan responsibility.

Marriage was often marked by a symbolic ceremonial exchange whereby the groom presented his bride with game and the bride reciprocated with vegetable food. Because residence after marriage normally found the man moving into the wife's natal household, the husband was expected

to contribute to the economic maintenance of his wife's family, as a form of bride service. After a few years the couple might leave to form their own household. Most Southeastern tribes permitted and some even encouraged pre-marital sexuality. After marriage, however, adultery—especially on the part of the wife—was often severely punished. Nevertheless, divorce seems to have been a frequent and, often, almost casual event. Polygamy was permitted in most groups, although a man usually had to gain the assent of his first wife before taking on a second spouse. The levirate, a custom by which a widow was remarried to her deceased husband's brother, was fairly common, particularly as male mortality increased during the wars of the European period.

Socialization. During a woman's late pregnancy, both she and the father were often subjected to various dietary taboos and restrictions on their activities. Children were nursed until they tired of the breast or until the mother again became pregnant. Responsibility for the child's early education was vested in the mother. Later, a young boy received instruction in male skills from his father and his mother's brother; in many systems the mother's brother, as the senior male in the matrilineage, assumed considerable importance as a disciplinarian, tutor, and sponsor for his sister's son. Young girls remained at their mother's side and were trained in various duties associated with the domestic household. Behaviour considered proper was reinforced with praise and encouragement, as when a boy killed his first deer or a young girl manufactured her first basket; behaviour considered improper might be greeted with mild rebuke, ridicule, or shame. Children were rarely subjected to physical punishment. In those few instances in which punishment was deemed necessary, it was generally meted out by someone other than the parents. A popular method of chastisement throughout the Southeast was raking the skin with briars or a special pointed scratching instrument, but, even here, such action was regarded as strengthening or toughening the youth, rather than as delivering direct retribution for misdeeds. Young boys enjoyed considerable permissiveness. They spent much time with their peers in wrestling, playing games imitative of adult activities, and stalking rabbits, squirrels, and birds with blowguns and scaled-down bows and arrows. The freedom and wide behavioral space permitted the young boy contrasted markedly with the restricted sphere, close surveillance, and early responsibility training that characterized the daily routine of his sister.

Puberty rituals were either absent or only weakly developed in the Southeast. Girls were secluded during their first menstruation, but this event occasioned no public celebration. (Menstrual blood, though, was regarded as a potent and polluting substance, and women either absented themselves from the household during their periods or were subjected to restrictive taboos.) Similarly, no special rituals attended the transition from boyhood to manhood. A boy might receive instructions from tribal elders in esoteric lore or in preparation for special ritual offices, but graduation from such training seldom was marked by a formal commencement. A young man's first participation in a war party and the achievement of military honours were, however, given public recognition. Probably the clearest marker of the passage from adolescence to adulthood was marriage.

Economic systems. As already implied, the primary division of labour was by sex. Women were responsible for cultivating the fields, gathering wild-plant food, cooking and preserving food, rearing the young children, and manufacturing such basic domestic items as cordage, baskets, pottery, and clothing. Men assumed the primary roles of warriors and hunters, occupations that often took them away from the village for extended periods of time. Men also cleared the fields by girdling trees, assisted in the harvest, constructed houses and public buildings, and manufactured ceremonial objects and implements for personal use.

Except for the marginal groups on the western Gulf Coast, villages were semipermanent and located near rich alluvial soil or, in the Lower Mississippi region, near natural levees. Such land was easily tilled, possessed adequate

Social
ranking
among the
Natchez

Rites of
passage

Marital
customs

drainage, and enjoyed enduring productivity. Fertility was enhanced by the custom of annually burning off the brush. The length of the growing season in most regions of the Southeast allowed multiple crops. Planting was done in spring, and some produce was available by mid-summer. The major harvest time, however, was late summer and early fall, a time of plenty when most of the major ceremonies were celebrated. Many villages became deserted, except for older people, during the winter months, when families took to the woods in search of game. Men also departed for a shorter hunt in late spring and early summer, after the crops had been planted.

Cultiva-
tion of
maize

Principal foods and goods. The economic mainstay of the Southeast was maize, the cultivation of which was well established in most areas by the time of first European contact in the mid-16th century. Several varieties of maize were grown, including "little corn" (related to popcorn); flint, or hominy, corn; and flour, or dent, corn. Early corn was baked as roasting ears; later corn was pounded into hominy or cornmeal in wooden mortars made of large, upright, partly hollowed logs. Associated in the maize complex were varieties of beans and squash. Fields were prepared with mattocks and hoes and planted by punching holes in the ground with dibbles (digging sticks), inserting seed, and covering the holes with earth to form a small mound. Cornfields belonged to individual households, but among some tribes communal fields were also cultivated, with the produce going to the chiefs for support of the civil-religious hierarchy or for redistribution to the needy.

The importance of maize cultivation to the way of life of the southern Indians cannot be overemphasized. Not only did maize provide a high yield of nutritious food with a minimal expenditure of labour, but maize, beans, and squash could be easily dried and stored for later consumption. This reliable food base enabled men to spend much time away from their villages on hunting, trading, and war expeditions. It was not fortuitous that the standard war ration was parched corn.

Other
important
plants and
animals

Secondary cultivated plants included the sunflower (processed for its oil), chenopodium or orache (spinach-like greens), and tobacco. Many additional plants, such as species of wild grapes, plums, and perhaps walnut and pecan trees, can be regarded as being in a condition of incipient domestication, since there is evidence to suggest that Indians exerted some effect on selection. Important wild-plant foods were various types of berries, nuts and acorns, wild potatoes and amaranths, smilax, zamia root, and maple sugar or honey locust sap. The economic botany of the Southeastern Indians can be expanded to encompass the vast array of plants utilized for cordage, clothing, dyes, fish poisons, medicines, building materials, and various tools and utensils. Perhaps mention should be made of the distinctive Southeastern use of two species of holly (*Ilex cassine* and *Ilex vomitoria*) as ingredients in a special decoction, the "black drink," to induce sweating and vomiting in ceremonial and medical contexts.

The only native domesticated animal in the Southeast was the dog, which was used to a minor extent in hunting and was probably more important as a sentinel to warn of the approach of strangers. In accounts of the Hernando De Soto expedition (1539-43), there are several references to small, fat, barkless dogs that were served to the Spanish visitors by their Indian hosts. Spanish trail hogs, brought by De Soto to feed his troops, became wild and were ancestral to the modern mongrel razorback hog. Horses were introduced later, mostly through the intermediacy of tribes to the west.

The aboriginal Southeast also teemed with wild game: deer, black bears, bison, elks, beavers, squirrels, rabbit, otters, and raccoon—some of which were used for their hides, bone, or fat as well as for food. In Florida, turtles and alligators played an important part in subsistence. Among birds, wild turkeys were the principal quarry, but partridges, quails, and seasonal flights of pigeons, ducks, and geese also contributed to the larder. The feathers of eagles, hawks, swans, and cranes were highly valued for ornamentation, and in some tribes a special status was reserved for an eagle hunter.

Both on the coast and on inland rivers, streams, and

lakes, a wide variety of fish were taken in weirs, fish traps, and dip nets and dragnets and by hooks and lines, bows and arrows, and spears. In the interior, poison was administered in ponds and sluggish or dammed streams to gather a rich harvest of stunned fish. Coastal groups gathered oysters, clams, mussels, cockles, and crabs. Interior groups found freshwater mussels and crawfish.

Economic organization and ecology. In the well-endowed Southeastern area, each household group was fairly self-sufficient. The economic specializations and trade networks that did develop tended to centre on subsidiary and luxury items. Salt deposits were unequally distributed and formed one basis for trade. There also was regular trade between the coast and interior, with shells, which were used for beads, pendants, and horns, exchanged for soapstone, flint, furs, and other inland resources. The presence in the Southeast of artifacts made of imported copper and certain types of red clay suggests important trade connections with the western Great Lakes tribes.

Indians are popularly viewed as living in a primeval or virginal territory. Such was not the case in the Southeast. Indians maintained a delicate balance with their environment, and their presence was a vital link in a complex ecological chain. By tillage, controlled use of fire, and hunting, they altered the landscape significantly. Large areas of secondary re-growth favoured certain types of berry bushes and groundnuts. The presence of this secondary-growth flora was, in turn, essential for supporting large populations of browsing deer, squirrels, rabbit, and wild turkeys on which man depended for a large measure of his sustenance. In this process and in combination with hunting, the decline of other animals, such as the wood bison, was probably accelerated. In areas where intensive maize cultivation had already taken hold, such as in the Lower Mississippi, game animals had become scarce in historical time. In the central Southeast, however, the very diversity of plant and animal resources and the highly generalized adaptation of the Indian in exploiting these resources seems to have resulted in maintenance of an equilibrated balance between man and nature.

Belief systems. *World views.* The delicate man-nature relationship is well expressed in what is known of Southeastern religion and world view. The world was perceived as animated by a proliferation of ghosts, witches, and spiritual essences of animals, plants, and natural objects or phenomena. As can be inferred from the frequent elaboration of funerary practices, most groups professed belief in an afterlife. The location of the resting place for deceased souls was either in the direction of the western setting sun or up above in a celestial firmament. It was generally thought that the souls of the recently deceased would hover around the community and try to induce close friends and relatives to join them in their journey to eternity. The elaborate funerary rites and the extensive taboos associated with death were as much a protection for the living as a commemoration of the dead. Death was nowhere considered a natural event but always the result of malevolent animal spirits or witches or the deadly machinations of sorcerers. If death was thought to be caused by human agents, the soul of the deceased would never rest until vengeance had been secured by living relatives.

It was also believed that animals possessed souls. Slain animals sought vengeance against man through the agency of their species "chief," a mythological animal with great supernatural power. Hunting thus became a sacred act, much imbued with taboos, ritual, and sacrifice. Most disease was attributed to failure to placate the souls of slain animals.

The plant world was considered friendly to mankind, and the Cherokees thought that every animal-sent disease could be cured by a plant antidote. The economic significance of maize was memorialized by the near universality of the Green Corn, or Busk, ceremonies throughout the Southeast. This major ceremonial was suffused with an ethos of annual renewal in which the sacred fire was rekindled; old debts and grudges were forgotten; and a sense of community was regenerated.

Spiritual power might also reside in physical objects. Medicine men possessed sacred stones, quartz crystals, and

Death and
afterlife

other mystically endowed paraphernalia. Other objects were consecrated to symbolize the collective solidarity of the group. The Cherokees made use of a palanquin or litter within which were placed revered objects; the Tuka-bahchee Creeks possessed sacred embossed copper plates; the temples of several Lower Mississippi tribes contained an assortment of idols and icons. Natural objects could be infused with sacred power in a variety of ways: contact with thunder, as in lightning-struck wood; immersion in a rapidly flowing stream; exposure to the smoke of the sacred fire or of ritually prepared tobacco.

Mythology

Remnants of a formal theology can be reconstructed from early accounts of some of the stratified societies and of tribes who survived the immediate ravages of European contact. Most groups possessed origin myths, often involving a primal deluge into which prototypical beings from on high plunged to secure a portion of mud that magically expanded to create the Earth island. The subsequent course of mythological history is frequently related in terms of a cosmic struggle between good and bad culture heroes, one of whom bestows boons on mankind, the other serving as the source of the fatality and misfortune inherent in the human condition. Southeastern myths and folktales are populated by an incredible host of nature spirits, monsters, tricksters, giants, and little people.

Among many tribes, evidence survives that suggests belief in a supreme being, or master of breath. This ultimate divinity was frequently associated with the sun and its earthly aspect, fire. In addition, the world was viewed as divided into four quarters defined by the cardinal directions; each section had a presiding deity and appropriate colour symbolism. Concern with the remote supreme being seems to have rested more with the priesthood than with the everyday activities of the average man. The life of the latter was more intimately tied up with more proximal spiritual beings who were felt to intervene more directly into human affairs.

Priests and diviners. In some of the wealthier stratified societies, priests were given specialized training and became full-time religious practitioners responsible for the spiritual health of the community and assuming responsibilities for conducting the major collective religious rituals that punctuated the annual cycle.

Complementary to the priesthood were various individual magico-medical practitioners, such as sorcerers, conjurers, diviners, and medicine men, who were generally only part-time specialists and catered to individual needs and crises, especially the treatment of illness. Medical therapy

was intricately enmeshed in the magical view of the world but might include such practical procedures as isolation, sweating, bathing, bloodletting, sucking, vomiting, and the internal and external application of herbal medicines.

MODERN DEVELOPMENTS

The complex history of the Southeastern Indians after contact with Europeans can be outlined here only briefly. The 16th century witnessed European exploration of the Southeast, though without permanent settlement. During the 17th century, settlement was begun on the coastal fringes, and the deerskin trade made the Indians increasingly dependent on whites for firearms, metal tools, and luxury items. By the 18th century the Southeastern Indians became counters in the struggle between France, Spain, England, and the nascent United States for control of North America. With the ascendance of the United States, the military threat of the Indians became gradually neutralized, and Indians ceded large tracts of their land in an attempt to placate the insatiable appetite of land-hungry frontiersmen and the ensuing waves of white settlers.

A short-lived Indian renaissance occurred during the first third of the 19th century, when the major surviving Southeastern groups became known as the Five Civilized Tribes. Unabated pressure for Indian land continued, however, and federal policy eventually culminated in the 1830s in the removal of the Cherokees, Choctaws, Creeks, Chickasaws, and Seminoles to the Indian Territory west of the Mississippi. Allotment of tribal lands to individual Indians, which paved the way for Oklahoma statehood, began in the 1890s; some of the land was also opened to white homesteaders, held in trust by the federal government, or allotted to freed slaves. It was originally agreed that tribal governments would be dissolved in 1906, but they continue to exist in a limited form.

Most of the surviving Southeastern Indian population resides in Oklahoma. Although this population reflects a full spectrum of assimilation—from oil company executives to culturally conservative “full bloods”—the increasingly numerous segment of people occupying the culturally conservative end of the continuum exists in poverty. Small contingents of Cherokee, Seminole, and Choctaw who managed to escape the general removal of the 1830s live on tribal landholdings in their traditional homelands. In addition, several remnant groups, such as the Catawba, Lumbee, and Houma, remain in the Southeast, though much of their cultural distinctiveness has disappeared.

Territory

MIDDLE AMERICAN PEOPLES AND CULTURES

The physical spine of Middle America is the broad mountain chain extending from the southern end of the Rockies to the northern tip of the Andes, with Middle America in the area from northern Mexico to Nicaragua. The mountain chain marks off the area into four major regions. The heartland of Middle America is the central valley of Mexico. A second region is the highlands along the southern Pacific slope of Mexico. Beyond the Isthmus of Tehuantepec are the southeastern highlands in the Mexican state of Chiapas and in Guatemala. The arid region in the northwest of Mexico is a fourth region.

Within these four major geophysical regions there is tremendous variety in ecology, climate, soil, and the possibilities of human life. The mountains crumple the face of the land into a multitude of valleys and microenvironments; the result is a mosaic of crops, peoples, and settlements about which it is difficult to generalize. The high valleys of central Mexico, Oaxaca, Jalisco, and Guatemala have been the most densely settled parts of Middle America. But the lower slopes of mountains near the seacoasts have also carried substantial populations. The steamy tropics of the Isthmus of Tehuantepec and the hot limestone thumb of Yucatán have also been heavily populated.

The Indians of Middle America live almost everywhere in the region. The basic requirement for human settlement is water. The major river systems and the high

valley lakes have been the primary settlement sites since prehistoric times.

THE PEOPLE

The Indians of Middle America are all descended from Asiatic forebears who crossed the Bering Strait and moved southward. They tend, except in the Isthmus of Tehuantepec, to be small in stature (155–160 centimetres or a little over five feet on the average), with brown to copper skin, straight black hair, and dark-brown eyes often set above high cheek bones, sometimes with epicanthic folds. The Maya facial features are particularly distinctive, being flatter than those of the other groups; the Maya also have more prominent noses, and a tendency to rounder heads. Mexico is basically a mixed (*mestizo*) nation; there has long been extensive interbreeding between Indians and non-Indians. In Guatemala there has been much less interbreeding. But the term “Indian” is not a biological designation so much as a social, cultural, economic, and linguistic summary of the differences between some rural ways of life and the dominant national culture. Race in and of itself is not socially as important as it is in other parts of the world. The usual census definition of “Indian” is based on linguistic criteria, and the population figures for Indians must therefore be read as figures for speakers of Indian languages.

The Mayan cultural area

Cultural areas. While the social heritage of Middle America is highly complex, within the broad historical flow five separate cultural areas can be distinguished. They are regional configurations of the basic Middle American cultural patterns. One cultural area is that of the Maya. The southern, highland Maya were and are concentrated in western Guatemala and the state of Chiapas in Mexico. The northern Maya inhabited the Yucatán Peninsula of Mexico and the jungle of Petén in Guatemala. The Maya of these two regions form a continuous territorial and historical entity. (There are also contemporary Maya people in Veracruz and San Luis Potosí in Mexico, known as the Huastec.) The monumental ruins left by the pre-Columbian Maya are one of the puzzles of anthropology; theirs is the only civilization known to have flourished in a tropical rain forest.

The southern Mexican highlands and the adjacent coastal regions form a second cultural area within the basic Middle American pattern. This region covers most of the present Mexican states of Guerrero and Oaxaca, the southeastern part of Veracruz, and parts of Puebla and Morelos. Its highland people developed the traditions of the Mixtec and Zapotec, whose ruins survive at Mitla and Monte Albán, whereas the coastal people seem to have been somewhat isolated from them.

A third cultural area is the central Mexican highlands, including the valleys of Puebla, Toluca, and Morelos, along with the eastern slopes of the Mesa Central and parts of the Balsas River Basin. This area was the centre of the Aztec Empire. Mexico City is built on the ruins of the Aztec capital of Tenochtitlán, and descendants of the Aztecs still live in the area.

The mountain chain around the high lake of Pátzcuaro, in present-day Michoacán, forms another cultural area. The relative isolation created by the mountains permitted the Tarascans to work out their own cultural variant. They reached a level of social and political organization comparable to that of the Aztec and the Maya.

A fifth cultural area is northwest Mexico. This region is not historically or culturally a single unit; it exhibits three major types of ecology and three major types of human adaptation. The high mountains provided possibilities for simple agriculture without irrigation, whereas the desert required settlements around valley bottoms dependent on floodwaters in the rainy season. In the west the abundant shellfish were the basis for a coastal culture. The historical forces at work in the northwest area were different from those in the four other cultural areas. The population was taken over by the Jesuits, who built mission communities. The relative isolation of the region following the collapse of Spanish power, together with the weakness of the succeeding Mexican governments, permitted the survival of a blend of Spanish-Indian culture.

Language groups. Hundreds of languages were spoken in Middle America. Some linguists have grouped them in a number of phyla, or superfamilies, each phylum being at the same classificatory level as, say, Indo-European. The Hokaltecan superfamily includes the Yuman family (four surviving languages, two extinct); the Serian family (one surviving language, four extinct); the Coahuiltecan family (four extinct languages); the Tequistlatecan family, with one living language; the Supanecan family (one surviving language, two extinct); and the Jicaquean family, with one living language. A second phylum, Uto-Aztecan, comprises the Piman family (four surviving languages, eight extinct); the Taracahitian family (two surviving languages, 39 extinct); and the Aztecoidan family (three surviving languages, 18 extinct).

Attempts have been made in the past to associate the large family of Mayan languages (about 27 living languages) with several other Meso-American Indian languages (the Mixe-Zoque and Totonacan families, primarily) as the Macro-Mayan or Macro-Penutian languages; the latter term supposes an association also between the Mayan languages and the Penutian phylum of North American Indian languages. These groupings are not generally accepted by modern linguists.

The Oto-Manguean phylum includes the Oto-Pamean family (six surviving languages, one extinct); the Chinan-

tecan family (one living language); the Zapotecan family (two surviving languages, one of which, Zapotec, is so diversified that its many dialects constitute mutually unintelligible languages); the Mixtecan family (three living languages); the Popolocan family (four surviving languages, one extinct); the Chorotegan family (eight extinct languages); and the Amuzgo family (one living language).

In addition to the four phyla there are the Tarascan family of one living language; the Huavean family of one living language; and the Xinca-Lenca languages spoken in small enclaves in the southern part of the region. Finally, there are also 39 extinct languages that linguists have not been able to relate to each other or to any other (see LANGUAGES OF THE WORLD).

Characteristics of Indian cultures. This linguistic variety shows how diverse were the aboriginal cultures. Even though it is possible to generalize broadly about cultural resemblances or patterns, the actual cultural unit was local or regional. This is true despite the existence of larger political units, such as the Quiché of classical Guatemala, or the Aztec Empire. The broad characteristics of the Indians of Middle America may nevertheless be sketched in profile, with the caveat that the profile is everywhere varied by local circumstance. When the Spaniards conquered the Indians, they removed the indigenous ruling class and placed themselves at the apex of society. They also brought Roman Catholicism, horses, cattle, wheels, iron, and new forms of political and economic organization. The Indian culture of today is a blend of indigenous elements, the culture of the Spanish, and the historical precipitate of the 500 years since the conquest.

Middle American cultures exist in located, named communities, each of which has a physical centre housing the patron saint of the community. The basis of subsistence is maize (corn), cultivated in small plots; but there is a myriad of crafts and artisans, and communities tend to be economically specialized. The family is the basic social unit, each living in a separate structure. Males and females wear distinctive costumes; where they have adopted modern dress, it is chiefly among the men rather than the women. Men do the heavy agricultural tasks and women the domestic chores. Men are in charge of the indigenous cults; women are more prominent in the Catholic aspects of religion. There is little restriction on any economic activity, and no taboos hedge occupational choice; but modern economic organization is little developed. The marketplace is the focus of economic life.

Families are internally hierarchical, with males and elders dominating. Both the father's and the mother's kin are recognized in tracing relatives, but there is a patrilineal emphasis in the transmitting of names and of some real property. Marriages are arranged for sons and daughters by their elders, who negotiate among themselves through a series of fixed visits and gift exchanges. Often the groom must perform service for his in-laws; during this period he may reside with them, later to set up his own abode. Marriages are easily dissolved in the absence of children, and a man may have a succession of wives; when children arrive, however, they stabilize a marriage.

The community's political organization is housed in a central building, usually opening upon a plaza. The personnel of the political organization form a hierarchy, with its top members recognized as spokesmen or representatives of the Indian community by the national government. The political offices are closely interwoven with a similar hierarchy, whose personnel serve the local church and the religious brotherhoods (*cofradías*), and plan the annual festal cycle. The personnel of the two hierarchies tend to alternate their periods of service between the civil and the religious wings. All adult men serve in this civil-religious hierarchy; in small communities they eventually reach the top posts and retire to become respected elders (*principales*). The annual change of personnel is accompanied by ritual.

There are no social classes in the Indian communities, but there are considerable differences in prestige, wealth, and individual achievement. There is an age hierarchy, especially among males, largely based on previous public service in the civil-religious hierarchy.

Community
political
organization

In the life cycle of these Indians, the important events are baptism and marriage. There are no puberty rites; and death is accepted matter-of-factly, followed by a Catholic wake. The concepts of sickness and disease are various. Illness is often thought to be caused by invasions of wind (*aires*) into the body or by disturbed emotional states, or it is thought to be most likely to strike during certain periods. Foods and natural substances are thought to be hot and cold, strong and weak; these conceptions are used both in diagnosis and in curing. Those who cure are specialists or semispecialists, frequently believed to perform witchcraft or other noxious magic.

In the realm of the sacred there are a large number of supernatural beings and places. The deities are arranged in a vague hierarchy, sometimes with the Christian God at the apex. Christian saints are the chief focus of worship, but with them are associated various pagan attributes and forces, including the natural forces of wind, rain, and lightning. Some saints have strong cults, their effigies being housed in a cult house or special temple and cared for on a daily basis. Liquor is consumed during sacred ceremonies and in that context is itself sacred.

The annual cycle is regulated by the European calendar. There is a series of religiously derived festivals, the chief of which are All Saints' Day, All Souls' Day, Easter week, and the Day of the Cross (in September). At least 82 different Indian communities still use the old pre-Conquest calendars in some agricultural rituals and for purposes of divination.

The prevalence of animism

The world view is animistic in the sense that the Indians see the world as peopled by spirits, souls, ghosts, and witches capable of inflicting harm if the proper ritual precautions are not taken. Omens, dreams, and talismans are of great importance. People are also believed to transform themselves into animals and mystically eat the life from a victim. Some communities execute witches. In religious practice, ritual conformity is more important than inner piety; if a person does not hold a ritual office, he engages in very little daily religious activity.

Slander, gossip, and envy are strongly condemned, although they are an important means of influencing social behaviour. In general, however, the rule of law, as expressed in the formal organization of the civil-religious hierarchy, is much more important than personal leadership. Great ambition is discouraged, but industry and diligence are much lauded.

This generalized profile of Middle American cultures fits most closely the areas of the former high cultures—the Aztec, Maya, Zapotec, Tarascan, and Mixtec areas. It needs modification for the northwest culture area, where the communities have less economic specialization and interdependence. It also does not fit some coastal Indians who have become part of the export economy, such as the vanilla-growing Totonac of Veracruz, or the Indians who work on the sisal plantations of Yucatán, where many approach the status of a rural proletariat.

THE PREHISTORIC PERIOD

The earliest inhabitants

More than 10,000 years ago, the Middle American Indians were hunters who roamed the country in bands of four to ten persons. Their quarry were mammoths, llamas, bison, and wild horses, as can be seen from the remains found at Tequixquiac, north of the central valley of Mexico. Some also hunted small game and gathered the seeds of wild plants. The seed gatherers and the big-game hunters coexisted for thousands of years, until a climatic shift around 7500 BC favoured the seed gatherers.

About 4500 BC, cultivated squash and gourds became part of the subsistence of the Indians, and they adopted a seasonal nomadic pattern. Around 3500 BC the basic crops were domesticated: maize, beans, and squash have been found in remains at Tehuacán. The Neolithic Period was beginning. By 2500 BC farming supplied about 10 percent of the food intake of the people, and by 2000 BC the first permanent settlements based on farming had been established, apparently villages of fewer than 100 persons. After 2000 BC farming became of major importance, and in the main areas the people were fully sedentary. They now produced forms of pottery.

From 1500 BC to the beginning of the Christian Era (often called the Formative period), the basic techniques of intensive agriculture were worked out, the full range of cultivated plants was developed, the pottery and art styles were formed, and the transition from small villages to ceremonial towns of 5,000 inhabitants was completed. The archaeological evidence of this may be seen in the central valley of Mexico at El Arbolillo, Zacatenco, Tlatilco, and, finally, Ticoman. The same developmental sequence occurred in the Formative period of highland Guatemala, as shown in the excavations at Kaminaljuyú near Guatemala City.

From the beginning of the Christian Era to about AD 1000 the cultures of Middle America passed through their Classic, or Florescent, period. In the Pyramids at Teotihuacán and at Cholula, in the Oaxaca valley at Monte Albán, in the ruins at Tikal and Uaxactún in Petén, and at Copán and Piedras Negras, there is monumental testimony to the rise of theocratic civilizations. The differentiation between the earthbound peasants and the class of priests is marked by the spread of the hieratic art called by archaeologists the Olmec style, the greatest example being at La Venta in Tabasco, Mexico. Olmec art made much use of carved jade and the symbol of the jaguar. In the symbolic vocabulary of Middle America, the jaguar is associated with Tlaloc, the god of rain and fertility, and therefore represents the forces of nature that make the crops grow. Tlaloc also dwells in caves from which lightning is thought to come; caves mean towns and settlements, so the jaguar probably represents the control of society as well as of nature. Jaguars are carved on axes, pots, and human likenesses; men wear jaguar skins; and human faces are depicted with jaguar-like mouths.

This symbolism fitted well the new theocratic societies of the Maya—the Nahuatl, the Zapotec, and the Mixtec. Large raised pyramids were built for the public enactment of religious rites by the ruling priestly class. These structures were ceremonial centres where priests and specialists lived, and where the populace assembled for periodic rituals. The priests were important in the agricultural cycle, for which the ancient calendars were first devised. These calendars evolved into precise instruments for the measurement of time and came to express the philosophical ideas of the priestly intellectuals. The full poetry of Middle American calendrics is expressed in the Maya calendar "long counts," for which stone pillars were erected.

Mayan theocratic societies

The ceremonial centres of the Classic period produced many luxury items made from imported goods such as seashells, feathers, obsidian, fine flint, jade, cotton, and cocoa beans. The centres paid for these imports by exporting finished ceremonial objects to the peripheries. The economy of the city-states of this period depended on the intensive cultivation of maize and on huge drafts of peasant labour for the building of the temple complexes. The building was done with a rather simple technology for beasts of burden, a functional wheel, and metal tools were lacking. The major achievements of the Classic period were its calendrics and its religious thought, which represented the efforts of the priestly class to systematize the universe and make it predictable.

Around the end of the Classic period a warrior group came into power. With the coming of the warriors a period of militarism began. War gods replaced the rain gods, and the jaguar symbolism gave way to the eagle complex in iconography. Human sacrifice, an occasional thing in the Classic period, became a mass phenomenon under the warlords of the Toltec and Aztec empires. The Toltecs, and later the Aztecs, were expansionist. When the Spaniards arrived, the Aztec Empire extended over most of Middle America, from the central valley to Yucatán, with garrisons, frontier fortifications, and foreign colonies. With the fall of the Aztec capital in 1519, the Guatemalan conquest of 1524, and the long-drawn-out battles with the Indians of the northwest region, the Spaniards ended the isolation of Middle America.

EVOLUTION OF CONTEMPORARY CULTURES

The Conquest and its effects. The Spaniards overthrew the urbanized, class-structured high civilization of the

From the
colonial
period to
independ-
ence

Aztecs and established a system of alliances with the tributary states. The conquerors decapitated native society, substituting the Spanish for the Indian nobility. They introduced a host of new agricultural techniques and crops, along with steel, horses and cattle, mines, European crafts, and new forms of social organization. They also created dichotomies between ethnic and racial groups, giving them different rights and obligations.

In the early colonial period following the conquest, a small minority of Spaniards administered and controlled vast Indian populations. The religion of the conquerors spread rapidly, as did many of their domesticated plants and animals. In this period the Indians were grouped into villages modelled on the grid plan, with a central plaza on which stood the church and town hall. The basic economic institutions were the *encomienda* and the religious reservation: the *encomienda* was an allotment of land and labour to a Spanish overlord, used in the densely peopled areas of the former high civilizations; the religious reservation was established by the Jesuits in the northwest.

The later colonial period saw the abolition of the *encomienda* and the secularization of the religious reservation. Where previously the upper strata of the Indian population had intermarried with the Spanish, the later colonial period brought a more rigid separation of the Spanish and the Indians. Although the *encomienda* was legally dead, its economic consequences persisted: the colonial-plantation economy developed, along with the cattle ranch and the mining complex. Indian lands were taken over at an increasing rate, and the Indians gave up whatever illusion they may have had as to the benefits to be gained from the white man's culture.

Mexico and Guatemala became independent of Spain in 1821. The early republican period involved the Indians only marginally. As the native Spanish and mestizos threw off European domination with the slogans and banners of the French Revolution, they neither considered the Indians nor involved them in their struggles. For the Indians it was a time of cultural and social consolidation, spent in the building of defenses against land encroachment and in the erection of communication barriers to protect their cultural heritage.

The later republican period was for Mexico and Guatemala a time of nation building, of moderate industrialization, and of commercial agriculture. The Indian was seen as anachronistic, an obstacle to the march of triumphant nationalism. For the Indian, the consequences were drastic. The national and international economy led him to develop a social structure and cultural pattern that would keep the Indian community intact, even at a low economic level. The strong corporate Indian community reached its most definitive form under the pressures of land-grabbing and anti-Indian social policies.

The 20th century. In the Mexican revolution that began in 1910, the Indians won a place in the political structure. The official policy became pro-Indian. This policy exalts the Indian heritage and makes it the root of the national heritage. In its economic and political aspects it aims at "incorporation" of the Indian into national society on terms set by the Indians themselves. It also provides special services to Indians, as demonstrated in the many programs of the Instituto Nacional Indigenista de Mexico in health, road building, agriculture, and literacy. It employs themes from Indian culture, as in the murals of the Mexican neo-Realists and the music of modern Mexican composers. In Guatemala a similar policy had a brief vogue, but it was reversed following the counterrevolution of 1954.

But the forces shaping contemporary Indian life lie largely outside these official policies. Population increase, the expansion of physical and cultural communication, industrialization, urbanization, and the power struggle between factions of the left and right are the basic forces that influence the lives of the Indians of Middle America.

(Ma.N.)

North Mexican Indian cultures

The generally accepted ethnographic definition of northern Mexico includes that portion of the country roughly

north of a convex line extending from the Río Grande de Santiago on the Pacific coast to the Río Soto la Marina on the Gulf of Mexico. This southern boundary coincides in a general way with the northern margins of pre-Columbian Meso-America. Northern Mexico is more arid and less favourable for human habitation than central Mexico, and its native Indian peoples have always been fewer in numbers and far simpler in culture than those of Meso-America. Today, the native peoples are extinct over all of northeastern Mexico; the only Indians present in that area are a group of Kickapoo who immigrated to Coahuila from the United States in the 19th century. In the west the Sierra Madre Occidental, a region of high plateaus that break off toward the Pacific into a series of rugged *barrancas*, or gorges, has served as a refuge area for the Indian groups of the northwest, as have the deserts of Sonora. At present only the northwestern states of Baja California, Sonora, Sinaloa, Nayarit, Jalisco, Chihuahua, and Durango have Indian populations.

Although accurate population data is lacking in parts of this region, estimates place the total population that is still Indian in language and culture at approximately 130,000, a tiny minority among the several million non-Indians of northwest Mexico.

Surviving Indian peoples of northern Mexico today fall easily into two divisions. By far the greater number are members of the first type, the ten groups which speak some language of the Uto-Aztecan linguistic stock and are traditionally agriculturists. The second type is now reduced to four groups—the descendants of nomadic bands who resided in Baja California and coastal Sonora and lived by hunting and gathering wild foods. The second type spoke various languages not related to Uto-Aztecan.

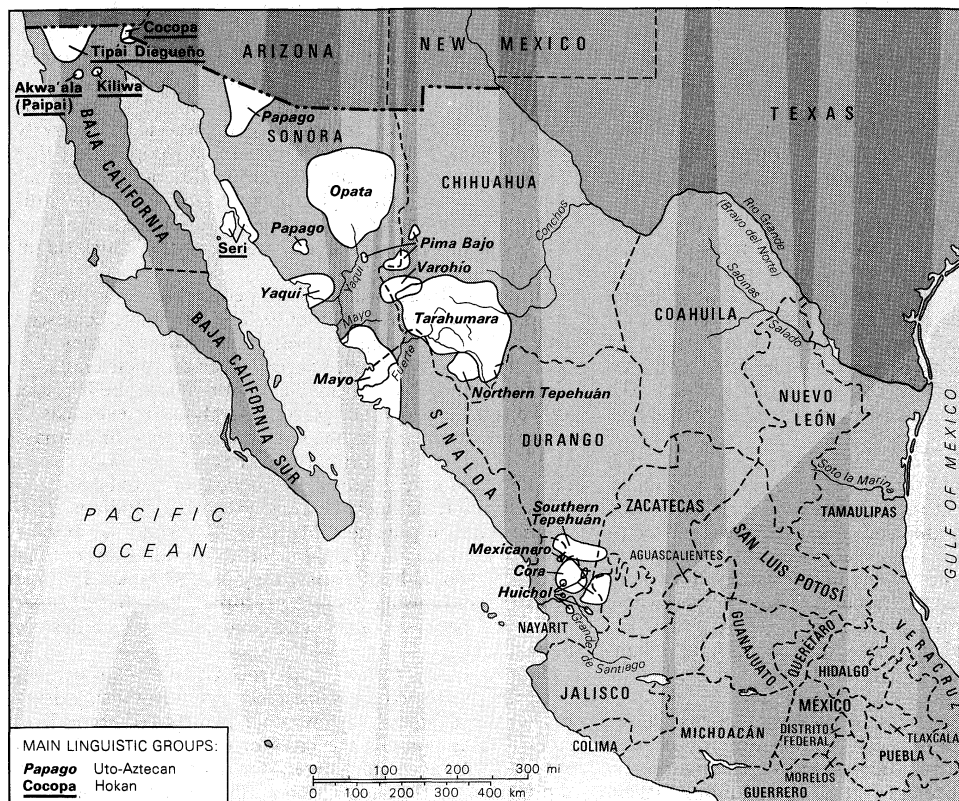

Uto-Aztecan peoples of northern Mexico have been divided into three branches—Taracahitian, Piman, and Aztecoidan. The Taracahitian branch consists of the Tarahumara of the southwestern Chihuahua; the Varohío, a small group which borders the Tarahumara on the northwest and are closely related to them; the Yaqui, in the Río Yaqui valley of Sonora and in scattered colonies in towns of that state and in Arizona; and finally the Mayo of southern Sonora and northern Sinaloa. Another Taracahitian group, the once prominent Opata, have lost their own language and no longer maintain a separate identity. The Piman branch consists of three groups: the Pima Bajo of the Sierra Madre border of Sonora-Chihuahua; the Papago of northwest Sonora, identical with a much larger portion of the same tribe in Arizona; and the Tepehuán, one enclave of which is located in southern Chihuahua and another in the sierras of southern Durango and Nayarit. The third branch of Uto-Aztecan is the Aztecoidan family, including the Cora located on the plateau and gorges of the Sierra Madre of Nayarit and the Huichol in similar country of northern Jalisco and Nayarit. A final member of this branch, locally called the Mexicanero, includes speakers of Nahuatl, remnants of central Mexican Indians introduced into the area by the Spaniards. The Mexicanero number only a few hundred and live in the mountains of Nayarit and southern Durango.

The remnants of the Baja California Indians—the Tipai (Diegueño), Akwa'ala (Paipai), and Kiliwa—live in ranch clusters and other tiny settlements in the mountains near the American border. Speaking Yuman languages of Hokan stock, they are little different today from their relatives in American California. A small number of Copca in the Colorado Delta in like manner represent a southward extension of Colorado River Yumans from the American Southwest. The remaining Seri are found along the desert coast of north central Sonora. This famous group also speaks a language of Hokan origin and is probably related to now extinct peoples who lived across the gulf in Baja California two hundred years ago.

Missions and isolation helped to preserve the several surviving Indian groups of northwest Mexico through the colonial period (1530–1810), but all underwent considerable alteration under the influence of European patterns. Nearly all the agricultural tribes adopted some form of Roman Catholicism and much Spanish material culture. It was at this time that the traditional cultures of northern

The people

Baja
Californi-
an and
coastal
Sonoran
peoples

Distribution of north Mexican Indians.

Mexico were formed, the basic patterns continuing until the present. Many groups faded away—gradually losing their languages and identities in the emerging mestizo, or mixed-blooded European and Indian population, the predominant people of present-day Mexico. Only the Huichol, Seri, and Tarahumara remained primarily aboriginal cultures, but even these groups adopted many items and ideas from the Spanish invaders.

Today, all these peoples exist as ethnic enclaves surrounded by, and in most cases sharing their lands with, non-Indians and manifesting some of the characteristics of ethnic minorities everywhere. There is competition for lands with mestizo ranchers and, in most groups, a conscious desire for survival as distinct cultural entities.

TRADITIONAL CULTURE PATTERNS

Basic
orientation
in life

Although in some aspects of culture the Indian groups share much with other rural Mexicans, psychologically they tend to be very distinct. The basic orientation of life of the traditional Indian cultures is primarily religious in that they look to the supernatural to solve their problems and tend to see their own lives as requiring continuous service to the deities. This is in strong contrast to the practical and materialistic orientation of other northern Mexicans. The average Uto-Aztecan Indian in this area is reserved toward outsiders, especially non-Indians, and prefers not to be too much in evidence. The ideal person is industrious, carries out his religious obligations, and does not seek change in his traditional lifeways. In contrast, the Seri and Yuman groups, being of another tradition, are less inclined to secrecy and more aggressive toward outsiders.

Social structures. The social structure of the Uto-Aztecan peoples of northwest Mexico are variations of one basic type, while those of the Seri and Baja California remnants follow other forms.

The Uto-Aztecan agriculturalists of modern times possess only two real social units, the family and the Indian village community. No real tribal organizations exist, and only among the Cora and Yaqui are there strong feelings of tribal solidarity. For all these peoples the community is the society, and there is little movement in or out—or even interaction with other communities of the same “tribe.”

The traditional Indian community is largely the result of colonial missionary efforts to concentrate the scattered rancherías, or hamlets, of aboriginal times into Spanish-type villages in which the natives could be more easily administrated. Usually furnished with land grants, these communities survived the close of the mission period and remained viable social units. The modern Indian community is built around a political and religious structure having its origin in the village organization set up by early missionaries to carry out church fiestas. It consists of a series of *cargos*, or civil and religious offices, in which most males of the village participate, the higher offices being achieved with age and experience. Some version of this structure or copy of it is or was present among all these groups. Today, among most groups it is still the backbone of the community, serving to produce the village fiestas as well as settle disputes among the people. While serious crimes or major issues are now handled by the Mexican government, in most situations the Indian *gobernador* (governor) and elders are consulted as well.

Kinship patterns. The family is of one type for all the agricultural peoples. Kinship is based largely on descent from both parents, though with some orientation toward the authority of the father. The judgment of the elder males is highly respected, and in most groups the advice and permission of family elders is sought on all important occasions—to produce a ceremony, sell a cow, contract a marriage. Everywhere, however, the role of women is more nearly equal to that of men than is the case among the heavily male-dominated rural mestizo families. Needless to say, there is little of the famous Mexican *machismo* (cult of the male) among the aboriginal peoples of northern Mexico. The normal system of Spanish Christian and family names is present in all these groups.

Marriage is primarily monogamous, though some informal polygyny occurs. Polygyny is most common among the Huichol (constituting about 5 percent of the marriages), which suggests that it was more common in northern Mexico in aboriginal times. Marriage tends to be brittle, and many unions are not permanent. Parents commonly arrange a match, though the custom is not uniform over the area. Among the Cora and Huichol, the boy's parents must make a series of ritual requests

The typical
Indian
community

Marriage
customs

before the match is accepted. In most cases there is little or no ceremony; a few seek church marriages and have wedding fiestas. Among the Cora, the young couple are given formal advice by family elders in the manner of ancient Mexico.

There is a strong tendency for marriages to take place within the community. In most areas intermarriage with the mestizo population is not approved but occurs to a small degree. Among the Mayo and Tepehuán, however, there has been so much outside marriage that the ethnic status of many individuals is uncertain. In most of northern Mexico the offspring of mixed marriages pass easily into mestizo society and tend to ignore their Indian origin.

The Seri have an elaborate system of gift exchange for marriage in which the groom is expected to furnish the family of the bride with certain valuable gifts, such as a rifle, fishing canoe, or, more recently, a pickup truck. His services to the bride's family may continue for several years.

The institution of *compadrazgo*, or coparenthood—that complex of ritual relationships between parents, godparents, and child set up at the baptism of a child—has been deeply integrated into the traditional cultures. Indeed, a copy of it occurs among such non-Christians as the pagan Tarahumara and Huichol. Many minor variations of *compadrazgo* occur among the Indians. It serves everywhere to extend the kinship structure and provide “spiritual” kin on which one can call in times of need. Some Indians may choose mestizos to serve at the baptism of their child; others, such as the Cora, do not favour this.

None of the Indian peoples of northern Mexico shows even minimal evidence of social stratification. Egalitarian societies exist everywhere, and historical accounts suggest that this has always been the case. Only among certain extinct coastal peoples of southern Sinaloa and Nayarit is there found some mention of stratification on the Meso-American pattern. Prestige accrues to wealth and ceremonial knowledge, but this seldom passes to the children.

Socialization and education. Socialization and native education follow traditional patterns. A child is given little formal training, but is often admonished by his elders as to proper behaviour. Training in household tasks for the girls and men's work for the boys is through observation and gradually increasing participation until the techniques of maintaining oneself and family are mastered. Both boys and girls are expected to contribute their work as soon as possible. At an early age, children haul water, gather wood, or herd sheep. Small Seri boys spear crabs with miniature turtle harpoons as training for their adult pursuit of the sea turtle. Among the farming peoples all ages take part in the work during critical periods, such as periods of weeding and harvesting.

Rites of passage survive for children among several of the least Hispanicized groups. Cora, Huichol, and Tepehuán have rites in which a newborn is introduced to the gods. The Cora have a ceremony in which children are symbolically introduced to the use of alcoholic drinks.

Today, all Mexican Indian groups have access to schools, usually federal rural schools, and most attend to some degree, though the remote areas in which most Indians live and their lack of interest in education designed for the mestizo world does not make for the most effective program. In some areas native Indians have been trained as teachers with somewhat better results. The Kickapoo have steadfastly refused schools, seeing in them a strong threat to their cherished way of life.

Economic systems. Settlement patterns and housing. The aboriginal settlement pattern of the agricultural Indians centred on the *rancheria*, which consisted of a number of household units clustered in spots convenient to cultivation sites or water. When colonial missionaries incorporated these into larger villages, the lowland peoples, such as the Yaqui, Mayo, and Opata, accepted this arrangement. They continue to live in concentrated settlements today. In the Sierra Madre, subsistence patterns did not lend themselves to such towns, and the Indians returned to their *rancherías* when the missionaries withdrew.

As a result, all contemporary Indians of the mountain regions live in scattered ranch clusters using the village

itself as a religious and political centre. Most Indian villages have a church (often the original mission structure), a school, government buildings used for courts or meetinghouses, and small mestizo-operated stores as well as a few houses owned by Indians who spend most of the year at their ranches. In many areas the once exclusively Indian village has acquired a non-Indian population that resides there permanently. Communities of the Tarahumara, Pima, Tepehuán, Cora, and Huichol follow this pattern. Yaqui and Mayo settlements are more like towns. Many Mayo settlements are now on the outskirts of Mexican towns.

The originally nomadic Hoka peoples now tend to live in small permanent settlements. The Seri have coalesced into two fairly permanent settlements, though they still move about to fish, hunt sea turtles, or sell their crafts.

Housing utilizes the available local material, be it stone, adobe, wattle and mud, planks, bamboo, or even caves, which are occupied seasonally by some of the Tarahumara and Pima. Dwellings primarily consist of one room with a dirt floor and no chimney. The kitchen tends to be an auxiliary structure as does the corn crib. Many Indians sleep on the floor on mats and blankets, but crude bamboo or rawhide beds are also used. Furniture is seldom more than a stool or two, although a few may possess tables. In most areas Indian housing is more primitive than that of other poor rural people. Water, lights, and sanitary facilities are nonexistent.

Patterns of production. All the Uto-Aztec peoples of northern Mexico are subsistence agriculturalists raising maize, beans, squash, a few other plants, and some livestock. Maize remains the basis of life and everywhere is a sacred substance, considered, for instance, as a deity by the Cora and Huichol. Cultivation methods range from the primitive digging stick used in slash-and-burn plots on hillsides and ox-plow agriculture in level fields, to some mechanized agriculture among the Yaqui. Characteristically, farm technology is primitive and of low yield. Few of the Indians have any considerable amount of good productive land, and there is competition with mestizos for even the poor mountainside plots of the Sierra Madre Occidental. The corn supply seldom lasts out the year, and in many areas it is significantly supplemented by gathering wild plants, cactus fruits, wild greens, maguey, and the usually abundant seedpods of mesquite, guamuchil, and other tree-like legumes. The cash needed for outside items comes from the occasional sale of a young bull or from sporadic wage work in which many Indians engage. Deer and other game once abundant both in the sierra and in the desert are now rare. All the Uto-Aztec tribes still hunt, but scarcity of game makes hunting relatively unimportant. The rivers yield a few fish and crayfish, which are much esteemed. Among the Seri, hunting of deer and sea turtles as well as fishing is still common but, even so, is of decreasing importance.

For centuries individuals from all these groups have worked for wages first in Spanish and then in Mexican mines and fields. The great silver mines at Hidalgo del Parral, Chihuahua, in colonial times made use of Tarahumara, Pima, Opata, and Yaqui labour. Yaqui and Mayo have long laboured on ranches and railroads and in mines away from their own country, even in the United States. Today, wage work is a factor in every Indian community in northern Mexico with some members of every group working for wages in the new agricultural areas of the Mexican west coast. The typical pattern is for young men or whole families to go to the coast for a few weeks to pick cotton or harvest corn or tobacco, returning to their own homesteads to plant and care for their maize. Some Tarahumara and Tepehuán work in lumber camps. No matter how important wages are as supplementary income, these peoples all prefer their own agriculture in their own communities, and few are drawn away permanently. It is rare indeed for sierra Indians to live and work in cities. This is not as true for the Yaqui, who have permanent settlements in several large Sonora towns.

About 1930 the Seri adopted commercial fishing and developed a mixed economy that included traditional hunting and gathering. Since 1965, however, a new industry

Egalitarianism

Subsistence agriculture

Wage labour

Villages and rancherías

has grown up in which the Indians have learned to carve animal figurines from the dense wood of the palo fierro, a desert tree. A large number of Seri families turned to production of the figurines for sale to tourists and appeared to be abandoning gathering and fishing as primary means of livelihood.

Property and personal customs. The Indian market system of central Mexico does not exist in northern Mexico. All Indian areas are served by small rural stores almost entirely owned by non-Indians. Here the few but important necessities such as cloth, metal tools, soap, salt, tin cups, and matches are purchased. Money, in use everywhere, is completely a part of modern Indian culture.

Clothing
and
grooming

Clothing combines the older styles of rural Mexico with modern lower class dress. Only the Tarahumara, some communities of whom still wear a type of loincloth, and the Huichol, with a colourful embroidered costume, have retained forms that stand out as distinct. Some, like the Cora and Tepehuán men, favour the pajama-like muslin garments of two generations ago and today consider their Indian dress. All others wear modern clothing with few reminders of earlier attire. Huaraches (sandals) are generally worn, as are homemade or commercial hats, usually made of palm; people near the United States border, however, prefer modern shoes and cowboy hats. Women's dress throughout tends toward a skirt and blouse with a rebozo, or head scarf.

Long hair is worn by males in some Tarahumara and Huichol communities and by many adult Seri. Elsewhere, short hair is the custom. Women wear the hair loose or, among the more Mexicanized, in braids.

Food is largely vegetable and consists of local varieties of the rural Mexican staples—tortillas, tamales, beans, and cheese. Indians, however, make much use of *atole* (corn mush) and pinole (ground parched corn) both of which were aboriginal favourites and are not as popular with the mestizos.

Crafts, nearly everywhere disappearing, are very largely limited to household necessities and are seldom made primarily for sale. Wool blankets are produced by the Mayo, Tarahumara, and Cora and woven shoulder bags by the Cora and Huichol. Utilitarian pottery and twilled containers and mats are still made in most groups, using native Indian techniques. The only objects produced for the tourist market are copies and elaborations of colourful ceremonial material by some Huichol and the figurines and shell beads produced by the Seri.

Other technology differs but little from that of other rural Mexicans of the northwest. Ranch tools and the paraphernalia used in handling livestock are identical. None of the sierra Indians possess automobiles. Some individuals in the other groups, including the Kickapoo, have acquired motor vehicles.

Blend of
Roman
Catholicism
and
native
religion

Religion. The northern Mexican tribes, like all Mexican Indians, have had contact with Christian missionaries for centuries, and all the agricultural Indians of northern Mexico are nominal Roman Catholics except for a few communities of pagan Tarahumaras, called "gentiles," and the majority of the Huichol. Even pagan groups, however, have incorporated Christian ideas and ritual practices. It can be generally stated that all the Uto-Aztecans of northern Mexico today practice some form of Roman Catholicism blended with native religion. The extent of aboriginal retentions varies from group to group, with the Huichol approximating pre-Columbian patterns to the greatest degree, keeping their gods, pilgrimages to sacred places, and native religious concepts almost intact. Others like the Cora have fused these, retaining native gods but equating them with Christian personages. The Yaqui and Mayo, both with a strong religious orientation to their culture, have an even more homogenous mixture. It is doubtful, though, whether any of the groups have absorbed Christian philosophy or belief systems to any great degree. Religion retains its aboriginal functions of protecting one's health, bringing the rains, and insuring the abundance of agriculture, rather than as a means to a glorious afterlife.

The relationship of many of these peoples to the modern Roman Catholic Church is tenuous. Modern priests tend to discourage folk observances such as the fiestas; the Indi-

ans, by and large, produce them without help of a priest. In the southern Sierra Madre, among the Cora, Huichol, and Tepehuán, there are modern Franciscan missionaries, while in the Tarahumara area there are Jesuits. Among all the Uto-Aztecans, religion remains central to the traditional culture, and it is an area in which there is great resistance to outside pressure for change.

Protestants have been active among the Seri and Yumans, achieving their greatest success with the Seri, who in the 1950s were all converted by an evangelical sect and largely abandoned their non-Christian practices. The Kickapoo, though also contacted by Protestants, remain, for the most part, followers of their aboriginal religion.

The shaman, or medicine man, still exists in most of these groups. Called a *curandero* in Spanish, he uses supernatural means to cure illnesses, to insure the success of crops, or to assist in other situations requiring divine aid. He is very distinct from the mestizo *curandero*, who utilizes European folk medicine. Huichol medicine men, or *marakame*, are especially famous among the tribes of the Sierra Madre for their knowledge and power. Belief in witchcraft still exists among all these peoples. A shaman himself may be accused of being a witch.

or *curan-
deros*

MODERN DEVELOPMENTS

The traditional Indian cultures of northern Mexico that emerged from the Spanish colonial world remained remarkably stable throughout the 19th century. Combinations of isolation, poverty, and conservatism resulted in what were essentially static societies. There were sporadically some uprisings, but it was not until the Mexican Revolution of 1911 and after that most Indian cultures were significantly affected by changes taking place elsewhere in Mexico. All these peoples took part in the revolutionary conflicts, and some disorganization took place everywhere. Thousands of individual Indians followed the armies, many never to return. The aftermath of the revolution marked the beginning of governmental concern with the Indians. The Instituto Nacional Indigenista was established and took upon itself the task of raising living standards and gradually integrating the Indians into the national life. Some groups benefitted significantly by the revolution and its results. Many Yaqui and Mayo escaped from hacienda peonage, and the Yaqui had a large portion of their ancestral lands restored to them.

It has been only since World War II that real changes have been taking place in the cultures themselves. There are multiple reasons for increased pressures from the outside world, but the primary cause is simply the development of modern transportation and a corresponding loss of centuries-long isolation. A major factor has been the construction of dams in the rivers flowing out of the Sierra Madre and the development of major irrigation projects and large modern cities on the coastal plain. There is now greater interest in the resources of the mountain hinterlands on the part of non-Indians, and there are opportunities for the mountain and desert peoples to engage in migrant farm labour.

Develop-
ments
since
World
War II

Opening of the Mexican west coast highway brought major changes in the whole area. The desert lands of the Papago, the Sonoran seacoast of the Seri, and the thorn forests of the Yaqui and Mayo were penetrated by paved roads. A railroad across the Sierra Madre from the city of Chihuahua to Los Mochis on the Pacific bisects the Tarahumara country, and roads have made numerous villages of this tribe accessible to truck traffic. Truck roads are approaching even the gorges of the Cora and the Huichol. Many parts of the Sierra Madre previously accessible only by animals or by foot are served by local airlines that fly small planes hauling freight and passengers to most of the mountain communities. It is a common sight at the airport in Tepic, Nayarit, to see rural mestizos, Cora, and Huichol Indians waiting to board a plane for airstrips near their remote homes. Although there are still vast areas in these mountain regions not reached by modern transportation, the outside world has become more accessible, and all of these peoples have been affected to some extent.

Development of modern transportation has greatly increased the possibility that many Indian communities in

time will cease to exist. There is growing competition for lands in all areas as non-Indian cattlemen, lumbermen, and farmers exploit these regions more intensely. Almost everywhere Indians find themselves being pushed or crowded out of ancestral lands by more sophisticated forces who have use for their resources. The Instituto Nacional Indigenista has come to the aid of some, such as the Tarahumara and Huichol, and given them legal assistance in securing land titles. In most areas, though, Indians, having no legal knowledge and lacking sophisticated leadership, are severely handicapped in dealing with these problems. Without a land base it is doubtful that communally oriented societies such as these can long survive.

The basic strength of the Indian groups in the late 20th century is found in their village organization and associated ceremonial structures that effectively preserve ethnic boundaries. Those retaining the strongest organized communities—the Tarahumara, Yaqui, Cora, and Huichol—while threatened, appear to be in no immediate danger of cultural disintegration. Others, few in number (such as the Pima) or lacking well preserved independent village structures (such as the Mayo), appear less likely to survive the impact of modernization.

Fear of alienation of lands and ultimate loss of ethnic identity has led to avoidance of innovations in many cases. Most still continue to resist social and religious change and avoid too close contact with non-Indians. There is, it is true, less reluctance to adopt material objects. The spread of modern communications media, even to the depths of the Sierra Madre, has resulted, among other things, in the increased learning of Spanish. The cast-iron corn mill is now used to grind *masa* (tortilla dough), saving hours of kneeling at a *metate*, or millstone, grinding by hand. Pedal sewing machines and metal containers are common. Nevertheless, most northern Mexican Indians express concern that their lifeways are dying. They fear that loss of community lands and the cultural seduction of their youth will mean that their days as separate peoples are indeed numbered.

(T.B.H.)

Meso-American Indian cultures

Indigenous to Mexico and Central America (roughly between latitudes 14° N and 22° N), Meso-American Indian cultures had a common origin in the pre-Hispanic civilizations of the area. Most Meso-American peoples belong to one of three linguistic groups: the Macro-Mayan (or Mayan), the Oto-Manguean, or the Uto-Aztecan. Macro-Mayan peoples, with the exception of a northeastern enclave, the Huastecs, live at the southeastern extremity of Meso-America. Oto-Mangueans are to be found in a wide area of Meso-America between Uto-Aztecan peoples to the north and east and Mayan and other peoples to the south. Oto-Manguean languages (now extinct) were spoken south of the Mayan area along the Pacific coasts of El Salvador, Honduras, and Nicaragua; and one Oto-Manguean language, North Pame, spoken in the central desert of highland Mexico, is outside Meso-America to the north. The main branches of the Oto-Manguean family are Oto-Pamean, Amuzgoan, Popolocan, Chinantecan, Mixtecan, Zapotecan, Manguean, and perhaps Huave and Tlapanec. The Tlapanec and Chontal languages of Oaxaca, spoken on the Pacific coast of Mexico, are held by some scholars to be related to the Hokan Coahuiltecan (sometimes termed the Hokaltecán) languages farther north. As a result of the expansion of the Aztec Empire centred in the valley of Mexico, Uto-Aztecan enclaves are found throughout the area. Tarascan, a language the filiation of which is still in doubt, is spoken in the highlands of Michoacán, Mexico. (See also LANGUAGES OF THE WORLD.)

TRADITIONAL CULTURE PATTERNS

Settlement patterns. The territorial unit that has prime importance for most Meso-American peoples is the *municipio*, a unit roughly corresponding to a county in Great Britain or the United States. Each *municipio* has a municipal centre where most civic, religious, and marketing activities take place. In the modern pattern, this centre

is the largest settlement in the area. The usual elements, which vary according to the size and importance of the community, are laid out according to the standard pattern imposed by early Spanish administrators throughout New Spain: a plaza surrounded by public edifices (church or chapel, curacy, jail, perhaps a school, and a meeting place for civil authorities). Houses nearest the plaza are those of the principal persons. Larger communities are often divided into sociopolitical enclaves called *barrios*.

An older pattern, still found in some areas (as among some Mayan peoples of the south and among the Huichol of the north), is for the *municipio* centre to be an empty town, occupied continuously only by civil and religious authorities and perhaps a few merchants. The bulk of the population resides in hamlets or on individual farms most of the year, moving to town residences only for short periods either to transact business or to participate in a religious festival.

Social, political, and religious institutions. The basic social and economic unit of Meso-America is the extended family of from two to four generations. There is a strong tendency for the extended family to fragment into individual nuclear families, each consisting of one couple and their children. Kinship is reckoned bilaterally, no distinction being made between kinsmen related through males and those related through females. Such distinctions are made in a few Mayan and Zoque communities, and they are common immediately north of Meso-America. These and other facts have led some anthropologists to suggest that small preconquest communities were patrilineal clans or lineages. Named clans and lineages have actually been reported in a few present-day Tzeltal (Mayan) communities.

Throughout Meso-America generally, newly married couples tend to locate near the groom's family in a slight majority of cases. Inheritance also generally favours the male line, including family names, which are almost invariably inherited from males. Inherited names are now most commonly of Spanish origin, but native surnames are known among some Mayan groups. In certain Mixtec (Oto-Manguean) communities, a man's first name becomes the surname of his offspring.

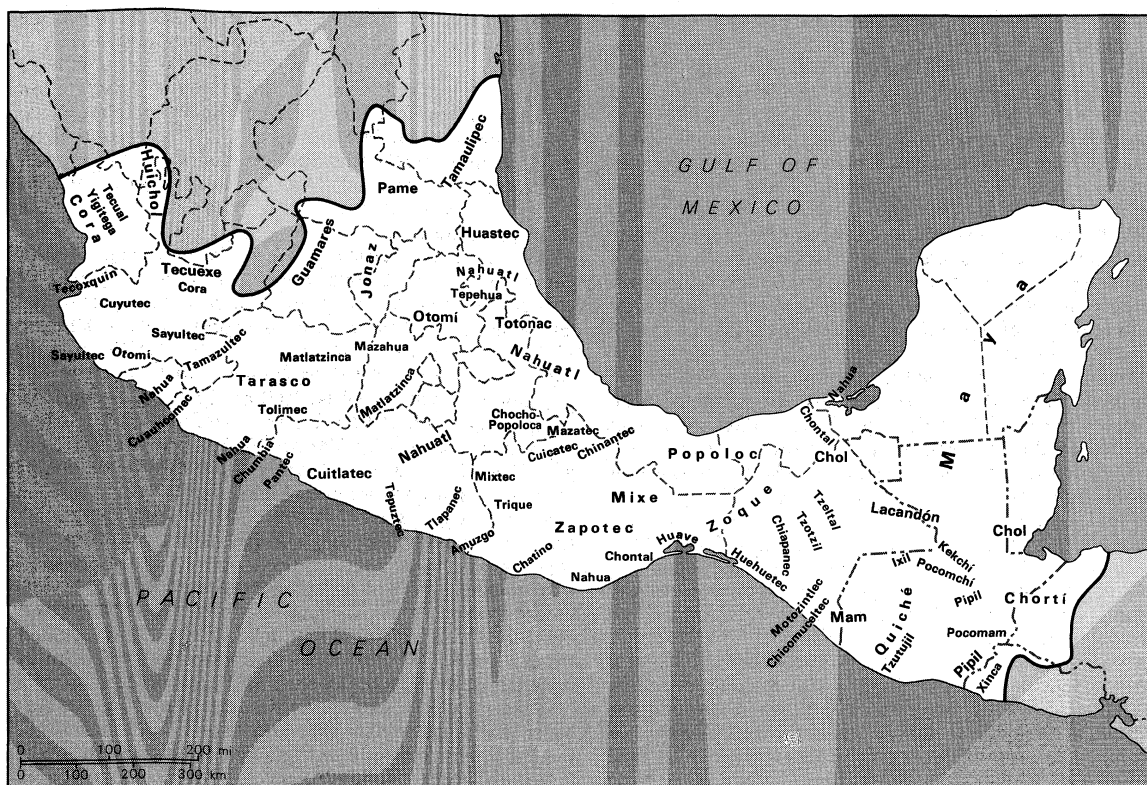

Marriage, traditionally an alliance between two families, is initiated by the groom's parents and arranged by them directly or through the services of a go-between. A period of bride service by the groom, often involving at least temporary residence with the bride's family, is not uncommon. Polygyny is known and socially acceptable but is not common.

Political and religious institutions are traditionally bound together into a complex of hierarchically arranged year-long offices through which adult males may attain status and power in the community. All males must serve in the lower ranked offices at one time or another, but only the most successful attain the highest positions.

Progress through the ranks typically involves an alternation between civil and religious offices. Successful passage to the highest ranks results in election to the position of elder. Elders form a more or less informal group of senior men to whom the community looks for experienced guidance in policy matters and in times of crisis.

Meso-American religion, called Christo-pagan by anthropologists, is a complex syncretism of indigenous beliefs and the Christianity of early Roman Catholic missionaries. A hierarchy of indigenous supernatural beings (some benign, others not) have been reinterpreted as Christian deities and saints. Mountain and water spirits are appeased at special altars in sacred places by gift or animal sacrifice. Individuals have companion spirits in the form of animals or natural phenomena, such as lightning or shooting stars. Disease is associated with witchcraft or failure to appease malevolent spirits.

Economic institutions. The cultivation of Indian corn, as well as of a number of secondary crops, provides basic subsistence for all Meso-America. Secondary crops include the bean, the squash or pumpkin, the chili pepper for seasoning, and tomatoes of both cooking and eating varieties. Additional foods with a limited distribution because of differing climates and terrain are the pineapple, sweet

Distribution of Meso-American Indians.

From H. Driver *et al.*, *Indiana University Publications in Anthropology and Linguistics* (1953)

potato, cassava (manioc), chayote, vanilla, maguey, nopal, mesquite, cherimoya, papaya, and avocado. Pre-Hispanic commercial plants included cotton, tobacco, henequen for its fibre, and cocoa beans, which served as a medium of exchange. Important commercial crops that have been introduced since European contact include Old World cereals (wheat, barley, oats), bananas, coffee, sugarcane, sesame, and the peanut.

Traditional slash-and-burn agriculture persists in the most isolated areas, but plow agriculture has replaced it in many places. *Chinampa* agriculture is limited to the valley of Mexico: small artificial islands are built up about one foot above the level of shallow waters of a freshwater lake, formed from the mud and vegetation of the lake floor. After settling, this serves as a rich bed for mixed-crop rotation, nurseries, and seed plots.

All Meso-American communities are tied to national and international markets, but the extent of this relationship varies considerably. The Lacandón of the Chiapas lowland jungles bordering Guatemala lie at one extreme. If the machete, ax, rifle, matches, and similar items from the outside became unavailable to the Lacandón through some catastrophe, they, of all Meso-Americans, would have perhaps the least difficulty in adjusting to the challenge of their ecological situation. Living members of the community still retain personal knowledge of such traditional skills as working flint and stone and the making of fire, cloth, and pottery.

A larger segment of Indian populations is tied to the outside cash economy by one or more products, such as coffee, citrus, vanilla, livestock, or manufactured goods. Specialization is not the norm, but from pre-Hispanic times certain communities have developed products and skills that depend upon trade relations. An entire community may be known for its pottery, weaving, or basketry.

Markets are typically organized into a network in which each of several towns hosts the market in its central plaza, a different town each day of the week. The network may or may not include a central market that is held every day of the week. Such a market consists of a core of local merchants the ranks of which are swollen once a week by merchants from the outlying hamlets of the area. All of the merchants, whether from the central market

or from outlying markets, tend to be organized in single household units.

Craft specializations that figure in marketing operations are also widely practiced to meet family needs only. Before the appearance of inexpensive commercial cloth, it was the norm throughout Meso-America for every young girl to learn to weave cotton cloth and, as a married woman, to provide clothing materials for her family. This skill is declining in the face of easy access to materials of cotton, wool, silk, and synthetic materials and blends. The introduction of the treadle loom by the Spaniards brought men into the weaving industry, especially as a commercial operation.

Both men and women are hat and basket weavers. Commercial products are produced from grasses, reeds, and palms, and lowland peoples also produce baskets of vine for local use.

A variety of pottery-making techniques is known in Meso-America. Before Hispanization, female potters made most ware, forming vessels by hand modelling, by building with coils, or by using a wooden paddle or molds. The Spaniards introduced the potter's wheel. Present-day techniques are a synthesis of indigenous and Spanish methods.

A lacquering art, now an integral part of the tourist trade, was practiced at the time of the conquest. A variety of gourd vessels of many sizes and shapes are artistically painted, using local materials and techniques. The beautifully decorated vessels serve a range of purposes, from simple utilitarian items, such as dippers, to elaborate ceremonial bowls.

The life cycle. Christian baptism is the first major event in the life of an individual. Indeed, among Chinantecs, a child is not considered fully human until the rite has been performed. If an unbaptized infant dies, the body is buried immediately without the usual ritual observances—ringing of the church bells, burning of incense, and reading and singing of prayers in the home, at the church, and at the graveside.

Nursing may continue for as long as three or four years, and childhood is a period of little discipline except for the responsibility placed on older children to care for their younger siblings while the parents work. Formal schooling is now available in most areas for at least a few years, but

Arts and
crafts

Agricultural methods

Formal
education

monolingualism in less acculturated areas severely limits the efficacy of the training, which is almost always conducted in Spanish only. There is no puberty rite, so that the transition from infancy to adolescence is unmarked ritually.

A girl becomes an adult at marriage, but a boy becomes an adult in two ways: through marriage and through citizenship attained when he reaches the proper age, usually 14 or 15 years. At this time he must enter the labour pool of adult men who maintain community property and must contribute his share of any assessment the citizenry may impose upon itself to cover community expenses. He becomes eligible (and obligated) to serve in the lowest ranking offices of the political and religious institutions of the community.

Death is marked by ritual and burial within 24 hours of death, with repetition of the ritual at periodic intervals after death, sometimes ending on the ninth day, sometimes repeated on the anniversary. An All Saints feast of several days' duration is prepared annually in the fall of the year for all of the dead.

MODERN DEVELOPMENTS

Indigenous communities have in most cases made a healthy adjustment to the larger non-Indian community around them. Although this has and will continue to involve many kinds of cultural change, the indigenous communities have been able to maintain their cultural integrity with little sign of the kind of disorganization leading to cultural collapse that is often found when two cultures meet. And though, in the late 20th century, the Spanish-speaking community has come to accept (even to take pride in) its Indian heritage, its direct attempts to bring the Indian way of life more in line with that of its own have met with much resistance. While it has been possible to introduce technological changes that have improved the economic position of Indian communities, attempts to change those parts of the culture that have symbolic value—political and religious ideologies that tend to preserve indigenous social systems—have met with less success.

(Ed.)

Central American and Northern Andean cultures

The Central American and Northern Andean culture area comprises most of Central America (south from Guatemala) and the northern coast of South America (including the northern drainage of the Orinoco River); the West Indies are also customarily included. Although the area has meaning in terms of the distribution of indigenous cultures and languages, it does not coincide with any

named region in a geographic sense, nor does it coincide with contemporary national political boundaries.

The area is situated entirely within the tropics, and the seasons are marked more by differences in precipitation than in temperature. Lowlands tend to be hot, but elevation tempers the climate on some of the islands and along the mountain ranges that run through Central America, Colombia, and Venezuela. Areas of heavy rainfall support dense forest, whereas a few dry regions support little more than sparse grass.

In archaeological terms, this area is of strategic significance for various reasons. First, as the relatively narrow corridor between the northern and southern continental land masses, Central America is a promising area in the search for remains of the ancient culture of the palaeo-Indians, of a generalized Mongoloid stock, who moved into South America at least 10,000 years ago. Second, an exceptionally rich and diverse variety of local cultures had evolved in the area by 500 BC. Third, between AD 1000 and 1500 the area was intermediate between the major centres of high civilization in Mexico and Peru.

In this region, unlike much of Latin America, most native cultures did not long survive the arrival of the Europeans, and there is controversy among anthropologists over whether many of the indigenous groups may, by reference to such criteria as language, patterns of beliefs and behaviour, or political affiliation, be justifiably designated tribes. Almost 200 "tribes" were reported in early Spanish documents, but descriptions of most are imprecise.

Native languages spoken in the area at the time of European conquest were many and varied. Although some historical and structural linkages can be traced with other groups in North and South America, individual languages reflect millennia of relative isolation (see LANGUAGES OF THE WORLD).

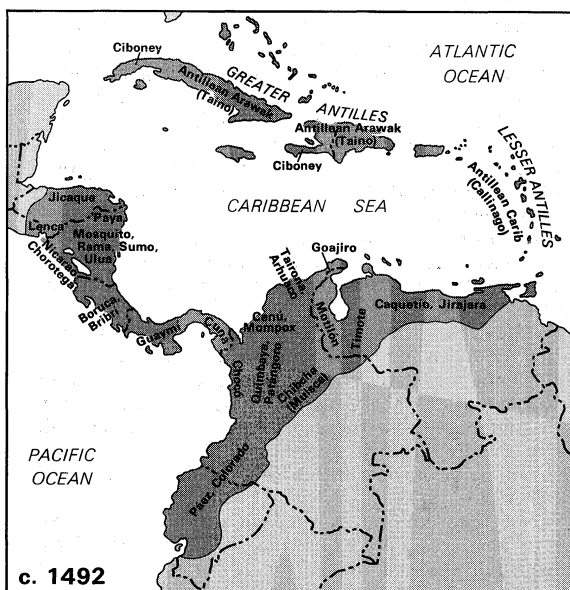

TRADITIONAL CULTURE PATTERNS

Accounts of the indigenous cultures are fragmentary and based largely on occasional reports by missionaries, explorers, and soldiers. In some instances, widespread and apparently important cultures are represented by little more than archaeological evidence, but it is possible to note a series of characteristic patterns and variations on those patterns that recur in the area.

With respect to basic subsistence, for example, intensive horticulture by the slash-and-burn (swidden) method was general. A variety of crops, including manioc, maize, sweet potato, bean, and others, were staples in various regions. Numerous other vegetables, as well as tropical fruits and sometimes cotton, were also grown in some areas. This form of horticulture was far more efficient than is popularly believed and produced abundant food

The people

Economic practices

Distribution of Central American and Northern Andean cultures.

without enormous or constant effort. In the cultures of this region, unlike many of those in the Amazon Basin, such intensive farming was usually done by the men. Improvements on the basic slash-and-burn pattern have been rare throughout the world, but in this area they included irrigation, and even occasional terracing, by the Antillean Arawak, Arhuaco, Chibcha, Jirajara, Pérez, and Timote, all of whom showed evidence of other cultural elaborations as well. In contrast with such highly developed groups, a few cultures in the area were based more on hunting or fishing than on even simple farming; among those were the Antillean Carib, Chocó, Ciboney, and Motilón.

The form and scale of communities tended to be closely linked to economic activities. Those groups, for example, whose subsistence base was fishing or gathering, had the smallest houses and most dispersed settlement patterns in the area. Similarly, the largest and most permanent buildings, as well as the most densely populated villages, occurred among those tribes that had the most intensive and varied food production, including some with highly developed agriculture. The warring expansionist groups, such as the Chibcha and Guaymí, even built palisades around their larger towns, many of which included palaces and temples. Ball courts and large ceremonial plazas were constructed only among the Antillean Arawak, who were unusual in having communities with as many as 3,000 people.

Arts and crafts

The high degree of regional variation in crafts is probably related to the small scale of political organization, in which regional chiefdoms predominated. The hammock apparently originated in this area and was widespread; little other furniture was used. Houses varied considerably in size and shape, although virtually all had palm-thatched roofs and walls of thatch or adobe. A wide variety of baskets was made, usually by women; bark cloth was made in those few regions where loom weaving was unknown. Clothing was simple, usually comprising no more than a breechclout for men and a short skirt for women, and few remains of textiles have survived. Most of the Indians adorned their bodies richly, however, with painted designs, tattooing, and a wide variety of jewelry and feathered ornaments.

Nearly all of the peoples in the area made at least some pottery, and a few of the mainland groups produced exceptionally abundant, fine, and varied ceramics. Excellent in their own right, some of these wares reflect styles, media, and techniques from both the Andean and the Mexican centres of high civilization. The same few groups—notably the Chibcha, Chorotega, Guaymí, and Nicarao—carved jade and other stones and worked copper, gold, and several alloys with an unusual combination of technical skill, imagination, and aesthetic sensitivity. Abundant ornaments were made of metal and of precious and semiprecious stones, both for adornment and for interment in the graves of distinguished men, but few utilitarian tools are known.

Overland transportation was by foot, and widespread trade was carried on throughout much of the area without the benefit of either draft or pack animals. Dugout canoes, often of considerable size, provided transportation from island to island and along rivers.

Outposts of the sophisticated and warlike Aztec Empire extended as far south as the region inhabited by the Nicarao, where military and commercial operations linked what is now Costa Rica with Mexico. In the south the Colorado and Pérez peoples of the northern Andes similarly faced the frontier of an empire—that of the Incas—and carried on trade with the centre of high civilization in what is now Peru. The Chibcha proper (also called Muisca) comprised several feudal states, among whom war and tribute were commonplace, and their fine manufactures of gold, copper, and pottery became widespread through extensive trade. Not only were there regular markets but in some regions even a standard of exchange (namely cacao) was recognized.

The majority of the cultures of this region, however, were small chiefdoms, in which a single village or a small group of nearby communities was led by a chief whose semidivine position was inherited through the maternal

line of descent. Such men were powerful within limited regions, but widespread confederations of such chiefdoms were rare, and warfare among them was typical in some areas. The Antillean Caribs, for example, had been encroaching on the peaceful Antillean Arawaks just prior to the arrival of the Europeans, taking both territory and captives. In general, it was the cultures with more highly developed agriculture that had the greatest degree of political integration, whereas those with the simplest subsistence economies rarely had any organization beyond the local community.

The practice of shamanism for curing and sorcery, as well as the popular worship of natural phenomena, was widespread. In areas of relatively dense population there were full-time religious practitioners who maintained temples dedicated to idols at ceremonial centres. The elaborate and bloody state religion of the Aztec Empire extended as far south as the Nicarao region; the Chibcha practiced large-scale human sacrifice; and the cannibalism of the Antillean Caribs also apparently had some religious significance. A trait distinctive of the Antillean Arawaks was the *zemi*, a triangular carved stone that represented the hierarchically ranked individual guardian deities of each household in the society.

Social stratification varied in much the same way as political organization. It ranged from virtually absent among the nonagricultural Ciboney to fairly complex among the warring tribes that had highly developed agriculture. At most, four classes were differentiated: semidivine chiefs (whose Arawakan name, *cacique*, has come through Spanish into English), who usually enjoyed considerable power and luxury; nobles (usually by descent but sometimes on the basis of wealth or military exploits), whose prestige and perquisites included little political authority; commoners; and often slaves. The meaning of slavery in this context is somewhat different from the Western tradition of using human beings as chattel. In many instances, women taken in warfare were kept as low status wives or concubines, their children not being slaves. Captive men were usually slain in religious sacrifice, as human trophies, or for cannibalism.

The idea that a man should have many wives was widespread, especially among chiefs and nobles, and descent was often reckoned through the maternal line, but there is no firm basis for popular accounts of female-dominated societies that were given by some early writers. An unusual outcome of the pattern of marriage with prisoners was the use of Arawak as “the language of women” in Carib society, illustrating how a vanquished people can change the customs of their conquerors.

MODERN DEVELOPMENTS

The coming of Europeans resulted in the downfall of most of the cultures of the Central American and Northern Andean region. Few of the chiefdoms survived beyond the 17th century, and none exists in similar form today. Many of the cultures summarily described above are now extinct, including all of those in the West Indies and most of those in Central America. Vestiges of some cultures remain, significantly transformed, in a few areas remote from cities and roads.

Although this was the area first explored by the Spaniards, it was soon surpassed in importance by Mexico and Peru, both of which were rich in minerals and had large native populations accustomed to paying tribute in wealth and labour. Shallow sources of gold in the Antilles were quickly exhausted, and neither Central America nor the northern coast of South America offered much of interest to the conquistadors. None of the peoples of the region worked effectively under the Spaniards.

One striking feature that characterizes the history of contact with European culture in virtually every one of these instances is the disintegration or impoverishment of the indigenous culture. Whereas many observers might have expected new and increasing elaborations in those cultures that survived, the opposite has occurred. Agriculture is less varied and less productive; pottery and weaving are practiced less and are less sophisticated, and metallurgy has disappeared. Communities are generally smaller now

Religious practices

Disintegration of indigenous cultures

than they were four centuries ago, and even regional political integration is lacking. The temples, warfare, and class stratification characteristic of many chiefdoms are gone, and, with few exceptions, the contemporary peoples try to avoid contact with others.

Although there had been warfare, trade, and other kinds of intercultural contact in pre-Columbian times, the impact of the Spanish conquest was different in kind as well as in scale, involving as it did not only unprecedented military power but also a wholly new economic system and a deliberate policy of reshaping Indian life to conform to European ideals.

One need not believe literally in the "black legend" about Spanish cruelty toward the Indians to understand the rapid depopulation of the West Indies. Newly introduced diseases took a heavy toll among the natives during the early years of contact, as did forced labour at unaccustomed tasks. Survivors often fled to the forested mainland coasts that were scorned as useless by the Europeans. Others quickly lost their cultural and racial identity as a result of mixture with blacks who had been imported from Africa as slaves. Some of the mixed populations remained in the islands while others sought refuge from the Europeans on the coasts. Noteworthy among this latter group are the Black Caribs (descendants of Carib Indians and Africans, also called Bush Negroes), who went to British Honduras and Guyana.

There are, however, a few exceptions to the general pattern of extinction or isolation. The Cuna of Panama, for example, became largely Hispanicized, although their colourful dress made them an asset in terms of the tourist trade, unlike the similarly acculturated Lenca of Honduras. As early as 1550, the Goajiro of northeastern Colombia had virtually abandoned their pre-Columbian slash-and-burn horticulture in favour of an economic pattern previously unknown in the New World—the herding of goats and cattle. Small nomadic bands, based on ties of kinship, travel constantly to find pasturage within their limited and arid territories, which are the subject of frequent feuds. The hot, humid Mosquito Coast of eastern Honduras and Nicaragua was long used as a base by English loggers, buccaneers, and others who sought to undercut Spain's commercial and political dominance throughout the Caribbean, and the Jicaque, Misquito (Mosquito), Paya, and Sumo Indians, as well as many free and runaway blacks, collaborated with them. These peoples, however, have again been relegated to an economically and politically marginal position.

During the 20th century the remaining cultures resisted modernization to a degree unusual among Indians of the Americas. As pressures on their refuge areas mounted however, it was not clear whether they would adapt or become extinct.

(D.B.H.)

SOUTH AMERICAN PEOPLES AND CULTURES

The customs and social systems of South American peoples are closely and naturally related to the environments in which they live. These environmental relationships are mediated by the systems of technology that the people use to exploit their resources.

Four basic types of social and cultural organization of South American peoples emerge from the archaeological and historical records: (1) central Andean irrigation civilizations, (2) chiefdoms of the northern Andes and the circum-Caribbean, (3) tropical-forest farming villages, and (4) nomadic hunters and gatherers. Each type developed in its own fashion during thousands of years, and since the 16th century each has made a distinctive adjustment to the impact of European civilization.

Early men, hunters and gatherers with no knowledge of agriculture, gradually worked their way across the Bering Strait in pursuit of food and meandered over North and South America in small, migratory bands for thousands of years. They reached Tierra del Fuego in approximately 6000 BC, after passing through the bottleneck of Central America, dispersing in the rugged terrain of the northern Andes, following the resource-laden Caribbean coastline eastward, and filtering southward through the tropical lowlands now making up part of Venezuela, the Guianas, and Brazil. They also hunted game through the highland basins of the central Andes and hunted and fished along the west coast of South America until they reached land's end.

THE PEOPLE

In South America, native language families encompassed large blocks of territory and numerous societies. They cut across different cultural and social types and are found represented in different geographical and environmental surroundings. Languages may be grouped in many ways, but the major language groupings or families of South America may be conveniently divided into the Macro-Chibchan, Andean-Equatorial (including Tupian), Ge-Pano-Carib, and Hokan. This is the most simplified classification of South American Indian languages (see also LANGUAGES OF THE WORLD).

Racially, the Indians of North and South America belong to a Mongoloid subtype known as Amerind. They show certain diagnostic physical traits of Mongolian peoples, among which are the shovel-shaped incisor tooth pattern, the distinctive fold of the eyelid, and the darkening of the lower back known as Mongolian spot. Such traits were

scattered in South America. Hair form is generally straight and hair colour black, but there are instances of brownish, reddish brown, curly, and even frizzy hair.

Great physical variation is to be expected in so large a population dispersed over an entire continent. Wide differences are apparent in body form, height, skin colour, and head shape. Of the more than 100 societies for which there are physical data of reliable value, height ranges greatly between means of about 57 inches (145 centimetres) and about 69 inches (175 centimetres). The peoples of smaller stature are found in the northwestern part of South America (for example, the Chocó and the Cuna) and continue southeastward in a broad band that extends into south central Brazil. They overlap considerably, however, with peoples whose mean height falls between 60 and 64 inches (152 and 163 centimetres). These peoples of moderate height extend farther south, down into Chile as far as the Isla de Chiloé, where there is again overlap with a very short people, the Chono. The next tallest groups of peoples comprise a narrow band from northern Brazil to southern Argentina. The tallest peoples in South America were the hunters and gatherers of the southern plains and Tierra del Fuego—the Puelche, Tehuelche, and Ona.

In the 1500s, the central Andes, the area of greatest population density in South America (about 10 persons per square mile), was sparsely populated compared to centres of Old World civilization. Yet its population of approximately 3,500,000, crowded into narrow coastal valleys and small highland basins on approximately 1 percent of Peru's total land area, constituted a much higher density than could be found in any other part of South America. The chiefdoms of the northern Andes, northern Venezuela, and the Antilles had an estimated total population of 1,900,000, with densities ranging from 6.6 to 1.1 persons per square mile (2.5 to 0.4 persons per square kilometre). The southern Andes was inhabited by the Atacama, Diaguita, and Araucanians, whose combined population was possibly 1,131,000, with a density range of 0.38 to seven persons per square mile. Tropical-forest peoples numbered about 2,200,000 and had a density of 0.6 per square mile. Hunting and gathering peoples of the Chilean archipelago, Patagonia, the Gran Chaco, and eastern Brazilian uplands had a combined population of less than 800,000 and a density range of 0.2 (Chilean archipelago) to 1.1 (western Chaco).

The population density of the central Andes was about 200 times greater than that of the hunters and gatherers,

Population densities in the 16th century

20 times greater than that of the tropical-forest farmers, and 30 to 40 percent greater than that of the Araucanians and the chiefdoms of the northern Andes and the circum-Caribbean.

THE PREHISTORIC PERIOD

Human life forms did not evolve in the New World, despite certain claims to the contrary which have never been taken seriously by most scholars. Man migrated from Siberia to Alaska, probably some 20,000 to 35,000 years ago, when there was a land and ice bridge between the two continents. He seems to have remained locked in the northwestern sector of North America for eons, held back by impenetrable glacial formations. When the glacial cap retreated and valleys opened up, a full-blown *Homo sapiens* (then existing as a hunter and gatherer) began to follow the southward progression of game animals, fanning out over North America and wedging through Central America into South America, again a process occupying thousands of years. Archaeological discoveries have unearthed man's skeletal remains in association with now-extinct species of animals and in geological deposits of the last phases of the Ice Age.

Early man. Archaeological evidence demonstrates that South America was occupied by early man at least 10,000 years ago, ample time for high civilizations to have evolved in the central Andes and for ecological adjustments to have been worked out elsewhere on the continent. Scientific dating techniques establish that agriculture was practiced along the Peruvian coast at least as early as 2300 bc. By 1000 bc agricultural societies flourished. This does not mean that all of South America had reached this stage of development nor that it was densely populated by farming communities. On the contrary, the continent was spottily inhabited by simply organized hunters and gatherers who then occupied the most favourable regions. As knowledge diffused from the central Andes to other parts of South America and as agriculture and other techniques were adopted by those peoples living in favourable environments, farming communities took form, and populations among them began to increase. Thus, on the foundation of early hunting and gathering societies, the more complex social and cultural systems gradually were built in those areas where agriculture developed; cultural growth and social complexity followed apace. Hunters and gatherers were pushed out of the farming regions to agriculturally marginal areas, where some of them are found today.

The original migrants to the New World had no knowledge of the domestication of plants or animals, with the exception of dogs, which were used in hunting. Recent discoveries in Mexico indicate that agriculture was independently discovered in the New World in roughly the same era that it was in the Near East (about 7000–8000 bc) and that New World civilizations were built on an indigenous agricultural base.

It is known archaeologically that cultural influences from Asia, as well as latter day migrations of people such as the Eskimo, continued to impinge on parts of the New World over the millennia, but New World cultural developments that culminated in the formation of high civilizations in Mexico and Peru were overwhelmingly the product of native, independent invention in almost all spheres of cultural and social life. Sporadic influences probably reached Peru and the western parts of the tropical forests from across the Pacific Ocean, but their effect on the course of cultural development in this hemisphere was negligible. Native America constituted a separate cultural unit, compared with the Old World.

The development of civilizations. The archaeological record for the central Andes shows a step-by-step development of cultural and social forms from a pre-agricultural, hunting and gathering baseline some 10,000 years ago to the Inca Empire in the 15th century AD. The record does not show any significant cultural influence on this development from transpacific contacts.

The evidence on early hunting and gathering peoples in Peru is still sparse. It is not yet possible to reconstruct social patterns, since most of the remains consist only of shellfish middens and small, widely scattered campsites

along the coast. It was a period of thousands of years' duration, however, toward the end of which some knowledge of plant domestication reached the Peruvian coast.

The next major era is set off by incipient agriculture and is also characterized by the remains of small, hamlet-type communities along the Pacific Ocean near river mouths, where the alluvial soil was able to support crops. Technology remained simple, irrigation was not practiced, and population remained small.

After the passage of 1,000 years or so, marked developments appear in the archaeological record. These include many new crops, irrigation ditches that extended the arable area and controlled the supply of water, more and larger communities that attest to a growing population, and important temple mounds that formed the symbolic centres of theocratic government controlled by a priestly class. The formative era saw the development of the basic technologies and life-styles that were to become elaborated into even more complex cultural forms and state institutions. The emergence of city-states and empires in the central Andes is the result of local cultural-ecological adjustments of this sort, based on an irrigation agriculture that supported growing populations and necessitated controls in the hands of priests and nobles, with a warrior class subservient to the state.

Around 500 bc strong regional styles began to appear in the manufacture of utilitarian and luxury goods and public buildings. An abundance of large temple mounds, more extensive and intricate irrigation networks, cities, roads, bridges, reservoirs, and other works calling for mass labour and tight controls characterize this cultural florescence. It was capped by the crystallization of class-organized societies, supported by masses of farm families and conscripted labour, defended by well-organized and well-disciplined troops, catered to by a large number of master craftsmen, and ruled and regulated by a class of priests and nobles.

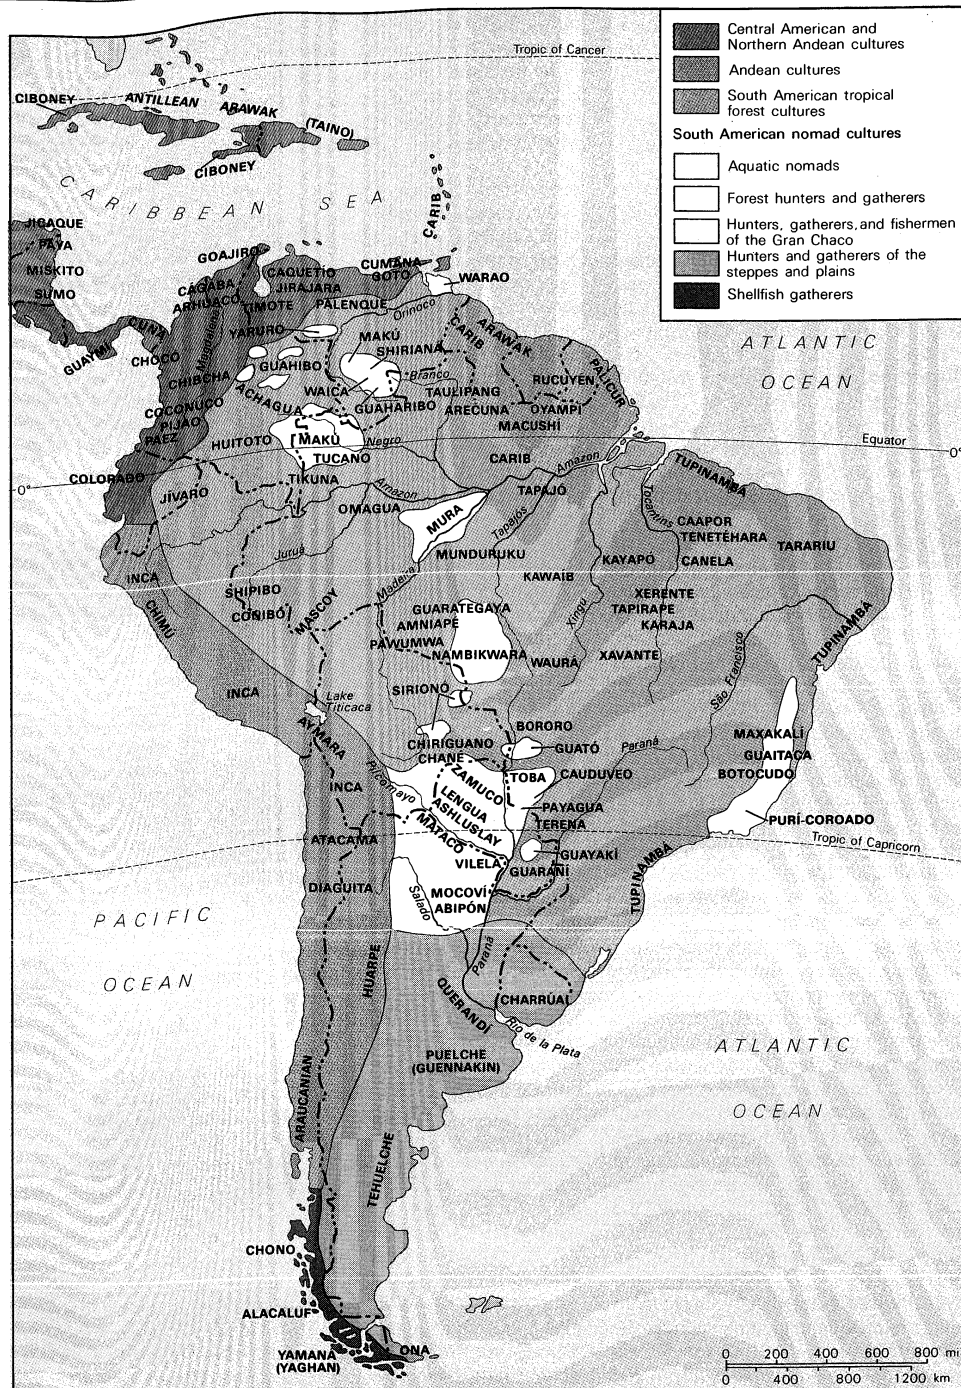

During the last phase of the prehistoric era in the central Andes, which began around AD 1000, regional states came to be absorbed into vast empires, the best known of which was the Inca Empire. The Inca began their expansion in 1438 and completed it in 1532, by which time the Spaniards landed on the northern coast of Peru at what is now the seaport of Paita. The Inca spread their imperial bureaucracy from Ecuador to central Chile and implanted their religious beliefs and practices, as well as much of their culture and the Quechua language, in the process of empire building. Their achievement was cut short by the Spanish Conquest under Pizarro, at a time when the Inca Empire seemed on the verge of civil war.

Traditional ways of life. *Hunters and gatherers.* Peoples who led a nomadic hunting and gathering life inhabited the agriculturally marginal areas of South America and were peripheral to the centres of great cultural development. All of Argentina and the archipelagic zone of southern Chile comprised the habitat of such hunting and gathering peoples as the Chono, Alacaluf, and Yámana (Yaghan) of Chile, the Ona of the island of Tierra del Fuego, and the Tehuelche, Puelche (Guennakin), Charrúa, and Querandí of mainland Argentina. In the Gran Chaco region were the Guaycuruan-speaking Indians, the Abipón, Mataco, Vilela, and others, who were migratory peoples roaming the grassy plains of their small territories in search of rhea, guanaco, peccary, and jaguar. In the tropical rain forests of Brazil and neighbouring countries, societies that are off the mainstreams of diffusion of ideas and technologies have remained at a hunting and gathering subsistence level. Many such peoples became extinct shortly after contact with Europeans, through warfare, enslavement, and disease. Others, such as the Guaraní Indians of Paraguay, made prolonged adjustments to European colonization and gradually mixed with the conquerors biologically and culturally.

In the tropical forests were the Jívaro, Yaruro, Makú, and many other small societies eking out a livelihood mainly by hunting, fishing, and gathering wild plants. They kept a wary eye on their more powerful neighbours, the village agriculturalists, who coursed the main rivers and their tributaries in canoes, searching for food and sometimes human heads.

Imperial expansion in the central Andes

Independent American development

Distribution of aboriginal South American and circum-Caribbean cultural groups.

Social behaviour of hunters and gatherers

The hunting and gathering peoples of aboriginal South America were organized into small social units made up of a single kin group or of several loosely linked groups of relatives. Members of these societies were differentiated almost entirely on the basis of their sex and age rather than on status characteristics of an economic, military, political, or religious nature, as in more complexly organized social systems. Behaviour was sanctioned by tribal customs that involved kinship rights and obligations and constituted the basis of morality. These peoples had very similar rites throughout the South American continent and similar beliefs in cures and magic. Their technology and material culture, though not homogeneous from one society to another, was always rudimentary and generally lacked agriculture, well-developed building arts, and manufacturing processes found among other South American Indians. They lived in marginal areas, exploiting the limited natural resources with elementary techniques. This

kept their social units small, widely scattered, and simply organized.

Tropical-forest farming villages. The agricultural villagers of the tropical forests had more developed exploitative techniques than the hunters and gatherers. Farming, food storage, and canoe transportation along rivers made for greater economic sufficiency and the ability to live in larger and more stable units. The forest-dwelling agriculturalists included the bulk of the Arawakan-, Cariban-, and Tupian-speaking peoples, such as the coastal Arawak proper and those of the Greater Antilles, the Achagua, Guahibo, Palicur, and many other societies; the Carib of the Guianas, such as the Barama River Carib, the Taulipang, and the Makushí (Macushí); the Tupians of the coast of Brazil, such as the Tupinambá; and inland groups among whom were the Mundurukú, Kawaib (Parintintín), and their neighbours.

Tropical-forest farming villagers, like hunters and gather-

Society and economy of the tropical forest

ers, had sociocultural units consisting mainly of kin-based populations which were structured along lines of age and sex, without much in the way of economic, political, or religious grounds for social-status differentiation. Social controls were largely based on kinship rights and obligations of a moral nature, except in cases of certain military activities that were often under the temporary leadership of special chiefs. Their richer technology and production of agricultural surpluses enabled villages to remain in the same place for many years, even though the depletion of soils necessitated the periodic reestablishment of new villages and the abandonment of older ones. Populations were larger and, of course, more concentrated. They were supported by a more adequate and dependable food supply, which included maize (corn), beans, squash, manioc, and tropical vegetables and fruits, as well as the riches of the rivers on which these peoples lived, such as turtles and the thousands of turtle eggs harvested annually and abundant fish and game. Hunting was important but subsidiary to agriculture. The rites of these peoples—those surrounding birth, puberty, initiation into men's secret societies, marriage, and death, and the shamanistic practices involved in the supernatural curing of illness—tended to be similar throughout the tropical-forest region. Many of the rites were similar to those of the simpler hunting and gathering peoples.

Chiefdoms of the northern Andes and the circum-Caribbean. In this extensive and geographically varied region there existed many peoples who lay in the main path of the Spanish conquistadores and who were overwhelmed by them. The Spaniards were attracted by the abundance of gold ornaments and religious objects displayed in the native villages and were excessive in their search for even greater wealth.

Among the chiefdoms were the Chibcha of highland Ecuador (the greatest chiefdom of them all) and the Coconuco, Pijao, Páez, Puruhá, Cana, and Palta of the northern Andes; the Jirajara and their neighbours, the Caquetío, Palenque, and Cumanagoto of northern Venezuela; and the Arawakan Taino of the Greater Antilles.

Though having a technology similar to that of the tropical-forest farming villages and sharing a basic material culture with them, the chiefdoms of the northern Andes and the circum-Caribbean areas had a still more productive food complex, which supported much denser populations in quite large and permanent villages and towns. Natural resources were more varied and abundant in the regions that they inhabited, and farming was more productive.

Villages were composed of multikinship groups organized on the basis of social strata which had attributed statuses, rather than merely on the basis of kinship considerations such as age, sex, and the moral obligations these incurred. Some social ranks were hereditary, such as chieftainship and ritual office. Warfare was of great importance in many societies of this type. Participation in military activities insured upward social mobility for individuals and families and the eventual achievement of membership in the topmost strata of the village. War captives were taken as drudge servants and for sacrificial victims in religious rites. There was a foreshadowing of state institutions in the offices of priest, chief, military leaders, and nobles and captive slaves. In the chiefdoms, however, these institutions had not crystallized as they eventually did in the Andean kingdoms and empires. A major diagnostic feature of chiefdoms was their priest-temple-idol complex, a ritual organization of a different order of complexity from the supernatural beliefs and practices of the tropical-forest villagers and the hunters and gatherers.

Central Andean irrigation civilizations. First occupied by small groups of hunting and gathering peoples who filtered southward along the Pacific coast and through the highland basins thousands of years ago, the central Andes eventually became the seat of the highest form of civilization developed in native South America. The earliest archaeological evidence of agriculture in this region has a date of 2300 bc, which is probably much later than the first domestication of plants. With the spread of agricultural knowledge throughout the central Andes, populations increased in size and attained more settled and

larger communities. A thousand years before the Spanish Conquest, the central Andes had the most developed agricultural and irrigational system in all of South America, the densest population south of Mexico, and the most efficient system of overland transportation in the Western Hemisphere. The combination of these features permitted the growth of true urban centres, an intricate class system, a strongly entrenched bureaucracy, and the extension of social controls over vast areas by means of political, religious, and military institutions.

Two of the most famous early kingdoms in the central Andes were the Tiahuanaco and the Chimú; the former spread its culture from what is today highland Bolivia northward to the vicinity of Lima and beyond. In the north of Peru arose the Chimú kingdom, which expanded southward and overlapped the northern extension of the Tiahuanaco culture, as the latter's influence had begun to decline. Following these two great cultural spreads and military conquests came the expansion of the Inca state. When Inca civilization reached imperial proportions it controlled the area occupied today by Peru, Ecuador, Bolivia, and the northern half of Chile. The expansion of the Inca Empire preceded the Spanish Conquest by slightly less than 100 years.

All of these imperial states, as well as other smaller ones before them, shared a number of characteristics that set them apart from the chiefdoms and other peoples. They were based on state-controlled irrigation works, which made the production of huge agricultural surpluses possible. These surplus crops were controlled by the emperor and apportioned among the state, the church, and the populace according to a standard formula. As a result of an abundant food supply and surpluses that could be stored against adverse times, population steadily increased. There developed a rigidly hereditary class system—with the agricultural masses at the bottom and the Inca royal family at the top, with ranks of nobles, chiefs, lesser administrators, artisans, and others in between. The state waged war for territorial conquest and taxed the defeated peoples. It imposed the Inca religion, with its emperor-god and hierarchy of deities, its shrines and temples attended by priests and sacred virgins, and its ceremonial calendar. The Inca were masters of bureaucratic regimentation who ruled the lives of the commoners through political controls enforced by state machinery and statute law rather than by customary sanctions. Inca institutions overshadowed and to some extent replaced the traditional behaviour patterns of the thousands of farming communities that made up the empire.

Central Andean technology differed little from that of surrounding areas, except in metallurgical skills and in the building arts, but it was outstanding in the quality, variety, and excellence of its products, the most outstanding of which were produced for the state and the nobility by highly skilled artisans.

Irrigation, agriculture, and bureaucracy in Andean civilizations

EVOLUTION OF CONTEMPORARY CULTURES

The European conquest. A full appreciation of the force and nature of the European conquest of South America must take into consideration postcontact population trends among the indigenous societies. Today, there are at least as many people of overwhelmingly Indian ancestry as there were just prior to the European conquest, but the vast majority of these, approximately 7,000,000, live in the central Andes and represent a resurgence after a marked population decline following the conquest. Elsewhere in South America, Indian populations declined rapidly after contact with Europeans and, for the most part, have not increased appreciably since. This loss of Indian populations is related directly to the intensity of European exploitation and the density of the native populations in question, two principal factors in adjustments during the colonial period.

Population decline was heaviest along the South American coastlines and major rivers, where Indian concentrations were greatest. Along the coasts of Brazil, the Guianas, Venezuela, Colombia, and Ecuador, where Europeans came in great force, the Indians were killed in large numbers, died in the course of enslavement, succumbed

Social and political life of the chiefdoms

to new diseases, or fled into the hinterlands in depleted numbers. Conditions were similar along the great river systems, where native populations declined sharply in the first decades after coming into contact with Europeans, their places being filled in the labour pools of colonial society by African slaves, who have made a great contribution to South America's mixed population.

Spanish influences

Indians who survived European intrusions are those small communities in the marginal, unattractive areas scarcely touched by soldiers and settlers. South of the tropical-forest area, in Argentina and Uruguay, where Indian populations were small and scattered, the coastal groups were again the first to succumb to conquest. In the Gran Chaco, resistance to Spanish settlement was fierce and temporarily successful, but, in time, these Indians were nearly wiped out by disease in mission centres and elsewhere, and the survivors were absorbed into the gaucho population that developed along with Argentine cattle raising. In Chile, the Atacama and Diaguita Indians were rapidly suppressed and absorbed, as were the northern Araucanians (Picunche). The southern Araucanians (Mapuche and Huilliche) held out against white subjugation and developed a military organization to defend their heartland until the latter decades of the 19th century. The southernmost groups—the Puelche, Tehuelche, Ona, Yaghan, and Alacaluf—have become virtually extinct.

In contrast to the rest of South America, the highland populations of the Andes are today larger than at the time of conquest. They have maintained great cultural stability, have survived epidemics, and continue to live in small farming and pastoral communities established centuries ago. Their population is steadily and rapidly increasing, and there is great population pressure on arable land, which constitutes a national problem in Bolivia and Peru.

Effects of colonialism. The kinds of changes induced by European conquest varied according to the intensity of settlement and exploitation, the density and organization of Indian populations, and the ecological adjustments made by the conquerors. Three examples of these variables may serve to indicate general trends.

Peru. Inca culture and society were deeply affected by the Spanish Conquest and the intensive settlement that followed. Spanish patterns of bureaucratic government replaced those of the Inca Empire, land use and ownership changed radically, tribute and forced labour threatened the agricultural base of the old society, ancient deities succumbed to Roman Catholicism, and community and domestic life were geared to the demands of the new colonial regime.

Economic and religious effects of European influences

Inca agriculture underwent great change through the introduction of European crops demanded by Spanish overlords. Indians were parcelled out among the settlers as tribute producers, menial labourers, and house servants. The abuses of exploitation were so great that very quickly most of the land was alienated from the Indians, who became a large, landless, and rootless population available for conscript labour in service of the colony.

The Spaniards imposed the Roman Catholic religion and tried to stamp out native beliefs and practices, a work of long duration that has not been wholly successful. Although the Inca state religion was totally suppressed with relative ease, an almost incalculable number of cults of lesser deities persisted in the villages.

The Inca upper classes were most readily assimilated into Spanish colonial society, whereas the agricultural masses retained much of their traditional culture. The native nobles entered the administrative ranks of colonial society and adopted Spanish dress and other customs. Artisans, servants, and others in direct contact with the settlers also became rapidly acculturated to a colonial way of life. Where native communities remained outside the main force of the colonial economy and where communal land was retained, the traditional culture was preserved somewhat intact, with customs of land use, ownership, family organization, marriage practices, and some home industries surviving into the 20th century. Villages have economic links with the cities through the production of marketable crops and may now be considered as peasant communities in a national economy.

Chile. The Spaniards conquered the northern half of Chile several years after having become established in Peru. They brought the Picunche under their control with relative ease by 1544 and used them to placer mine gold in the rivers, perform agricultural labour on settlers' farms, and build and provide services in colonial towns, cities, and military outposts.

In response to the colonists' demands for more Indian labour, Spanish troops attempted to conquer the southern Araucanians, the Mapuche and Huilliche. These Indians rebelled against harsh treatment at the hands of the Spaniards and succeeded in burning all their outposts and settlements and driving them north again. The history of northern Chile, after that, is one of peaceful colonization and the assimilation of the Indian population into a colonial labour force. Mapuche-Huilliche territory, however, remained a frontier zone for centuries. The Mapuche and Huilliche were placed on reservations after they sued for peace in 1884.

Panama. The Chocó Indians of the tropical forests of Provincia de Darién and nearby Colombia survived the Spanish intrusion because they had nothing of value to the Europeans and were bypassed. In turn, the Chocó were not especially warlike and avoided the dangers of contact.

The Chocó retained many of their traditional values and ways of life into the 20th century. They emphasize magical curing, observe age-old marriage practices, and live in pole and thatch houses built on pilings along rivers, where they have small groves of plantains and also grow manioc, cacao, and other tropical crops in jungle clearings. Most Chocó have no knowledge of Spanish. They are by no means integrated into national life and prefer to live apart in the densely forested areas. (L.C.F.)

Andean cultures

Although the Andes mountain chain extends from Venezuela to the southern tip of the continent, it is conventional to call "Andean" only the people who were once part of Tawantinsuyu, the Inca Empire in the Central Andes, or those considerably influenced by it. Even so, Andean is very wide. It encompasses the peoples of Ecuador, including those of the humid coast, many of whose contacts were as frequently with maritime peoples, to both north and south, as with the peoples of the highlands. Most of the populations and civilizations of Bolivia and Peru are Andean in a central, nuclear way, and here again are included the kingdoms of the irrigated desert coast. The peoples who for the past four and a half centuries have occupied the northern highlands of Chile and Argentina also must be included. (For a description of northern Andean peoples, see above *Central American and Northern Andean cultures*.)

CENTRAL ANDES—TRADITIONAL CULTURE PATTERNS

There is a stereotyped image of the Andes showing poverty against a background of bleak, unproductive mountains, where millions insist, against all apparent logic, on living at 10,000 feet (3,000 metres) or more above sea level. Nowhere else have people lived for so many thousands of years in such visibly vulnerable circumstances.

Yet, somehow this perception of the Andean peoples coexists with another, based on the breathtaking stage setting of such archaeological sites as Machu Picchu, the majesty of Inca stone palaces at Cuzco or Huánuco Pampa and such Chimú mud-walled cities as Chan Chan, the beauty of Andean textiles or ceramics in museums the world over, the reported concern of the Inca kings for the welfare of their subjects, and the mostly abandoned large-scale irrigation works or terraces constructed by these peoples.

These two visions of Andean peoples and their accomplishments can be reconciled only if it is recognized that what the resources and ecologic potential of an area and a people may be depends on what part of these resources the people use or are allowed to use by their masters. The Andean region was once rich and produced high civilizations because, over millennia, its people developed an agriculture, technologies, and social systems uniquely

adapted to the very specialized if not unique ecologic conditions in which they lived.

Economic systems. Since 1532, under European rule, extractive activities, such as silver, tin, and copper mining, for foreign markets have been favoured to the point to which Andean agriculture and the ecologic wisdom in handling productively the extremely high altitudes have been gradually devalued and mostly forgotten. The population of the Central Andes is both less dense and less urban today than it was in 1500. The coastal cities of South America, from Guayaquil to Buenos Aires, are filling with highlanders who have been convinced by four and a half centuries of colonial rule that cultivating at 12,000 feet is too strenuous.

Andean agriculture

Although human occupation began over 20,000 years ago, the beginnings of agriculture and population growth are much more recent. Within the last 8,000 years a specialized desert-and-highland agriculture was developed. There are two significant achievements in the Andean agricultural endeavour. First, given the wide range of geographic circumstances—very high mountains in equatorial and tropical latitudes, a 3,000-mile coastal desert, the Amazon rain forest to the east—there were thousands of quite different ecologic pockets, each with its own micro-environment to be understood and exploited. Dozens of crops, with literally thousands of varieties, were domesticated; most of them remain unknown outside the Andean area. Only the potato has acquired a following elsewhere; and only maize (corn) and possibly cotton were known in the Andean region as well as in the rest of the Americas. It is this multiplicity of minutely adapted crops and the domestication of the alpaca and the llama that made the mountains habitable to millions (the bulk of the population in the Central Andes has always lived between 8,000 and 13,000 feet).

Second, no matter how specialized Andean plants or herds may become, the leap from bare survival to dense populations and civilizations requires something more. The high altitude, with its 200, 250, even 300 frost-threatened nights a year, represents a challenge to any agricultural system. On the high, cold plains, known in the Andes as *puna*, there are only two seasons: summer every day and winter every night. By alternately using the freezing temperatures of the nocturnal winter and the hot sunshine of the daily tropical summer, Andean peoples developed preserves of freeze-dried meat, fish, and mealy tubers (*charki*, *chuñu*) that kept indefinitely and weighed much less than the original food. The giant warehouses that lined the Inca highways could be filled with these preserves and used to feed the engineers planning cities and irrigation canals, the bureaucracy, and the army, not to mention the royal court, with its thousands of male and female retainers.

Political systems. Even these two technological developments, however, are not enough to characterize and explain the emergence of Andean civilizations. From the intimate knowledge of their environmental conditions, the people developed a set of values that may have started from a desire to minimize risks but that soon was elaborated into an economic and political ideal. Every Andean society—be it a tiny, local ethnic group of 20 to 30 villages in a single valley or a large kingdom of 150,000 souls, such as the Lupaca—tried to control simultaneously a wide variety of ecologic stories up and down the mountainsides; some of them were many days' march from the political core of the nation. If the society was small, the outliers (herders or salt winners above the core; maize, cotton, or coca-leaf cultivators in the warm country below) would be only three or four days away. When the political unit grew large and could mobilize and maintain several hundred young men as colonists, the outliers could be 10 or even 15 days' walk away from the core.

The colonies were permanent, not seasonal establishments. Since more than one highland kingdom or principality would have maize or coca-leaf oases in a given coastal or upland Amazonian valley, there would be not only competition for their control but also coexistence for long periods of time in a single environment of outlying colonies sent out by quite different core societies.

The Inca state, or Tawantinsuyu as it was known to its own citizens, was perhaps the largest political or military enterprise of all. It reached from Carchi in northern Ecuador to at least Mendoza in Argentina and Santiago in Chile. Its scouts roamed even wider, as recent Chilean archaeology has shown. The Incas expanded and projected on earlier, pre-Inca solutions and adaptations; in the process, many tactics that had worked well on a smaller scale became inoperative; others were reformulated in such ways that their original outline was barely recognizable. For example, they kept an old Andean method of creating revenues for their princes, which involved setting aside acreage for regional authorities and demanding from the conquered peasantry not tribute in kind but rather labour on the field thus set aside. In this way the granary of the peasant household was left untouched; the authority took the risk of hail, frost, or drought decreasing its own revenues.

The Inca state at its zenith did not breach this tradition overtly; the local ethnic groups continued to work the state's acreage and owed nothing from their own larders. But since the needs of kings kept growing, revenues produced on state lands were soon inadequate; acreage could be and was expanded through such public works as irrigation and terracing. A more tangible way was to increase the amount of energy available for state purposes. For some reasons, still insufficiently understood, the kings did not increase productivity by introducing tribute; they preferred to magnify on an imperial scale the patterns of reciprocal obligations and land use familiar to everyone from earlier times.

Beyond the strategic colonies set up on an expanded model, the Incas did not interfere too much with life of the many local groups that they had incorporated into Tawantinsuyu. Most of the cultures that existed in Ecuador, Peru, Bolivia, Argentina, and Chile before the Inca expansion can be identified. In fact, because the European invasion beginning in 1532 was mostly concerned with breaking the resistance of the Inca overlords, frequently more is known about the pre-Inca occupants than about Cuzco rule. Inca power was broken and decapitated within 40 years of 1532. The ethnic groups, many of which (like the Wanka or the Cañari) sided with Europeans against the Inca, were still easy to locate and identify in the 18th century. In isolated parts of Ecuador (Saraguro, Otavalo) and Bolivia (Chipaya, Macha) this can still be done today. (J.V.M.)

Inca expansion

SOUTHERN ANDES—TRADITIONAL CULTURE PATTERNS

The area commonly referred to as the Southern Andes is separated from the Central Andes by a broad band of desert covering extreme southern Peru and northern Chile and Argentina. The Southern Andes includes those peoples occupying the mountain regions of northeastern Argentina and northern and central Chile south to Isla Grande de Chiloé. (Tribes farther south are discussed below; see *South American nomad cultures*.) Generally, it is an area of moderate to extreme aridity, with a temperate climate. Agriculture has been an important feature of village life and, in many places, has been sustained by irrigation techniques; however, the agricultural potential—limited by the availability of moisture—has always been much less than that of Peru.

Prior to the advent of farming, the peoples of the area followed a life pattern based on hunting, collecting, or fishing, depending upon their geographical location. Cultivation of plants, including corn, was introduced at some time after 500 BC, almost certainly diffused to the Southern Andes from Peru; and Inca influence finally appeared in the latter part of the 15th century AD. It is known from ethnohistoric sources, as well as from the presence of Inca-style fortifications and way stations, that the Cuzco government had established its authority over these peoples of the south. These southern tribesmen—the Atacama of northern Chile, the Diaguita of northwestern Argentina, and others—lived in small, compact towns or villages and practiced irrigation farming and llama and alpaca herding. In general, the cultures of the area may be said to show a marginal and somewhat delayed expression of Andean

civilization. These primary influences were also blended with influences from Amazonian cultures by way of the Bolivian lowlands. Socially, for instance, the people were organized into autonomous villages of related kinship groups, much like the tropical forest village farmers and not at all like the highly class-stratified imperial Incas; war was conventionally waged for human trophies, not for territorial conquest. (Ed.)

South American tropical forest cultures

Problems
of
generaliza-
tion

The tribal cultures of South America are so various that they cannot be adequately summarized in a brief space. The mosaic is baffling in its complexity: the cultures have interpenetrated one another as a result of constant migratory movements and through intertribal relations, leading to the obliteration of formerly significant differences, and to new cultural systems made up of elements of heterogeneous origin. Hundreds of languages, in very irregular geographic distribution, with innumerable dialects, are or have been spoken in the tropical area of South America. Thus, only the broadest generalizations can be made; one can mention certain cultural manifestations that are present in a great number of groups, even though varying in their actual expression, and illustrate them with specific examples—but always with the qualification that in a neighbouring tribe or group a distinctly contrasting idea or institution may exist.

The people

The innumerable native peoples differ in their patterns of adaptation to their natural environment. Whether they live in the rain forest, in the gallery forests lining the rivers, in the arid savannas, or in the swamps, however, they share a common cultural background; they often combine fishing and hunting with rudimentary farming. Most are relatively sedentary, but some are nomadic or semi-nomadic. Greater differences are sometimes found among neighbouring groups living in the same forest than between some forest and savanna peoples. And some tribes, when migrating to open areas, maintain to a great extent the forest characteristics of their culture.

On the banks of the great rivers but also in zones between the forest and the savanna live tribes who gain their subsistence from farming and fishing. Hunters and gatherers, almost all of whom also practice some farming, have settled near the heads of rivers, in open land, or in gallery forests.

Tribes speaking related languages are scattered over a large part of the continent. The tribes of the Arawak and the Carib linguistic families are most numerous in the Guianas (French Guiana, Guyana, Suriname, and the adjacent regions of Venezuela and Brazil) as well as in other parts of the northern Amazon, but the former have representatives as far south as the Chaco and the latter as far south as the upper Xingu. The Tupí tribes extend to the south of the Amazon valley.

The Ge family includes groups most of which are located in the semi-arid lands of central Brazil. In the extreme northwest of Brazil and in the jungles of eastern Peru and Bolivia live the Pano tribes. The Jívaro of Ecuador are famous headhunters. They cut off the enemy's head, separate the soft part from the skull, and, with the help of hot sand, reduce it to the size of a fist without altering the physiognomy. They attribute great magical power to these trophies, or *tsantsa*.

TRADITIONAL CULTURE PATTERNS

A characteristic feature of the tropical forest cultures is their combination of farming with hunting, fishing, and gathering. Before the arrival of the white man, the Indians of the tropical forest had no domestic animals except the dog. These people did not write or erect stone buildings as did the Indians of Middle America. They did not form states with centralized political organizations. They had no castes of warriors or priests. Their utensils and instruments were almost all of vegetable or animal origin, since in large sections of the area stones for making axes, arrowheads, and other objects were quite scarce. One finds evidence of metalwork only in the regions near the Andean civilizations, although objects of copper and other

metals occasionally found their way across the continent, through channels of trade.

Social organization. In almost all of the tropical forest area the population density was low, averaging probably less than one person per square mile.

Populous centres existed only along the coast and the main rivers, particularly the Amazon; the latter, according to reports by early white explorers, was fringed with Indian villages. For the most part, however, the Indians were dispersed throughout the vast territory in innumerable tribes and tribelets. This is why a classification by languages and cultures gives only a vague idea of the complex picture of the forest populations. Peoples having the same dialect and culture might exist as separate groups, even as enemies. While some Indians considered themselves primarily members of their local group, others, like the Xerente (Sherenté), gave greater value to a common language and culture than to village divisions. But differences in dialect and culture often imposed obstacles to the recognition of tribal solidarity.

There were no permanent political associations or confederations encompassing tribes of different languages and cultures. At most, some tribes might form ephemeral confederations for warfare against a common enemy. Certain close relations sometimes existed between groups of diverse origin, especially through tribal intermarriage. The best known examples are along the Río Negro in north-west Brazil, where numerous populations, mostly Arawak and Tucano, are united in a vast network of interethnic relations. At the headwaters of the Xingu, a complex system of intertribal institutions also exists among formerly autonomous groups.

Few tropical forest tribes are strictly monogamous. Marriage with two or more women is usually restricted, however, to chiefs and other men of prestige. Polygyny is perhaps most accentuated among the Jívaro, where head-hunting has killed off many of the men; it frequently takes the form of marriage with two or more sisters. Examples of polyandry are rare.

The choice of a partner is sometimes limited by the division of the tribe into clans and segments to which an individual belongs by heredity and within which marriage is prohibited. In some cases, for example in the Guianas and in the Río Negro region, the individual must find a mate outside his village or even outside his tribe (exogamy). The Terena of the southern Mato Grosso divide themselves into endogamous groups: the man and wife must come from the same group, called by ethnologists a moiety. Marriage between cross cousins, that is, between children of siblings of different sex, is considered ideal in many tribes; that of parallel cousins, children of siblings of the same sex, is frequently prohibited.

Kinship groups and household communities are based predominantly on the principle of lineage, that is, on relation through either the male or female line. Communities of extended patrilineal families were typical of the Tupi-Guaraní. In many Amazon tribes and in others farther north, the lineages or groups of lineages are patrilineal exogamous clans. Tribes with matrilineal clans, although less numerous, can be found throughout South America. In some tribes the clans number 40 or more, as among the Mundurukú; they are generally organized into two groups so that the whole tribe comprises two exogamous moieties. The dual divisions of the Ge Indians, often not related to kinship and marriage, are mainly ceremonial.

The tropical forest cultures do not exhibit much social stratification. When there is a servile element, it is normally made up of ethnic outsiders who do not constitute a class as such. War captives may be reduced to slavery, as among the northern Carib and Arawak, the Huitoto, and the Mundurukú. Among the extinct Tupi of the Brazilian coast, slavery was the fate of those destined for ritual sacrifice. In many cases, chiefly among the northern Carib, slavery has primarily an economic function: the captives form a servile group known as *peito*—the same term that is applied to a fiancé during the period in which he is obliged to work for his future father-in-law. The Rucuyen, a Carib tribe of French Guiana, for some time maintained in servitude a great number of the Oyampi,

Marriage
customs

their Tupí neighbours. In the northwest Amazon valley, Arawak and Tucano tribes hunt and enslave Makú men, who are forced to work in their gardens; the Makú women and children are used as domestic servants.

A tendency to form a class of nobility has been found in many Arawak groups, who not uncommonly impose themselves over other tribes by means of intermarriage, especially among families of chiefs. In some regions, relatives of chiefs constitute a kind of nobility. In tribes divided into clans, it is common to attribute superior status to a certain clan or even to scale them in hierarchical order. Nevertheless, the local or tribal community is essentially egalitarian.

Education
and
socializa-
tion

The children learn through play and imitation. Boys acquire skill in the use of weapons by practicing with small bows or blowguns made by their fathers. Girls learn to cook in little clay pots and to weave on small looms; they help their mothers in the preparation of manioc flour. The young also participate in the general religious life. The transmission of moral standards is rarely of a formal nature, and there is little punishment or repression.

The institution of the couvade is found throughout the forest culture. The father of a newborn infant must observe a rigorous diet for a week or so after the infant's birth. It is based on the idea of a mystical relation between the father and the child.

Puberty rites are often quite elaborate. In many tribes, such as the Guaraní, the symbol of masculine maturity is the labret, an ornament worn in a perforation of the lip; the ritual is preceded by an instruction period during which the boys, isolated from the community, learn the religious chants and dances, and it culminates with the perforation of their lower lips. Initiation rites may be limited to boys or to girls or may be for both sexes. The initiation of the boys is generally done collectively for those who have reached the eve of sexual maturity, while that of the girls is normally held individually on the occasion of the first menstruation.

In many of the Indian cultures these rites take a central position among other important ceremonies such as funerals and fertility rites. In the Guianas and the northwest Amazon region, the initiation of the boys is very complex. The Yurupary celebration inducts the boys into the secret society of mature men. Special rites are revealed to them; they are shown the sacred trumpets or the masks representing ancestral spirits. They are subjected to violent whippings, which they must tolerate without the least expression of pain. In the Guianas, the ritual torture consists of the stings of hornets or the bites of poisonous ants. The girls' initiation, generally more developed in the Amazon area near the Andes, is also frequently accompanied by difficult tests. Among the Tikuna (Tucuna) and other Amazonian groups, all the hair of the girl is pulled out; its regrowth symbolizes the emergence of a new adult personality.

The initiation of the boys assumes great importance in the social structure of some Ge groups of central Brazil, whose complex of rites begins at ten years of age and continues in cycles until 20. In one such tribe, the Xerente, candidates spend three years isolated from community life preparing themselves for manhood. In these Ge groups, those who have been initiated together form a distinct set of persons who feel united the rest of their lives.

Economic systems. Most of the tropical forest Indians are neither entirely sedentary nor entirely nomadic. Some wandering bands do not remain in the same place for more than a few days. Some farming populations are more or less attached to the earth. But even the latter make seasonal moves, especially those in semi-arid regions. The semi-nomadic tribes live in villages during the rainy season and go hunting in dry spells—e.g., the Xavante and other Ge—or break up into little bands for gathering, as do the Nambikwara (Nambicuara). The Karajá (Carajá) of the Araguaia build their villages in rows of houses on high ground near the river, but in the dry season they move down to the long beaches. Most of the villages of the tropical forest farmers are not permanent; after some years they have to move because of soil exhaustion.

Housing

While the bands of gatherers rarely exceed a few dozen

individuals, the farmers' villages have been known to include as many as 2,000. As a rule they are much smaller, dividing whenever the population becomes too large. A characteristic arrangement is the circular village of houses placed around a central plaza. This is found, for example, in the upper Xingu, in various Ge tribes, and among the Bororo of the Mato Grosso. The plan of the Bororo village, like that of the Ge, is a real map of the social structure. Each household represents a particular segment of the local group, such as an extended family or a patrilineal or matrilineal clan. The centre of the plaza is often occupied by the men's house, where the men spend the night and the greater part of the day, and which is at times the locus of ceremonial activities.

The house reflects the economic organization and social structure. Designs range from the simple shelter of the Guayakí and the wind screens of the Nambikwara up to large communal houses containing 200 or more individuals, even the entire tribe. The latter, known as *malocas*, have been found in the Guianas, northwestern Amazonia, and in some regions farther to the south in the area of the Purus and the Guaporé rivers. The Tupinamba houses are reported to have measured up to 20 metres in length. Houses on piles are found in marshy and swampy locations, for example among the Warao (Warrau) and other Indians of Venezuela but sometimes also among tribes that inhabit dry lands and savannas. The Mura, who live on the Madeira and Purus rivers, and the Guató of the upper Paraguay River, who spend a good part of the year on rivers and lagoons, fishing and hunting aquatic animals, have made their canoes into dwellings. At other times they live in small shacks at the water's edge.

Most houses are made of rough wood, covered with palm leaves or grass. The great circular *malocas* with conical roofs in southeastern Venezuela merit special attention for their size and solidity. Although there are no walls in the *malocas*, the space is customarily divided according to social distinctions, giving a specific place to each family and sometimes even to each of its members. The furniture is very rudimentary. Some Indians sleep on mats or on platform beds, but more of them use hammocks which are found throughout the tropical region.

A great variety of economic systems is found in the tropical forest. The tribes cannot accurately be classified as hunters and gatherers on the one hand or as farmers on the other. The differences lie in the emphasis given to agriculture rather than in the presence or lack of it. The Guayakí of the forests of eastern Paraguay are one of the few tribes without any agriculture; they feed on wild honey and larvae, catch fish with arrows, and hunt jaguars and armadillos. The Sirionó of Bolivia and most of the Makú (a denomination that comprises rather heterogeneous Amazonian groups) are nomads who hunt, fish, and gather. A few Makú groups, however, influenced by their neighbours, have become more or less sedentary farmers. The same holds for the Shirianá and Waica of the Orinoco–Amazon headwaters.

The crops are chiefly bitter manioc as well as other tubers and roots, and, in the western regions, maize (corn). Some Ge tribes grow mainly sweet potatoes and yams. The forest is cleared by felling the trees (the stone axe has now been everywhere replaced by the iron axe) and, when the underbrush is dry, setting fire to it. The same plot is used for several (but never more than six) consecutive crops and then left fallow for several years until it is covered by new vegetation. The group must therefore move periodically. The slash-and-burn system does not, except in the more fertile lowlands, permit the growth of dense populations. It does, however, provide a seasonal food surplus that might in many cases, considering the available techniques, be increased. But the Indian has no incentive to store up goods in a generally egalitarian society, since goods are not a source of prestige.

The tropical forest Indians are highly inventive. They have developed many types of harpoons, arrows, traps, snares, and blowguns. In fishing they employ a variety of drugs that stun or kill the fish without making them inedible. The bow and arrow are today known everywhere; in some Amazon regions they have replaced the spear

Production
and
technology

thrower, a device still in use in certain western tribes. The bow and arrow are the principal weapons of warfare, although some groups fight with clubs and lances.

The techniques of basketry have a wealth of variations, mainly in the Guianas, the northwest Amazon region, and among the Ge peoples. Along with many kinds of baskets and hampers, these folk plait sifters, traps, fans, mats, and other household articles out of palm leaves and shafts of *taquara*, or bamboo.

The potter's wheel was traditionally unknown, but coiled ceramics reached a high degree of development, particularly among the Arawak and Pano tribes. Among nomadic groups pottery is either nonexistent or very rudimentary; instead, the nomads use gourds, calabashes, baskets, and fibre pouches.

Spinning and weaving, though well-known, remain at an elementary level since most tropical forest Indians, instead of dressing, prefer to paint the body and to embellish it with all sorts of adornments. From cotton, growing wild or planted, they make tunics, as well as belts of various types, skirts, and particularly hammocks. They use simple spindles, which they whirl like tops. The most common loom is the heddle loom: the threads of the weft, separated by heddles, are wound around a vertical frame. In regions close to the Andes, especially in eastern Bolivia, the Indians make cloth of beaten bark.

The roots of the manioc or cassava plant is a staple of the Indian diet, and its processing requires a number of implements including baskets and sifters, graters made of planks with little stones embedded in them, the *tipiti* (a plaited cylinder used to squeeze the prussic acid from the grated pulp), great clay pots for preparing the flour, and earthen fryers for making flat cakes.

Land is generally owned by the group occupying or exploiting it—a band, a village, or a clan—and parcelled out to families or other small units for hunting, fishing, or planting. Collective tribal land or territory exists only in rare cases, when the solidarity between the various groups of a people is particularly strong. There are rigorous norms for the distribution of game among the hunter's family and among other families to which he is associated by certain ties; the hunter himself may receive a rather small share. Cleared land almost always belongs to the family using it, but when necessary others may have access to its products. Generosity is greatly valued: the generous person is good, the miser bad. This also holds for intertribal relations, when gifts are exchanged on the occasion of visits or celebrations.

Weapons and household utensils are the property of individual men and women, but canoes and other objects used collectively are not. Body adornments generally belong to the wearer. Intangible property may belong to the clan or other social unit, but it may also be individually owned, as in the case of the name or ritual functions among Ge tribes, and magical-religious chants among the Guaraní.

Brisk trade among tribes is carried on in parts of the Guianas, in northwest Amazonia, and in upper Xingu. Indians of the upper Orinoco export *urucu*, a red dye, to groups living downriver. The Arawak frequently trade ceramic wares produced by their women; they also supply blowguns in exchange for poisonous curare and barter manioc graters. Carib tribes often trade cotton products. Some groups specialize in the manufacture of canoes, which are much in demand by neighbouring groups. The most complex trading system is that of the upper Xingu; it includes a dozen tribes, each with its own products. Commerce contributes significantly toward reducing cultural differences among the tribes, the more so because it is accompanied at times by ceremonial activities through which religious ideas and practices, as well as elements of social organization, are transmitted.

Belief and aesthetic systems. The jungle Indians believe that their well-being depends on being able to control innumerable supernatural powers, which in personal or impersonal form permeate or inhabit objects, living beings, and nature in general. Through shamanistic rites or collective ceremonies, man must encourage and maintain his harmonious integration in the universe, controlling the forces that govern it; their beneficial or harmful effects

are largely determined by human action. In most of the cultures, magical measures and precautions are more important than the religious cult as such. The strength and health of the body, the normal growth of children, the capacity to procreate, and even psychic qualities are obtained by magical means. For the individual these means may include the perforation of the lips, nasal septum, or ear lobes, the painting of the body, and the use of various adornments. A little stick passed through the nasal septum, such as that used by the Pawumwa of the Guaporé River, prevents sickness. The hunter or fisherman, in order to be successful and not to be *panema* (unlucky), as they say in many Amazonian regions, takes precautions such as scarring his arms or abstaining from certain foods. The magical devices of the hunter, the fisherman, and the warrior are considered much more important than their ability. Arrows must be treated by rubbing with a certain drug, since their magical attributes are believed to be more effective than their technical properties.

Stimulants and narcotics are of great importance in the magic and religious practices of most tropical forest Indians. Secular use of drugs is much rarer. Tobacco is known by almost all tribes. The Tupinamba shaman fumigates his rattle with tobacco, which he believes contains an animating principle that confers on the rattle the faculty of "speaking," that is, of revealing the future. Alcoholic beverages, consumed mainly in religious festivals, are obtained by fermentation of manioc, corn, and other plants. They are unknown among the Ge, in the upper Xingu, and in some regions of Bolivia and Ecuador. Coca leaves are chewed, especially in the sub-Andean regions. Infusion of maté is taken in the Paraguay area, as well as by the Jivaro and other groups of Ecuador. Hallucinogens are used mainly in the Amazon-Orinoco area; they include species of *Banisteriopsis* (a tropical liana), from which is made a potion that produces visions. In certain tribes the use of this drug is restricted to shamanistic practices; in others, as in the Uaupés River area, it is an essential element in religious festivals in which the community revives its mythic tradition. Other narcotics in ritual use, among them the *yopo*, or *paricá* (*Piptadenia*), known among many northern groups, are often breathed in the form of snuff, which partners blow into one another's nostrils; the Omagua of the upper Amazon used it as an enema.

Some magical practices are reserved for the shaman, who acquires his status by natural endowment, by inspiration, by apprenticeship, or by painful initiation. The shaman may practice medicine, perform magic rites, and lead religious ceremonies. Rarely, however, is he a priest in the usual sense of the term. In many groups his influence is superior to that of the political chief; in some, as among the Guaraní, the two roles may coincide. Not uncommonly, his influence continues even after his death: in the Guianas and elsewhere, his soul becomes an auxiliary spirit of his living colleagues, helping them in their curing practices and in the control of harmful spirits; among the Rucuyen, the bodies of common individuals were cremated, while that of the shaman was kept in a special place so that his soul might live on.

In curing the sick, the shaman must remove the object causing the sickness: a small stone, a leaf, an insect, any substance that has been sent through the black magic of an evildoer. The cure consists of massages, suction, blowing, and fumigation. If the illness comes from loss of the soul, the shaman must search for and recover it. If it comes from a bad spirit, he tries to overcome the evil influence with the help of one or more auxiliary spirits.

The soul has its seat in the bones, the heart, the wrist, or in other parts of the body. Some Indians believe that two or more souls are responsible for various vital functions. One finds also the idea of a purely spiritual soul. The Guaraní believe that man has an animal soul governing his temperament and his instinctive reactions but that he also has a second, spiritual one, sent by a divinity at the moment of conception. Thanks to his second soul, man thinks, speaks, and is capable of noble sentiments. After death this second soul returns to live among the gods, while the other soul wanders the Earth as a ghost menacing the living.

Magic

The shaman as healer

Nature is believed to be peopled by demons and spirits that are beneficial or malevolent, depending on man's behaviour. Besides the soul that gives life to every living thing, many plants and animals have a "mother" or "master," as do manioc, maize, and game animals.

The mythology of almost all tribes includes a creator of the universe and of man. This creator seldom sustains interest in his handiwork, and thus there is usually no cult attached to him. Social institutions, customs, knowledge, techniques, and cultivated plants are deeds or gifts of a culture hero or a pair of them, sometimes twin brothers who may represent the Sun and Moon. A number of myths are told about these figures; sometimes the pair consists of a hero and a trickster who opposes him.

Ceremonial practices vary, depending on the tribe and its way of life. Some great collective ceremonies have been associated with war, as among the northern Carib and the coastal Tupí, both famous for cannibalism, and the headhunting Mundurukú and Jívaro. Ceremonies are often believed to be indispensable for regulating the course of the Sun and the Moon, the sequence of the seasons, the fertility of plants, the procreation of animals, and the very continuity of human life. Their objective may also be to commune with the dead or with mythical ancestors; when they are connected with the disposal of the dead, they are at the same time passage rites, by means of which the spirits of the dead are made harmless. Among the Guaraní, most religious ceremonies mean profound spiritual communion with the gods.

Corpses are commonly disposed of by ground burial within or without the house. Urn burial has also been known, especially among Tupí groups; some groups have been known to unearth bones, clean them, and then rebury them. The Tarariu (Tarairiu) of northeastern Brazil and some Pano broiled the flesh of their dead and mixed the pulverized bones and hair with water or with a manioc-base beverage that they drank. Tribes of the Caribbean coast, after drying the body by fire, allowed it to decompose and later added the powder to a drink. In other northern regions, one still finds the custom of cremating the cadaver and consuming the charred and crushed bones in a banana mush.

Aesthetic
expression

Artistic efforts are most commonly applied to decoration, whether of the human body, objects of practical or ritual use, or even houses. The most common body adornments are paint and feather ornaments. Tattooing has also been practiced, especially among the Mundurukú and many Arawak tribes. Magical and religious ideas are usually expressed in these adornments. The Carib tribes of the Guianas and some Tupí were outstanding in featherwork. The plumed mantles of the Tupinamba, the delicate and elaborate adornments of the Caapor of Maranhão state, and the rich and varied ones of the Mundurukú are much celebrated.

The design of ornaments is almost always geometrical, with characteristic patterns for particular tribes; the styles vary with the cultural areas.

Masks, generally used in ceremonial dances, are restricted to the tribes of certain areas: the Cágaba of northern Colombia, the Tikuna and others of the northwestern Amazon, the Tucuna and their neighbours of the upper Amazon, the Guartegaya and Amniapé (Amniepe) of the upper Madeira, the tribes of the upper Xingu, the Karajá and the Tapirapé of the Araguáia River area, some Ge of central Brazil, and the Chiriguano of southern Bolivia. The masks represent the spirits of plants, fish, and other animals, as well as mythical heroes and divinities. They are highly stylized in form but, on occasion, naturalistic in expression.

The Waurá women of the upper Xingu are famous for their pots and animal-shaped bowls. Of the historic tribes, the Tapajó of the Amazon had the richest style in ceramics, excelled only by the archaeological remains of the Ilha de Marajó. Among some groups in the Guianas and western Amazonia, artistic activity includes wood carving.

MODERN DEVELOPMENTS

The great majority of the Indian groups are closed societies, despite intense intertribal relations in certain areas.

They lack institutions that would enable them to become part of a larger, all-embracing, and technologically superior society. Their relations with the whites have placed them in a situation of dependency that usually ends with their breaking up. The white man's prohibition of warfare, headhunting, cannibalism, polygamy, and other institutions that have profound meaning in tribal life sets in motion a process of social disorganization. In addition, numerous tribes have been extinguished by violent destruction, slavery, the loss of lands required for subsistence, epidemics, and by marriage with whites and blacks. Innovations introduced by the whites often have harmful effects: *e.g.*, iron utensils, which not only subject the Indians to those who supply them but also change the traditional division of labour in tribal society, and clothing, which alters personal hygiene and makes its wearers susceptible to new diseases.

Contact with the white man creates a profound crisis for the tribal leadership. Either the chief of the group is deprived of his authority, since the conditions for realizing the values essential to tribal life no longer exist, or he becomes despotic and a tool of the whites, using his power to benefit himself at the expense of his community.

Agricultural tribes are sometimes able to adapt to the new conditions for a time by trading their products, especially manioc flour. The sale of products such as fur skins, babassu nuts, copaiva oils, and carnauba wax helps in certain cases, as with the Tenetehara of Maranhão state, to maintain economic stability without breaking up the community organization. This is impossible, however, when the Indian undertakes to collect rubber for commercial firms, since this obliges the tribe to split into family units and to spread over vast areas; the result is an enormous cultural impoverishment. The transformation of the Indian into a labourer has generally led to the rupture of tribal bonds, much misery, and the disappearance of the tribes as ethnic entities.

There have been cases in which the Indian successfully integrated into the regional economic system as a paid worker or even as an independent producer. The Terena, an Arawak group of southern Mato Grosso, work on cattle breeding farms, an activity they learned long ago while vassals of the Guaycurú, who had become horse breeders after the Spanish conquest. The Goajiro of Colombia, another Arawak group, own great herds of cattle.

The disruption and crisis that follow inevitably upon contact with the whites are, however, less serious when the Indian has had earlier contact with a hybrid population carrying a cultural system that already incorporates many of the elements of civilization. These mixed cultures, such as those on the Brazilian-Paraguayan frontier and in some parts of Maranhão state, act as a kind of sieve between the system of tribal life and that of the white invader. In the past such cultures took numerous solutions, especially of an adaptive kind, from the Indian culture, helping to give the Indian a feeling of worth when facing the invader. Today he no longer has this privilege, since the hybrid cultures already possess whatever Indian elements they can use.

The cultural crisis the Indians undergo in contact with the whites has brought about sporadic messianic outbreaks. Since the Indians face a problem for which there often seems to be no solution, they may appeal to the supernatural and wait for a miracle to happen. They hope for a return to the "lost paradise," that is, to the old life without the white man, whose expulsion or destruction may be part of the miracle. At the same time they want to avail themselves of some of the advantages of civilized life. Insofar as civilization seems an ideal impossible to realize without recourse to supernatural aid, because of the Indian's economic and social inferiority, the messianic miracle in many cases takes the form of a social and cultural revolution: in the new era the Indian will dominate over the white man and will have all those things in the civilized world that to him symbolize superior status.

In certain regions of the tropical forest these movements appear from time to time. Along the Río Negro in north-west Brazil, there have been several messiahs since the end of the 19th century. These leaders combined elements of

Disruption
and crisis

Messianic
movements

their tribal religion with teachings and rites of Christian origin, although the predominant note was always hostility to the whites. Such movements have also occurred among the Tikuna of the upper Amazon; in one in 1956 the leaders proclaimed, among other things, that a city would appear suddenly in the middle of the forest, lighted by electricity and providing all the comforts of modern civilization. In 1963 the Canela, a Ge tribe of Maranhão state, had a messianic movement announcing that, when the new day came, the civilized people would be obliged to live in the forest or in the savanna, hunting with bow and arrow, while the Indians would become rich farmers. In this, as in other cases, the miracle was to be brought about by the great hero of tribal myth. The Guaraní of Paraguay and adjacent Brazilian regions are most famous for their frequent messianic movements, the fundamental myth of which is that a cataclysm will destroy the world and the Indian will find salvation in a distant paradise called the Land Without Evils. Probably the messianic tradition of the Guaraní dates from before the coming of the whites, but it seems to have undergone great expansion since then.

South American nomad cultures

In the past, South American nomadic hunters, gatherers, and fishers could be found all the way from Cape Horn to the Orinoco River in northern South America. The most variable groups were found in the southern half of the continent, occupying a variety of habitats and exploiting differing resources. With the technology known to them, food production was low, the population sparse, the social organization simple. Constant movement within prescribed territories prevented large permanent villages or the accumulation of material wealth.

TRADITIONAL CULTURE PATTERNS

Types of South American nomads. *Shellfish gatherers.* In the south, the Chono, Alacaluf, and Yaghan Indians occupied the whole Chilean archipelago down to Cape Horn. This is a rugged terrain of islands and fjords with heavy rainfall, an average winter temperature of 32° F (0° C), and an average summer temperature of 50° F (10° C). The dense forests make land travel extremely difficult and horticulture impracticable. The area is poor in game, fish, and edible plants. The archipelagic tribes thus depended on shellfish and seals or whales that had been stranded on the beaches. Travel was almost entirely by canoe.

Hunters and gatherers of the steppes and plains. The large area of the steppes and plains extends from Tierra del Fuego, in the south, through Patagonia, to the Pampas of northern Argentina and Uruguay. The Ona occupied the islands of Tierra del Fuego. The brush-covered, semi-arid Patagonian plateau was the home of the Tehuelche, while the Puelche and Querandí inhabited the flat grassy Pampas. The Charrúa lived in the grasslands north of the Río de la Plata. In aboriginal times, these people practiced no agriculture and had no domesticated animals, with the possible exception of the dog. Throughout the region the tribal groups depended on hunting guanaco, rhea (the South American ostrich), and smaller animals and on gathering some roots and herbs. The population was one of the sparsest in South America.

Hunters, gatherers, and fishermen of the Gran Chaco. The Gran Chaco extends northward from the grasslands of the Pampas to Paraguay and southern Mato Grosso in Brazil. It is an arid region covered with drought-resisting vegetation. The area is drained by the Paraguay River and its western tributaries, such as the Pilcomayo, Bermejo, and Salado rivers, that originate in the Andean foothills. During the summer months the Chaco experiences the highest temperatures in South America.

The people subsisted on plant food, supplemented near the rivers by fish at certain times of the year. The plant foods were supplied by such pod-bearing thorny bushes as the algarrobo and by many local trees. Some wild rice was also available. Honey and larvae were also eaten. In the southeastern part, guanaco and rhea were hunted. On the

whole, however, the people depended primarily on plant foods, in contrast to the nomads to the south, who were essentially hunters.

In aboriginal times all the nomadic peoples of the Chaco travelled on foot or, in some cases, in canoes. The horse was introduced into the Chaco after the Spanish conquest, and its adoption by some tribes had far-reaching consequences in the area. It is convenient to separate the Chaco tribes of historic times into foot Indians and horsemen. Among the foot Indians were such groupings as the Zamuco, of the northeast, and the Mataco, of the central Chaco. Each such grouping consisted of a number of tribes. The mounted bands, who spoke Guaycuruan, consisted of such groups as the Abipón, Mocoví, and Caduveo (Mbaya, or Guaycurú).

Forest hunters and gatherers. North of the Chaco, the country merges gradually into the tropical forest zone, particularly in the western section of Bolivia. In Brazil the forest zone comprises columns of forests on both banks of the major rivers. There are also island forests—large patches of forest standing on a plain or plateau, evidently supplied by springs that flow the year round. Typical nomadic tribes in this area were the Sirionó of eastern Bolivia and the Nambikwara (Nambicuara) of Mato Grosso, Brazil, and the Guayakí of eastern Paraguay.

Aquatic nomads. In the marshes of the upper Paraguay River in Brazil an unusual tribe of Indians, called the Guató, lived most of their lives in canoes, fishing and hunting cayman and other aquatic animals. They built temporary shelters on small islands that stood slightly above flood level. There are also other aquatic nomads in the north of South America and in the Caribbean.

Economic system. Because of their nomadic habits, all the hunters and gatherers had very little in the way of such material equipment as weapons, textiles, clothing, ornaments, and buildings. Their technical processes were very simple and appear to have been invented long ago.

Shelter was provided by caves if available. In the colder climate of the south, the archipelagic tribes of Chile and the nomads of the Chaco made domed huts of bent poles covered with bark, skins, or brush. When the people moved on they left the frame for others to use, taking only the skin coverings with them. The Patagonians made a skin-covered hut known as the *toldo*. The Yaghan used a conical tepee-like shelter or a double lean-to. The Nambikwara used a lean-to in the dry season or camped under trees, sleeping on fire-warmed ground. During the rainy season a larger double lean-to was used. There were no permanent settlements, although people sometimes gathered together to perform ceremonies and to feast when food was plentiful.

The forest hunters, such as the Sirionó and Nambikwara, wore no clothing. The southern nomads wore skin robes and crude moccasins. There was no sewn clothing. Earplugs, nose plugs, and lip plugs were widely used, except by the archipelagic people. Featherwork, armbands and leg bands, necklaces, and body painting were common in many areas. Some of these ornaments were used to distinguish bands or lineages and other groupings, but they were not used as status symbols.

Finger weaving of yarn spun from native cotton and palm frond fibres was practiced in the Chaco and among the Sirionó and Guató. The heddle loom, a later development, was known among the Sirionó, Nambikwara, and Chono. Long strips of fabric were woven for making armbands and leg bands and other decorations. Netting was used for making fishnets and bags for the transportation of goods, particularly in the Chaco.

Pottery was known to some of the nomads but was little used because pots were difficult to transport. Coiled basketry was widely used by the nomads. In the Chaco, twilled baskets made from palm fronds were used at campsites and abandoned when the people moved on. The Patagonian and Pampean hunters used containers made of skins.

Two methods of making fire were widespread. The first involved a spark with flint on iron pyrite. A later technique involved twirling a hardwood pointed stick in a socket in softer wood: dried pith was then placed around the drill, and by gently blowing on the spark the pith ignited. Meat

Housing

and fish were cooked by placing them directly on coals or putting them into earth ovens, lined with heated stones and covered with earth and coals. The Chono boiled food by placing heated stones in tightly woven baskets. The hunting and fishing people used no salt, but the Chaco tribes, who depended primarily on plant food, traded for salt with the highland people. Some of the forest nomads used ashes in place of salt.

Weapons

Bows and arrows were used by all the nomads. Among the Patagonian and Pampean hunters, however, there is archaeological evidence to suggest that the bow and arrow was preceded by the bola. Before the introduction of the horse, guanaco and rhea were hunted by stalking, the hunter throwing the bolas around the neck or legs of the game. Bolas were made by attaching stone weights to two or three short cords that, in turn, were fastened to a longer lasso. With the coming of the horse after the Spanish conquest, the bolas became very important, for from horseback they could be easily swung to ensnare guanaco, rhea, wild cattle, and other large game. Among the Patagonians, Pampeans, and inhabitants of parts of the Chaco, it became the principal hunting device. Spears and the *atlatl*, or spear thrower, were used to some extent.

Among the forest nomads, such as the Sirionó and Nambikwara, the principal weapon for hunting and fishing was the longbow, which was six feet in length. The barbed arrows were from five to eight feet long. Because they had no canoes, both shot fish from the banks of a stream.

Among the archipelagic tribes of southern Chile it was predominantly the women who gathered shellfish on the beaches at low tide and who, from bark canoes, dived with a shell blade and a basket held in their teeth. The shellfish gatherers were careful not to exhaust the supply in one area. These people also always carried a fire on a clay platform in their canoes, both for warmth and for roasting shellfish over the coals. The men hunted cormorants, penguins, steamer ducks, petrels, and other marine birds at night with torches while they roosted, and clubbed them to death. Ducks and geese were lured by decoys, then captured with pole snares.

Seals and sea lions were harpooned in the water or clubbed on shore. Porpoises and sick whales were harpooned. Whale hunting was a cooperative enterprise involving many men, who risked their lives in flimsy bark canoes. Fish were sometimes found in shallows or in pools at low tide and, with the help of dogs, were driven into nets. Because the Indians had no knowledge of food preservation, they had to be constantly on the move to provide for their food supply.

Social organization. The typical organization among nomadic hunters, gatherers, and fishers was the band, which, depending on the resources, could be large or very small. Low productivity and the lack of developed transportation prevented the accumulation of a surplus to maintain permanent communities. There were no social or occupational specialists; every family produced its own equipment. Despite these general similarities there was wide diversity in social structure depending on the methods of obtaining food.

Among the Chono, Alacaluf, and Yaghan of the Chilean archipelago, the natives were dispersed in elementary family units of father, mother, and children with perhaps an elder or two. These small family bands, if they can be so called, moved from one beach to another. There were no permanent territorial claims to shellfish beds, although individual families repelled others while they were using a particular shellfish bed. Sometimes close relatives or friends would move together briefly; and at times a number of families would gather together to feast on a stranded whale or join in hunting seals or seal lions. The family was also the economic unit among the Guató and, during the dry season, among the Nambikwara. This, of course, does not mean that the people did not visit relatives when circumstances permitted or when certain religious and ceremonial activities demanded.

Multifamily bands. The hunting of guanaco and rhea among the eastern Yaghan and Ona and among the Patagonian and Pampean tribes was more productive when carried out cooperatively by a number of families banded

together. Such bands numbered from 40 to 100 persons and had defined hunting territories, which the men defended against trespass. Chieftainship does not appear to have been hereditary but was ceded to a leader able in settling both internal disputes and conflicts between bands.

Composite bands. With the introduction of horses and cattle, a great change took place in the band organization. Horse nomadism permitted greater mobility, new techniques of hunting, and much larger bands. The former foot hunters joined into bands ranging from 500 to 1,000 persons. They roamed over ill-defined areas hunting wild cattle and raiding Spanish settlements and other Indians lacking horses. Each of these bands consisted of a number of lineages under a leader of proven ability; a strong leader might attract a huge following, including members drawn away from other bands. Warfare between bands increased because of uncertainties over rights to territory.

The southern hunters of Patagonia and the Pampas were patrilineal (descent was reckoned in the male line) and patrilocal (a wife resided with her husband's lineage and band).

Forest nomads, such as the Guayakí and Sirionó, on the other hand, were matrilineal and matrilocal; that is, an individual traced his ancestry through his mother's lineage, and a man went to live with his wife's band. Matrilineal descent and matrilocal residence were associated with the importance of women in collecting wild plant foods.

Although little is known about the social structure of the Chaco tribes in aboriginal times, there appears to have been a contrast between the peoples of the dry western area and the wetter eastern area. Because the people in the west depended on water holes, they were forced to shift camp frequently as holes dried up. The groups nevertheless seem to have claimed territorial rights to gathering, fishing, and hunting areas. With the arrival of the Spaniards and an increase in warfare, the authority of the chiefs was strengthened, although chieftainship was rarely hereditary. In the eastern Chaco, on the other hand, the presence of fish runs in the larger rivers and the practice of fairly productive cultivation permitted the settlements to be larger and less mobile. After acquiring the horse from the Spanish, however, the Caduveo and other Guaycuruan-speaking peoples gave up what little horticulture they practiced and became predatory nomads raiding Spanish settlements, taking cattle, and capturing slaves from more sedentary tribes. Other Chaco tribes, such as the Abipón, Mocoví, Toba, and Lengua, also became horsemen and raiders. These tribes continued to move their camps in search of pasture for their herds of horses and cattle. Incipient class differences based on war honours and wealth appeared.

The Caduveo were outstanding raiders in the Chaco. Although roaming over great areas, the warrior bands always returned to their base settlements, where they had permanent houses and kept their slaves and livestock. The Caduveo also exhibited the clearest form of social stratification, which, although pre-Spanish, crystallized with the coming of the horse and the intensification of warfare. Caduveo society became stratified into nobles, warriors, serfs, and slaves. The nobles were divided into those who inherited their titles and those upon whom titles were bestowed for lifetime only. The warrior class was basically hereditary, but other men demonstrating greatness in war could become members, thereby establishing new hereditary lines. The serfs, who served only the members of the noble class, were from subjugated peoples. The lower class was made up of captured and purchased slaves, who included not only Indians from neighbouring tribes but also mestizos from the Spanish settlements. Slaves could gain their freedom by marrying into the warrior class.

Family and kinship. Marriage among most nomadic tribes was consensual, similar to common-law marriage. It was easily entered into and easily dissolved, although there were strong forces supporting its continuance, especially whenever women played an important role as food gatherers. Noble classes, where they existed, as among the Caduveo, were practically endogamous; virtually all men, that is, married within their own class.

Marriage
customs

archipelago, on the other hand, was a stronger institution. Postmarital fidelity was demanded. The family formed a strong autonomous unit that performed nearly all cultural activities on its own and cooperated with other families only briefly during sea hunts and initiation ceremonies. Marriage between known relatives was forbidden, but in practice this meant merely that first cousins and closer kin could not marry. A widow, however, could marry the brother of her deceased husband; and a widower could marry the sister of his deceased wife; these practices of levirate and sororate helped to maintain family alliances, when almost everything else tended to draw families apart.

The larger nomadic bands in South America practiced band exogamy; that is, a person in one band could marry only someone in another band. These marriages were not made at random, however, for (as among the Nambikwara) cross-cousin marriage was preferred; in a matrilineal society a man married his mother's brother's daughter; in a patrilineal society he married his father's sister's daughter.

Rites of passage. Birth ceremonies were simple family affairs. After the birth, both parents fasted for a few days and observed food taboos. Couvade was practiced; that is, the father stayed in the hut several days, mimicking labour, while relatives and friends provided essential needs.

Among the Sirionó a child was born openly in the communal house; and after birth the parents walked in the forest scattering ashes as a purification rite and then lit a new fire that signified new life.

Before the age of puberty, boys and girls learned by imitating older children and adults. Among the shellfish gatherers, children by the age of four began to gather shellfish and spear sea urchins close to shore, returning to camp to roast them and eat them. From an early age children thus took care of their food needs as far as shellfish were concerned. Boys and girls were separated after the age of seven. The boys played with bows and arrows. The girls learned to swim and dive. Males did not learn to swim or dive, since diving for shellfish was women's work. Corporal punishment was rare, but children were lectured by elders on manners and morals.

Socialization was formalized especially in the initiation rite, which marked the passage from youth to adulthood for both sexes. There was usually no fixed date, the time depending upon the number of neophytes and the opportunity to amass a supply of food for the feast.

Initiation
rites

The initiation ceremonies began with the men preparing sealing clubs and shellfish poles in a special hut in which they painted their faces and participated in singing, dancing, and mummery. The men then went out to hunt seals on the coastal rookeries, and the women went for shellfish. The men then built a large hut, where they sang, danced, and instructed the young men in proper vocational and moral behaviour. Later, women joined in the ceremony instructing girls in the proper behaviour for women. Then followed a mock battle between the sexes. After a feast, the assembly disbanded.

Among the Patagonian and Pampean tribes, a special hut known as the pretty house was erected for initiation ceremonies (as well as for some other rites, such as first menses). Medicine men bled themselves and smeared the novices with blood. There was dancing by the men and singing by the women. Horses were killed and roasted, and horsemeat was passed out to the guests.

In the Chaco there was considerable variation in the details of the initiation rites, but the underlying purpose of education and socialization was the same as among the shellfish gatherers and the Patagonian and Pampean guanaco hunters. Boys went through several rites, and when blood was drawn from their genitals they were considered

mature warriors. On the Bermejo and Pilcomayo rivers, girls' puberty rites were attended with singing and dancing designed to protect the girls from evil spirits. A girl was kept in isolation and observed a special diet. After the rites pubescent girls were allowed sexual liberty and often took the initiative in love affairs.

Among none of the nomadic peoples did marriages involve any special ceremonies; gifts, though, were exchanged between the bride's and the groom's parents. Death rites were more complex. Mourners painted their faces black, beat on the outside of the dead person's hut, fasted, and lamented. They also directed their anger at the supreme deity. In the Chilean archipelago, the dead person and his effects were either buried or cremated. Among the Patagonian and Pampean tribes, the corpse was left on a hilltop or placed in a cave; some belongings were placed near the body.

Religion. Among the Yaghan shellfish gatherers there was a belief in a Supreme Being who was not a creator but a ruler. He was one who gave life to men and who gave humans animal and plant foods. People prayed to this being for success in fishing and hunting. Among the Patagonian and Pampean tribes there was a belief in a supreme being who, after creating the world, did not enter further into human affairs. There was a belief in good and evil bush spirits.

The Chaco groups did not believe in a supreme being. Although celestial bodies sometimes were thought to affect human beings, they were not objects of worship. The Chaco people had great fear of the ghosts of the dead and disposed of the corpse as quickly as possible. The body was buried in a cemetery, and food offerings were made. The house and property of the deceased were burned.

Among such forest nomads as the Sirionó and Nambikwara, rituals and ceremonies were much less developed than in the Chaco. This no doubt was due to incessant search for food and the inability to accumulate surpluses for large-scale feasts. Although the Sirionó did not believe in a supreme being, they did consider the Moon to be a culture hero who gave them maize and manioc and other features of their culture. They also feared the ghosts of the dead and bush spirits.

Shamans, or medicine men, who were thought to receive their curative powers through the ghosts of dead shamans and special guardian spirits, were important among all the tribal groups. Among the Chaco groups shamanism was very highly developed, both for curing illnesses and in working for the general welfare of the tribe. Sickness was caused, it was thought, by one of two means: mysterious foreign objects would magically penetrate the body, causing disease, or a person's soul would leave the body, leaving him ill. In the former instance, the shaman would suck out the foreign object; in the latter, he would go out at night and bring the wandering soul back.

Forest
nomad
ceremonies

MODERN DEVELOPMENTS

The existing nomadic hunters and gatherers are marginal survivors who retain many archaic culture traits and share very few of the more recent inventions. In areas in which they have not been disturbed by the whites or in which they have had opportunity to withdraw into refuge areas, they have been able to maintain much of their original culture. In areas in which they have come into permanent contact with the whites, some have become rudimentary agriculturalists, building permanent houses, making pottery, and weaving. In the late 20th century, the conversion of the nomadic habitat into large-scale agricultural projects seemed to be bringing many of these tribal peoples to the verge of extinction. (K.Ob./Ed.)

ARTS OF THE AMERICAN INDIAN PEOPLES

To achieve an understanding of American Indian art requires at the outset a willingness to discard many long-standing preconceptions and judgments based upon an evaluation of Western art. Because the basic aesthetic tenets and artistic goals are different, any art critic em-

ploying the usual Western ground rules in an attempt to comprehend Indian art is bound to be unsuccessful. At best, it is difficult for non-Indians to evaluate Indian art. Although it is not necessarily true that one must be an Indian to appreciate their art, it is true that the finer

subtleties and depths of significance that are so obvious to the Indian are often lost to the non-Indian observer. Finally, it is deeply to be regretted that most if not all of the major commentaries on Indian cultures have been recorded by those who were natural enemies; the white man, however sympathetic he might be, simply cannot ignore the fact that he is, after all, evaluating the product of a culture that he has successfully suppressed. This inevitably introduces emotional and psychological elements into the act of judgment that result in tremendous distortions. Not until the 20th century did Indian art begin to enjoy serious, balanced consideration, and even this has been in meagre terms.

One of the obstacles to a realistic evaluation and appreciation of Indian art is the belief held by many that the mere fact that the primitive artist occupies a place so close to nature somehow endows him with a privileged status insofar as "natural art expression" is concerned. To regard a product as artistic simply because it was Indian-made defies reason. While it is a fair statement that no Indian tribe existed that did not develop some degree of art—and many were responsible for aesthetic masterworks—it is not true that all expressions were equally impressive. The quality and beauty of these arts varied widely; for, just as in the Western world, there were good and bad artists, and the fact that a native craftworker turned his hand to a given task in no way guaranteed success. Another obstacle to a full appreciation of the arts of the Indian peoples is the belief held by many sympathetic viewers of aboriginal art: that there are eternal aesthetic truths, expressions of which can be found in all cultures, and that to the truly sensitive eye these aesthetic verities are manifest wholly independent of the particular cultural milieu, the purpose of the art expression, or the relative level of the cultural development. The position taken in this discussion is that, since the literature, music, dance, and visual arts of the Indian peoples did not evolve in isolation from the sociological, religious, and political milieus of those peoples, an understanding of the latter cannot be divorced from an appreciation of the former.

(F.J.D.)

Literature

GENERAL CHARACTERISTICS

Folktales have been a part of the social and cultural life of American Indians regardless of whether they were sedentary agriculturists or nomadic hunters. Gathered around a fire at night, the hardworking Indians could be transported to another world through the talent of a good storyteller. The effect was not only derived from the novelty of the tale itself but also from the imaginative skill of the narrator, who often added gestures and songs and occasionally adapted a particular tale to suit a certain culture. One adaptation he often used was the repetition of incidents. He would repeat an incident a specific number of times (depending upon the ceremonial number in the culture, three, four, five, or seven), with the hero killing that many monsters or that number of brothers who had gone out on the same adventure. This type of repetition was very effective in oral communication, for it firmly inculcated the incident in the Indians' minds much in the same manner that repetition is used today in radio and television commercials. There was an aesthetic value to the rhythm gained from repetition and an additional dramatic effect, for the listener knew that when the right number of incidents had been told, some supernatural character would help the hero, sometimes by singing to him. For this reason oral literature is often difficult and boring to read. Oral literature also loses effect in transcription because the reader, unlike the listener, is often unacquainted with the world view, ethics, sociocultural setting, and personality traits of the people in whose culture the story was told and set.

Because the effect of the story depended so much on the narrator, there were many versions of every good tale. Every time a story was told, it varied only within the limits of the tradition established for that plot and according to the cultural background of the narrator and the listeners.

While studies have been made of different versions of a tale occurring within a tribe, there is still much to be discovered, for instance, in the telling of the same tale by the same narrator under different circumstances. These gaps in the study of folktales do not indicate lack of interest but rather the difficulty in setting up suitable situations for recordings.

The terms myth and folktale in American Indian oral literature are used interchangeably because in the Indian view the difference between the two is a matter of time rather than content. If the incidents related happened at a time when the world had not yet assumed its present form, the story may be regarded as a myth; but even if the same characters appear in the "modern" present, it is considered a folktale. Whereas European fairy tales traditionally begin with the vague allusion "once upon a time," the American Indian myth often starts with "before the people came" or "when Coyote was a man." To the Eskimo, it is insignificant whether an incident occurred yesterday or 50 years ago—it is past. Thus, while the mythology of nonliterate people has a historical development of its own, it cannot be admitted to the present-day classification of historical because it lacks documentation.

American Indian mythology can be divided into three major cultural regions: North American cultures (from the Eskimos to Indians of the Mexican border), Central and South American higher civilizations, and the Caribbean and South American simpler cultures. Though each region exhibits a wide range of development, there are recurrent themes along the cultures, and the importance of mythology itself within each culture varies. In North America, for example, stories are not involved with a panoply of divine beings, as are those of Middle America and South America, where the tales bear some resemblance to the complicated mythologies of the surrounding higher cultures and are quite confusing with many hybrid monsters and giants. In North America many mythologies (like the Dreaming of the Australian aborigines) deal with a period in the distant past in which the world was different and people could not be distinguished from animals. These mythologies are related to the concept that all animals have souls or spirits that give them supernatural power. Because man has subsequently been differentiated from the animals, they come to him in visions, and in the stories they help the hero out of trouble. When there are many tales involving a single character, such as Raven, Coyote, or Manabozho, the transcriptions are linked together today and called cycles. Whether this cyclic presentation of tales is or is not indigenous to the Indian mind remains questionable, but it is used by folklorists who have been accustomed to legendary cycles of medieval European literature, such as the tales of *Beowulf*, *La Chanson de Roland* (*The Song of Roland*), or even *The Canterbury Tales*.

The body of American Indian folklore does not include riddles as found in African folklore, for example, nor does it include proverbs, though there are tales with morals attached.

The importance of mythology within a culture is reflected in the status of storytellers, the times assigned to this activity, and the relevance of mythology to ceremonialism. In many instances the relationship between mythology and ceremonialism is very close. The Navajo ceremonials, like the chants, are based entirely on the characters and incidents in the mythology. The dancers make masks under strict ceremonial control, and, when they wear them to represent the gods, they absorb spiritual strength. The Aztec ceremonials and sacrifices placate the gods who are the heroes of the mythology. If, however, the mythology is made up primarily of animal tales and stories of personal and social relationships, the actors and characters involved in the stories are also an index to the beliefs and customs of the people.

ORAL LITERATURES

North American cultures. *Eskimo.* Eskimo culture can be divided into two major subgroups: one culture extending from Greenland to the Mackenzie River and another west from the river to the Pacific Ocean. The Eskimo culture embodies simple stories of hunting incidents in

Use of
the terms
myth and
folktale

Importance of
mythology
within a
culture

which the heroes are sometimes helped through supernatural power. Other stories include themes in which people ascend to the sky to become constellations: maltreated children become animals, and an orphan boy becomes successful. Still others surround the exploits and priestly magic of the shamans. In the region from Greenland to the Mackenzie River, Sedna is the highest spirit and controls the sea mammals; the Moon is a male deity who lives incestuously with his sister, the Sun. When she discovers he is her brother, she seizes a burning faggot and rushes away into the sky, the Moon pursuing her.

There are many stories involving family life and others dealing with the feuds between Eskimos and the Indians south of them.

Stories of
the western
Eskimos

The western Eskimos along the Pacific and Arctic coasts have the Raven cycle, a series of tales centred around Raven, a protagonist whose role ranges from culture hero to the lowest form of trickster. Many of the same plots and themes also occur in tales of the Northwest Coast culture. Around some coastal villages, a story about a flood that took place in the first days of the Earth is told. Many stories are especially intended for children and stress proper behaviour. They are often told by young girls to younger ones and are illustrated by incising figures in the snow or on the ground with an ivory snow knife. On the lower Yukon, a migration legend is told about a long journey from east to west. The usual incident breaking up this party of travellers is a quarrel, after which they divide into two groups, occupying separate villages, and for years make constant war on each other. Tales of hunting begin as personal adventures but become stylized with supernatural characters and events.

Northwest Coast. There is greater similarity in the mythology of the various tribes along the Northwest Coast than in other regions of North America. Collectors of folktales have gathered a long series of stories told in the region from the mouth of the Columbia River through southeastern Alaska and have gathered them into a Raven cycle. The protagonists of these stories—from south to north, Coyote, Mink, and Raven—again vary from culture hero to trickster. In each subarea the stories elucidate the origin of a village, a clan, or a family and are regarded as the property of these clans or families. Thus, they can only be used by others through permission or, sometimes, purchase. Examples of this type of myth are Bungling Host, Dog Husband, and Star Husband. In Bungling Host, Trickster, after seeing his host produce food in various ways (e.g., letting oil drip from his hands), fails to imitate the magic methods to procure food and barely escapes death. In Dog Husband, a girl has a secret lover who is a dog by day and a man by night. When she gives birth to pups, she is deserted by her tribe. She then destroys her children's dog skins, and they turn human, becoming successful hunters. In some versions parents lose all their sons to a monster, and when a new baby is born, it grows rapidly, kills the monster, and restores the brothers. Star Husband, another widely known myth, relates the story of two girls sleeping outdoors who wish the stars would marry them. They ascend to the sky, marry the stars, and experience a series of remarkable adventures.

Mythology of the
Kwakiutl
and Salish-
speaking
tribes

Among the Kwakiutl of Vancouver Island, the mythology is represented in an elaborate series of dances that illustrate characters and incidents with masks, puppets, and other mechanical devices. The principal events during the winter ceremonial season, these ceremonies include initiation into the secret societies, the highest of which is the Cannibal Society. Less elaborate forms of this winter ceremonial are found among the southern tribes who base their activities on the quest for the guardian spirit and on the return of the spirits to those who have seen them in visions. In order to exorcise these spirits, their songs must be sung and their dances performed. The Salish-speaking tribes of southern British Columbia and Washington have less complicated costumes for this ceremonial, but their dancing is very interesting and vigorous. The attitude of the Indians of the Northwest Coast toward animals is expressed in rituals such as the first salmon ceremony and the ceremonial attitude toward the bear. When the first salmon of the spring run is caught, it is ceremoni-

ally cleaned and placed on a clean mat or a bed of fern leaves. It is welcomed with an address of thanks and promised good treatment. The entrails are wrapped in a mat and thrown into the river so that they can return to the land in the west where the salmon can tell how well he was treated. The salmon is carried to the house by a selected group—children, women only, or the family of the successful fisherman—and is roasted and eaten, also by the selected group. The bear is never killed wantonly. When seen, it is addressed in terms of kinship, expressing an attitude that is known sporadically from the Ainu of northern Japan to many places in northwestern America.

California. The many small tribes of California exhibit more unity in their mythology than is present in many other features of their culture. In the north central area, the Kusu cults enact the myths of the creator and culture hero with Coyote and Thunder as the chief characters. In southern California in ceremonies of the Chungichnich cults, contact with the highest god is achieved by smoking datura or jimsonweed, which produces hallucinations of animals. The boys initiated into the cults regard the animals as their guardian spirits. This concept relates the cult activity with the most fundamental feature of American Indian religion, the concept of the individually attained guardian spirit.

In general, the Californian tribes have a very confused mythology, which was disintegrating even before the white man settled in their territory. Though some animal stories and a few themes about vague characters existed, little of it has been recorded and carefully studied.

Southwest. The Indians of New Mexico and Arizona, along with a few small tribes related to them in southern California, have cultural traditions with some features in common. In the folklore of the Southwest, the emergence and migration myths show the Indians emerging from an unpleasant underworld at the time when the Earth is not yet completely formed. They start a long trek southward, some looking for a sacred spot, others looking specifically for the centre of the Earth. In some instances they are led by a pair of culture heroes, the Twins, also called the Little War Gods, who help stabilize the surface of the Earth and teach the Indians many features of their culture, including ceremonials. When the people were weary during the migration, the gods, the kachinas, came and danced for them until someone made fun of their peculiar faces and insulted them. They allowed the people to copy their masks and costumes, and then they returned to their home in the underworld. Since that time the men from the kivas, the ceremonial chambers to which all the men belonged, have made these costumes and masks and have performed the dances necessary to stimulate and protect the harvest, bring rain, and promote the general welfare.

The Twin Gods of the Pueblo villages are a combination of the helpful god and the trickster. They sometimes behave like unruly children and tease their grandmother to death. Coyote, in the Pueblo literature, is not the trickster he often is in the folklore of cultures farther north. Though he does share some of the trickster plots and is always sly, he is often caught in his own wiles. A group of very crude and vulgar tales about him exist, which have been transcribed from Spanish days, surrounding two characters who travel together named Djos and Ley, a corruption of "God" and "King." Certain European tales, such as the Cinderella stories, have been added to the collections of Pueblo folklore.

The Athabascan-speaking tribes of the Southwest are the Navajo and Apache. Nowhere in America are mythology and ceremonial more closely associated than among the Navajo, where the myths are poetically expressed through great "chants." The principal characters are the gods of the wind, the rain, the dawn, the Sun, the semiprecious stones, the sacred plants, corn, tobacco, squash, and the bean. The ceremonials are intended to cure sickness, both mental and physical, and to protect people on dangerous missions, rather than to inspire any sense of worship. All the arts are combined in the ceremonies: the story itself, the poetic expression of it, the painting of the masks, the beautiful combinations of feathers in the headdresses, the sand paintings illustrating the story while the chants are

Ceremoni-
als of the
Navajo and
Apache

sung, and, finally, the dancing of the characters who wear the regalia. This is one of the most inspiring ceremonials devised by the American Indian.

The other Athabascan-speaking people, the Apache, are divided into several groups, of which the Lipan are particularly interesting. The southernmost of North American tribes, they live partly across the Mexican border. They have an emergence myth and share with all southern Athabascans the culture hero known as "Killer-of-enemies" and his younger brother "Child-of-the-Water" (comparable to the Twin War Gods of the Pueblos). One of the monsters in the tales is Big Owl, a destructive cannibal in the form of a large owl. The story of the man seeking spiritual power from the gods who goes down the Colorado River in a hollow log to reach the holy places where the spirits live is almost identical to its Navajo version. There is a Lipan Coyote cycle, but there are no Spanish-derived tales.

The White Mountain Apache tell stories only between dusk and dawn and during cold weather. They have two major cycles, the creation myths, in which something is created out of nothing, and Coyote myths surrounding the trickster par excellence of that name. Two minor cycles centre around Big Owl and Gain, a supernatural being who lives in mountains and caves and underground worlds. The White Mountain Apache learned some European stories from captives in Spanish and Mexican towns in the late 18th and early 19th centuries. The Jicarilla Apache divide their didactic stories into sacred and secular, telling them at night during the winter with a break at midnight for a festive meal. The Jicarilla are seriously absorbed in their mythology, into which they inject objects of modern life such as the telegraph and the automobile. They also have creation stories and the legend of the man who went down the Colorado River in a hollow log. Among the trickster stories, the Coyote cycle is well developed. The Colorado River tribes, which are closely affiliated with the people of southern California, comprise the last division of the Southwest cultures. These tribes were Christianized by missionaries so early that little of their mythology remained to be recorded. It is known that Coyote played an important part in their sacred stories, though he was also portrayed as a deceitful trickster. Like the Pueblo tribes, the Luiseño also migrated, looking for the centre of the world, where their god, Wiyot, had died. His death was the first among the people, and they lost their immortality. Wiyot later returned as the new moon. There are many stories about the stars, which were regarded as the souls of the dead. The Chungichnich cult was also known here but may have come within the mission period.

Eastern Woodlands. The northeastern Algonkins were the first groups of American Indians north of Mexico to have protracted contact with Europeans, so their own ways of living were disrupted at a very early date. Some of their culture traits can still be found among the Central Algonkin to the west, and some of the most elementary stories are known to all groups in this region. This mythology centres around a culture hero known as GlusKap to the Micmac and as GlusKabe among the Algonkin; his consistently altruistic character and human appearance distinguish him from many other culture heroes. He carries out the usual exploits, one of the most popular being the episode in which he kills a Monster Frog who has been impounding the water. Though he revels in the trickster adventures of all American Indian characters, he appears somewhat exempt from the crude buffoonery of other culture heroes.

To the west, the Central Algonkin developed the Midewiwin or the Grand Medicine Society—shared by the Eastern Sioux—whose activities revolved around the quest for a vision that would bring them in direct contact with supernatural beings who instructed them in curing ceremonies. The members of the society were not shamans, had no individual powers, and were only effective when they acted together. In its use of certain mnemonic devices containing a series of symbols used for instructing initiates, the society foreshadowed an approach to writing.

The Iroquois, who developed one of the great confederacies of American Indians, had a strong religious and

mythological background for their folklore. In their creation story, which is the basis of their religious beliefs, they acknowledged a supreme being "beyond the conception of man." This "being" sent from heaven is a woman who in her descent fell on a big turtle imbedded in mud. She gave birth to a daughter conceived by the turtle who bore two sons. The good one was born first; the other was born through the mother's side and killed her. The sons grew up and helped their grandmother finish the formation of the Earth. The Iroquois had curing societies similar to the Midewiwin; their members were not shamans, and they cured in a group rather than as individuals.

Many tribes in the Southeast exhibit cultural systems very similar to those of the northeastern tribes; but others, especially in the lower Mississippi Valley, had a more elaborate religion and mythology that divulged a definite relationship to the higher cultures of Meso-America.

Plains. The expansive area of North America between the Mississippi River and the Rocky Mountains, extending from the Gulf of Mexico to the sub-Arctic Indians of Canada, embodied many cultures whose various rites and ceremonies emerged from a common background. Many tribes were seminomadic and depended more on buffalo hunting than on agriculture for their living. The more sedentary groups, the Eastern Siouan, included the Mandan and Hidatsa. Marginal groups, which seem to have continued an older form of Plains culture before the advent of the horse, lined the borders of the Plains area.

The Sioux narrate the following creation story: the Old Man, Waziya, lived beneath the Earth with his wife. Their daughter married the Wind and bore four sons, the winds North, East, South, and West. Together with the Sun and Moon, the winds were the "Controllers" of the universe, and a series of very involved stories tells of their powers. As the world was being formed by the invisible being, Iktoma, the trickster made trouble wherever he could. The usual plots are found in this collection of trickster stories. In order to reach the supernaturals or "Controllers," rituals and ceremonies had to be conducted. The most important ritual was the Sun Dance, because the Sun was one of the principal powers. A medicine man was responsible for the whole ritual, which had to be recited in letter-perfect fashion, because great harm could be inflicted on the whole group if the performance was not exact.

In contrast to the Sioux, the Crow are a bit more lighthearted about their approach to the universe. Their culture speaks of a creation myth in which Old Woman's Grandchild, the son of an Indian woman and the Sun, destroys monsters. He then goes to the sky and becomes Morning Star. The genealogy of this character very closely resembles the Navajo myth of Changing Woman, the Sun's mistress who bore the children Monster-slayer and Child-born-of-Water. This concept of change into an astral body is quite widespread in the Plains. In a Cheyenne version of the Dog Husband story, the mother and her children go to the sky and become the Pleiades constellation. The Crow liked to express themselves poetically, and often they recited in song. The military societies have many songs that express their high aims and others that are songs of bravado. In many of their amusing stories, there are plays on words that are often difficult to translate.

The last of the Plains tribes, the Comanche, believe that the Great Spirit created some people, but that there were white people existing before them. A flood washed these white people away, and they turned into white birds and flew away. A secondary spirit was then sent to create the Comanche. But they were not perfect at first; therefore the spirit came a second time, giving them intelligence and showing them how to make everything. There are the usual trickster stories with Old Coyote as the central figure. Since the Comanche were a very aggressive tribe, there are many stories based on war exploits.

Middle American cultures. The cultures of Middle or Central America comprise the highest developments of the New World and have been considered comparable to some of the oldest cultures of the Mediterranean. Included are the Aztecs of Mexico, the Maya of Central America, and the Inca of Peru.

The Maya, who will be mentioned again below, have a

Creation
myth of
the Crow

Mythological eras of the Toltec period Aztecs

very complicated creation myth relating the several stages at which man did not satisfy his creator. After each stage he was destroyed, and another attempt to create a more perfect being was made. Since Maya culture in its highest form can only be reconstructed from the art and the hieroglyphics, little is known except the mythology that can be derived from the religious ceremonial art (see below *Written language* for details).

The Aztecs of the Toltec period had four mythological eras: those of (1) the Water Sun, which was destroyed by flood; (2) the Sun of the Earth, which was destroyed by earthquake; (3) the Wind Sun, which was destroyed by a giant and only Quetzalcóatl, the feathered serpent, remaining, prophesying the destruction of the Earth by wind and the evolution of humans into monkeys; and (4) the present Sun of Fire, which will end in a general conflagration. Quetzalcóatl, the survivor of the age of the Wind Sun, brought civilization to the people. This mythology, which was the basis of the ceremonial life, was maintained by the ceremonial priest, but there were also simple folktales that resembled those of North America.

Much more information about the Aztecs exists than about the Maya, because their civilization was still functioning at the time of the Spanish conquest; whereas Maya culture had completely changed, and the old traditions were almost unknown. What is available is the result of painstaking scholarly work in the analysis of the hieroglyphics.

The Inca civilization of Peru has been added to the higher cultures of Meso-America because it resembles them more closely than it does its neighbours, the simpler tribes of South America. As far back as mythological history can be traced, the Incas have worshipped Viracocha, the creator. He was the omnipotent being who took part in every mythological incident. He created man from painted stone dolls, a specific way of saying that man evolved from the living rock. He also had the primitive capacity for infinite self-multiplication, and some of his offspring also became local gods. Another cycle of creation in which Viracocha functions bears some resemblance to the periods listed for the Aztec. The "Origin People" came out from their caves, and the creator organized the process of living for them. They became the ruling class. Then the "Wilderness People" came from other caves and became the common people, who increased rapidly. Many diverse languages and cultures developed. The next cycle produced the "Warlike People," who placed a premium on being ruthless, strong, and cunning. They took whatever they wanted and forced people to move to more unfavourable places; in this way, they spread the population. In all of these myths the flood is present, which requires the re-creation of man after each incident.

Since Peruvian mythology covers a large and difficult terrain, local cults developed in many places utilizing the same characters in different incidents. When all the incidents are assembled they seem very confusing and contradictory.

South American and Caribbean cultures. There are so many cultures among the Indians of South America, and so little is known about many of them, that a selection was made of four tribes, some of whose mythology has been published. The Aymara in northern Chile share the culture hero creator Viracocha with the Peruvians. According to the Aymara, he rose from Lake Titicaca, created the Earth, the sky, and man, and then resubmerged. Man was disobedient to him, and he therefore led man to Tiahuanaco and turned him into stone. Viracocha created the Sun, Moon, and stars because man, whom he created again, lived in darkness. Another mythological character of the Aymara culture is Thunnupa, a bearded white man from the north who opposed polygamy and chicha, the national drink. Animal tales are also very common in this culture, some having Aesop-like plots. Fox is the comical character in tales, and, because of this European aspect, it is often postulated that the tales might have been brought in with the Spanish conquest.

The Mapuche culture, also in Chile, relates tales characterized by fairly long narratives about such supernatural characters as Shooting Star, who may also be a canni-

bal, hybrid monster, winged serpent, ghost, or apparition. Again, the wily Fox is the principal character in the animal stories, though he is often outwitted. Folktales are told at night and are accompanied by mimicry and gestures.

The many folktales of the Cágaba, who inhabit the Sierra Nevada de Santa Marta in Colombia, are religious in nature, having supernatural characters who arrange the world for man and who try to control the demons that plague him.

Finally, the Chibcha, who live in Colombia north of the Orinoco River, have a body of mythology that reflects the lack of organization found also in their culture. The stories are cosmological and ritual but lack all perspective of time. Many are concerned with Bochica, a culture hero who is one of the major gods of the Chibcha pantheon.

Because many islands in the Caribbean were populated by people who came from the northern parts of South America, the scanty information available concerning their folktales and mythology is included in this section. The Arawak were the first Indians encountered in the New World by Columbus at Hispaniola. A typically Caribbean type of Indian who migrated from the tropical forests of South America, they combine the concept of a guardian spirit with fetish worship and fabricate idols representing plants, animals, and human spirits. The Sun and the Moon, who are connected with a myth about human emergence from a cave, together with various astral beings and a culture hero, are typical characters of Arawak mythology.

The Arawak Indians were soon decimated by Spanish invaders in the Caribbean, and by 1535 only about 500 were left at Hispaniola. The Spanish therefore brought blacks and other Indians to work on plantations. This situation also occurred on Puerto Rico and Jamaica, where the Indian cultures were totally changed because of the influx of blacks and the subsequent mingling of the races. One outstanding collection of tales from this region consists of stories about Spider, a culture hero of West African folklore.

WRITTEN LITERATURES

One of the great scholars of Maya culture, J. Eric Thompson, has said:

In the New World only Maya culture extends to us the privilege of sharing its thoughts and its struggles, its triumphs and its failures, for in the glyphs the dead past has left a chart to guide the living present along the corridors of time.

In the 16th century, the area of hieroglyphic writing did not coincide with that of Maya speech. It appears that the hieroglyph originated in such lowland languages as Olmec and Zapotec. Though people may have used hieroglyphs at an early date, they seem to have never passed the rudimentary stages. Maya hieroglyphs on stone and wood are confined to the Classical period (AD 300-900). Inscriptions on monuments record the passage of time, often the close or decline of certain periods, and invoke images of the gods, the "rulers" of each day, to which they could bring fortune or disaster. Written codices comprised books of divination and a mixture of prophecy and history that were similar to the historical codices of Mexico. Three codices remain extant: Dresden Codex, Paris Codex, and Madrid Codex Tro-Cortesianus (in two parts), each named for the cities in whose museums the codices are currently exhibited. Maya hieroglyphic writing manifested a calendric system and also certain religious concepts of the Maya culture that reveal a mythology of surprising richness, demonstrating the independent growth of New World civilization.

The Maya culture is divided by scholars into four periods: first, the Formative or middle culture horizon in the second half of the millennium before Christ. During the latter part, the earliest known carving has been found, dated in terms of the Maya calendar at AD 320. Second, the Classical period, from about AD 300-900, saw the development of the great "cities," architecture, sculpture, and ceramics. At this time a series of sophisticated deities appeared that were no longer directly related to the soil or the elements. The culture became divided into two levels, a theocratic government and priesthood and a lay culture that remained simple and agricultural, with home indus-

Mythology of the Caribbean Indians

Maya hieroglyphs

tries, a simple family organization, and a religion built around the personification of powers of nature, which was served by a nonprofessional priest. Toward the end of this period, influences from Mexico made themselves felt. The third period, or the Early Post-Classic period, from 900 to 1200, followed a transition period when metal appeared. The first gold working area was Panama and Costa Rica. In this period, the Mexicans or the Chontal Maya conquered and settled in several large cities in Yucatán, including Chichén Itzá. Itza, the conqueror of Chichén Itzá, introduced Mexican architecture and religion, including the cult of Quetzalcóatl, the feathered serpent god, as well as militaristic organizations such as the fighting orders of the Eagle and the Jaguar. Influences from Tula also modified Maya culture. According to later records, some mural texts and codices were made during this period, but they no longer exist.

Concurrently with the Classical period of the Maya, the Mexicans were also developing a written language, which was not so highly sophisticated as that of the Maya and could more correctly be called picture writing. The pictographic writing of the Aztecs was too simple to record literature, offering no way of making general statements or expressing abstract ideas. Though there was no alphabet in this writing, a picture of an object or an animal could be combined with another and given a new meaning. This writing was taught by the priests who were entrusted with the education of the young boys.

Develop-
ment of
picto-
graphic
writing

Pictographic writing developed in several areas, including the Mixtec-Puebla region and Texcoco. Meanwhile, the Aztecs were becoming more powerful along the outer borders of a highly civilized region, and about 1200 they moved closer to the centre of activity. As the government became more centralized, reports had to be submitted, and pictographic writing provided a satisfactory medium for this task. Even after the Spanish conquest, these reports were still presented in the same manner and form. Even when the writing was scribed by the Spaniards, Indians continued to do the illustrations.

After the conquest, historical accounts were written that reiterated the past history of the principal Aztec regions. Much of what is known today about the early history of the Aztecs is derived from these works. A method of recording Nahuatl, the language of a large portion of Mexico, was combined with Spanish to supplement the graphic records. It is believed that some of the graphic records represent oral traditions possibly learned in chants that were recited on ceremonial occasions.

Historically, the only recognized attempt at writing an Indian language (other than by linguists) was made by Sequoyah, a Cherokee born at Taskigi, Tennessee, about 1760. The son of the mixed-blood daughter of Chief Echota and a German father, he became a trapper and hunter until crippled in an accident. In 1809 he became interested in writing and printing, and in 1821 he gave a syllabary of his language to the chief men of his nation, which they accepted. Two years later he visited the western Cherokee in Arkansas, where he took up residence. In 1824 parts of the Bible were written in his script and others followed in 1828. The *Cherokee Phoenix*, a weekly paper, was published, to which Sequoyah contributed, and he exerted much influence in the reorganization of Indian Territory by the government. He set out to find the origin of his language but died en route to Mexico.

STUDY AND EVALUATION

Many large collections of Indian folktales exist that are historically important, though they lack information necessary for a modern study of the works. To make such a study, the folklorist must have a biography of the raconteur and the circumstances and exact date of the collection. If the study is to encompass literary style as well as theme, the folklorist must know whether the tale was originally told in a European language or, if an interpreter was necessary, his relationship to the raconteur and his experience as an interpreter.

Anthropo-
logical and
linguistic
studies

In the 1920s and 1930s anthropologists experimented with a type of ethnographic recording in certain tribes, which served two purposes: it explained cultural activities

and attitudes of a culture and supplied the anthropologists or folklorists with a new vocabulary not found in the transcribed folktales. The folktale has served as a source of study for linguistics scholars, and tales recorded in an accepted phonetic code have always been a great asset to their study also. In order to get more text of this kind, the famous anthropologist Franz Boas taught a Kwakiutl to write phonetic text, which was then translated. Anthropologists also realized that the folktale reflects the culture in which it is told and sometimes keeps up with culture changes or, conversely, retains historic patterns of the culture. Again Boas pioneered in a study of Tsimshian mythology, recording the pattern and customs of Tsimshian life as revealed in the myths.

Students of mythology in the 19th century were interested in distributional studies or in following a plot or a group of motifs around the world to discover how myths spread and how plots disintegrate and become motifs in other plots. They concluded that the life of a folktale among preliterate people depended upon how often it was heard and remembered, and that each place it was found it became part of its history.

Studies have been made of personality traits of a culture as expressed in their tales, and scholars search for symbols that articulate human experience in a culture. A raconteur's analysis of the ethical code expressed in a story often reveals the ethics of a particular society. Such studies have been made by Margaret Lantis in "Nunivak Eskimo Personality as Revealed in the Mythology" and by Melville Jacobs in his analyses of the Chinook myths, *The People Are Coming Soon*.

Indians have attempted to collect and publish stories of their own tribes. So far they have not been very successful, however, because they have made too great an effort to conform to the literary style and taste of the non-Indian reader, and hence the tales have lost much of their vitality.

(E.Gu.)

Music

Native musicians of the New World have preserved many traditional songs and, at the same time, have also been receptive to European influence; thus, any examination of their music raises the problem of distinguishing native from hybrid music. This consideration of American Indian music involves an outline of the dominant features of native styles, such as melodic and rhythmic characteristics and the meaning of song texts, and includes a description of the principal musical instruments used. There follows an examination of the stylistic features of various Indian cultures within North America, Central America, and South America.

DOMINANT NATIVE STYLE

The definition of the native American Indian musical style is complicated by variety between tribes and within tribal repertoires. It is feasible to approach the problem by contemplating the songs in prominent native rituals of four different North American tribes—Iroquois midwinter rites, Dakota war (grass) dance ceremonies, Pueblo plaza dances, and Navajo medicine ceremonies.

An evident feature of the music is male dominance. Equally evident is the limitation of music to song, performed without harmonization and with percussion accompaniment. The singing voice is well supported from the diaphragm and has a pulsating quality caused by rhythmic expulsion of the breath. Yet within this basic vocal-tone quality the tribes show considerable variation. The voice of the Dakotas and other Great Plains Indians is shrill, loud, and ornate, compared with the full-toned vocalization of the other three tribes—especially the deep, rich Pueblo quality.

Melody and rhythm. Despite exceptions among other tribes, melodies are sparse, sometimes even monotone. Only rarely do songs expand beyond the notes of the five-tone (pentatonic) scale, for example, c-d-e-g-a-(c'). In Navajo songs there is a preference for the intervals of the triad, that is, for two successive rising or falling thirds (the third is the interval, or distance between notes, en-

compassed by three notes of a European major or minor scale plus the octave, as in bugle intervals, thus c-e-g-c'). The tones of the melody most commonly spread over the range of an octave (as, from c to c'; eight notes of a Western scale), although special song types may have narrower or wider ranges. Melodies characteristically descend from a high note, frequently by a sequence of repetitions of the theme on ever lower pitch levels. Sometimes they end with the maintone as the lowest note; sometimes they dip below the maintone but conclude on this note.

The melodic themes vary in complexity. They may include syncopations (accents not coinciding with the normal musical beat) and melismata, flourishes with many notes to a syllable of text. The musical metres are almost always in irregular patterns, in contrast with the regular patterns of two, three, or four beats found in most European folk songs. The theme may be repeated or may be varied in pitch level and length, or it may lead to a second theme or a free development.

Drummer and singer coordination

Although some chants flow in free timing, most melodies adjust their accents to the duple beat (alternation of two beats, one strong, one weak) of the accompanying drums or rattles. The melody may lag behind the accompaniment or may syncopate the instrumental beat; but it holds to the same tempo, or basic speed, as the accompaniment, whether speeding up, slowing, or maintaining a steady tempo. This occurs whether the singer himself is the percussionist or whether he follows a separate drummer. If the percussionist uses a tremolo in certain song sections, the singer continues with the basic beat. At all times the musical pulse of the singer reinforces that of the instruments.

This vocal-instrumental pulsation guides the dancers, especially in the self-accompanied Iroquois stomp dances with their bouncy step. At all times the song structure guides the dancers. The structure as a whole may consist of a series of short songs—from six to 100 or more. Perhaps there is an increase in tempo and force, as in the Iroquois bear dance. Perhaps there is a succession of paired songs, slow and fast, as in the Pueblo harvest dance. Perhaps each song is split into two parts, one marked by vibrato, the other by duple beat, with corresponding different dance motions, as in the Iroquois eagle dance and the Pueblo buffalo dance. Since the tunes are set—be they ancient or newly composed—the dancers know exactly how to follow the musicians. In Iroquois rites the dancers often engage in some improvisation within the basic framework, although the singers do not improvise.

Within these four North American groups and among other tribes as well, these definitions would require modification. Some tribes, as in British Columbia, use microtonic scales (*i.e.*, having intervals smaller than a European half step) and complex percussion rhythms. To the south, flutes and other instruments are used. In Latin America hybridization of European and Indian styles presents the challenge of disentangling native elements from imported elements.

The significance of song texts. The language and the meaning of the song texts provide evidence of the extent of European influence. Many texts consist of repeated syllables formalized within each tribe, *e.g.*, Iroquois "yo yowine," Plains "wida weha wehiyo." The meaningful words in native rituals may address the supernaturals, the animal spirits, the deities of the four cardinal points of the compass, or the sacred mountains. Navajo texts are especially rich in symbolic imagery.

European influences on text and tune

European influence manifests itself in various ways. Songs of the Peyote Cult, or Native American Church, may introduce the name of Jesus. Hymns of Great Lakes Christian Indians fit native words to European folk tunes or Wesleyan, harmonized hymn tunes. On a more secular plane, Oklahoma social round dancers sometimes include amorous English texts; yet the tunes are clearly indigenous. By contrast, Mexico's Aztecs have invented Aztec poetry to go with tunes in Spanish style to honour the Virgin Mary or the beloved. As the final stage of de-Indianization, the dance songs of the Zapotecs of Mexico combine love poetry in Spanish with languorous waltz-like tunes.

MUSICAL INSTRUMENTS

Musical instruments may be clearly native, clearly imported, or ambiguous in origin. Percussion instruments—drums and rattles—are the mainstay of New World instrumentation. In Arizona, Sonora (Mexico), and areas farther south, wind instruments, native or imported, add to the tonal richness. Stringed instruments have a tremendous vogue in Latin America. Despite their adaptation to native ceremonies and musical styles, they reveal their Iberian origin.

Drums: membranophones. As in many Asian tribal societies, the single-headed shaman's drum with its narrow, round frame is widely distributed. More unusual are the square drums found in British Columbia in Canada, Veracruz State in Mexico, and Guatemala. Other hide-covered drums are more localized. The Iroquois use a water drum made by stretching hide on a small, wooden keg partly filled with water. The same type of water drum also accompanies the incantations for the Midwestern Midewiwin medicine rite. A similar pottery drum serves the singers for the peyote rites of many tribes. The gentle tone of these drums contrasts with the power of the Great Plains powwow drum, a doubleheaded boomer suspended horizontally from a frame. In the drum society ceremonies, war dance ceremonies, and secular Oklahoma war dances, four men surround the drum and beat it relentlessly as they shout their aggressive tunes. The ceremonial drum of Pueblo dances, played by one drummer, is equally forceful but has a different, vertical shape; four or five drums can produce a volume balancing that of the 70-odd singers. These drums are always struck with a stick rather than by the finger.

As exceptions, the Aztec upright, wooden, carved drum, the *huehuel*, and the Maya pottery *kayuum* are finger drums. Skillful manipulation of the head produces various tones. The *huehuel* is paired with the horizontal, wooden *teponaztli*, which is a slit-drum, a hollowed-out, carved log struck with sticks on various parts of the resonant body. The *teponaztli* is not a membranophone but an idiophone, an instrument whose hard body vibrates to produce sound. Another curious idiophone is the ancient *ayotl*, a turtle shell that was scraped with bone sticks in pre-Hispanic rites of the Olmec and Zapotec peoples of Mexico.

Rattles: idiophones. The forms and materials of rattles, which are classified as idiophones, are derived from the natural resources at the disposal of various cultures as well as from the purpose of the instrument.

The jingler. The jingler, or rattle, attached to a dancer's body or clothing, is probably the oldest form of rattle. Prominent in nomadic and hunting tribes, it frequently consists of animal hoofs or of imitations. Alaskan Eskimo dancers shake mittens with attached puffin beaks and belts with animal teeth. Deer hoofs are fastened to the belts of both the *maso*, or deer dancer, and the *chapayekas* dancers of the Yaqui tribe of Arizona and Sonora, Mexico, and also to bands worn across the shoulders of the peyote (*hikuli*) dancers of the Huichol, a tribe of northern Mexico. From northern Mexico to South America deer hoofs are worn on the girdles and ankles of curing shamans, or medicine men. Deer, peccary, or tapir claws are worn on the legs or ankles among Brazilian tribes such as the Kamakán, Apinayé, and the Amazonian Huitoto. Antelope, elk, goat, ox, or buffalo hoofs may augment or substitute for the deer hoofs, as on Iroquois dancers' knee bands in the knee-rattle dance. Among eastern tribes in the United States, they are used by the Shawnee and Delaware and in the Penobscot and Wabanaki leading dance. In modern times, metal cones in hoof shapes have been fastened onto the dress of the adolescent girl in the Apache puberty rite and onto dresses of women dancers among the Havasupai of the Grand Canyon. Siberian shamans wear iron, cone-shaped jinglers on their drums and kilts and collars, the iron itself conferring power over demons. Aztec dancers fastened gold, copper, or shell bells on ankles or breast. In South America snail shells or nuts are commonly substituted, as among the Brazilian Bororo and Amazonian Jivaro. The Incas of ancient Peru used anklets of fruits shells or gold.

Shaken rattles of animal origin. Deer-hoof rattles in

Drums peculiar to Middle America

puberty
rites

clusters are shaken by the Yuma Indians of Arizona and by kachina dancers of the Rio Grande Pueblos; by the leader of the California Diegueño *keruk*, or mourning rites; and by Brazilian Kamakán dancers. Bunches of hoofs are fastened to short sticks in the rattles of numerous men's societies of the Great Plains, particularly the dog societies of the Crow, Hidatsa, and Kiowa and the corresponding Oglala and Iowa Mawatani society. Among the Flathead of Montana such a rattle was used in the hysterical cures of the Bluejay shaman's dance and in bison-calling rites. Rattles of hoof clusters spread east to the Sauk, Fox, and Iroquois Indians, west to the California Hupa dancing doctors, and southwest to the shaman-singer of the Apache puberty rite. In California and South America the deer-hoof rattle is commonly associated with girls' puberty ceremonies. Among the Maidu and Karok of California, the girl herself shakes the rattle. Usually, older women surround the girl and thump long, hoof-tipped poles on the ground, as among the California Klamath, Tolowa, Shasta, Achomawi, and Maidu mountain tribes, as well as among the Chaco tribes of South America.

Sand-filled butterfly cocoons were fastened on sticks manipulated by the leader of boys' initiation rites of the Yokut, Maidu, Pomo, and Miwok of California. In the rain ceremony of the Arizona Papago tribe, the singer-dancers wear cocoons, along with bells and shells, and the Yaqui native dancers all tie strings of cocoons around their ankles.

Metal rattles. In recent times the Indian has taken with delight to the sleigh bells and metal-pellet bells (jingle bells), as well as to metal rattles introduced by the white man, preferring them to natural materials that are harder to obtain. The dancers and runners of the Hopi and Tiwa Pueblo Indians at Taos, New Mexico, and, generally, Oklahoma festival dancers tie them around their ankles, below their knees, around their waist, and in a strip from belt to knee.

Turtle shells. Another animal source for both worn and shaken rattles is the turtle or tortoise. With attached deer hoofs, a turtle shell is worn behind the right knee of members of Hopi men's societies and Snake societies and commonly by Hopi kachina dancers. Small tortoise shells are worn at the knees of the leading woman in Oklahoma stomp dances. In the eastern United States, Delaware reciters of visions shook a tortoise shell, and (a borrowing from the Cherokee) the Iroquois society of women planters passes such a rattle from singer to singer. In the Great Lakes region Huron shamans are reported to have shaken a tortoise shell, filled with pebbles, near the ears of their patients. Cure motivates the most spectacular use of the turtle rattle, namely by the therapeutic rituals of the Iroquois, Delaware, and Cherokee-Shawnee. The shells are cleaned and filled with cherry pits, and the neck is reinforced by inserting a wooden handle. In the Iroquois False Face Society ceremony, the huge turtles furnish instruments for "doorkeepers," the 10-inch ones for the singers, and the little ones for the False Face beggar boys.

Ornamen-
tation
of gourd
rattles

Gourd rattles. Agriculture introduced the gourd rattle, which is always shaken by the dancer or singer, never worn. Its shapes and sizes are as varied as those of the squash and gourd, and it is ornamented with ingenuity. The Arizona Papago shaman, sometimes the Iroquois and Cherokee, leaves the stem on as a handle. Usually a wooden handle is inserted, perhaps decorated with beads or feathers or with carvings. Perhaps the largest ones are the pair used in the *maso*, or deer dance, of the Yaqui of Arizona and Sonora, Mexico. The smallest gourd rattles are the tufted rattles of the Iroquois eagle dancers. In between are the flat Hopi and the egg-shaped Cherokee rattles and the small round *sonaja* rattle common throughout Mexico, particularly in the *Matachini* ritual dance. These are an inheritance from the ancient Aztec *ayacachili* rattle used, for instance, in the springtime ceremony. The designs of perforations that covered these calabash rattles have spread to northern Brazil and to California and have even been imitated in wood by the Tsimshian of British Columbia. Symbolic painted designs may cover the surface, particularly of the Hopi kachina rattles. Ritualistically, they should be filled with maize kernels, a few squash

seeds, and, in the Southeast, grains of wheat. The Iroquois prefer chokecherry seeds. Nowadays unsymbolic materials are inserted: buckshot, pebbles, even macaroni.

Other varieties of rattles. Where gourds are not available, other materials are pressed into service. Tribes of the North Pacific Coast have developed a fine art of carving wooden rattles into animal and bird shapes. North American Plains Indians and South American Patagonian tribes make them of hide, in various shapes: spherical, doughnut-shaped, or flat disks attached to drumsticks. The Ojibwa (Chippewa) and Naskapi (Eastern Woodlands tribes) shaman's *cicigwan* resembles a small drum. The Iroquois and Cherokee-Shawnee have introduced cowhorn rattles, and the Ojibwa construct cylinders out of birchbark. The Yaqui *pascola* (clown dancer) shakes a wood-and-metal *sen'a'som*, a form of sistrum, an ancient type of rattle consisting of small metal bars hung with copper rings and set loosely in a small, oval, wooden frame. Peruvian pottery and Argentine Araucanian basketry rattles add to the wealth of variety of materials used, but they by no means exhaust the list. For again civilization has introduced harsh substitutes in the tin can, spice box, and almost any old box that is handy: even for the sacrosanct Midewiwin ("medicine ceremony") of the Ojibwa and Menominee of the Great Lakes region.

Wind instruments: aerophones. In North America, flutes are limited to courtship, except for a whistle in an Iroquois medicine rite and in a gens (kinship-group) ceremony of the Meskwaki. In Mexico and southward, wind instruments provide colour and symbolic significance. At least two dances feature a one-man drummer-flutist who holds a flute in his left hand and plays a drum with his right. These are the *pascola*, or clown dance, of the Yaqui (performed with a cane flute and 15-inch [36-centimetre] drum) and the *volador*, or flying acrobat, dance of eastern Mexico. Such flute-drum combinations resemble the pipe and tabor combination found in Europe, raising the question of importation. Yet it is probable that this is a coincidence and that the one-man drummer-flutist of Middle America is native. In contrast, the penetrating, oboe-like *chirimía* of Oaxaca, Mexico, originated in Spain.

Wind instruments have a long history in Arizona, Middle America, and South America. Archaeological repositories have proved that the Aztecs had many kinds of flutes of diverse materials, including double and triple flutes capable of playing harmonies. They also paired trumpets in harmony.

In Bolivia, Peru, and Ecuador the ancient panpipe is still in use. Its harmonized, plaintive, pentatonic melodies provide an enchanting accompaniment to ritual and secular dances. In South America, the long *botuto* horn of Venezuela resembles the alphorn of the Austrian Alps and the gigantic Tibetan trumpet. Among the Araucanians of Argentina the horn appears in two forms, both fashioned of bamboo—the doleful ten-foot *tutruka* and the more melodious, three-foot *llokin*. Particularly in Central and South America, conch-shell trumpets are important ritual instruments.

Stringed instruments: chordophones. With one exception, stringed instruments used in Indian music are of Spanish origin. Despite their nativistic ideology, even Central Mexico's Indian performers of the *concheros* society manipulate their armadillo-shell lutes in guitar harmonies and with a brushing technique. In the *matachines* dance-dramas of the Pueblos and Yaqui, the accompaniment of fiddle and guitar or fiddle and harp uses tunes resembling those of England's Morris dances—harmonized, four-square, in diatonic (seven-note) major scales. Picturesque stringed instruments include the fiddles of the Tarahumara of northern Mexico. Small ukuleles, called *jaranas*, are plucked by the *viejitos* (little old men) dancers of the western Mexican Tarascan tribe. The only native stringed instrument is the Tarahumara earthbow. Serving as a percussion instrument, it consists of a bow held vertically upon a gourd set over a small hole in the ground. The bowstring is struck with a stick, the gourd and hole acting as a resonator.

The list of instruments gives some idea of their rich variety. Their playing techniques and their materials and

Flute-
drum com-
bination

forms show tribal and functional variety. So does the relation to melody and dance movement.

REGIONAL CUSTOMS: NORTH AMERICA

North American cultural areas include the Far North, the Eastern Woodlands, the Great Plains, the West, and the Southwest.

Decline of
Eskimo's
ancient
songs

The Far North. *Eskimo music.* The Eskimos are rapidly losing their ancient songs for shamanistic cures and animal dances. They retain a shadow of the creative contests in the "drum dance" exhibits of individual songs with asymmetrical, complex rhythms and narrow-ranged, erratic melodies. All around Hudson Bay, the acculturated tundra dwellers delight in the hymnody of the Catholic and Anglican missions, singing "What a Friend We Have in Jesus" in the Eskimo language.

Far northern tribes. The far northern Indians of Canada—e.g., the Catholic Dogrib near Lac la Martre, Northwest Territories, and the Anglican Cree near Rupert House, Quebec—have also become experts in plainchant and in native versions of "Nearer, My God, to Thee." Among the few native retentions are the Dogrib songs for the Hand Game and for the drum dance and the tea dance, social round dances. These songs are remarkable because they show similarities between these Indians of the Athabaskan linguistic group and their linguistic relatives, the Southwestern Navajo and Apache. The Dogrib prefer triad melodies and vocal pulsations, carrying pulsation to extremes of speed and complexity. The few reports on the music of other northern tribes indicate a substitution of hymnody in the native language for native songs, even among the isolated Mistassini Indians.

The Eastern Woodlands area. In the Eastern Woodlands, all along the northern Atlantic Coast and inland to the Great Lakes (even to Lake Winnipeg in Canada), some older people deplore the young people's lack of interest in the Indian hymns, from the 17th-century chants of the Catholic Penobscot of Maine to the vigorous, 19th-century Ojibwa (Chippewa) revival songs, with piano, organ, saxophone, guitar, and male and female vocal harmonies.

The Algonkian musical renaissance. Algonkians old and young, however, manifest a resurgence of racial pride. They usually show their enthusiasm in public programs, in New Brunswick and Maine for St. Anne's Day (July 26); in Cape Cod, Rhode Island, and Long Island at the ancient harvest time, August. Women have played a prominent role in musical resurrections at various locations, on Manitoulin Island, Ontario, and in Michigan.

The Algonkian song-and-dance repertoires contain a few local vestiges of earlier tribal music, besides introductions by visiting Iroquois, Oklahoma, and Pueblo Indians, and some inventions. They always feature corn dances, war dances, calumet (peace pipe) dances, and antiphonal (alternating two groups of singers) stomp dances.

Survivals
of
antiphonal
singing

Collections of surviving music of the Abnaki (Wabanaki) and Penobscot tribes suggest a traditional prevalence of antiphonal singing throughout the Eastern Woodlands as far west as the Mississippi River. This singing style survives among the Cherokee of North Carolina; the Seminole of Florida; and most potently among the Creek and Yuchi tribes, now removed to Oklahoma; and among the Iroquois of New York state and Six Nations Reserve, Ontario.

Traditional Iroquois music. In their scattered reservations, the Iroquois preserve a rich tradition of native, ritually functional music. They provide for individual creativity in the variations between various renderings of ancient songs and in new compositions for women's dance and the social fish dance. But they insist on tradition, admit no European influence on their music, and have been reluctant to accept the pan-Indian songs from Oklahoma.

Their vast and varied repertoire defies categorization. Most of their songs, however, reveal four styles, each with a separate historical origin. Some shamanistic medicine songs and individual men's songs recall Eskimo chants in their wavering, limited melodies, although they use much simpler, repetitive rhythms. Another style, for war and animals, fits into the definition at the beginning of this article, with pentatonic, sequentially descending melodies. These songs have two repeats, contrary to the quadruple

repeats common in songs of the Great Plains Indians. In some ceremonies, women pick up the tune and render the second repeat during their dancing. The somewhat similar third style, exemplified by the eagle dance and several other rites, provides the most terse examples of the dual, Iroquois musical structure. Paradoxically, these songs probably emanate from the Central Plains. The moiety system, dividing the tribe into two groups of matrilineal clans, dominates the cast of singers and dancers. Each song has two repeats, within an extended series. Each melody—that is, song half—contains two parts: one with drum vibrato and tremulous movement and the second with a rhythmic beat and dance progression. The song cycle starts with a free, introductory invocation, and it ends with a more complex finale.

The fourth type is the antiphonal, self-accompanied song; it prevails in agricultural rituals. One distinguishing feature is the "rise" in the middle of the song. That is, after several repeats of the antiphonal theme, it reappears on a higher tone, with change also in the dance movements; then it subsides to several repeats on the original level. Thus, there is a three-part, not a dual, pattern. The Iroquois also use a more ancient and primordial type of antiphonal singing. Thus, there are numerous responses sung at the end of certain songs. These responses, primarily monotone with a temporary rise of one step, have in performance an insistent power that unites the song-dance leaders and the chorus of people, who sing the response.

The Great Plains. The Indians of the Great Plains have spread their influence far and wide—to the Eastern Woodlands Iroquois and the Pueblos of the Southwest. Their influence on the Algonkians of Wisconsin and Minnesota has been so strong that it has drawn them into the Plains rather than the Woodlands area. Thus influences of the Dakota tribe have fashioned the present Algonkian drum society and war dance and have displaced the ancient Great Lakes animal songs with their simple, repetitive themes and imitative dance movements.

Conversely, the Plains tribes of North Dakota, Manitoba, and Saskatchewan have borrowed several Algonkian rituals. In powwows they feature war dances with duple drumbeat and round dances with a triple beat (beats in groups of three: strong-weak-weak), and with a shrill female chorus an octave above the men. Within the dominant song-dance style, the war-grass dance displays such special characteristics as high pitch, wide intervals in the melody, and wide melodic range. The singers vary the intensity. They attack notes with barks, slides, glottal stops, hiccoughs. On a second rendition of a chorus phrase, they shift from the duple beat to four or six strong beats; then they continue softly, tapping the edge of the drum, gradually increasing to the final strong, loud volume. In Oklahoman versions of this type of dance song, the dance responds to the musical changes, but in the Northern Plains there is no corresponding change of step or movement.

The more northwesterly Plains tribes, especially the Salishan Flathead and Algonkian Blackfoot, do not include Algonkian rites. They intensify some musical features of the Dakotas—the pulsation, strident vocal quality, and the wide range of musical scales in war dances. But they also retain some old medicine songs and sun dance songs with a less dramatic style. The Flathead have substituted such Plains traits characteristic of the Dakota for the wavering, more subdued musical qualities of the Salishan tribes.

The West. *The tribes of the Northwest.* The tribes of British Columbia share the dramatics of trancelike, Eskimo shaman dances, as well as their rhythmic complexity. But the British Columbia tribes have evolved a unique musical style, with elusive tonality, or musical orientation, around the maintone and clearly perceived notes of the scale. Thus, they use semitones, or half steps, and even microtones, with counter-rhythms of song and percussions, erratic musical metres, and complex song structures. Other special features are a drone (sustained note heard against a melody), which provides a rudimentary harmony; occasional use of simple flutes; and an extensive vocabulary of musical patterns and performance techniques, especially among the Nootka and Kwakiutl tribes. Their flamboy-

ance differs from that of the Plains Indians and even more from the other western tribes in the deserts of California and Arizona and the Rocky Mountain Plateaus.

Music of desert and plateau tribes. The tribes of the deserts and plateaus can be grouped together because of the simplicity of their aboriginal cultures and musical styles. Unifying factors are ritualistic preoccupation with visions, cures, and death (as in the elaborate Yuma mortuary rites) and long, mythological ballads. They also share a nonpulsating, relaxed vocal quality, an undulating, narrow-range melodic contour, and simple rhythmic patterns. Variations among tribes include instruments like the Ute scraping stick and the Pima upturned-basket drum.

A special Yuman feature is termed the "rise," a higher pitch level in the middle of a song that recalls a "rise" of the Woodland stomp-dance song but without its antiphonal singing style. These simple people, however, have become very susceptible to Euro-American culture and religion and are losing their traditions and accepting Mormon hymns and jazz dances.

The Southwest (Arizona and New Mexico). Geographically, Arizona tribes such as the Pima, Papago, and Havasupai can be included in the heterogeneous Southwest, but their subdued musical styles differ from the styles of the vigorous nomads—the Navajo and Apache of the Athabaskan language group and the richly endowed Pueblo-dwellers, with similar cultures but diverse languages.

The Navajo and Apache. The Navajo and Apache live miles apart and have been subjected to diverse influences, but they retain common qualities in their consistent preference for melodies with "bugle" intervals and their pounding percussion beats. Their social round dance songs and chants of the Peyote Cult are related to the Plains Indians. The Navajo corn-grinding songs and the masked *yeibichai* spirit dance suggest Pueblo influences, although the eerie falsetto voice and light rattling used in the *yeibichai* dance songs are distinctive. The Apache songs for the masked crown dance fit the incisive musical beat to the angular postures and gestures of the four mountain spirits.

Pueblo music and ritual. The Pueblo peoples, from the Arizona Hopi and Zuni to the Tewa of the Rio Grande Valley, have in the course of hundreds of years evolved analogous musical arts with local differences, such as greater complexity in the westernmost villages. The most sacred songs for the appearances of the masked kachina rain gods resemble songs for unmasked, public, summer rain and corn dances. These songs (specifically as studied along the Rio Grande) combine terse, traditional musical forms with elusive tonality and rhythm. In the rain dances and so-called basket dances, the men provide their own rattle-and-song accompaniment. In corn dances they and the female dancers are supported by numerous separate singers and a chorus. The male singers start on a low, growling pitch, sometimes increasing in speed from a slow tempo. In the course of three or four melodic themes, repeats, and interpolated melodic fragments, they raise their voices an octave and a half. Finally, they subside to the growl, marking time all the while with the right foot on the powerful, pulsating accents. While the dominant beat is duple, the metre shifts at times to triple beat or to a slower beat, which they call *t'a*, or "pause," then returns to the earlier pulsation. The rain dances are simple and stationary; the performers of the corn dances move in elaborate designs within an allover pattern of a slow and a fast dance.

Two-part song structures and elaborate dance patterns govern a dance type that shows influence from the Kiowa and Comanche tribes of the adjacent Plains. The buffalo and game animal dances, eagle dance, and Comanche dance precede the slow-fast parts with an entrance song of evident Kiowa origin. The dance songs resemble the typical American Indian style of pentatonic, descending melodies, in contrast to the pyramiding, rise-and-fall melodies and elusive tonality of the agricultural songs. The fast dances tie in with the Plains Calumet dances and Iroquois eagle dances, having a repeated pattern of a drum tremolo, followed by a section with a regular duple beat. The wintertime animal dances follow diverse Pueblo patterns, with a repeat of the dance in several plazas and with

four appearances during the day. These dances require traditional songs for specified occasions and new creations within the frame for other occasions.

In addition, various Pueblo tribes perform an assortment of unclassifiable dance-songs, such as the San Juan Deer Dance with its Apache musical characteristics. For public shows, Pueblo Indians of Taos and other northern communities show their expertness at secular, clearly Kiowa war dances, hoop dances, and round dances. Most Rio Grande Pueblos also display Spanish influences. On saint's day fiestas they hold a Catholic mass, with Roman Catholic chants and hymns in English or Spanish. At Christmas and at other times they perform a *matachina* dance (a ritual dance for men), usually with fiddle and guitar accompaniment. At Santa Clara and Jemez, New Mexico, the accompaniment is with voice and drum, and the dance movement is in native style. The *matachina* dance relates the Pueblos to Mexican peoples—the Yaqui of Arizona and Sonora, Mexico. The polytheistic religion of the Pueblos resembles that of the ancient Aztecs and Maya. But their indigenous styles of music and dance appear very different from the aboriginal and contemporary styles of Latin America, even from those of the adjacent tribes of northern Mexico.

REGIONAL CUSTOMS: MEXICO AND MIDDLE AMERICA

The cultures in Middle America include both the tribes of northern Mexico and peoples of southern Mexico who are grouped with those of Central American countries such as Guatemala.

Northern Mexico. *Yaqui music and dance.* The Yaqui of Arizona and Sonora have had much contact with Southwestern tribes. They relate to the Pueblos in their ceremonial *matachina* dance, using the same kind of longways formations (two parallel lines of dancers) and instrumentation (fiddle and harp) but without the Pueblo farce of a bull killing.

At Eastertime this dance forms part of a festive complex in church and atrium. A fantastic, Jesuit-Indian Passion Play bypasses the drama on Calvary. It consists of stations-of-the-cross processions, with plainchant wailing by women; surging groups of black-robed *pilatos* (Pontius Pilates), and wriggling, jumping, masked *chapayekas* clowns to spastic fiddle scratchings. It also features the native dances of the deer and his pursuers, the *pascola* clowns, next to a group of coyote impersonators.

For their animal drama the Yaqui have evolved their own native orchestra—for the deer an ensemble with rubbing of mechanically precise notched sticks and with a drum consisting of a half gourd floating in a bowl of water, along with subdued singing of ancient, symbolic deer chants; for the *pascolas*, first a fiddle and harp in jig tunes, then a one-man flute-and-drum in irregular, pentatonic tunes; for the coyotes a low, gurgling chant to drum and the dancers' brushing across a bow that they straddle. The repetitious tunes with their limited scales and the medium-loud production seem to contradict the free and forceful dance style. By their restraint they blend with the subtle sounds of the dancers' rattles, deerhoof belts, gravel-filled cocoons, and bells.

The various passive and active rattles of the deer dance interplay with the musical accompaniment. The cocoons swish with every step. The deer hoofs descend with the knee and foot in thumping steps, but in leaping steps their momentum causes them to syncopate—to work in opposition to the dance movements—to fly apart as the dancer descends and to strike together as he rises. Add to this the circular swish of one gourd and the alternately accented beat of the other. The *pascola* dancer shows a similar complexity, in the syncopated rhythm of the *sena'asom* rattle against the left hand. At times he vibrates it back and forth in front, with a motion of sowing seeds. He is probably replacing a native rattle by this brass-and-ironwood sistrum known in Mesopotamia and ancient Egypt.

The Yaqui have been given much attention because of their accessibility and their extraordinary ceremonial arts. They seem stylistically related to other, less publicized tribes of northern Mexico.

Other northern Mexican peoples. Northern Mexico's

Relation of the Pueblos to Mexican peoples

Yaqui Easter ceremonies

Interplay of dancers' rattles and music

Pueblo music in sacred dances

Uto-Aztecans share with the Yaqui a medium-loud, nonpulsating song style, with repetitious, undulating melodies emphasizing the tonic and third in a scale using only the fifth, fourth, third, and tonic notes of a European major scale (as, g-f-e-c). The Seri Indians of coastal Sonora state show their affinity with Arizona's desert tribes in this singing style and also in their long, legendary narrative songs. East of the Sierra Madre Occidental Range, the Cora, Huichol, and Tarahumara have retained some examples of music in this same style. One might expect a link across the United States border in the *hikuli* ("peyote") songs of the Huichol, the alleged originators of the widely diffused Peyote Cult, yet the Huichol songs are quite distinct from peyote songs in the United States.

Middle America. The northern boundary of Middle America is rather vague, lying somewhere in the central Mexican state of Jalisco, where the Indians are largely acculturated to Mexican society. The area from Jalisco to the Panama Canal displays a bewildering network of native musical styles in mountain and jungle, hybrid and modern music, and rural and urban styles. It would be convenient to assign the flute and drum music to native rites and the stringed music to Spanish fiestas, but there are exceptions. Flutes, not stringed instruments, accompany the European-derived dances of *moros y cristianos* ("Moors and Christians") and *conquista* ("conquest") dramas with clearly medieval tunes. These and other dances, such as the *santiaguitos* and the *matachines*, are derived from European ritual dances for small groups of men. Cacophonous flute ensembles hail the birth, marriage, and death rites of the acculturated Tarascan Indians in Michoacán state. On the other hand, stringed instruments appear in Carnival and Lenten festivals, in the armadillo-shell lutes of the *concheros* dancers, and in the fiddle accompaniments for the *arrieros* ("mule-drivers") dance. The shrill, oboe-like *chirimías*, probably originally from the Mediterranean island of Majorca, accompany fireworks fiestas in Oaxaca. Again, the delightfully sour village bands present clearly Euro-American marches and polkas.

Every fiesta is a conglomerate, with, perhaps, a native *volador* (flying acrobat) performance; a variant of the *santiaguitos-matachines-moros y cristianos* dances; morality plays with chants and fiddles; and, finally, *huapangos*, lively couple dances with fiddles in jig tunes.

To further confuse the issue, contiguous tribal groups manifest contrasting styles. In southern Chiapas state, city dwellers delight in the Indian *chiapanecas* girls' dance and its music. The mountain Tzotzil Indians of Chamula and Zinacantan, Chiapas, have devised their own versions of stringed music, with handmade guitars and harps, and, again, contrapuntal combinations (*i.e.*, with two or more simultaneous melodies) of trumpet, reed flute, and drum. In the nearby swamps, the Lacandón, an isolated branch of the Maya, maintain their ancient, shamanistic chants, their conch-shell trumpets, and prehistoric drums. Again, descendants of the ancient horizontal slit-drums of the Maya survive in the city of Mérida, Yucatán.

A special oddity is the marimba, a wooden xylophone probably derived from Malaya via Africa, with primitive forms extending even into South America. The well-constructed marimbas of Mexico and Guatemala serve various purposes, from Guatemalan religious dances to regional and jazz dancing in plaza socials of cities like Mazatlán, Salina Cruz, Tehuantepec in Oaxaca state, and Zacatecas in Zacatecas state.

Though it would be a vast simplification, it is not impossible to set off the native musical styles retained in mountains, jungles, deserts, and generally in rural settlements as distinctly different from the music encountered at urban political fiestas and tourist attractions.

REGIONAL CUSTOMS: SOUTH AMERICA

The same overgeneralization of rural-urban styles fits South American music, with qualifications. Native music survives among remote tribes of jungle and desert, but the highest Indian musical cultures remain in the Andes. Geographically, the distribution contrasts with that of Mexico, where native survivals surround the centralized cultures of the mestizos. In South America, simpler tribes have oc-

cupied the interior. The rural-urban distinction is similar on both continents, with Indian influence stronger in the villages and Iberian secular styles in the cities, especially on the coasts.

Musical traits of Amazon peoples. Amazonian tribes have proved to be fairly tenacious because of their inaccessibility. Some, like the Chaco tribes, have been losing their aboriginal arts. But other Amazonians display complex music for voice, percussion, and flute. The songs of two of the best known tribes—the Motilón of Venezuela and the Jívaro of eastern Ecuador—are medium-fast and generally medium-loud and show a preference for the interval of the third, as in songs of northern Mexico. Some Jívaro songs are pentatonic. The range varies from two tones to an octave. Frequently, the maintone lies in the centre. The rhythms are often complex and irregular, with triplets (three notes where two would normally lie) and dotted notes (two-note figures that either divide the beat into long-short values instead of notes of equal length or divide the beat into a snapped short-long rhythm known as the Scotch snap). The Motilón have some heterophonic songs, that is, songs in which the singers simultaneously vary the same melody in different ways. Such songs serve for amusement rather than for ritual.

Andean music. Andean tribes, across the mountains from the Jívaro, also favour pentatonic scales, but they evolved a more sophisticated musical style during prehistory and in the period of Spanish colonization. They retain fragments of ancient ceremonial music, such as the invocation to the rain god on the Island of Taquila in Lake Titicaca—a repetitious tune for whistle and drum. The Pampa Hash, a district in Canas Province near Cuzco, Peru, perpetuates an ancient agricultural rite, with the flutes and chants both crossing each other and sounding in unison, or with chant accompanied by a background of two chords played on the *chillador*, a tiny, lutelike instrument. The elaborate, composite fiesta of the *chunchus* and *collas* near Cuzco combines native and hybrid components. A native prologue for side-blown flutes and drum is played on the eve of this continuation of the ancient Inti-raymi, the Inca festival of the solstice on June 24. A drama of *chunchus* ("Spaniards") and *collas* ("Indians") ends with the defeat of the *collas*, as in the Mexican *conquista* dramas. The music combines voices, flutes, conch-shell trumpet, and *chillador*. There is social dancing in the streets, and, finally, the *kacarpari* farewell music, for flutes and drum.

Among social dances, the *wayno* (or *huayno*), is preeminent. This paired longways dance (*i.e.*, in a double line of couples) in duple time sometimes uses a background of *sicuris*, or panpipes, their tuning corresponding to the Western G major scale with F natural. Highland mestizos prefer a combination of the *charango*, a five-stringed ukelele, with harp and other strings, sometimes with shifting metres, from $\frac{3}{4}$ to $\frac{4}{4}$. In either case, the melodies in pentatonic scales shift continually from a tonality suggesting a European major key in the higher register to a cadence, or stopping point, in a tonality suggesting a European minor key. The harmonies change correspondingly.

This uncertain major-minor tonality pervades the Andean music. It appears in the *chinguinada* for church festivals, with a basso ostinato (repeated melodic-rhythmic pattern); in the mestizo *yaraví* serenade and in the mestizo *marinera* couple dance, with its metre alternating $\frac{3}{4}$ and $\frac{5}{8}$ patterns. Other, more urban dances, such as the *vals criollo*, use European major and minor scales. They fall in line with regional couple dances of Venezuela, Colombia, the Pacific coast through Chile, and inland to the pampas.

Mestizo music of the coast. The Creole people of the coast and plains have been replacing the indigenous music of the mountains with their own music, especially with the ubiquitous *cueca*, or *zamacueca*, couple dance. Their string ensembles, analogous to the Mexican mariachi bands, play to fit waltz steps or *zapateados* ("heel strikes"), with syncopations and shifts of metre. At times the instruments provide counter-rhythms with the gay songs in major scales. The lively, popular *pericón* and *firmeza* dances reveal very little black influence in their music, in contrast with dance music of Brazil and coastal

Songs of the Motilón and Jívaro tribes

Uncertain major-minor tonality of Andean music

Colombia; but they owe much to the *contradanza*, or longways couple dance, of Spanish colonial times.

Although North America's tribes did not mix native and European styles, the natives and mestizos from Middle America to the tip of South America have created infinitely varied hybrid musical styles.

STUDIES AND PUBLICATIONS

Musical fieldwork, recording, transcription, analysis, and publication in books, articles, and records have been prolific since the turn of the century. The early musical transcriptions taken down by ear were not too accurate and musical scores based on phonograph-cylinder recordings leave much to be desired. The improved quality of disc recordings about 1930 greatly helped fieldworkers and analysts. The tape recorder, especially in its transistorized form, has boosted the studies of tribal repertoires before their extinction and during changes and revivals.

At first the field collector and the musical analyst were frequently different people, anthropologists enlisting musicians to transcribe their field recordings, sometimes with success.

Musical transcriptions and analysis. The techniques of musical transcription and methods of analysis are in flux. Various scholars have employed machines for tonometric and sonometric transcriptions. Such devices, based on sound-wave frequencies, show melodic intervals more precisely than normal musical notation. Nevertheless, most transcribers have found it convenient—and generally easily readable—to use the conventional European musical notation, with various diacritical marks to show divergent pitches and ornaments. Some transcribers have copied the scores to show analogous musical phrases next to each other, for convenient comparison. Usually they include the corresponding texts with translations.

In the realm of musical analysis there have been many experiments. The most useful method for melody analysis is the long-standing system of "weighted scales," according to which the scales used in given melodies are presented in terms of frequently and infrequently used initial and final notes and important intervals. Presentations of music in the form of graphs have been useful in the determination of tribal styles and in the comparisons of tribal and European tonalities.

Other fields of American Indian musicology. One aspect of the study of American Indian music still underexplored is the relationship of musical rhythms and structures to their associated dances, though some workers have included descriptions and diagrams of dances. The process of music and dance coordination is laborious, little used; yet it is important for the future.

Another aspect, the harmonization of native tunes and the composition of Indian ballet music, has been exploited but with questionable success. As in tribal performance of traditional music, modern study and use of Indian elements in contemporary compositions combine a knowledge of traditions with creative imagination.

(G.P.K.)

Dance

The dances of the American Indian peoples are comparable in many ways to the folk dances of Europe. They represent forms passed down over centuries and modified through interaction with foreign and other Indian cultures. The origins are similar, lying in religious rite; in attempts to invoke magic and thus cure illness or assure success in food production, hunting, and warfare; and in such life-passage rites as birth, puberty, and death.

Nowhere among the many diverse Indian cultures is there a sense of dance comparable to that expressed in the staged art dance of the West. A number of influences from European dancing passed into the American Indian dance, but in many places the descendants of the aboriginal inhabitants of the Western Hemisphere have retained the traditional dances.

The treatment of American Indian dance in this article is meant to focus first on certain general features of dance and their manifestation in a number of areas. The

diversities existing within this larger framework then become apparent through consideration of the dances of the several cultural regions or tribal groupings. (More detailed comparisons between American Indian dance and the folk dance of European and other peoples will be found in the article FOLK ARTS.)

GENERAL CHARACTERISTICS OF AMERICAN INDIAN DANCE

Among the essential factors in an overall picture of American Indian dance are the diverse kinds of dance, the organization of the dances in terms of participation, and the relations of man and deity expressed in the dances. In addition, a variety of other stylistic considerations are relevant, as are the foreign influences that have been absorbed.

Extent of dance forms. Many themes, typically the celebrations of life crises, developed in the New World during millennia of residence, migration, and exchange. These were most prominent in the marginal cultures of California, Venezuela, and Tierra del Fuego in the most southerly reaches of South America. Mortuary rites were prominent in the northland and the deserts. War and hunt dances have had different degrees of prominence, their greatest development being among the hunters in the Great Plains of North America. So-called animal dances varied according to the local fauna, a tiger mime belonging to tropical peoples and a bear cult reaching across the northern part of the New World and into Siberia.

Religious magic, or shamanism, practiced by societies or individual priests is probably derived from such Siberian tribes as the Tungus and Chukchi. In various forms and used usually for cure, it extends to southeastern Brazil but is most potent and most trance-oriented among the Eskimo. From Mexico, and probably earlier from Peru, agricultural rites fanned out into the southeastern woodlands and the Southwest. More recent than the other rites, their forms show enrichment from Iberian rituals.

Patterns of participation. A distinction between performer and spectator has long existed in American Indian dance, though it is not the artificial separation that characterizes much of Western stage dancing. This latter condition has occurred only with the performance, largely in North America, of dances for tourists and during Indian participation in folk dance festivals or regional "powwow" gatherings.

Spirit impersonations, including maskings and noise, were used in widely separated areas to frighten nondancers. Specific instances of such practice included the puberty rites of the Yaghan and Ona of Tierra del Fuego; and among the Kwakiutl Kusiut of British Columbia in Canada, similar ceremonies were held in dance houses with a definite performing area. Except for a few specialized rites

like the eagle and False Face dances, the change of roles among spectators, dancers, and musicians is characteristic of the sacred ceremonies of the Iroquois longhouses in the Eastern Woodlands region of North America. White visitors are welcomed, especially into such dances for the Creator as the great feather and drum dances; and all Indians, from the aged to mothers with babies in arms, are expected to join in.

Among the Pueblos of the U.S. Southwest, the dancers remain separate because they require special rehearsals and ritual blessings. When they emerge from their sanctuaries, or kivas, onto the dancing plaza, they dance to invoke rain, health, and other blessings for the people from the supernatural spirits. After the ceremony the Indians often join in less formal social dances uniting all participants and observers. Though they have religious connotations, as among the Iroquois, these dances are secular, and anyone may enter or drop out at will.

Socially determined roles in dance. Visitors may not perceive the patterns of social organization reflected in the dances. It is clear that men or women alone begin some dances and the other sex may then join in, and that men monopolize some dances, women others. Less clear are the relations, especially complex in the longhouse dances of the Iroquois, between the moieties, the complementary divisions of the tribe based either on kinship or on ceremonial function. In all Iroquois dances, specific traditions decree the nature and degree of male and female participation and whether they dance simultaneously but separately or in various sexual pairs or other combina-

tions. The leader of the dance and song and his helper, however, must be of different moieties, whether they lead from the floor or from the sidelines. When women enter a dance line, singly or with another, they must pair with a moiety opposite, or "cousin."

The Iroquois moiety pattern is crossed by another comprising various public or secret societies whose members are bound together for life, often joining the society during illness or other catastrophe. These societies perform such dances as the False Face curative rites, the female mortuary dances known as *ohgiwe*, and the dances of the sexually integrated Bear and Buffalo medicine societies. Elsewhere, religious dance societies were based on ages, as in the male warrior societies of the northern plains.

Some of these societies crossed local and even tribal boundaries, as in the extremely complex organization of Mexico's *concheros*, whose intertribal hierarchy runs from a *capitán general de la conquista de Tenochtitlán* through various local commanders and military ranks with specific duties to the attendant devil, sorcerers, and mythological figures. The *concheros'* claim to an Aztec heritage is given considerable credence despite some Spanish mixture, but, compared to that of the pre-Columbian Aztec, their ceremonial organization appears to be limited.

Aztec round dance for Quetzalcóatl and Xolotl, detail from a facsimile Codex Borbonicus (folio 26), c. 1520. Original in the Chamber of Deputies, Paris. 76 × 20 cm.

In the organization of, and participation in, dance according to priestly or social status, the earlier Aztec dances were images of the completely theocratic government. A far cry from the democratic customs of the Iroquois, the circumscribed ceremonial roles of Aztec actor-dancers reflected the social structure comprising priests, nobles and warriors, commoners, serfs, and slaves. The priestly and noble-warrior classes took active roles in the many festivals of the Aztec calendar, and the priests trained noble youths for the priesthood or in dancing and singing. Warrior youths performed ceremonial combat, and the warrior orders of the eagle and of the ocelot fought captive slaves during certain festivals. Both commoners and serfs constituted the audiences, the former sometimes doing serpent dances with the nobility, the latter sometimes ceremonially attacked and routed by the priests. There were age roles and sexual roles as well, but the slaves, captives of sacred war with other city-states or purchased in the marketplace, as victims, had a passive role in the ceremonial activities.

Opposites played dramatically against one another in these rites: nobles and commoners, old and young, male and female. The warrior orders symbolized the clash of the sky and light with the earth and darkness, and, as aggressors against poorly armed captives, they enacted the drama of sacrificer and victim. It was the priests and the passive slaves, however, who played the supreme moment of the ritual. The circle of social gradations was closed as the highest and the lowest ranks performed together the most crucial act of the Aztec dance-drama, human sacrifice.

Religious expression in dance. Religious symbolism is significant even in the human interactions of the dance. Men often symbolize phallic, aggressive supernatural beings and rain-bringing deities, whereas women symbolize actual fertility. In Iroquois ceremonies, women represent the "Three Life-giving Sisters"—i.e., the spirits of corn, beans, and squash, with no mimetic representation. Similarly, Pueblo women promote plant and human fertility by their symbolic dancing.

With no mimetic elements, the basket dance of the Tewa Pueblo rites includes invocations for plant growth and for the transmission of the gift of human life. The ceremony symbolizes the woman's central role in sustaining of the life of the pueblo.

In the animal realm there are also separate roles for men and women. Ottawa and Winnebago women imitate the winged flight of wild swans and geese, whereas the Iroquois and Pueblo men represent eagles. Both sexes join in the mime of supernatural bears and buffalo in ceremonies of the latter tribes, more realistically in Iroquois dances. In the Southwest, especially in the New Mexican pueblos, male representations of supernatural deer show gradations of stylization ranging from the naturalistic portrayals of Taos pueblo to the semistylization in the Santa Clara, San

Early Aztec dances

Degrees of stylization of animal representations

Ildefonso, Cochiti, and San Felipe pueblos, in which sticks replace forepaws, to the abstract, upright deer dancers of San Juan pueblo and masked, unreal deer in the kachina dance of the Hopi. The solo deer dancer of the Arizona and Sonora, Mexico, Yaqui, always a man, is relatively realistic, with mime of the hunt and killing.

On the whole, in both Americas agricultural dances tend to be abstract, and animal dances are usually decidedly mimetic. The animal maskers of British Columbia are terrifying portrayals of supernatural beings. In Venezuela,

oriented concept of space differs from that of Western man's folk and art dance, which has only geometrical or emotional significance. The geometric ground plans, however, show similarities with Western practices. The circling dances are sunwise in areas of former hunting people and countersunwise, or widdershins, among agriculturalists. Serpentine line dances also prevail among agriculturalists, among the Iroquois, Pueblo, Middle American, and Andean peoples. Among the Iroquois, many round dances are open, with a leader, coincidentally resembling dances of the Balkans of southeastern Europe.

Aboriginal line dances are quite simple, whether they are single file or double file. Spanish influences are apparent, however, in the elaborations used in the double-file dances of the Southwest and Latin America. Spanish and Austrian influences probably inspired the couple dances of Latin America, for aboriginal dances juxtapose male and female partners only rarely, and never in overt courtship mime.

In body movement, the Indian style differs from that of northwestern Europe but coincidentally resembles the posture and quality of Serbian dancers. Characteristic of Indian dancers is a slightly forward-tilted posture, forward raising of the knee, flat-footed stamp or toe-heel action, and tendencies toward muscular relaxation and restraint in gesture. This basic style of body movement varies not only from area to area or from tribe to tribe but also from dance to dance and even from one individual to another. The agricultural dances generally are performed with an upright posture and an easy manner. Male war dances may include complex gyrations and flexion of the torso, as do animal dances. Vision and clown dances may induce bodily distortion.

Throughout Europe and the Americas, the posture varies with sex. Women tend to be more erect than men, to lift their feet and knees less, and in general to perform in a more restrained manner. Except for the war dances, Indian women use the same steps as the men, within the stylistic restrictions. In the woodlands of eastern North America, everyone proceeds with the stomp step, a flat-footed trot. In the Pueblo area, where men and women use a similar step, the dancers also specialize in a foot lift and solid stamp. In certain dances, especially clown, animal, and war dances and in some social round dances, individuals often invent variants of the basic steps. Sometimes the innovators borrow American ballroom steps such as those of the Charleston, though they adapt them to their own

Nature-oriented concepts of space

Yaqui deer dancer from Sonora, Mexico.

masked beasts of the former Maipure puberty dance, *mauari*, threatened a pubescent girl and her cortege and had to be subdued magically.

Here and there the man-deity relationship is expressed in hand gestures. The Kwakiutl of northwest North America evolved codified ceremonial sign languages, as did the Pueblos, Aztecs, and Maya. In the San Juan Pueblo of New Mexico, the appearance of the rain gods is heralded by two ceremonial clowns using traditional gestures. Looking for the rain gods in the clouds, one of the clowns claps from his hands the ashes representing a cloud. He looks upward, shading his eyes to indicate his attempt to see into the distance. This gesture is always used whenever the clown speaks of what he "sees." The clowns repeat this action toward the four points of the compass, continuing to see the approaching rain gods, who bring with them the rain cloud. Similar performers may appear in the pueblo's plaza, outside the kiva, or sanctuary. Dancing, unmasked clowns enact motions of luring rain, of sowing seeds, of digging, and of gathering the plants as they rise from the ground. Clowns also appear in the men's spring dances and in the summer corn dances. After their entrance with a large group of male and female dancers, the corn dance singers station themselves in an arc near the drummers. They fit gestures to tunes and texts that are composed for each occasion but follow a traditional pattern and trend of ideas, beckoning to the rain gods in their cloud homes in the north, west, south, and east.

Invocations to the directions survive in the Great Plains and Great Lakes area, especially in the pipe dance. A single man offers a pipe to the thunderbird in the east, south, west, and north, moving clockwise, then to the deities of the sky and earth. Similar invocations to the directions survive in Middle America as fragments of the rich gestural symbolism of the Aztec and Maya. There, as in New Mexico, counterclockwise patterns emphasize the cardinal points.

Patterns and body movement. This religious, nature-

styles. The steps and formations of the Indian dance, as well as the overall structure of a dance or ceremony, follow the music closely. This connection is covered in more detail in the foregoing section on Indian music.

Foreign influences. Among the influences from the Old World, the dances of northern Europe and the Anglo-American dances have found little acceptance. The Longhouse Iroquois reject all white men's dances. Among the few influences are some Oklahoma jazzlike, war-dance steps, an Indian two-step danced by couples, a waltz in a Pueblo social dance, and numerous couple dances of Latin America.

Iberia, on the other hand, has not only loaned some steps but has metamorphosed the dances of Middle America and western South America to Argentina. The hybrid dances reveal every conceivable shade of stylistic adjustment.

Adaptations of mazurka, waltz, and other European dance steps occur in some ritual dances as well as in such secular couple dances as the Mexican *jarabes*. The European origin, reinforced by the Europeanized music, is obvious despite the subdued manner of performance. The most significant dances are the religious dance dramas taken over from such medieval religious productions as *moros y cristianos* (Moors and Christians) and the *matichina* dances—both for trained male societies.

Black influences on Indian dance are scattered—the *huapango* couple dances of Vera Cruz, Mexico, the carnival dances of the Black Caribs in British Honduras, the *tamborito* of Panama, and couple dances of coastal Colombia. Except for the Indian-influenced *candomblé de caboclo*, a ritual of the *candomblé* sect (a variant of the voodoo cult), the religious dances of Brazil comprise only African and Portuguese elements. Such popular Latin-American ballroom dances as the samba of Brazil contain no Indian elements.

REGIONAL DANCE STYLES

The most distinctive tribal dance customs originated in response to animistic religious beliefs—*i.e.*, that all objects and living things have living souls. The customs changed with prehistoric and historic migrations, with intertribal contact, and, since European contact, with upheavals in the way of life and thought. Although many dances became extinct, some survived European influences; others are amazing hybrids or new creations of the period after European colonization.

To give an accurate understanding of the role of dance in traditional Indian society it is necessary to examine both dances that became extinct as European influences weakened tribal customs, and dances that have survived, with or without European modification.

Eskimo. The traditional shamanistic exhibitions and masked animal rites are being replaced by Western-style square dances among the Eskimo. The most prominent ritual figure was the *angakok*, the shaman who communed with spirits by the rhythm of a single-headed drum and by ecstatic dancing, usually inside an igloo.

Formerly Eskimos held elaborate outdoor ceremonies for whale catches and similar events. In Alaska, preliminaries included the rhythmic mime of a successful whale catch, with a woman enacting the whale. A sprinkling of ashes on the ice drove away evil spirits, and there were incantations and songs when leaving shore, when sighting the whale, and before throwing the spear, all of them songs that the "great kashak" sang when he created the whale. As the whale was towed in, Fox Islands men and boys danced naked in wooden masks that reached to their shoulders. At Cape Prince of Wales on the Bering Strait, the whaler's wife came to meet the boat in ceremonial dress, dancing and singing, and boys and girls performed gesture dances on the beach. Then inside a circle of large whale ribs, the whaler's wife and children performed a dance of rejoicing. On the west coast of Hudson Bay in Canada, communal feasting, dancing, singing, games, and shamanistic performances took place within a circle of bones or one of stones. The men's motions consisted of vigorous and angular arm jerking and jumping, the women's of curving gestures and swaying with the torso and arms, in a seated or standing posture.

Eastern Woodlands. In the area from the Atlantic coast to about the Mississippi River and across the Great Lakes and the St. Lawrence River, dream, medicine, plant, war, calumet (ceremonial peace pipe), and animal dances predominate. Among the northern tribes of this area, mortuary and hunting rites are dominant; among southern tribes, corn, bean, and squash rites are most frequent. The recurrent dance pattern is a counterclockwise circling by large groups, with a running step or stomp to antiphonal singing (alternation of two groups or of leader and group). Medicine rites are often exclusively for female or male

Moros y cristianos dance-drama from Guatemala. The Moor is on the right and the Christian on the left.

members of a society, but dances for hunting or agriculture admit men, women, and children. In winter and in war or hunting ceremonies, men are the organizers and leaders; in summer and in agricultural ceremonies, women are featured performers.

The Iroquois continue to maintain their ancient ceremonies and a large repertory of dances and songs, including rites for crises of life and for animals and plants. They also have acquired steps and dances from other tribes, especially those of formations in two straight lines. The Iroquois bear dance combines former hunting associations both with a clan-origin legend and with a curative society. When the bear spirit is displeased, he causes neurotic spasms in a person and must be appeased in a ritual at midwinter or in private summer ceremonies. The focal personnel consist of the patient and paired conductors, dance leaders, and singers from opposite moieties. Ceremonial songs and ritual offerings are followed by group dancing in which visitors and society members participate.

Although the Cherokee of the Smoky Mountains in North Carolina and Tennessee, a southern Iroquois people, have animal dances, they emphasize corn dance ceremonies. The Creek, Yuchi, Seminole, and other tribes of the southeastern United States greatly emphasize the summer green corn harvest ceremony, or Busk. Before the removal of many of those tribes to reservations in Oklahoma, they acquired few dances outside their own traditions. They carried the stomp circling to its utmost development by winding the line of dancers into a spiral or even into four spirals at the four corners of the dance ground. They differed from the northerners in preferring an outdoor dance setting.

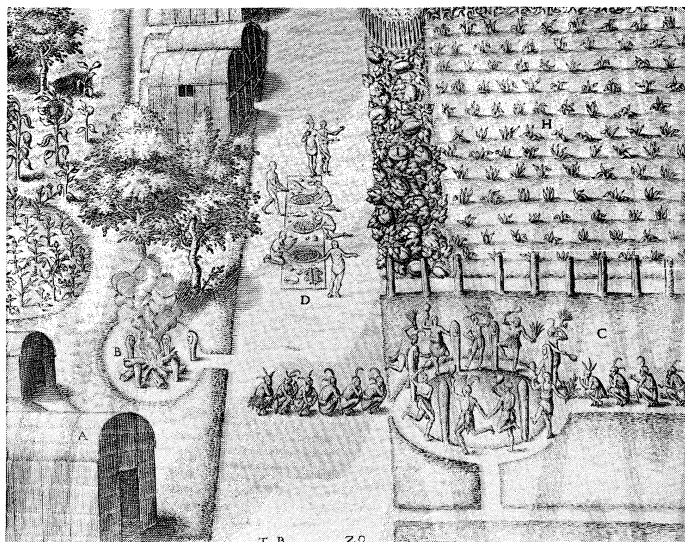

Among tribes of the large Algonkian family, survivors on the northeastern Atlantic coast of North America have long forgotten their tribal lore. The stomp dances performed until a few decades ago by the Penobscot of Maine and Narraganset of Rhode Island have experienced

a strong revival. Algonkian tribes around the Great Lakes share many of the medicine and animal dance ceremonies known to the Iroquois, and the more southerly groups hold corn dances. The Ojibwa (Chippewa) in the Upper Peninsula of Michigan and the Menominee and Winnebago of Wisconsin have maintained a hunting dance and a special wild-rice ceremonial danced in September when this crop is harvested. These groups show the influence of the adjoining Great Plains tribes in some of the circle dances, men's war dances, and buffalo dances.

The Great Plains. In the area extending from the Mississippi River to the Rocky Mountains and from Texas and Oklahoma into Canada, the dream dance ritual is made part of a visionary cult associated with boys' puberty and with a votive sun dance ceremony. During the one to four days' duration of the sun dance, usually held during the summer solstice, the participants abstained from food and drink. Dancers painted their bodies in symbolic colours and carried an eagle-wing bone whistle in their mouths. To a large drum and special songs, they circled in procession and saluted the sun with lamentation. They danced in place facing the sun, and continued until they fell unconscious or achieved their vision.

"Bull Dance of the Mandan Indians," oil painting by George Catlin, 1832. In the National Collection of Fine Arts, Washington, D.C. 70 × 57 cm.

The calumet (peace pipe) or peace dance originated in the tobacco rite of such northern Plains tribes as the Crow, Dakota, and other Sioux tribes. Its most elaborate development, however, was in the central plains ritual of the Pawnee and the neighbouring Omaha, Iowa, Ponca, and Osage. The war dance is organized into male war societies. Women have few such societies, although they perform a scalp dance. Animals are associated as tutelaries, or guardian spirits, both in the vision and war cults. The most spectacular hunting ceremonies, such as the bull dance of the Mandan Indians, developed from the economic significance of the buffalo herds. Buffalo rites merged with sun and war ceremonies and spread to tribes in other areas. The individual warrior, his prowess, and dancing skill were extolled as women progressed clockwise in a closed circle, with a sideward shuffle or bounce unlike the running step of the woodlands Indians.

The Northwest Coast. Indian tribes along the Pacific coasts of Washington and British Columbia developed masked medicine dances and elaborate fishing ceremonies, such as that performed for a bountiful salmon catch. Their two most striking types of ceremonies are the potlatch, a feast and a dance for display and distribution of the host's wealth, and the midwinter initiation ceremony. Lasting several months in a special dance house, this rite initiates young men into a ceremonial society and includes many highly individual masked enactments of totemic spirits.

The northern desert and California. Southerly tribes, such as the Havasupai of the Grand Canyon and the related Yumans, developed agricultural dances. The Yuman Mojave (Mohave) stress cremation processions and ceremonies, but, like the Navajo, they also have curative and animal dances with long song cycles. In this area, the vision quest ceremony is at its peak, and in southern California the Diegueño and Luiseño aided the vision by means of a narcotic, *Datura*. The Northern Plateau tribes, such as the Paiute and the Salishan, individually danced themselves into trances. In this area arose the Ghost Dance, a hypnotic circle dance that spread to the Great Plains in the 19th century. The ceremonies are frequently addressed to the spirits of the dead. There are also many two-line dances, especially among the Ute and southern Paiute. The innumerable small tribes of California shared some of the preoccupations with vision, cure, and death, as well as the seed and root gathering economy of the tribes adjoining them on the east. They specialized in elaborate masked ceremonies for the initiation of boys and less elaborate circle dances for girls' puberty rites. The more northerly groups also stressed exhibition of dexterity and costuming.

The Southwest. The semi-arid desert country from the Rio Grande west to the Mohave Desert of southern California and into northern Mexico and the southern Rocky Mountains is subdivided into three tribal areas: the Pueblo farmers along the Upper Rio Grande, the Zuni of New Mexico, and the Hopi of northern Arizona; the Navajo nomads, now turned shepherds; and the desert tribes that include agriculturists such as the Pima, Papago, Yaqui, and former nomads, such as the Apache. The Pueblo dwellers of New Mexico and Arizona perform medicine rites and many winter animal and fertility dances. But the cycle of summer corn ceremonies and continuous prayers for rain form the core of their ceremonialism. The dances, organized by a male priesthood, are mostly well-drilled collective performances. Summer and winter clan groupings or moieties dominate ceremonies in alternation rather than through interaction as among the Iroquois. The most characteristic step is a stamp followed by a foot lift in a stationary line. This predominates especially in the very sacred dances held in the kivas, or sanctuaries. Semi-sacred dances in the village plaza add other steps and formations such as double lines, circles, and interweavings.

The most spectacular public dances of the Pueblos are the corn dances or *tablita* dances, after the women's tablet crowns with cloud symbols. They recur at various times during the spring and summer, with most pageantry after Easter and on the Pueblo's saint's day. The Indians pay homage to the patron saint in an early morning mass and a procession to the plaza carrying his image, followed in

The Ghost Dance

Masked medicine dance of the Clallam Indians, British Columbia, Canada. Oil painting by Paul Kane (1810-71). In the Royal Ontario Museum, Toronto. 76 × 46 cm.

the evening by a recessional to the church. By tradition each performance of the corn dance includes a slow and a fast dance. In the slow dance for entering the plaza, a chorus of seven to 70 older men shuffles across the plaza, singing and invoking the rain gods. A banner bearer leads a double file of 12 to 200 dancers, with a pair of men always ahead of a pair of women. For 10 minutes they trot counterclockwise around the plaza. Following a pause, the singers form an arc, and the dancers line up face to face in two or four long files. They cross over, circle, and interweave in elaborate formations. Clowns meander in and out among the lines. The entire set is repeated at the other end of the plaza, and the group retires. The two moieties make alternate appearances. On the last appearance they combine, the two choruses singing simultaneously.

The Hopi snake-antelope dance

One of the most famous ceremonies is the snake-antelope dance of the Hopi in Arizona, a rite in which snakes are released in the four directions to seek rain. It includes swaying dancing to rattles and guttural chant, circling of the plaza with snakes, and ceremonial sprinkling of corn meal on the principal dancers by women of the snake clan.

Masked dancers are a striking feature of Pueblo ceremonialism. The kachina dancers are sacred and represent the rain gods. Clowns with various names represent an ancient ritual heritage; in their black-and-white striped disguise of paint, they are eerie and also comical. Pueblo masking influenced neighbouring tribal dances such as the curative *yeibichai* of the Navajo. Curative ceremonies, with long song cycles, are emphasized by the Navajo, along with circular social dances, recalling those of the Great Plains tribes. The Apache have developed a spectacular masked

dance, called the *gahan*, to obtain cures but chiefly to celebrate a girl's coming of age. They also have rites for vision and divination, sometimes with the aid of a vision-inducing communal drinking ceremony. The male dance style is strong, angular, even acrobatic, while the women's style is subdued.

Mexico and Middle America. The triple teams of *pascolas*, or wooden-masked clown dancers, of the Yaqui Indians in Arizona and the Sonora desert in Mexico, descend from prehistoric clown-shamans. They dance without masks in semi-Spanish style, then, with masks, in an aboriginal, mimed deer hunt. By contrast, the *chapeykas* clown society recalls the Pueblo *tsaviyo* clowns in their antinatural behaviour and hide masks. The serious, vowed-membership society of the *matachini* dancers ties in with the semi-Hispanic *matachina* dancers of the Rio Grande tribes and of the northern Mexican mountains. These dances are related to those further south such as the various types of *moriscas*. A fantastically hybrid Passion drama points toward Middle America.

A few indigenous dances survive in the mountains of Mexico. The circular *mitote* remains the ritual dance of the southern Tepehuan and other tribes of the Sierra Madre Occidental, like the Tepecano, Cora, and Huichol. Men and women skip in a counterclockwise circle, five circuits in one direction, then five in the other. A shaman accompanies with native songs, assisted by a musical bow on a gourd resonator. Formerly a deer dance followed the rounds.

The *hikuli*, or peyote dance, held in November, follows Huichol and Tarahumara pilgrimages for peyote. The dance of the Huichol is the more ecstatic. After consuming the trance-inducing peyote, men and women move in a counterclockwise progression, leaping jerkily and twisting their bodies.

The *rutuburi* is the typical ritual dance of the northern Mexican Tarahumara for three agricultural festivals—rain, green corn, and harvest—and for death and memorial rites. After triple invocations by a shaman, the women cross the dance space six times, then circle counterclockwise, holding hands and leaping with a stamp from left to right foot.

Tribes of the Sierra Madre Oriental also engage in native survivals such as the *quetzales*, with great disc headdresses, and *voladores*, or flying acrobats. After ritual preludes to a fiesta, the flyers first dance around the pole with their musician and his flute and tabor. Traditionally there are four dancers, but the Otomí prefer six, including a man-woman, Malinche. They climb up a rope ladder and seat themselves on a small framework near the top, while each in turn dances on a two-foot central platform. During the flight songs they launch themselves into space with ropes tied around their waists and descend head down in 13 ever-widening circles until they reach the ground and land

The *voladores*, or flying acrobats

"Hopi Snake Dance," watercolour by Awa Tsireh, c. 1920. In the Denver Art Museum, Colorado. 62 × 48 cm.

on their feet. The musician often performs special acrobatics, leaning back in an arc as he sits on the platform or jumping or pirouetting as he salutes the four directions. He may slide down one of the ropes amid acclaim.

The numerous clown dancers throughout Middle America are usually associated with various rituals. Some impersonate animals, like the *tecuanes* (tigers) of Guerrero state. Some, like the *viejitos* (little old men) of Michoacán state, combine native and Spanish features. Some, like the *catrines*, wear ragged modern outfits and poke fun at the bourgeoisie. Always connected with the dance dramas held in conjunction with religious fiestas, the clowns are not simply comics but also social satirists.

The semi-urban Indian fiestas of Middle America include three types of European-influenced dance dramas: the *morisca* and its variants, *moros y cristianos*, *santiagos*, *matachini*, and related plays; Passion plays; and *posadas*, *pastorelas*, and Guatemalan *loas*. These are often true dramas, with dance and music. The dialogue may be in Spanish or in an Indian language or a mixture of both.

Moriscas, ritual dances deriving from ancient European ritual dances, abound during carnival (the week before Lent begins) but also occur at Corpus Christi (second

Gulf Coast area, also contribute to the merriment of the Veracruz *huapango*.

These regional couple dances blend European and native steps and styles and use European or European-derived instruments and tunes. Even though they are mestizo dances, Indians enjoy them and give them a native flavour—e.g., in steps or posture. The dances' European origins must usually be deduced from the style—Andalusia for the *zandunga*, the flamenco *fandango* for *huapangos*, and the *jota* of Aragon for *jarabes*.

South America. South American dances resemble those of Middle America. Native dance rituals have their last strongholds in the jungles and highlands of the interior. Iberian dance-dramas show their relationship with those of Middle America. Couple dances are prominent.

Northern South America. In Venezuela several tribes of the Orinoco River held masked puberty rites. For example, among the Maipure and Baniva tribes, Mauari, the spirit of evil, is impersonated by a dancer who is fully covered with red and black body paint, a face-covering of puma or jaguar pelt, and a crown of deer antlers. At the initiation of a youth or girl, he emerges from the forest with maskers representing lions, tigers, deer, bears, and other wild beasts. Their bloodcurdling growls and howls mingle with the groans of the *botutos*, the sacred trumpets, to fill the night with a gruesome din. With wild leaps and contortions, they dance around the neophyte and four shamans.

Ancient puberty ceremonies evidently had wide distribution, with distinctive features, in the Amazon Basin and in the Mato Grosso highlands of Brazil, the Gran Chaco region of Bolivia and Paraguay, and Patagonia and the Tierra del Fuego in Argentina. They formed part of a complex emphasizing shamanistic cures, death rites, and animal dances for the hunt.

Today the most prominent dances of Venezuela are the many versions of the *morisca* on Christian holidays and a dance of medieval devils on Corpus Christi. The *joropo*, a lively couple dance in waltz time, is the national dance of Venezuela.

Colombia has fewer religious celebrations and a greater profusion of courtship dances. The *joropo* extends into eastern Colombia. On the Caribbean coast the *bullerengue*, *lumbalu*, and the circular *cumbia* mingle Indian reticence and black ebullience. The Colombian *fandango* derives more from Spanish diversions. The national dance, the *bambuco*, originated in the Andean zone. Male and female partners, waving kerchiefs, enact a courtship mime of pursuing and flirting, combining dignity with sensuousness.

The Andean region. Along the Pacific coast and in Ecuador, Peru, Bolivia, and Chile, native dances have received Spanish influences. On Catholic holidays the northern Andean Indians perform vestiges of aboriginal animal rites for the vicuña, the tiger, and the condor by a solo mime within a large circle. Conveniently, Corpus Christi synchronizes with the Inca solstice ceremony, *intiraymi*, and presents an excuse for the reappearance of the native sun god in a huge, gold disc headdress.

The Araucanians of Chile, who resisted Incan influences, preserve a shamanistic harvest ceremony, the *ñillatun*, a combination of Christian ritual and an indigenous mass dance. During interludes two men mime ostrichlike rheas, with shawls as wings.

The highland fiestas of Andean Indians show more European influences than the *ñillatun*. Generally timed in accordance with Catholic festivals, the dances feature battles of Moors and Christians, clowns, demons in fantastic masks, and European animal characters. Some dramas ridicule the Spanish. The mountain fiestas often conclude with gay couple dances.

The coastal celebrations feature widespread couple dances of mixed Indian-Spanish origin. Only the *cumbia* shows Negro qualities. The mournful *huayno* (or *wayno*), *yaraví*, and *sanjuanito* of Ecuador, Peru, and Bolivia reveal Incan origins in their restrained manner and haunting music. The gay *marinera* of Peru and the headstrong *cueca* are more Spanish. The *fandango* and *pasacalle* are also at home in the urban ballroom.

The southern plains. Argentinians have developed such ritualistic mestizo (Spanish-Indian) dances as *las cintas*, a

Voladores of Mexico.

Thursday after Pentecost), Santiago (St. James Day, July 25), and on other feasts. In the drama of *moros y cristianos*, two factions mimetically tangle in arguments and battle with the ultimate victory of the Christians and the conversion of the Moors.

Posadas and *pastorelas* are danced episodes of the Christmastime *coloquio de los pastores*, or "Play of the Shepherds." Most popular in southern and central Mexico, New Mexico, and Texas, the *posadas* are generally processions by city boys and girls who go from house to house asking gifts and lodging and singing special hymns. On Christmas Eve, youngsters dance quadrilles of *pastores* and *pastoras* (shepherds and shepherdesses). The Guatemalan *loas* are short religious dramas presented at Christmas, during Holy Week, and on other holy days.

In form, the regional, secular dances are distinct from the ritualistic dances. Except for the circular *mitote* types, they are all for couples who do not touch. Among the best known are the *jarana* of Yucatán, the *zandunga* and *llorona* of the Zapotec Indians of Oaxaca state, the *chiapanecas* of Chiapas state, and the *huapangos* (called *fandangos* in some locales) of the east coast. The *jarabe* has many regional variants, as the *jarabe tapatio* (or Mexican Hat Dance) of Guadalajara, the *jarabes* of Tlaxcala and Michoacán states, and the *zarabanda* of Guatemala. Sometimes the theme of flirtation or female coyness blossoms forth in humorous interludes. Contests of improvisations to *la bamba*, widely danced in the Mexican

Secular couple dances

Profusion of courtship dances in Colombia

maypole dance, and the *sumamao* ("beautiful river") celebration. Argentina shares some Andean social dances, as the semi-Indian *carnavalito*, a collective circle dance. The richest repertoire of Argentina and adjoining Uruguay developed among the cowboys, or *gauchos*, of the Pampas. Their dances reveal more of the Spanish elements than those of the Andean regions. In the *pericón*, the dancers manipulate handkerchiefs; and in the *pericón*, *chacarera*, and *gato*, couples perform *zapateados* as groups. In the *bailecito*, *cuando*, *firmeza*, and *cueca*, they enact courtship mime with emphatic waltz steps. Other dances are urban, as the *milonga* of the lower classes and the sophisticated Spanish-French tango ballroom dance. Andeans and Argentinians have exchanged dances. In fact, the diffusion of dances is much greater in this area of South America than in Middle America.

STUDY AND EVALUATION

The secular pan-Indian dances of North America, such as the Oklahoma dances, the round and war dances of plains tribes, and the stomps of southeastern tribes all have in modern times spread from coast to coast—to the salvation of tribes who lost their heritage but want to perform something Indian, especially in urban gatherings. The most copious and reliable materials on these and other aboriginal dances are strewn through the works of anthropologists, folklorists, and a few musicians. General descriptions are often incorporated into anthropological studies and into notes on earlier observations by colonists, missionaries, and 19th-century scholars. Lacking a major specialist, Middle American Indian dances are in large part unstudied in a scholarly manner. Essential to future studies is an examination of the arts in their cultural context. It is equally important to recognize the dance as an expressive art, to learn and analyze the movements, and to present them in dance notation alongside musical scores. Such presentation facilitates intertribal and intercontinental comparisons. The materials must stem from field work, but they can be supplemented by the many motion pictures in college archives and museums and in repositories such as the Wenner-Gren Foundation and the American Philosophical Society.

Visual arts

NATURE AND ELEMENTS

The role of the artist. The very use of the word art suggests one of the basic differences between Western and American Indian concepts. For not only did few Indian groups allow art to become a major way of life, as in the West, but many Indian languages even lack a term for "art" or "artist." If one wished to refer to a beautiful basket or a well-carved sculpture, it was usually necessary to rely upon such terms as well-done, effective, or perhaps powerful (in the magical sense). And the concept of an artist was largely of a person who was simply better at the job than was another. Generally, artists were accorded special significance only where wealth was a major factor in the culture. Wealthy chiefs, particularly on the Northwest Coast, hired stables of carvers for their personal aggrandizement, giving rise to a class of professional artists. Yet, the fact that the talented artist was in such demand did not set him apart as a person of undue importance; rather, his role was important at the moment his product was in demand—and if he happened also to be a religious, political, or war leader, so much the better.

Although Indian people, unlike Westerners, may not consider artistic skill in terms of a superior individual attribute, the difference between a well-woven basket and a careless piece of work or a particularly well-designed carving and a crudely made example did not go unnoticed. Fine workmanship commanded a premium, even in pre-European times, and with the advent of the dollar system, it was even more highly prized.

Collective versus individual art. The basic role of the American Indian artist is the same as that of the artist in any culture: to arouse an emotional response in his audience. In Indian cultures, the artist's ability to com-

municate successfully with his own people depended largely upon his recognition of the force of tradition. The social organization of the various tribes allowed less latitude for experimentation than Western cultures and usually compelled him to work in familiar channels. (The frequent failure to communicate with a non-Indian audience does not necessarily mean that the Indian artist has failed as an artist but that many of the cultural, racial, social, and political traditions involved in his work have proved to be almost insuperable barriers to understanding.) Yet, within this rigid framework of tradition, there was sometimes a surprising degree of freedom of expression. There are recorded instances of individuals having made considerable changes in the art (and the economy) of their tribes. Perhaps the most striking have been the careers of Nampeyó (1859?–1942), the famed Hopi potter, and María (1881?–1980) and Julián Martínez (1897–1943), of San Ildefonso pueblo. Through sheer individual talent these people achieved a personal triumph by developing a style that not only was copied by other artists but in time also was regarded as "traditional" in that particular village. Although there is no way of knowing how often this happened in the past, there are suggestions that it occurred at Mimbres, among the Haida slate carvers, and quite possibly in some areas of the so-called Mound Builder cultures of the Southeast.

The origins of most Indian decorative designs cannot be traced accurately today; most of them are lost in antiquity. Many obviously came from natural forms, while others are simple developments of geometric or lineal motifs. Some have become so interwoven with alien concepts—Western, after the advent of the European, for example—that it is impossible to completely unravel their sources. There is evidence, however, that some of the original forms were creations of individual artists and were often inspired by what the Indians called a vision. The vision is closely akin to a dream. To the Indian, the dream world was a mysterious, supernatural land, where his soul, which had left his body, participated in many strange activities and saw many strange sights. Since many of the designs or creatures that he saw were regarded as protective forms or beings, sent as signs from the spirit world, he would carefully re-create this dream world during his waking hours. If he were not an artist, he would occasionally describe his dream creature so that the proper individual could record it on hide, in wood, or in stone. But since these supernatural vision designs were extremely personal, they were usually recorded by the individual himself; hence, they vary tremendously in aesthetic quality.

Because art designs were regarded as personal property, an artist could buy a design or receive it as a gift from its creator, but to appropriate and use it for his own purposes was taboo. This custom amounted to quasi-religious and social copyright.

The function of art. Since the early Indian peoples travelled extensively, their household goods had to have the maximum utility; thus, Indian art objects are basically intended to perform a service—for example, to act as a container or to provide a means of worship. Only in later years could these peoples afford the sophisticated luxury of household possessions that did nothing but "look nice."

The particular utilitarian form that Indian arts take often reflects the social organization of the cultures involved. Political and military societies seem to have found their major art forms in the world of weaponry, pageantry of costume, and panoply. This is most pronounced in the Plains, Aztec, and Inca civilizations, all of which reflect the dominant warrior cult forces active in their arts. Those cultures in which life was heavily governed by religion—the so-called theologies of America—tended toward a greater degree of ceremonial art than those in which life was less ritualized. All of the aesthetic expressions that have come down from the Maya, for example, obviously reflect the considerable weight of theocracy that existed in their world.

Generally, but not necessarily, the best of Indian artwork was applied to those objects intended to please a deity, soothe the angry gods, and placate or frighten the evil

Role of tradition

Origins of Indian decorative designs

Importance of utilitarian considerations

spirits. Through such means, the Indian sought to control his environment and the human or supernatural beings that surrounded or threatened him.

Some specific articles were reserved solely for religious uses, and some were for secular needs alone. Decoration does not always provide a clue as to these uses. Some of the most highly revered religious articles are completely devoid of ornamentation—in fact, may be rather ugly—while others are highly embellished. Sometimes plainware bowls were used for food preparation, while other peoples did the same chore in polychrome bowls. Many objects served a dual function: normally, they were used for everyday household purposes, yet under a different set of circumstances they could fulfill a religious function. Beneath the surface, there was a magic at work, and, in initiated hands, a mundane article might release its supernatural power, calling upon unseen forces to aid the owner. This power might be visually evident in the form, shape, or decoration of the object, or might simply be “believed in” no matter what the physical state or appearance of the object might be.

Supernatural powers of art objects

The aim of the Indian artist was not merely to set down realistic records but to create the semi-magical designs so common in primitive art. He quickly realized that he could not draw a tree as perfectly as it could be made by the Creator; so, with common sense, he did not try. Instead, he sought the spirit or essence of the tree and represented this in his design. Carvings, paintings, effigies, or “realistic” portraits are not simply pictures of people or objects; they embody the essence of that particular subject as well. In a sense, this can be called a form of witchcraft, since it captures the soul of the object or the person. This semi-magical character of Indian art is difficult for the Western mind to understand. Not infrequently, the non-Indian will ask, “what does that design mean?”—a question that makes little sense to the artist. He might reply, were he so inclined, that it meant what he wanted it to mean. Also confusing to the questioner is the fact that the Indian often attaches names to designs, largely for convenience. When asked, an Indian will frequently call a given design a “leaf,” or an “arrowhead,” when what he actually means is that the design is “leaflike,” or “leaf-shaped,” and so on. But the inquirer immediately translates this to mean that the design signifies a leaf or an arrowhead and tries to impart a “story” to the overall visual concept that may have no basis in reality insofar as the original artist is concerned.

Ritual was often interwoven into the very process of creating Indian art. The Westerner, whose attention is devoted primarily to the product and not the process of art, is satisfied to define the Zuni war god Ahayuta as wood sculpture of a religious nature; other details are simply added ethnographic data. To the Zuni, however, it is vitally important that the wood come from a tree that has been struck by lightning and that it be ritually prepared for carving. This is equally important in the making of an Iroquois False Face mask, which must be carved from the trunk of a living tree—hence the term “live mask.” The tree is ritually addressed before the carver begins, and the mask and the tree are “fed” tobacco before separating the two. Such prescribed ritual is of equal, if not more, importance than the artistic skill employed in the production of the work. If the ceremonial acts were ignored, the article would lose its efficacy—and might even prove dangerously counteractive. This ritual aspect of Indian art, which permeates most of the ceremonial paraphernalia, is extremely complex and must be considered throughout the creation of the work of art.

Not all Indian art, however, was religious or political. There was also a considerable amount of mundane, humorous, and even profane art produced by most cultures. Although much of the eroticism has disappeared in the Puritan fires that continue to burn the Westerner, sufficient examples remain from prehistoric and recent times to indicate a wholly relaxed freedom of expression reflecting a healthy, naturalistic outlook.

Materials. Working in the materials natural to their respective homelands, the various Indian cultures produced art that reflected their environment. Those peoples living

Wooden figure of the Zuni war god Ahayuta, c. 1900. In the Denver Art Museum, Colorado. Height 70 cm.

Courtesy of the Denver Art Museum, Colorado

in heavily forested regions, for example, inevitably became gifted sculptors in wood; those for whom clay was a major resource became skillful potters; and those living in the grasslands became fine basket weavers. There is virtually no medium, however, that has not been explored and mastered by the Indian: jade, turquoise, shell, metals, stone, milkweed fibre, birch bark, porcupine quills, deer hair, llama dung, sea lion whiskers—all were used by the artist to lend colour or texture to the finished product. In many instances, such materials became desired commodities in themselves, to be traded over great distances; for certain objects were not regarded as “official” unless they were manufactured from a prescribed material, and, especially for religious purposes, a substitute could not be tolerated. Often, in such cases, the materials became, in a sense, currency, for they achieved a standard value within the economy, with ready acceptance wherever they were in vogue.

Role of art materials in trade

The relationship between material and design in Indian art was quite different from that in the Western tradition. The Western painter usually imposed a design on the artificially limited surface of a flat, rectangular canvas; and the sculptor, following predetermined spatial arrangements, imposed a shape on his material. On the other hand, the Indian painter and sculptor were less likely to force their materials to conform to a preconceived design. They tended instead to adapt their design to the natural outlines of their materials, which often happened to be a complete and therefore irregular buffalo hide, a tree branch, or a stone. This naturalism is one of the most pleasing aspects of Indian art and often demonstrates the artist's remarkable ability to incorporate the natural form into his composition.

REGIONAL STYLES OF AMERICAN INDIAN VISUAL ARTS

The term “Indian art” covers an extremely broad category, encompassing all art expressions of the original inhabitants of the Americas and their cognate descendants. It thus includes not only varied and completely disparate cultures but also spans great time sequences—from the mid-20th century back to prehistoric times. (Sur-

viving artifacts clearly demonstrate that ancient man was already possessed of considerable aesthetic ability; flint, for example, was carefully flaked into attractive, well-balanced forms; and stone carving and pottery were capably handled.)

Although the dissimilarities between the artistic expressions of different cultures and different times are great, there are also similarities; for the borrowing of art forms from distant and occasionally alien peoples was a common practice. Objects in museum collections reveal, for example, that prehistoric merchants travelled thousands of miles seeking and bringing back from other tribes such ornamental materials as feathers, shells, jade, and turquoise. This far-flung trade expanded the limits of tribal styles, for the Indian merchant returned with new ideas as well as materials. In time, new designs and motifs became part of the stylistic concepts and traditions of his own people. Intertribal marriage, too, affected regional styles. While in some tribes marriage within the group was required, in others it was forbidden. In the latter case, the girl—who was often the artist—took her own artistic traditions to the new group, into which they were subsequently incorporated.

It is becoming increasingly evident that there were common forces at work in the art of various groups, even if widespread in time and space. There are certain symbols that are widely encountered, and some would seem to have had similar significance over a wide area. It is likely that trade routes or political hegemony levied the major influences upon this phenomenon, and it may be said that the depth and spread of symbols is relatively equal to the migration of the peoples involved. In Middle America, for example, the so-called Plumed Serpent motif is to be found in one form or another in almost every culture, and this motif extends even into the United States, where it is encountered in visual form as well as in legend. The existence of the feline deity virtually throughout South America, from the south up into the northern Andean region, is another instance of the travel of an idea and a visual element. Certain customs also have enjoyed wide acceptance; for example, the role of trophy heads, the use of masked personations, and winter solstice New Fire ceremonies. And each of these customs was accompanied by related visual art expressions.

Despite the similarities between the art forms of different cultural groups and different times, one cannot speak of Indian art as though it were a single concept. Just as there were several hundred native tongues, dialects, and speech forms, so were there an equal number of tribal styles, motifs, and design forms. In trying to establish a common aesthetic bond, the well-schooled researcher generally finds as many differences as he does similarities.

When two completely different peoples move into a

common area, such as occurred with the migration of the Athabascan Navajo into the Pueblo Southwest, the eventual result may be a melding of cultures, the loss of certain ancient individualities—since each contributes to the new expression—and the emergence of new aesthetic qualities. It is not certain just how skilled the Navajo weavers were when they arrived in the Southwest, but the Pueblo people were highly developed in that art. Subsequently, the Navajo not only learned new weaving techniques and designs but in time also improved upon the acquired Pueblo methods, transferred the sex role of the weaver from male to female, and matured as far more sophisticated craftspeople. On the other hand, under the same circumstances, surprising differences can sometimes be found; for example, while the Hopi and Zuni people live almost side by side and under similar cultural conditions, it is quite possible to identify the art products of both groups without great difficulty. This is equally true of cultures in ancient times, such as the Aztec and Mayan, or in another time and another region, the Sioux and the Crow.

It is in those tribes or cultural entities that at one time were part of a whole but have subsequently split off that one most often finds common themes, art elements, and cultural patterns so similar as to be confusing.

To most readily understand some of the artistic impulses active among the Indian tribes of the New World, it is convenient to take them in geographical sequence, north to south.

North America. The aesthetic products of the prehistoric Indian artist in North America are perhaps the least well known to the non-Indian public. This is partly because these early people left few spectacular architectural ruins as compared with their Latin-American cousins. This is not to say that architectural monuments did not exist. Spanish accounts report that great temple mounds were in use in the Southeast at the time of the first European entry, in the mid-16th century. But most of these structures were of perishable wood and have long since disappeared—as have most examples of the great use of colour (in which the ancient folk gloried) and their tremendous range of textiles.

So many Indian materials were perishable that scholars have little by which to judge their arts and must, in effect, evaluate a people by only a small proportion of their achievement.

American Southwest. In the United States, it is only in the Southwest that any major prehistoric architectural sites are to be found. The monumental stone cliff dwellings that remain are eloquent testimony to the culture that existed there. Progressing from a simple pit house through aboveground homes, these people moved out onto the plateau regions of Arizona and New Mexico and built

Pueblo Bonito

remarkable multistoried structures, some—such as Pueblo Bonito in New Mexico—sheltering hundreds of families in over 400 rooms.

These apartment houses were well suited for the demands of their environment; their walls were of stone, clay, and sand mixed as an adobe—although true mixed adobe in block form did not come into use until the arrival of the Europeans. The thick stone walls provided excellent insulation, being warm in winter and cool in summer. Heights reached to seven stories, although most villages were of three or four levels.

Major divisions of these early Southwestern Indians, often called by the generic name *Anasazi*, include the Hohokam, of southern Arizona; the true Anasazi, of northern Arizona–New Mexico; and the Mimbres, of southwestern New Mexico. In addition to these groups—each of which produced a style of its own distinct from all others—were dozens of lesser subgroups that archaeologists have been studying for decades in an effort to assemble the pieces of this giant jigsaw puzzle.

The people living in the pueblos produced some of the most successful Indian art work. They were masters of weaving, painting, and particularly of pottery-making. Their weaving techniques long antedated the arrival of Spanish sheep; a native cotton provided ample fibre for intricate weaves coloured with native dyes. Mineral and vegetable pigments provided colourful decorations when applied with a fibre brush to wood, clay, or to white-plastered walls in a fresco technique. Fortunately, abundant kaolin deposits yielded high-quality clay for the creation of excellent pottery forms. Although small stone effigies have been found, sculpture was not a highly developed art form. Pueblo art is essentially linear or geometric in design and reveals a preference for applied decoration. The large underground kivas (rooms used for religious purposes) were decorated with murals executed in brilliant mineral-pigment colours.

Pueblo art became a strongly conventionalized art, held to relatively rigid forms. This characteristic was determined, no doubt, by the closely knit communal nature of a culture that depended upon close cooperation for survival. At its best, early Southwestern art is marked by technical competence and fine control of line and form; but it reflected little experimentation, tending more to rework established patterns in many intricate designs.

Conventionalized forms and technical competence

Because of this conservatism, the culture of the contemporary Pueblo Indian shows striking parallels to that of his ancient ancestors.

In more recent times, the richest variety of art expressions is to be found in the Southwest. Whereas in other regions the arts flourished and waned, here they are still active forces in the lives of the Indian people. Almost all of the crafts practiced in prehistoric times are still practiced today, along with some newly introduced expressions.

Following early trade routes, merchants brought new ideas to the Pueblos, departing with the finished products they had sought. Thus, new creations continued to develop, and new markets strengthened—as continues to be true today. Yet, because of its essential conservatism, Pueblo art remains a closely related continuum of ancient techniques, affected more by the introduction of new tools than of new ideas.

Along the same trade routes came invading tribes from other regions, particularly the Navajo and Apache, who subsequently settled in the Southwest and in time surpassed their teachers in certain arts that they adopted, improved upon, and made their own—notably, silversmithing and weaving. Whereas Pueblo weavers once dominated the textile field, the work of the remarkably inventive Navajo weavers became highly sought after in the late 20th century. Silversmithing, another famed Navajo art, is more recent; it was only in 1853 that the first Navajo smith took up the tools of his craft, but within the next century Navajo jewelry and ornaments acquired a wide appreciation.

As in the prehistoric era, Southwest sculpture has failed to develop as a major art form. The most active sculptural work in the Southwest is reflected in the carved and painted cottonwood kachina dolls of the Hopi and Zuni, which have enjoyed wide popularity as collectors' items. Many variations of these wood carvings are also found in altar and shrine figurines, which are not produced for commercial consumption.

The crafts of basketry and pottery are moderately active. Both face the problems of economic balance: the problem of the time invested as against the economic return of the craft object exacts a serious price. By and large, a craftworker today can enjoy a more stable income from manual labour, or by clerking in a store, than from any creative activity. This is particularly true if one includes

the time required to go into the desert, find grasses or pigments, then wash, grind and process them—all preparatory to the tedious hours spent actually forming the products for later sale. It seems certain that, in time, the former will entirely disappear, and only the luxury-scale pottery arts will continue. Even now, very little pottery is made for native use; it is largely intended for the outside market. Although pottery and basketry are produced in much smaller quantity, the work is of better quality than in years past.

Special-
ization in
Southwest-
ern art

Specialization has long been a factor in Southwestern art and has become increasingly so in recent years. Certain tribes produce almost all of the small carved fetishes, or tiny drilled shell and stone beads; the Zuni favour intricately worked silver jewelry with tiny turquoise settings, while the Navajo make use of massive silver castings with heavy turquoise sets. The Navajos also make most of the heavy rugs and textiles, while the Hopi supply lightweight ceremonial kilts, sashes, and similar costume fabrics.

Another art form that may have been brought from the north, but that was more likely adopted from Pueblo culture, is sand painting (more accurately termed dry painting). The use of a variety of finely-ground mineral pigments, which are allowed to trickle through the fingers to form a variety of complicated patterns, has become uniquely Navajo. These designs provide a focus for curing ceremonies.

Great Lakes—Midwest. The existence of rich textile art in the prehistoric Middle West is known, but its range and development are lost in hundreds of years of history from which few examples survive. Examples of basketry and wood are similarly rare. Enough of these perishable items have survived to indicate that these people had mastered the arts, but not enough to enable scholars to judge their aesthetic development. What has survived in profusion is stone, worked skillfully and in many ways. Pottery, too, though not of highest quality, and copper ornaments have been found. Of the relatively perishable substances, finely carved and incised shell is common, which, along with bone, indicates the artistic range of these early peoples. The quantity of objects found is impressive. Numerically significant groups, the peoples of the region were active in the production of materials and implements with which to meet the challenge of their environment. The function of all of the recovered examples of stonework is not known, but it is known that much of the archaeological wealth was ceremonial in nature, indicating a highly organized civilization.

“Effigy
mounds”

Ritual structures existed, such as the so-called “effigy mounds”—great piles of earth fashioned in various forms

Navajo sand painting, c. 1940. In the Denver Art Museum, Colorado. 115 × 111 cm.

Courtesy of the Denver Art Museum, Colorado

to represent animals. The Serpent Mound in Ohio is an example of this custom. Truncated pyramids apparently served as large bases for wooden “temples,” now long vanished but still in use when Spanish explorers first entered the region. Cahokia, in Illinois, was the largest such earthwork in existence before it was bulldozed to make way for modern buildings.

Major cultural expressions from this region included the Adena, Hopewell, Oneota, and copper culture peoples; their art was extensive, making great use of sculptured stone pipes, polished ornaments of both stone and copper, and incised shell decorations that may have served as both inlays and clothing accessories.

Great Plains. The later Great Plains region is the area most familiar to the average non-Indian, for this is the world of the “Buffalo Bill” shows, television and movie programs, and fiction. From it came the buckskin and beadwork costume, feathered war bonnets, colourful porcupine quill decoration, and painted shields that personify the American Indian in the minds of most people.

Yet, there was no monolithic culture. The arts of the Great Plains Indian varied from tribe to tribe; some peoples seem to have had superior aesthetic taste, with sensitive and inventive developments in the arts.

Very little woodcarving was produced here in proportion to the other arts; yet a respectable body of wooden bowls, clubs, effigies, figurines, and similar objects indicates that the Plains artist did not ignore this medium. Even less pottery and basketry was produced, for containers were primarily made from buffalo hide.

A great deal of Plains art served both decorative and spiritual ends. A given design might appear to be primarily a colourful decoration, yet to the initiated it was also the guardian spirit of the owner.

Colour was originally achieved by mineral pigments or vegetable dyes. In time, these were supplanted by commercial dyes and trade colours. Porcupine quilling—the use of small quills of the American porcupine, *Erethizon dorsatus*, which are flattened, dyed, and then applied to the surface of animal hides or textile materials—is an art produced nowhere else in the world. It became outmoded in favour of glass trade beads, which were not only technically similar in their application to quillwork but did not fade and gave a richness of colour unobtainable in any other way.

The art forms themselves range from realistic to extremely abstract and symbolic. Often they are narrative in content, as with the Winter Counts, those painted records that recounted tribal history by means of annual symbols, and the personal history paintings on hide that recount the exploits of the owner.

Not only did the Plains Indian decorate his home but also his person, with carefully coiffured hair, facial painting, and clothing enhancement. And he devoted the same aesthetic attention to his horse as he did to himself, creating beautifully decorated gear for special occasions. Statically displayed in a museum exhibit, much of this ornamentation loses the grace of motion. When worn as intended, the motion of the wearer and the wafting of the

plains breeze gives the feathered war bonnet or the fringed buckskin a lively grace and colour.

Peripheral North America. Four other art-producing regions of North America include the far west, northeast, central south, and southeast.

In prehistoric times, the central south and southeast were part of the most artistically exciting region of the North American continent. This land of temples, mounds, and monuments was an amazing world, and one can truly understand the legends that grew up around the riches that were evident when the Spanish arrived and that are still found in archaeological excavations. Testifying to the highly developed civilizations that existed are the beautifully carved shells, incised gorgets, and intricately decorated clothing ornaments; the carved stone effigies of ancestor figures or deities, which suggest a strong affinity with ancient Mexico; and the many bird and animal pipes in museums throughout the country. Had the Middle Mississippian culture diorite bowl (Museum of the American Indian, New York City) found at Moundville, Alabama, been the only masterpiece to survive, however, no other proof of the artistic brilliance of these peoples would be required.

Middle Mississippian diorite bowl in the shape of a crested wood duck, from Moundville, Alabama, c. AD 1500. In the Museum of the American Indian, Heye Foundation, New York City. Length 25.4 cm.

Wood was used in profusion, although little of it has been preserved in anything resembling its original condition. A quantity of textiles, albeit in fragments, has also survived. Other perishables include decorative freshwater pearls, featherwork, bone, and animal hides.

But it is in the claywork that the greatest vitality seems to have been expressed. While much of the clay used was of inferior quality, the results were astonishing. Exuberant forms, delicately traced surface lines, and strong, powerful designs were all executed with a confidence and grace that still attracts contemporary art students. A tremendous assortment of vessel designs was created in the Southeast: floral, geometric, clay appliqué, delicate polished water bottles and huge burial jars, as well as many lovely vessels created to hallow a shrine, decorate a temple, or do homage to a god—all providing evidence of the imagination, skill, and sheer love of clay for its own sake that these early potters must have felt. While much of this pottery art is extremely fragile, enough of the remarkably large output has survived to give an excellent idea of the aesthetic heights that were attained.

With the coming of the white man, this creativity was ended or diverted. Tribes were killed off or dispersed, or their social organization was so disrupted that normal pursuits were destroyed or directed into other, non-Indian channels. While the introduction of new and better tools allowed greater technical proficiency, the pride and dignity that had formerly provided such a strong creative impetus was no longer present. The artist had lost his old market—purchasers who understood what they were buying—and instead served a customer more concerned with external appearance than with the function of the object. The result was what is disparagingly known as tourist art—ostentatious elaboration that had little to do with the integrity of the product.

Prehistoric
art of
central
south and
southeast
North
America

Today, almost all of the aboriginal arts of the Southeast have been lost or are much less actively pursued. The great stone sculpture for which it was so famous has entirely disappeared, although excellent wood sculpture is a continuing art; pottery is quite different from the earlier styles and far less imaginative. The clays from which contemporary Cherokee and Catawba pottery is produced are better grade, but the range of design is markedly limited. The most active art, and probably the most successful, is basketry, in which the present-day artists are in every way equal to, or better than, their tribal predecessors.

The breakup of the great Cherokee tribe, when a major portion was forced to remove from South Carolina and Georgia to Oklahoma in 1838–39, destroyed the unity of the people. Today, very little Cherokee culture as such is to be found in Oklahoma; it has been kept alive largely by the smaller Eastern band still living in North Carolina. It is this group that is responsible for the pottery, wood sculpture, and basketry referred to above.

Basketry
of the
California
Indians

The great art of the California Indians was basketry; no other people in the world has produced such a wide variety of superb basketry. The Pomo, Hupa, Yurok, and Karok peoples of the north developed basketry to its ultimate with weaves so tightly composed as to provide a watertight container, baskets so small that they measure less than one-eighth inch (three millimetres) in diameter, huge grain-storage baskets, and delicately woven "gift" baskets with the feathers of birds interwoven that provided not only an opportunity for the weaver to demonstrate her mastery of the art, but also a means whereby she could display her affection for the deceased. Elsewhere the Chumash, Mono-Paviosto, Washo, and Koso proved no less skilled.

The Woodlands tribes of the East fall into two divisions: the south-southeast (discussed above), and the Great Lakes and northeast. The Great Lakes group produced various arts, including woodwork, a style of weaving with rush and hemp, and a strong porcupine quill art, later replaced by beadwork. This style of beadwork was popular around the turn of the 19th century, when large quantities of it became available. The art depended upon a weaving frame, which allowed the manufacture of long strips, useful for necklaces, belts, panels, and headbands. Wood art made effective use of burls (hemispherical outgrowths on a tree), from which bowls and containers were fashioned. Pottery was almost nonexistent.

The people of the Northeast, notably the Iroquois, are famous for their False Face Society masks, quillwork and beadwork, wooden bowls and ladles, and the woven wampum belts, which are important historical documents. Some pottery was produced, but not of significant quantity or quality. Woodlands basketry was common, but it was not of the quality found elsewhere. Primarily a splint-weave type, it was rarely ornamented, and when it was, the ornament consisted of stamped or painted vegetable-dye designs.

Eskimo. It may seem unlikely that art would occupy very much of the attention of the inhabitants of the bleak Arctic regions; not only is there little raw material to work with but the ever-present need to secure a food supply would seem to leave little time for craftwork. Yet, from this harsh environment came some of the most imaginative and humorous of Indian carvings. During the long winter nights, the Eskimo had ample time to work the ivory that came from the walrus and whale, much as the Yankee farmer passed the time during the winter whittling on a stick of wood as he sat by the stove.

Art styles of the area favoured carving in the round, decoration by incising, and a modest amount of inlay. Since the basic material was often a tusk or a tooth, these objects partially dictated the form, which was embellished after carving by incising or engraving. Black pigment, from charcoal fires, was rubbed into the lines for emphasis. Such prehistoric wood carving as may have existed has almost entirely disappeared, but enough has survived to indicate that it was a rich and varied art form. Ancient ivory carvings have also been excavated, revealing a sophisticated, formal style. The so-called fossil ivory from

which these carvings were made is highly prized even today and, when found, is invariably turned into beautiful carvings that gain value because of the scarce, richly colourful raw material.

A predominant characteristic of Eskimo art is the warm sense of humour that is so prevalent. Sometimes it is expressed in caricature, sometimes in sequential, "cartoon" form. Its surrealistic expression is probably a reflection of the Eskimo's awareness that, because he lives close to death throughout his life, humour is vital to his psychological health.

Another significant feature of Eskimo art is the remarkable mechanical skill that was often involved in the creative process. Part of the Eskimo's artistry was his ability to neatly piece together small parts to create a whole—and his ability to fashion the tools needed to carry out the operation, many of which were works of art themselves. This skill is evident in the Eskimo's most famous art form: the fantastic wooden masks used for various dances and social affairs. While many tribes made wooden masks

Humour in
Eskimo art

and decorated them with colourful ingenuity, no North American aboriginal people developed the art of imaginative characterization to such an extreme. Surrealism *par excellence*. These masks demonstrate a combination of realistic, imaginative, and supernatural qualities that is uniquely Eskimo.

In more recent times, with its inception around 1950, a stone art form, utilizing deposits of gray and green soapstone, or steatite, found in the vicinity of Hudson Bay, has become familiar to art collectors. Usually given an artificial colouring, these examples of small-scale sculpture are popular examples of genre art. While they reflect the inherent sculptural skills of the Eskimo, they owe their origin and promotion to non-Indian agencies that have worked closely with several of the crafts groups in the region. A form of graphic art derived from Japanese print-making techniques has also become popular in this way.

Northwest Coast. It was in this region, richly endowed with tremendous cedar and spruce forests, that the American Indian sculptor achieved his finest expression. It is probably here that the influence of tools upon the artist is best exemplified; for, with the introduction of steel cutting knives, the Northwest Coast artist was free to demonstrate his latent talent in the aesthetically superb sculpture that is rivalled by no other Indian people in North America.

Tall, straight cedar poles furnished the material for the huge totem poles, the smaller wooden figures, the masks, and the other carved objects so loved by the Northwest Coast Indian. Inlaid with *Haliotis*, or abalone shell, and carefully painted, these products took on a quality so distinctive that they are immediately identifiable.

Courtesy of the Denver Art Museum, Colorado

Haida painted wood and swansdown headdress, inlaid with abalone, c. 1870. In the Denver Art Museum, Colorado. Central section 15 × 18 cm.

Another remarkable quality of the Northwest Coast artist is his skill and interest in fitting designs into forms. He excels at fitting his designs into a given area, shape, or prescribed form, yet without sacrificing the integrity of the design.

The role of the tall totem poles from this area has not been well understood by non-Indians, and many erroneous accounts have been published as to their purpose and "meaning." In actuality, they were not religious and were never intended to be worshipped. They were historical documents of a sort, recording the social position, wealth, and relative importance of the person who had paid for the pole. Because family lineage, class status, wealth, and other social facts were thus recorded, it was possible to gain an "introduction" to the village chief or house owner by simply examining the tall pole.

The goal of most of this rich art was the exaltation of the individual—more specifically, a wealthy village chief or a great noble, for the society was based on a class system. Part of the insignia of social position was the accumulation of wealth, and *objets d'art* were an important part of that wealth. With the coming of the white man, who coveted the rich furs of the region, the control of the great fishing

Bob and Ira Spring

areas and strategic position of the Northwest Coast tribes enabled them to acquire staggering wealth in an extremely brief space of time. The existence of an Indian purchasing class, with its ever-increasing need for impressive possessions, created a supplier: the professional artist. This was thus one of the very few aboriginal cultures that gave rise to art patrons who hired artists on a commission basis.

More surprising, the works that were commissioned were destined to be destroyed, given away, or otherwise neglected. For the life goal of many of these tribes involved the belief that the greatest value was to give away all of one's possessions. While this may seem paradoxical the logic was simple: the more one gave away, the greater one's prestige.

Combined with the potlatch, this system tended to impoverish groups from time to time, sometimes to the point of enslaving whole villages. The rule was that the wealthy individual hold a feast to which his major rival was invited. The host would give away all of his possessions, and the rival would return the courtesy, giving back more than he had received. To show even greater contempt for material possessions (and one's rival), frequently goods were publicly burned, broken up, or cast into the sea. Slaves were even killed and families sold into slavery. From all of this megalomania came the surviving aesthetic masterpieces that are valued so highly today.

The Northwest Coast tribes were among the first American Indians to master metalcraft. While some copper came from local sources, most came from whaling ships,

The short existence of works of art

Totem poles

both as cargo brought in for trade and as scrap peeled from the hulls of wrecked ships. This metal was worked with great skill by Tlingit and Haida artists into fighting knives, masks, overlays for art works, and the great shield-shaped *tinneh* that were so highly prized.

Among the Northwest Coast tribes, the Tlingit people of Alaska seem to have produced the most sensitive and sophisticated sculpture. The Kwakiutl, on the other hand, expressed their feeling for line and form in extremely impressive and powerful painted carvings: the designs are usually outlined in strong colours; there is far less subtlety of form; and the overall feeling is of a potent force at work. Between the two extremes are the Haida carvers, whose work, often less strongly painted than Kwakiutl work, is marked by precision of design, skill in execution, and strength of expression. These are the people who were responsible for the familiar black "slate carvings," which are actually made of argillite, a stone found locally only on Queen Charlotte Islands, in British Columbia.

The work of the neighbouring Northwest Coast peoples, such as the Niska, Kitsan, and Tsimshian, who lived upriver from the Tlingit, is perhaps slightly less well known, due largely to the smaller population and their more remote interior location. It is, however, of equal aesthetic merit, and can stand comparison on any basis with the art of the rest of the peoples of this region.

With the coming of the white man, there was a brief period of economic benefit enjoyed by the Northwest Coast people, but this soon disappeared, and the arts rapidly degenerated to curio-shop products. In time, even these provided so little income that all but a few Indian carvers and basket weavers abandoned the arts. Today, again, there are several crafts products that seem destined to disappear, particularly the famed Chilkat blankets. On the other hand, some crafts objects, especially wooden masks that are often carved and painted replicas of older ones, have enjoyed a revival; but, in essence, this is a copying process, largely mechanical and lacking any of the creativity of the original. Argillite carving is experiencing a modest renaissance, but as yet most of the products are very small, ornamental, accessory forms. In general, the exuberance and power of the earlier forms is yet to be fully realized by these gifted, determined artists of Northwest Coast Indian descent.

Mexico and Middle America. Although Mexico is geographically part of the North American continent, its cultural world is so different that it is more convenient to consider it as part of Middle or Central America. The Indian groups in the region are also somewhat different in that they reflect a strong Spanish influence that was largely absent from most of the North American aboriginal peoples. It is true, however, that a strong intertribal trade existed between Mexican tribes and those of North America in prehistoric times, and this influence must be borne in mind when considering the arts of both regions.

The earliest identifiable art form of major significance in Mexico is that of the Olmec, the mysterious "rubber people," whose culture was flourishing as early as 1000 BC over an area from Guerrero to Veracruz in Mexico, and into Guatemala, Honduras, and El Salvador. These Indians carved the tremendous "colossal heads" that the American anthropologist Matthew W. Stirling found at La Venta; delicate greenstone "baby-face" figures; and figurines with a rounded facial form, thick features, heavy-lidded eyes, and down-turned mouth that are referred to as "were-jaguars" because the image of this mythological or quasi-symbolic, supernatural being is a humanoid type thought by many to combine human aspects with the jaguar concept.

Closely associated with, but somewhat later than, the Olmec culture came the people who inhabited Tlatlco, Chupicuaro, and related early sites, which have become well-known for their lovely clay figurines of nude women with fantastic coiffures. At about the time of the slow demise of these civilizations, other peoples had begun to develop their own way of life in western Mexico, notably in Colima, Jalisco, Nayarit, and Michoacán. Far less is known about the cultures of these areas, for relatively little professional archaeological work had been undertaken on

the scale that would be needed for accurate investigation. The tremendous amount of looting that took place before the major sites came under professional control has virtually destroyed all hopes of unravelling the story of these peoples.

The major architectural construction in ancient America was evolving at this time and reached its apogee about AD 600. The city of Teotihuacán (outside present-day Mexico City), the "Home of the Gods," exercised a tremendous influence from central Mexico into lower Central America; objects inspired by ideas originating at Teotihuacán are still being unearthed throughout the region. The famous masks, so typical of the style, were made c. AD 250–750. Their monumental quality formed by the great mass of stone from which the oval eyes, sensual mouth, and broad face are fashioned, provides a powerful sculptural

concept. Far too massive to have been worn, it is more likely they were intended as burial offerings, or perhaps facial coverings for wooden effigies.

The Toltecs, Mixtecs, and Zapotecs, widely separated one from the other, have also left their imprint. The former, spreading out from their home area around Tula, eventually travelled as far as the Yucatán Peninsula, leaving evidences of their culture wherever they went. The Zapotec and Mixtec peoples of Puebla and Oaxaca were famed for their unique arts, particularly Mixtec goldwork; these master craftsmen were sought out over great distances for the beautiful jewelry and finely fitted craftworks that are still so highly valued today.

Along the east coast, in the state of Veracruz, a group of Mayan people called the Huastec had settled by about 250 BC. In time they developed a new cultural expression, which, because they were isolated by Totonac settlers then building up a major centre at El Tajín, remained limited to their own group. Other pre-Totonac folk who were active in Veracruz produced innumerable “smilingface” figurines and related works that give an impression of an exuberant, happy people. Remarkable among these clayworks are the small clay whistles that abound in the area. They are valuable not only as artworks but also as examples of musical instruments popular during that period.

Unique to this region is the use of *chapopote*, a native asphalt commonly applied to clay figurines as a decoration; occasionally, *chapopote* entirely covers the figures, while in other examples, it is used to decorate only the face, mouth, or eyes.

Some puzzling stone carvings also have been discovered in Veracruz. Although these objects have been found throughout Central America from central Mexico to El Salvador, their centre seems to have been in the coastal Veracruz area. One of the objects, the *palma*, or palmate stone (shaped like a hand with extended fingers), was first thought to have had some religious significance. The thin-bladed *hacha*, or “axe,” so termed because of its resemblance to that implement, was thought to have a ceremonial function of some sort. The *yugo*, or “yoke,” was believed to have been used to hold down the head and neck of a sacrificial victim. Today, none of these theories is accepted. Although scholars are still uncertain as to the use of these objects, the best evidence suggests that the *hacha* had an architectural function, perhaps as a wall fitting, or protruding structural decoration. It is possible that some *hachas* were used with the *yugo*; extant sculptures suggest such a use, along with the *palma*, in connection

with the ceremonial ball game, *tlachtli*. These sculptures portray an elaborately costumed individual, wearing what is apparently a *yugo* around his waist. Supported by and protruding from the latter is a *palma*, indicating that the two may somehow have been fastened together, or were used in combination. It is not believed by scholars that the player actually engaged in the game so encumbered. *Tlachtli* was not unlike today’s soccer game; the object was to propel a gutta-percha ball through the air without touching it with the hands; if it went through a small hole in the carved stone disk, or hit that circular goal, the game was won. Tremendous exchanges of personal property resulted from such a victory—indeed, often life itself was forfeit in important contests.

As the Zapotec people of Oaxaca yielded in turn to the more warlike Mixtec, whose centre at Cholula was the site of the largest pyramid of the ancient world (it considerably exceeded the size of the pyramid of Giza in Egypt), so the latter in time became secondary to the Aztec. By 1200, these nomads, who came from the northwest, had established themselves in the central valley, which they called México, whence the name Mexico. The world they built gave rise to a powerful—at times brutal—art form, in which stone was a favourite medium. The rounded, muscular figures that they produced were originally brilliantly painted, much like ancient Greek sculptures. The Aztec turned out an astonishing quantity of these figures, which, standing in rows, served as standard bearers along the avenues leading to various buildings. The other arts, such as pottery and goldwork, seem not to have fared so well during Aztec times. Even the examples that have been found were perhaps less products of Aztec craftsmanship than creations of neighbouring peoples that were introduced into the Aztec empire as tribute or as trade objects.

Mixtec goldwork

Mayan fresco from Bonampak, original c. AD 800. Reconstruction by Antonio Tejeda F. In Chiapas, Mexico.

Ygunza—FPG

To the east and south, another completely different world appeared under the name of the Maya. Centring in Guatemala and Honduras, where the twin capitals of Quiriguá and Copán are still well-known sites, the Maya spread out to El Salvador, into what is today British Honduras, and into well over one-half of Mexico. The Yucatán Peninsula and the neighbouring state of Campeche are areas where a large number of Mayan sites have been found; of these, undoubtedly the most famous Mayan architectural monuments are at Uxmal, Labná, Kabah, and Sayil and the most renowned examples of Mayan fresco painting have been found at Bonampak. Chichén Itzá, the famous archaeological area near Mérida, combines both Maya and Toltec influences.

Just off the coast of Campeche is the island cemetery of Jaina, from which have come magnificently modelled figurines that are certainly among the finest clay works of antiquity. These sacrificial burial figures, replicas of Mayan personages in ceremonial finery, provide a remarkable insight into the customs, life-styles, and costumes of the classic Mayan people.

Unlike the brutal force of Aztec sculpture, Mayan art forms are relatively delicate. Yet, although light tracery is characteristic of their sculpture and painting, there are also occasional bursts of sheer power. Perhaps they were the most art-conscious people of the ancient Americas; certainly everything they created seems to have been in terms of aesthetics. They were competent in the use of many raw materials—shell, bone, stone of various kinds, wood, fibres, even feathers became part of their art. Surprisingly, with all of their skills, they seem never to have undertaken much metalwork: gold, silver, and copper objects are exceedingly rare from Mayan sites.

From an early beginning, around AD 250, the Mayan civilization had reached its apogee around 750 and had disappeared by 900. Remnant groups kept the cultural thread as a continuum up to about 1200; but by then, except for their language, they could no longer be regarded as cognate with the earlier Mayan.

Farther south, in Nicaragua, Costa Rica, and Panama, the relationships of the various people are less clear, due largely to the paucity of archaeological work that has been undertaken. Moreover, because Panama was something of a crossroads, both east-west and north-south, the variety of influences found there makes conclusive evaluations of the native art almost impossible. But even though far less is known about these peoples, there is no question about the excellent quality of their various kinds of artwork.

The two greatest artistic achievements of the region seem to have been in jade carving and goldsmithing. From the isthmus area come some of the finest gold castings known. Although some delicate, finely wrought goldwork

is known, most pieces consist of heavy casting, with lost-wax tracery (interlaced patterns of metal cast in a wax mold) in which animal and bird forms predominate. The polished jadework of Costa Rica is famous throughout the Central American area. The beautiful “ax gods,” carved from green jade, must have been as sought after in ancient times as they are today.

Pottery was not an unknown art, and the brilliantly painted vessels found here are emphatic proof of this fact. Surprisingly, the art has yet to receive the recognition due it on aesthetic grounds. Some of the designs are remarkably intricate, bold in form, and frequently as sophisticated as anything found in the Western Hemisphere. And here and there are intriguing touches of humour—a quality largely absent from Aztec and Mayan arts.

Little has survived of the architectural expressions from this area. Some large stone sculptures from Penonomé, in Chiriquí province, Panama, suggest that the use of stone in large structures was not unknown; but apparently all of these structures were destroyed, in the years after the Spanish Conquest, by people using the stones for building.

Following the Conquest, the eradication of native culture in Central America was more rigorous than in many areas, and the net result is that south of Guatemala, there is almost no truly indigenous culture to be found. There are some remnants in Costa Rica, but they are few, and evidence of their pre-Columbian culture is only marginal. Today, such arts and crafts as are pursued may reflect a continuum of design but they are basically dominated by European influence. The only regions in which considerable prehistoric aesthetic influence survives are Mexico and Guatemala, where the native craftsman has been able to keep his art somewhat alive by recourse to ancient designs and functions.

West Indies. The Caribbean region of the Americas has undoubtedly lost more of its aboriginal character than any other region. The total decimation of the islands shortly after the Conquest and the subsequent populating of the area by black slaves made any carry-over of Indian cultural expressions impossible. And so it is today that residents of those islands rarely feel any sense of relationship to the ancestral inhabitants. Certainly it is true that the average non-Indian has no understanding of the wealth of arts that were to be found there in the past.

The delicate wood carvings, textiles, featherwork, and related perishable objects that are known from references in Spanish accounts to have existed have largely disap-

Central American jade carving and goldwork

Jaina figurines

peared. Only a few wood carvings and a small number of shell and bone carvings are known. The great strength of surviving prehistoric art from the area is in stone; and in this medium there are remarkably sophisticated, powerful works. Small, tripointed carvings, that were often human or zoomorphic in form, represented the spirits (*zemi*) of the land. The Taino culture is famous for these *zemi* carvings, which are found in many of the islands, notably

Wooden effigy figure inlaid with shell teeth that is a variant of the *zemi* form, from Jamaica, c. AD 1500. In the Metropolitan Museum of Art, New York City. Height 69 cm.

Puerto Rico and Hispaniola. Carved stone pestles, with human and animal designs, are also common, along with strange "stone collars"—oval carvings that may be related to the *yugos* of Mexico and Guatemala. The most prevalent form, however, is the human head, often a death's-head, which suggests a culture preoccupied with mortality. The peoples of this area were also fascinated by odd shapes in stone. Unusual "comma stones," the meaning of which—if they had any—scholars have been unable to discover, have been found scattered throughout the Antilles. Their number and the care and skill with which they are carved suggests that they had an important role in the culture.

Although the Taino are thought to have surpassed the other peoples of the West Indies in aesthetic development, examples of later artistic forms and techniques characteristic of the Arawak, Carib, and related tribes still surviving in neighbouring South America may provide a link between ancient and modern. Since the Taino were a division of the Arawak, so may modern Arawak weaving indicate something of what must have existed among the prehistoric Taino.

The trans-Caribbean sea route from the islands to the mainland obviously carried influences, as well as materials, back and forth; but far too little is known about these influences to be able to determine which area (the islands or the mainland) was most affected. Little more is known about the West Indies civilization, therefore, than that it produced extremely successful sculpture. The civilization

disappeared so rapidly and completely that one can admire but not wholly comprehend it.

South America. The greatest single problem in assessing the Indian art of this region is the unfortunate historical tendency to lump everything together under the heading Inca, as though no other culture had ever attained significance. In fact, when one examines the continent critically, it is evident that the Incas were among the least aesthetically remarkable of the peoples of South America, almost all of whom attained artistic levels only occasionally equalled by the latecomers. It is probably only in the architectural use of stone and in the textile arts that the Inca held his own in artistic comparison.

Weaving was one of the three arts that were South American strengths, the two others being metalwork and pottery. No other peoples in the Western Hemisphere—and less than a handful elsewhere in the world—came close to equalling the aesthetic and technical accomplishment of the Peruvian weaver. One can imagine the astonishment of the early Spanish explorers when they saw this radiant clothing for the first time, even though they very soon passed it over for the gold they coveted.

Metalwork was at its zenith in Peru, Colombia, and Ecuador, each of which developed major cultures whose arts were equal to the demands of the raw material. Tairona gold, in Colombia, rates very high in design and craftsmanship, as does the work of the Quimbaya, whose skill in creating polished metal flasks is remarkable. Notable also is Sinú casting, which could execute works weighing several pounds. In Ecuador, the goldwork found at La Tolita is legendary and shows a skill in casting and overlay that did not seem to exist elsewhere in the region. In Peru, most surviving goldwork was created by the Chimú and Nazca peoples. Yet, that this was a well-advanced art as early as the Chavín era is demonstrated by major discoveries at Chongoyape; indeed, these pieces seem to be the earliest gold products in America, having been created around 900–500 bc.

Perhaps the art that was most widespread and had the greatest variety of form is pottery. In the exciting range of imaginative forms, exuberant vessels are found side by side with sombre, formal works. The use of brilliant colour is common, and the degree of careful modelling makes of many of these pottery containers veritable sculptural masterpieces.

A popular material, stone was used throughout most of South America for massive forms; the small delicately traced stone carvings found in Central America are rarely encountered south of that region. Architecturally, the Incas surpassed all others in their use of intricately cut, giant-size stone blocks, at the sites of Machu Picchu, Sacahuaman, and Ollantaytambo. Only in San Agustín, in Colombia, was there a similar monumental use of stone. In Manabí, in Ecuador, blocks of stone were skillfully carved into thrones and huge seats. None of this South American stonework, however, reflects the degree of skill common in Mexico.

Colombia. Colombia is among the first South American regions to have enjoyed settlement. A pre-pottery Indian culture is known to have come into the region around 10,000 bc; and Puerto Hormiga excavations reveal that a pottery-making culture existed as early as 3,000 bc. The more definite cultural expressions, however, are not found in quantity until San Agustín, which came into existence with the advent of the Christian Era. Little pottery has been recovered from the region as yet, but stone carvings are very well known. A later culture north of this site, which has yielded a more generous quantity of art objects, is Calima, known for its goldwork, and Quimbaya, whose gold and pottery are both important cultural indicators.

Since the southern and eastern regions of the country are almost unknown archaeologically, conclusive evidence is absent, but at the moment it does not appear that their prehistory was artistically rich. Early pre-pottery sites have been found, notably at El Jobo, in Falcón, that date to about 14,920 bc. Carved stone was used for such objects as small pendants or fetishes; shell and bone are also known to have been used.

It is certain that this was a contact point with many

Inca art

Antiquity
of Colom-
bian art

of the Antillean peoples and that travel back and forth between the two regions was a regular custom. Columbus reported such trade—which seems to have been a long-time practice—at the time of his arrival.

Ecuador. It is to Ecuador that one must turn for an examination of early art forms. Straddling the Equator, as the name implies, this region—today the smallest republic in South America—is one of the most intriguing on the continent. For decades the region had been ignored by scholars in favour of the more glamorous Peruvian area, but in recent years its tremendous antiquity has begun to be recognized. It now seems that ancient man may have established his first foothold in Ecuador and that the region is also the site of the earliest datable pottery. From perhaps as early as 15,000 BC until about 3200 BC, when pottery was known to exist at Valdivia, there was a long, steady period of development in the region. And the development was not spotty, for the population increase was also constant.

Although the great cities and some of the major cultural activities found farther south were not found in Ecuador, there was, nevertheless, considerable cultural accomplishment. Weaving was done in quantity, as evidenced by Spanish accounts; and, more spectacularly, goldsmithing was a major expression of the artist's skill. Large pieces, such as crowns and breastplates, and tiny miniatures reflecting the sureness of a master's hand have been found. None of these pieces is unique; they are known in sufficient quantity to prove the existence of a long-time craft. Literally hundreds of thousands of tiny gold beads, each cast individually, have been found in the sands of La Tolita; and others, slightly larger, with granulated surfaces indicating the mastery of a complex casting process, have also been recovered. The technique of inlaying had also been mastered, and the use of emeralds and other gemstones as settings was commonplace. Platinum was worked, as in Colombia; not only was it cast but it also was frequently used in combination with other metals. Copper, too, was worked, both in its "pure" form and combined with tin to make bronze; occasionally, it was gilded to create a pseudo-gold finish. Heavy cast copper axes were stock-in-trade, and many smaller objects were turned out in quantity.

The pottery that emerged from the hands of the clay workers was of high quality, beautifully designed, and well finished. Modelling was powerful, and there were touches

of humour. Scholars are not sure to what extent colour was used, for time and soil have removed much of it. Modelled clay effigies discovered in 1966 at Bahía de Manta are not only remarkable for their size and quantity but even more for the astonishing amount of original colour that had been preserved.

It seems evident that this was one of South America's major civilizations and that in time much more will be discovered about it.

Brazil. Like the archaeology of Venezuela, little is actually known of the archaeology of the vast region of Brazil. Only around the Amazon area has very much work been done, and there primarily on the Ilha de Marajó. Size has hampered much of the effort to unravel prehistory, but weather conditions and jungle overgrowth have also combined to resist penetration. What is known, however, is tantalizing to the scholar, for at Lagoa Santa, in Minas Gerais, the bones of a human being have been linked with a mammoth slaughtered for food as early as around 10,000 BC; and pottery vessels have been discovered attesting to a remarkably advanced civilization in the Amazon lowlands perhaps as early as AD 1000. But what lies between these two extremes in time is yet to be discovered.

The most aesthetically exciting object excavated in Brazil is a unique pottery form, found on the Ilha de Marajó and called Marajoara, which incorporates modelling and painting with a low relief carving of the surface. Several successful expeditions have recovered modest amounts of material, but the island, which is regularly flooded by the mouth of the Amazon, has resisted complete excavation. An individual style found on the tiny isle of Maracá, and another from Santarém, suggest the existence in this region of a hodgepodge of aesthetic expressions, some related, some alien. Surprisingly, the strong geometric Marajoara style seems not to have influenced any of the cultures around it.

Peru and highland Bolivia. The great civilizations of Peru and highland Bolivia—with their monolithic stone structures, major political organizations, and elaborate material wealth—have long attracted the attention of the outside world. This was the only area where structures of any real magnitude were built in South America; the ruins of Tiahuanaco, Cuzco, Chan Chan, and similar well-developed urban centres attest to the achievement of highly skilled peoples. Pottery has been found in all styles and types, from relatively crude wares to the most highly

painted and polished masterpieces. Whistling vessels are common, and the various forms of musical instruments perhaps exceed those found in other civilizations on the continent. Representations of daily life on the pottery reflect complete, well-rounded civilizations.

Man was definitely active in Peru as early as 10,000 BC, and his pottery making dates to no later than 1200 BC. Slowly, these dates will be pushed back, as scholars unravel more and more of prehistory; for, in view of the advanced stage of some early works, it is certain that they will be found to have been preceded by others.

The great Peruvian ruins around Chavín de Huántar have given the name Chavín to one of the most remarkable civilizations in South America—and one of the earliest, though it is not certain whether it was coeval with the Valdivia of Ecuador (c. 3200 BC). Here, remnants, famous throughout the archaeological world, have been found of one of America's earliest cultures. Carved stone objects, fantastic pottery that demonstrates the most advanced skills, evidences of stone construction, and remarkably sophisticated goldwork—all bear witness to a truly magnificent era in ancient history.

A recent discovery has brought to light evidences of a civilization at Ayabaca, in Piura, which was probably

coeval with the Chavín. Named Vicús after the valley in which it was uncovered and dating between 250 BC and AD 500, this civilization produced pottery that resembles the ware of nearby Ecuador and goldwork not unlike other early forms. The discovery of this wholly new civilization, unknown until just a few years ago, suggests the existence of others.

South of the Chavín region, another high culture developed around the Paracas Peninsula. This civilization produced a famous thin-walled pottery and some of the most extraordinary textiles in existence. Great woven mantles, ponchos, and small tapestries were created between 1000 and 250 BC.

Paracas
textiles

Just as elements from the Chavín civilization filtered south to influence the Paracas people, so they influenced a development in the north, around the Virú, Chicama, and Moche valleys from 250 BC to AD 750. Commonly termed Mochica, these people developed a mature art form that includes some of the finest plastic sculpture in the history of pottery. The range of designs makes these objects remarkable not only as art but also as revelations of the civilization from which they come. The extensive number of objects produced suggests that the civilization was an extremely populous one, in which power and wealth were major goals.

Gradually, this civilization gave way to that of invaders,

the Chimú, whose capital of Chan Chan was from AD 1000 to 1500 one of the great urban centres of ancient Peru. This huge city, now largely destroyed, once housed 100,000 persons and produced a spectacular array of artistic works: gold jewelry, feather mantles, great textiles, and considerable work in wood and clay. The arid climate has preserved more art from the Chimú region than from many other sections, and Spanish accounts aid scholars in understanding what they find here. Pottery was as skilled as any found elsewhere, although by now something of a paralysis had set in; certainly, many of the designs have a static quality, doubtless due to the extensive use of molds. By now customer demand was so great that the craftsman had to resort to mass production to keep up with his clients.

Chimú
and Nazca
pottery

In the south, a great pottery talent was at work from c. 250 BC to AD 750 around the Nazca Valley. There, perhaps the most technically advanced potters in South America were producing perfectly formed clay vessels, highly fired, brilliantly painted, and often intricately fashioned. Mostly mold-made, they were turned out in great quantities, with the same stiff formality seen in Chimú pottery. The Nazca

Art of the
Chavín
civilization

weavers, however, succeeded in defeating the mass market, for their work was devoted to highest quality, and their skill was such that even though miles of similarly patterned cloth were turned out regularly, the repetition did not destroy its beauty. In fact, the overall patterns so frequently seen provide a harmony that results in a beautiful fabric. There was literally no weaving process unknown to the ancient Peruvian. Nazca goldwork seems not to have been up to the standards achieved by other Peruvian metalwork; by and large, it is a listless product, having only the material to recommend it. Thin, hammered sheet gold was commonly used for Nazca ornamentation.

Closely related to, and extending from, the Nazca work is the art of the Inca civilization (AD 1000–1500). These people produced fine textiles, the designs of which were often reproduced on the pottery of the area. The dry climate has also preserved a wealth of wood carving, much of it in such fine condition that the quality of the art can be clearly seen.

In the central Peruvian area, a group of people emerged, built a modest civilization, and developed it into a world that was in existence when the Spanish arrived. The Chancay people are not known for great artworks; their pottery produced from AD 1000 to 1500 is a simple, black-on-white ware, usually painted in soft colours, simply defined, and frequently crude in appearance. Their one outstanding quality is humour; many Chancay vessels show a lively sense of the absurd, almost providing a Peruvian comic strip. Chancay weaving is excellent, and many thousands of surviving examples attest to this technical pre-eminence.

Farther afield, in Bolivia, another major civilization had been developing: the Tiahuanaco world. Its origin and the whole story of its development are not yet fully understood, but it is known that it came to exert a tremendous influence over a wide area of South America from AD 250 to 750. One of its most characteristic qualities was the use of stone—in walled cities, huge doorways with intricately carved panelling, and great paved roads. Tiahuanaco art is a rather angular expression, with repetitive, rather unoriginal motifs. The pottery from this site is equally uninspiring; although strong in colour, it does not show the variety and technical perfection seen in the wares of the nearby Inca and Nazca. Again, the great art is weaving. It seems that in many cultures the attention devoted to the textile arts far overshadowed that devoted to all of the other arts. And so it is with the Tiahuanaco, who produced ponchos, caps, pouches, and other costume pieces that are instantly recognizable wherever seen and challenge the contemporary weaver with their variety, fantastically tight weave, and remarkable richness of colour.

The Inca civilization had begun around AD 1200, but the empire itself was not established until 1438, with the accession of Pachacuti Inca Yupanqui, the greatest of the

Inca rulers. With the arrival of the Spanish in 1532, the empire was at its height but was suffering from a schism that proved fatal in the face of the European attack. So savage was the Spanish invasion that the empire, numbering some 6,000,000 individuals at its height, was left without a head, and, within a period of thirty years, its population had dwindled to 1,500,000. Part of this legacy is that less art survives from the Inca culture than from many of the far older Peruvian cultures; there are many more Tiahuanaco ponchos known than those from the Inca period, for example. Enough has survived, however, to enable scholars to characterize Inca art forms. The aryballus (globular bottle for liquids) is known the world over, and stonework was common and of excellent quality. Silver and gold were no mystery to the Inca: religious tribute was claimed in the form of worked metal, treated as a gift to the sun god. Indeed, it was this very practice that proved the Inca's undoing, for the Spanish treasure seekers abandoned all other pursuits in their greed for precious metals.

In due course, the Inca civilization declined to a point where it was little more than a shell, as it is today. While much of the ancient weaving is still an active art, there is no pottery of a quality similar to the old, nor is there the wealth of woodwork, stone carving, or other crafts products. As for goldwork, it can safely be said that this art is completely in the hands of Westerners.

Chile and Argentina. Farther to the south, as he continued on his long journey past the Peruvian and Bolivian highlands, man crossed the great Atacama wasteland into Chile and, in so doing, changed his aesthetic expressions. This journey probably took place not much before 500 BC, when pottery-making people became active in the south. However late man came, he quickly set up civilizations. Wandering back and forth over the Andes, he settled both Chile, where he was known as Diaguita, and northern Argentina, where he was known as Chalchaquí. Very soon the peoples of this region developed their own arts, some of which are unique. They produced fine pottery and strong, colourful textiles. Gold was never a major product, although copper became an important metal, due in part to its prevalence. The people cast huge copper disks and plaques and made special burial urns for their children, even reserving cemetery areas in a touching demonstration of affection. The period of Diaguita settlement covered about 1500 years, or from about AD 1 to 1500.

With the extension of the Inca Empire into the Chilean and Argentine regions, the ubiquitous aryballus form found its way there, as did other, similar Inca expressions. Indeed, the pottery forms give a clue as to the presence or absence of the Inca overlords.

With the arrival of the Europeans all of this changed.

Western
influence
on South
American
Indian
cultures

Of all of the South American Indian civilizations, only in Ecuador, Peru, Bolivia, and Chile is there anything like a continuum of native arts. And even in these, the Western influence has been so pervasive as to eradicate all but the most dominant aesthetic characteristics. Weaving retains more of its ancestry than perhaps any other art; pottery has taken on much of the Western aura; woodworking is not at all what it was in pre-Columbian times; and very little metalwork is done in what can be called prehistoric design. Although much of the work done today is of highest quality, it reflects more of the tastes and needs of the white man than the Indian.

ARTS OF THE AMERICAN INDIAN PEOPLES IN THE CONTEMPORARY WORLD

In the contemporary art world, American Indian arts occupy a peripheral role. Until the last few decades, the only strong effort to exhibit this art in galleries or museums was made by those few institutions specializing in ethnological, exotic, or art history subjects, together with the rare specialized museum devoted only to Indian materials or to those of the American West. And in these, the usual focus was upon sensational or romantic themes, not upon a carefully balanced understanding of the subject.

The most active interest in American Indian art seems to have been less in products of still-living cultures than in prehistoric arts; and less in the arts of prehistoric North American peoples than in "pre-Columbian art," which is generally understood to mean the works of the so-called high civilizations—notably the Maya, Aztec, Inca, and Mochica. This is to be regretted, for it not only results in an overemphasis that destroys intellectual balance but it also has relegated to the background some of the more ex-

citing aesthetic accomplishments of the native American. The diorite bowl representing a crested wood duck that has been called by some "the Portland vase of America" is not an isolated instance, for there are other fine sculptures equally deserving of attention.

The reasons for these attitudes are not difficult to discover. With the displacement of the Indian by the Westerner came the rejection of his products, other than as curiosities of a vanquished people. Only in the last few decades has there been a concerted effort to develop an appreciation for art and a concern for the survival of this New World heritage.

More active efforts to preserve Indian art have been made in the United States than elsewhere. The first was in the 1920s, when a group of white artists located in and around Santa Fe, New Mexico, found excitement in the work of the Indians of the Southwest. Together with the so-called Taos Colony of artists, these influential people succeeded in bringing the values of Indian art to the attention of the outside world through publications, exhibitions, and their own artworks, in which Indian design often figured predominantly. In time, this group saw to the establishment of a School of Indian Art in Santa Fe. Out of this school came many of the most familiar names in Indian art today. Oqwa Pi, Jack Hokeah, Awa Tsireh, Pablita Velarde, Andy Tsinajinnie, Allan Houser, Ben Quintana, Gerónima Cruz Montoya, Eva Mirabal, and Waldo Mootzka are but a very few of the students involved during this exciting period. Following an initial success, the school enjoyed a period of prosperity, but then fell victim to the Depression.

Another surge of interest came with the enactment of the Indian Reorganization Act of 1934, by means of which the Indian Arts and Crafts Board came into existence. Sparked by John Collier, then commissioner of Indian affairs, this body is one of the few governmental organizations set up specifically to promote, encourage, and revive native arts and crafts. While intended largely as an economic device to increase Indian income, the Board fortunately included members who were knowledgeable about, and sensitive to, the aesthetic and cultural strengths of the Indian. A program of exploration revealed surprising resilience in native crafts, and a core of still-active craftspeople who remembered older techniques was engaged to perpetuate their arts. Out of this program came a renaissance that still continues, even after the Board has become less influential, as the native artist more and more finds himself in his art. What promises to become the major factor influencing Indian art is the Institute of American Indian Arts in Santa Fe, New Mexico, an outgrowth of the early interest of the Indian Arts and Crafts Board in assisting young Indian artists to secure needed training.

Stimulated by these developments, the interest of art museums and collectors in native art brought home to the general public the existence of a remarkable, if overlooked, art form.

Today, a growing interest in Indian cultural expression is found among North American Indians themselves, as they seek their rightful place in contemporary society. Realizing the values in their heritage, and seeing much of it diminishing, many Indians want to learn what they can of their past and salvage what can be preserved.

Perhaps the greatest positive force to appear in some time are the Indian tribal councils, many of which support the arts in their own areas, not only to augment income but also out of an awareness of the cultural value of those arts. Many of these people, particularly the Navajo, Hopi, Cherokee, and Crow, have set up funds to develop crafts areas, sales centres, and museums to promote the appreciation of their traditional arts and thereby strengthen the fabric of the tribe. Some have set up crafts schools so that the younger people will have access to the necessary training.

With so many years of cultural denial, however, the native artist can no longer draw upon his rich heritage freely but must seek an adjustment with Western-derived motifs that have intruded upon, and in some cases overwhelmed, his world. Among all of the North American tribes, painting is perhaps the one art that has taken

a new and positive direction. Many younger Indians of talent are creating remarkable works in acrylic, tempera, oil, and related media, gaining recognition in the fine arts field and showing promise of successful careers in the non-Indian world. Their most serious problem is that of identification. Some prefer to paint in a completely "free" manner, meaning that their work will not necessarily reflect their Indian ancestry. Others remain concerned over the demonstration of the racial or ethnic strain and seek means whereby they can paint in "Indian style" and yet escape the stereotype so prevalent in the minds of most non-Indians.

In other parts of the Western Hemisphere, organizations similar to those in the United States have recently been established to promote native crafts movements. In general, such movements find their greatest support in areas where nationalism is on the rise and pride in one's background is pre-eminent. The Latin-American nation that has taken the most effective steps in this direction has certainly been Mexico; its Museo Nacional de Arqueología (National Museum of Archeology), built in 1964, is perhaps the finest such structure in the world and stands as a monument to the heritage of that country. Guatemala, Colombia, Peru, and Ecuador also have devoted major architectural attention to their native cultures.

(F.J.D.)

BIBLIOGRAPHY

North American peoples and cultures. Some of the more notable general surveys of the American Indians are ALICE B. KEHOE, *North American Indians, A Comprehensive Account* (1981); ROBERT F. SPENCER and JESSE D. JENNINGS *et al.*, *The Native Americans*, 2nd ed. (1977); CLARK WISSLER, *Indians of the United States*, rev. ed. (1966), and *The American Indian: An Introduction to the Anthropology of the New World*, 3rd ed. (1938); H.E. DRIVER, *Indians of North America*, 2nd ed. rev. (1969); A.L. KROEBER, *Cultural and Natural Areas of Native North America* (1939); RUTH M. UNDERHILL, *Red Man's America* (1953); PAUL S. MARTIN, GEORGE I. QUIMBY, and DONALD COLLIER, *Indians Before Columbus* (1947); FRED EGGAN (ed.), *Social Anthropology of North American Tribes*, 2nd ed. (1955); and E.B. LEACOCK and N.O. LURIE (eds.), *North American Indians in Historical Perspective* (1971). An extensive listing of books and articles on particular Indian groups is given in GEORGE P. MURDOCK, *Ethnographic Bibliography of North America*, 3rd ed. (1960). Names, locations, and historical events are summarized in FREDERICK WEBB HODGE (ed.), *Handbook of American Indians North of Mexico*, 2 vol. (1912, reprinted 1968). An encyclopaedic summary of current knowledge, literature, and research is provided by WILLIAM C. STURTEVANT (ed.), *Handbook of North American Indians* (1978-); when complete the work will comprise 20 volumes summarizing knowledge about 11 principal cultural regions north of Mexico, as well as cross-cultural themes such as race relations, technology, languages, biography, and the place of these peoples in contemporary society. An older, but still useful summary is provided by JOHN R. SWANTON, *The Indian Tribes of North America* (1952).

For archaeology and prehistory some useful introductory works are JESSE D. JENNINGS, *Prehistory of North America*, 2nd ed. (1974); DIAMOND JENNESS (ed.), *The American Aborigines* (1933); KENNETH MACGOWAN and J.A. HESTER, JR., *Early Man in the New World* (1962); and H.M. WORMINGTON, *Ancient Man in North America*, 4th ed. (1957). For physical anthropology some important surveys are W.S. LAUGHLIN (ed.), *Papers on the Physical Anthropology of the American Indian* (1951); T.D. STEWART, "A Physical Anthropologist's View of the Peopling of the New World," *SWest. J. Anthropol.* 16:259-273 (1960); and T.D. STEWART and M.T. NEWMAN, "An Historical Résumé of the Concept of Differences in Indian Types," *Am. Anthropol.* 53:19-26 (1951).

American subarctic cultures. Major ethnographic accounts of the pre-fur-trade period include, for the eastern or Algonkian area, FRANK G. SPECK, *Naskapi: The Savage Hunters of the Labrador Peninsula* (1935; reprinted 1977), an account of beliefs, many of which survive into the present; and JOHN J. HONIGMANN, "The Attawapiskat Swampy Cree: An Ethnographic Reconstruction," *Anthrop. Pap. Univ. Alaska*, 5:23-82 (1956). EDWARD S. ROGERS has written fully on pre- and post-contact culture of the Round Lake (Ontario) Ojibwa; see especially *The Round Lake Ojibwa* (1962). For the western or Athabaskan area, JOHN J. HONIGMANN has done an ethnographic reconstruction of *The Kaska Indians* (1954); and CORNELIUS OSGOOD, the leading authority on the Athabascans, reports exhaustively on *Ingalik Material Culture, Ingalik Social Culture, and Ingalik Mental Culture* (1940, 1958, and 1959). *Man in Northeastern North*

America, ed. by FREDERICK JOHNSON (1946), brings together authoritative papers on geography, physical anthropology, linguistics, mythology, psychological characteristics, and culture in general. A study of a northern town, Inuvik, where Indians live, is JOHN J. and IRMA HONIGMANN, *Arctic Townsman* (1970).

Northwest Coast Indians. There are few books that treat Northwest Coast culture on an area-wide basis; among the principal ones are: P. DRUCKER, *Indians of the Northwest Coast* (1963), and *Cultures of the North Pacific Coast* (1965). The former emphasizes material culture, technology, and art; the second, social and ceremonial organization. There are many good descriptions of individual Northwest Coast divisions: A. KRAUSE, *Die Tlinkit-Indianer* (1885; Eng. trans., *The Tlingit Indians*, 1956); V.E. GARFIELD and PAUL S. WINGERT, *The Tsimshian Indians and Their Arts* (1967); T.F. MCILWRAITH, *The Bella Coola Indians*, 2 vol. (1948); FRANZ BOAS, *Kwakwaka'wakw Ethnography*, ed. by H. CODERE (1966); P. DRUCKER, *The Northern and Central Nootkan Tribes* (1951); H.G. BARNETT, *The Coast Salish of British Columbia* (1955); and A.L. KROEBER, chapters on Yurok, Karok, and Hupa in *Handbook of the Indians of California*, 2nd ed. (1953).

Californian Indians. A.L. KROEBER, *Handbook of the Indians of California*, 2nd ed. (1953); ROBERT F. HEIZER and M.A. WHIPPLE (eds.), *California Indians: A Source Book*, 2nd ed. (1971); and EDWARD S. CURTIS, *The North American Indian*, vol. 15-16 (1907, reprinted 1970), provide the most general summaries of native California cultures, although each source is not wholly representative of the latest thoughts. More recent accounts appear in various publications of the University of California, such as *Anthropological Records*, *University of California Publications in American Archaeology and Ethnology*, and the *Reports of the University of California Archaeological Research Facility*. Many new interpretations of native California cultures are also contained in the *Annual Reports of the Archaeological Survey of the University of California at Los Angeles*. Several books of interest are RAYMOND C. WHITE, *Luiseño Social Organization* (1963); LOWELL JOHN BEAN, *Mukat's People* (1972); JACK D. FORBES, *Native Americans of California and Nevada* (1968); and ROBERT F. HEIZER and ALAN ALMQUIST, *The Other Californians* (1971). Books recently prepared for the nonspecialist, which are very readable, are THEODORA KROEBER, *Ishi i tuã världar* (1963; Eng. trans., *Ishi in Two Worlds*, 1964); and ROBERT F. HEIZER and THEODORA KROEBER, *Almost Ancestors* (1968). B.W. and E.G. AGINSKY, *Deep Valley* (1967), provides a readable fictional account of the Pomo Indians.

North American Plateau Indians. The archaeological background has been described by E.H. SWANSON, *The Emergence of Plateau Culture* (1962); and B.R. BUTLER, *The Old Cordilleran Culture in the Pacific Northwest* (1961). A noteworthy paper is R.D. DAUGHERTY, *Archaeology of the Lind Coulee Site, Washington* (1956). General ethnological perspectives have been presented in two papers by V.F. RAY, *Cultural Relations in the Plateau of Northwestern America* (1939) and *Culture Element Distributions*, pt. 22, *Plateau* (1942). There are several good monographs on single tribes: J.A. TEIT, *The Thompson Indians of British Columbia* (1900); H.J. SPINDEN, *The Nez Percé Indians* (1908); LESLIE SPIER, *Klamath Ethnography* (1930); V.F. RAY, *The Sanpoil and Nespelem: Salishan Peoples of Northeastern Washington* (1932); and the work edited by LESLIE SPIER, *The Sinkaitk or Southern Okanagon of Washington* (1938). Demographic, linguistic, and sociopolitical analyses may be found in V.F. RAY, "Native Villages and Groupings of the Columbia Basin," *Pacif. NW. Q.*, 27:99-152 (1936); T.R. GARTH, "Early Nineteenth Century Tribal Relations in the Columbia Plateau," *SWest. J. Anthropol.*, 20:43-57 (1964); and W.W. ELMENDORF, "Linguistic and Geographic Relations in the Northern Plateau Area," *ibid.*, 21:63-78 (1965). Kinship systems are discussed in M. JACOBS, "Northern Sahaptin Kinship Terms," *Am. Anthropol.*, 34:688-693 (1932); and W.W. ELMENDORF, "System Change in Salish Kinship Terminologies," *SWest. J. Anthropol.*, 17:365-382 (1961). LESLIE SPIER, *The Prophet Dance of the Northwest and Its Derivatives: The Source of the Ghost Dance* (1935), has become a classic, but must now be checked against D.E. WALKER, JR., "New Light on the Prophet Dance Controversy," *Ethnohistory*, 16:245-256 (1969). Modern culture contact problems are dealt with in a skilful way in D.E. WALKER, *Conflict and Schism in Nez Percé Acculturation* (1968).

North American Great Basin Indians. There is no general monograph on all Great Basin Indians. CATHERINE S. FOWLER, *Great Basin Anthropology: A Bibliography* (1970), lists some 6,500 sources on the area. Summary articles on various aspects of Great Basin anthropology are contained in W.L. D'AZEVEDO *et al.* (eds.), *The Current Status of Anthropological Research in the Great Basin: 1964* (1966); and in E.H. SWANSON, JR. (ed.), *Languages and Cultures of Western North America* (1970). The earliest systematic study of Great Basin Indians was by JOHN WESLEY POWELL; see D.D. and C.S. FOWLER (eds.), *Anthropol-*

ogy of the Numa: John Wesley Powell's Manuscripts on the Numic Peoples of Western North America, 1868-1880 (1971). Modern ethnographic studies include J.H. STEWARD, *Basin-Plateau Aboriginal Sociopolitical Groups* (1938); R.H. LOWIE, *Notes on Shoshonean Ethnography* (1924); R.F. and Y. MURPHY, *Shoshone-Bannock Subsistence and Society* (1960); V.C. TRENHOLM and M. CARLEY, *The Shoshonis: Sentinels of the Rockies* (1964); JAMES F. DOWNS, *The Two Worlds of the Washo, an Indian Tribe of California and Nevada* (1966); and I.T. KELLY, *Southern Paiute Ethnography* (1964). Religious beliefs are treated by W.Z. PARK, *Shamanism in Western North America* (1938); and B.B. WHITING, *Paiute Sorcery* (1950). Important linguistic studies include E. SAPIR, *Southern Paiute Texts and Dictionary* (1930-31); W.H. JACOBSEN, JR., "Washo Linguistic Studies," and W.R. MILLER, "Anthropological Linguistics in the Great Basin," both in W.L. D'AZEVEDO (ed.), *Great Basin Prehistory* is summarized in J.D. JENNINGS, "The Desert West" in J.D. JENNINGS and E. NORBECK (eds.), *Prehistoric Man in the New World*, pp. 149-174 (1964).

Southwest American Indians. EDWARD H. SPICER, *Cycles of Conquest: The Impact of Spain, Mexico, and the United States on the Indians of the Southwest, 1533-1960* (1962); and FRED EGGAN, *The American Indian*, ch. 5 (1966), are the most comprehensive, authoritative accounts. Among other significant studies of the region as a whole are: EMIL W. HAURY (ed.), "The Southwest Issue," *Am. Anthropol.*, 56:529-731 (1954); JOHN COLLIER, *Patterns and Ceremonials of the Indians of the Southwest* (1949); RUTH M. UNDERHILL, *Ceremonial Patterns in the Greater Southwest* (1948); ELSIE CLEWS PARSONS, *Pueblo Indian Religion* (1939); RUTH BENEDICT, "Psychological Types in the Cultures of the Southwest," in the *Proceedings of the Twenty-Third International Congress of Americanists*, pp. 572-581 (1930); and GEORGE FRANCIS CARTER, *Plant Geography and Culture History in the American Southwest* (1945). Recommended tribal studies are: for the Yumans, C. DARYLL FORDE, *Ethnography of the Yuma Indians* (1931); and LESLIE SPIER, *Yuman Tribes of the Gila River* (1933, reprinted 1970); for the Pima-Papago, WILLIAM H. KELLY, *The Papago Indians of Arizona* (1963); RUTH M. UNDERHILL, *Singing for Power* (1938, reprinted 1968); and ALICE JOSEPH, R.B. SPICER, and J. CHESKY, *The Desert People* (1949); for the Pueblos, FRED EGGAN, *Social Organization of the Western Pueblos* (1950); EDWARD P. DOZIER, *The Pueblos of the Southwestern United States* (1960); ALFONSO ORTIZ, *The Tewa World* (1969); CHARLES H. LANGE, *Cochiti* (1960); DOROTHEA C. LEIGHTON and J. ADAIR, *People of the Middle Place: A Study of the Zuni Indians* (1963); and LAURA THOMPSON and ALICE JOSEPH, *The Hopi Way* (1944, reprinted 1965). Other viewpoints regarding Pueblo personality development are found in ESTHER S. GOLDFRANK, "Socialization, Personality, and the Structure of Pueblo Society (with Particular Reference to Hopi and Zuni)," *Am. Anthropol.*, 47:516-539 (1945); and DOROTHY EGGAN, "General Problem of Hopi Adjustment," *Am. Anthropol.*, 45:357-373 (1943). Recommended for the Navajo are CLYDE KLUCKHOHN and DOROTHEA LEIGHTON, *The Navaho* (1946); DOROTHEA LEIGHTON and CLYDE KLUCKHOHN, *Children of the People* (1947, reprinted 1969); for the Apache, MORRIS OPLER, *An Apache Life-Way* (1941).

North American Plains Indians. ROBERT H. LOWIE, *Indians of the Plains* (1963), is a short but authoritative general work. Accounts of particular tribes include: Lowie's *The Crow Indians* (1935); ALFRED W. BOWERS, *Mandan Social and Ceremonial Organization* (1950) and *Hidatsa Social and Ceremonial Organization* (1965); ALICE C. FLETCHER and FRANCIS LAFLESCHÉ, *The Omaha Tribe* (1911); JOHN C. EWERS, *The Blackfeet* (1958); GEORGE B. GRINNELL, *The Cheyenne Indians*, 2 vol. (1923); and E. WALLACE and E.A. HOEBEL, *The Comanches* (1952). GEORGE P. MURDOCK, *Ethnographic Bibliography of North America* (1960), covers the Plains in general and each tribe specifically. Records by early observers include JEAN LOUIS BERLANDIER, *The Indians of Texas in 1830*, ed. by JOHN C. EWERS (1969); and GEORGE CATLIN, *North American Indians*, 2 vol. (1926). GORDON MACGREGOR, *Warriors Without Weapons* (1946), is a study of the society and personality of the Teton Dakota under reservation conditions.

Eastern Woodlands Indians. Names, locations, and historical events are summarized in FREDERICK WEBB HODGE (ed.), *Handbook of American Indians, North of Mexico*, 2 vol. (1907-10); and JOHN R. SWANTON, *The Indian Tribes of North America* (1952). Indian cultures of the area are summarized in ROBERT E. and PAT RITZENTHALER, *The Woodland Indians of the Western Great Lakes* (1970); W. VERNON KINIEZ, *The Indians of the Western Great Lakes, 1615-1760* (1940); and in general surveys of North American Indians as listed above. Descriptions of particular cultures include: FRANK G. SPECK, *Penobscot Man: The Life History of a Forest Tribe in Maine* (1940); W.D. and R.S. WALLIS, *The Micmac Indians of Eastern Canada* (1955); ROGER WILLIAMS, *A Key into the Language of America* (1643, reprinted 1971), despite its formidable title a delightful book and the best

description of a southern New England Indian people; ALDEN T. VAUGHAN, *New England Frontier: Puritans and Indians, 1620-1675* (1965); WILLIAM W. NEWCOMB, JR., *The Culture and Acculturation of the Delaware Indians* (1956); LEWIS H. MORGAN, *League of the Ho-de-no-sau-nee, or Iroquois* (1851, reprinted 1966); GEORGE T. HUNT, *The Wars of the Iroquois* (1940); ANTHONY F.C. WALLACE, *The Death and Rebirth of the Seneca* (1970); ELISABETH TOOKER, *An Ethnography of the Huron Indians, 1615-1649* (1964); BRUCE G. TRIGGER, *The Huron Farmers of the North* (1969); PAUL RADIN, *The Winnebago Tribe* (1923); WALTER JAMES HOFFMAN, *The Menomini Indians* (1896); RUTH LANDES, *Ojibwa Sociology* (1937, reprinted 1969); WILLIAM T. HAGAN, *The Sac and Fox Indians* (1958); and BERT ANSON, *The Miami Indians* (1970). Modern reservation life is described in EDMUND WILSON, *Apologies to the Iroquois* (1960); and FREDERICK O. GEARING, *The Face of the Fox* (1970).

Southeast American Indians. JOHN R. SWANTON, *The Indians of the Southeastern United States* (1946), is the standard starting point for information on the traditional cultures of the Southeast. Other indispensable works by Swanton are *Indian Tribes of the Lower Mississippi Valley and Adjacent Coast of the Gulf of Mexico* (1911), *Early History of the Creek Indians and Their Neighbors* (1922, reprinted 1970), *Social Organization and Social Usages of the Indians of the Creek Confederacy* (1928), *Religious Beliefs and Medical Practices of the Creek Indians* (1928), *Social and Religious Beliefs and Usages of the Chickasaw Indians* (1928), *Myths and Tales of the Southeastern Indians* (1929), *Source Material for the Social and Ceremonial Life of the Choctaw Indians* (1931), and *Source Material on the History and Ethnology of the Caddo Indians* (1942). A later summary is provided by CHARLES HUDSON, *The Southeastern Indians* (1976). Also valuable are various works by FRANK G. SPECK, including, *The Creek Indians of Taskigi Town* (1907), *Ethnology of the Yuchi Indians* (1909), and, with LEONARD BROOM, *Cherokee Dance and Drama* (1951). JAMES MOONEY, *Myths of the Cherokee* (1900), remains the basic source on the Cherokee and may be usefully supplemented by WILLIAM H. GILBERT, *The Eastern Cherokees* (1943). For the Seminoles, CLAY MACCAULEY, *The Seminole Indians of Florida* (1887); ALEXANDER SPOEHR, *Camp, Clan and Kin Among the Cow Creek Seminole of Florida* (1941), and *The Florida Seminole Camp* (1944); and various articles by WILLIAM C. STURTEVANT, referred to in his essay "Creek into Seminole" in E.B. LEACOCK and N.O. LURIE (eds.), *North American Indians in Historical Perspective* (1971), provide basic background. For the piedmont tribes, see JAMES MOONEY, *The Siouan Tribes of the East* (1894); and recent works by DOUGLAS S. BROWN, *The Catawba Indians* (1966); and CHARLES M. HUDSON, *The Catawba Nation* (1970).

On more specialized topics, MARY R. HAAS, "Southeastern Indian Linguistics," in C.M. HUDSON (ed.), *Red, White, and Black* (1971), is an important review of linguistic relations; WILLIAM C. STURTEVANT, *The Significance of Ethnological Similarities Between Southeastern North America and the Antilles* (1960), clears up some difficult issues; EMMA L. FUNDABURK and MARY D.F. FOREMAN, *Sun Circles and Human Hands* (1957), provides fine illustrations and commentary on prehistoric and historic Southeastern art; JOHN WITTHOFT, *Green Corn Ceremonialism in the Eastern Woodlands* (1949), is an important contribution to Southeastern religion; as is JAMES H. HOWARD, *The Southeastern Ceremonial Complex and Its Interpretation* (1968). Many detailed scholarly works exist on the post-contact history of the Southeastern Indians, among which might be mentioned GRANT FOREMAN, *The Five Civilized Tribes* (1934, reprinted 1971), and *Indian Removal* (1932); ANGIE DEBO, *And Still the Waters Run* (1940, reprinted 1966), and *The Rise and Fall of the Choctaw Republic* (1934); ROBERT S. COTTERILL, *The Southern Indians* (1954); VERNER CRANE, *The Southern Frontier, 1670-1732* (1929); DAVID H. CORKRAN, *The Cherokee Frontier* (1962), and *The Creek Frontier* (1967); and THURMAN WILKINS, *Cherokee Tragedy* (1970).

Middle American peoples and cultures. The most authoritative work on Middle America is the monumental *Handbook of Middle American Indians*, ed. by ROBERT WAUCHOPE, 16 vol. (1964-76). These volumes cover all aspects of the area from physical geography, linguistics, archaeology, physical anthropology, and ethnology to social anthropology. ERIC WOLF, *Sons of the Shaking Earth* (1959), is the best single book on Middle America. SOL TAX (ed.), *Heritage of Conquest* (1952), is a professional anthropological estimate of the content of Middle American Indian culture. *The Maya and Their Neighbors* (1940) is an introduction to the archaeological and historical problems of the region and contains the basic essay on Indian history by OLIVER LA FARGE. S.G. MORLEY, *The Ancient Maya*, 3rd rev. ed. (1956); J. ERIC THOMPSON, *The Rise and Fall of Maya Civilization*, 2nd ed. (1970); and MICHAEL D. COE, *The Maya* (1966), give views on that civilization. G.C. VAILLANT, *The Aztecs of Mexico*, rev. ed. (1956), is a basic book; and H.J.

SPINDEN, *Ancient Civilizations of Mexico and Central America*, 3rd rev. ed. (1968), is important for its calendrical correlations. For an understanding of the colonial period, the works of BERNARDINO DE SAHAGUN, trans. by A.J.O. ANDERSON and C.E. DIBBLE, *The Florentine Codex*, pt. 9–10 (1959); and A.M. TOZZER's annotated translation of Landa's *Relación de las cosas de Yucatán* (1941), is essential. For historical accounts, see R.N. ADAMS, *Crucifixion by Power: Essays on Guatemalan National Social Structures, 1944–1966* (1970); GEORGE M. MCBRIDE, *The Land Systems of Mexico* (1923, reprinted 1971); FRANÇOIS CHEVALIER, *La Formation des grands domaines au Mexique* (1952; Eng. trans., *Land and Society in Colonial Mexico: The Great Hacienda*, 1963); and NATHAN L. WHETTEN, *Rural Mexico* (1948), give an adequate picture. The modern studies in Middle American communities are listed in HOWARD CLINE, "Mexican Community Studies," *Hispanic American Historical Review*, 32:212–242 (1952); and in R.H. EWALD, *Bibliografía comentada sobre antropología social guatemalteca, 1900–1955* (1956). Modern developments are described in J.L. ARRIOLA (ed.), *Integración social en Guatemala* (1956); W.E. MOORE, *Industrialization and Labor* (1951); and by R.N. ADAMS in *Political Changes in Guatemalan Indian Communities* (1957).

North Mexican Indian cultures. CARL LUMHOLTZ, *Unknown Mexico*, 2 vol. (1902), gives the first modern account of North Mexican groups and is still a major source. Another excellent source is EVON Z. VOGT (ed.), *Handbook of Middle American Indians*, vol. 8 (1969), which contains articles covering each of the groups. A basic source on the history, cultural geography, and ethnography are the following bulletins of the *Ibero-Americana* series that cover western Mexico in depth: RALPH L. BEALS, *Comparative Ethnology of Northern Mexico Before 1750* (1932), *Acaxee: A Mountain Tribe of Durango and Sinaloa* (1933), and *Aboriginal Culture of the Cáhita Indians* (1943); CARL O. SAUER, *Distribution of Aboriginal Tribes and Languages in Northwestern Mexico* (1934), and *Aboriginal Population of Northwestern Mexico* (1935); ALFRED L. KROEBER, *Uto-Aztecan Languages of Mexico* (1934); EDWARD SPICER, *Cycles of Conquest: The Impact of Spain, Mexico, and the United States on the Indians of the Southwest, 1533–1960* (1962), presents the only overview of change since colonial times. CAMPBELL W. PENNINGTON, *The Tarahumara of Mexico* (1963), and *Tepehuan of Chihuahua* (1969), are very good for material culture and ethnogeography of the northern sierra. CARL LUMHOLTZ, *Symbolism of the Huichol Indians* (1900), furnishes much on Huichol gods and belief, as does R.M. ZINGG, *The Huichol: Primitive Artists* (1938). A definitive work on Cora religion is found in K.T. PREUSS, *Die Nayarit-Expedition* (1912), in German.

Meso-American Indian cultures. SOL TAX (ed.), *Heritage of Conquest: The Ethnology of Middle America* (1952, reprinted 1968), includes Paul Kirchhoff's ground-breaking article "Mesoamerica" and is the best early synthesis of ethnographic information on the area. A comprehensive statement on all aspects of the subject is found in ROBERT WAUCHOPE (ed.), *Handbook of Middle American Indians*, 16 vol. (1964–76). Volumes 4 and 11 of THOMAS A. SEBEOK (ed.), *Current Trends in Linguistics* (1968 and 1972), provide the latest syntheses of linguistic relationships. Ethnographic material includes: RALPH L. BEALS, *The Ethnology of the Western Mixe* (1945); GEORGE M. FOSTER, *Empire's Children: The People of Tzintzuntzan* (1948); ROBERT REDFIELD, *A Village That Chose Progress: Chan Kom Revisited* (1950, paperback 1962); WILLIAM MADSEN, *The Virgin's Children: Life in an Aztec Village Today* (1960); OSCAR LEWIS, *Life in a Mexican Village: Tepoztlán Restudied* (1963); EVON Z. VOGT, *Zinacantan: A Maya Community in the Highlands of Chiapas* (1969); and PHILLIP BAER and WILLIAM R. MERRIFIELD, *Two Studies on the Lacandonos of Mexico* (1971). Linguistic descriptions include: RICHARD S. PITTMAN, *A Grammar of Tetelcingo (Morelos) Nahuatl* (1954); VELMA B. PICKETT, *The Grammatical Hierarchy of Isthmus Zapotec* (1960); JOSEPH E. GRIMES, *Huichol Syntax* (1964); MARVIN K. MAYERS (ed.), *Languages of Guatemala* (1966); H. HARWOOD HESS, *The Syntactic Structure of Mezquital Otomi* (1968); WILLIAM R. MERRIFIELD, *Palantla Chinantec Grammar* (1968); and MARION M. COWAN, *Tzotzil Grammar* (1969).

Central American and Northern Andean cultures. A comprehensive work is JULIAN H. STEWARD (ed.), *Handbook of South American Indians*, vol. 4, *The Circum-Caribbean Tribes* (1948). JULIAN H. STEWARD and LOUIS C. FARON, *Native Peoples of South America* (1959), provides a convenient summary and relates the peoples of the area to their neighbours. On the prehistoric and early historic periods, useful articles appear in GORDON F. EKHOLM and GORDON R. WILLEY (eds.), *Handbook of Middle American Indians*, vol. 4, *Archaeological Frontiers and External Connections* (1966).

South American peoples and cultures. JULIAN H. STEWARD (ed.), *Handbook of South American Indians*, 7 vol. (1946–59), is a monumental compilation of articles on South Ameri-

can ethnography, archaeology, physical anthropology, and languages. JULIAN H. STEWARD and LOUIS C. FARON, *Native Peoples of South America* (1959), is a synthesis and updating of the *Handbook* written in a consistent theoretical framework. LOUIS C. FARON, *Mapuche Social Structure* (1961), is a study of the reintegration of these people of Chile since the time of conquest.

Andean cultures. The best account of Andean cultures as they appeared to an eyewitness of the early years (16th century) of European rule is PEDRO DE CIEZA DE LEON, *Crónica del Perú* (Eng. trans., *The Incas*, 1959). The earliest periods of human occupation are covered by R.S. MACNEISH, "Early Man in the Andes," *Scient. Am.*, 224:36–55 (1971). For an introduction to Andean archaeology, see JOHN HOWLAND ROWE and DOROTHY MENZEL (eds.), *Peruvian Archaeology* (1967), with selections mainly by American scholars. The role of irrigation in the cultural and political elaboration of coastal kingdoms is well illustrated in PAUL KOSOK, *Life, Land, and Water in Ancient Peru* (1965). Special regional problems are introduced in BETTY MEGGER, *Ecuador* (1966); and DONALD LATHRAP, *The Upper Amazon* (1970). Information on the Southern Andes is included in JULIAN H. STEWARD and LOUIS C. FARON, *Native Peoples of South America*, ch. 10 (1959); and in LOUIS C. FARON, *Hawks of the Sun* (1964).

South American tropical forest cultures. JULIAN H. STEWARD (ed.), *Handbook of South American Indians*, 7 vol. (1946–59), includes description and interpretation of the native cultures of the tropical forest; an abridged version is JULIAN H. STEWARD and LOUIS C. FARON, *Native Peoples of South America* (1959). JANICE H. HOPPER (ed.), *Indians of Brazil in the Twentieth Century* (1967), is a collection of essays by American and Brazilian specialists. BETTY J. MEGGERS, *Amazonia: Man and Culture in a Counterfeit Paradise* (1971), is a comparative study of Amazonian tribes and their adaptation to the natural environment. More specialized works include GERARDO REICHELDMATOFF, *Desana: simbolismo de los indios tukano del Vaupés* (1968; Eng. trans., *Amazonian Cosmos: The Sexual and Religious Symbolism of the Tukano Indians*, 1971); IRVING GOLDMAN, *The Cubeo: Indians of the Northwest Amazon* (1963); and ALLAN R. HOLMBERG, *Nomads of the Long Bow: The Siriono of Eastern Bolivia* (1950). The complex social organization of the Ge tribes is studied in CURT NIMUENDAJU, *The Apinayé* (1939, reprinted 1967), *The Šerente* (1942), and *The Eastern Timbira* (1946); and in DAVID MAYBURY-LEWIS, *Akwẽ-Shavante Society* (1967). A general view of the religious ideas of indigenous peoples may be found in RAFAEL KARSTEN, *Studies in the Religion of the South-American Indians East of the Andes* (1964). Acculturation among tribes in contact with whites is discussed in CHARLES WAGLEY and EDUARDO GALVAO, *The Tenetehara Indians of Brazil: A Culture in Transition* (1949, reprinted 1969); ROBERT F. MURPHY, *Mundurucú Religion* (1958), and *Headhunter's Heritage: Social and Economic Change Among the Mundurucú Indians* (1960); and JAMES B. WATSON, *Cayua Culture Change: A Study in Acculturation and Methodology* (1952).

South American nomad cultures. JULIAN H. STEWARD (ed.), *Handbook of South American Indians*, vol. 1, *The Marginal Tribes* (1946), is the outstanding authoritative work. JULIAN H. STEWARD and LOUIS C. FARON, *Native Peoples of South America* (1959), is a one-volume work summarizing the material in the handbook for the lay reader. ALLAN R. HOLMBERG, *Nomads of the Long Bow: The Siriono of Eastern Bolivia* (1950; paperback ed., 1969), is the best work on these people, a good example of the forest nomads. KALERVO OBERG, *The Terena and Caduveo of Southern Mato Grosso, Brazil* (1949), is a Smithsonian Institution monograph that includes an account of the Caduveo, a sub-tribe of the once powerful Mbaya. OBERG, *Indian Tribes of Northern Mato Grosso, Brazil* (1953), includes a short account of the Nambikwara.

Arts of the American Indian peoples. *Literature:* (North America—United States and Canada): VIRGINIA ARMSTRONG (comp.), *I Have Spoken: American History Through the Voices of the Indians* (1971), a graphic résumé of Indian oratory from the 17th to the 20th century, emphasizing the eloquent speech of the tribes of North America; JOHN BIERHORST (comp.), *In the Trail of the Wind* (1971), a survey of American Indian poetry from many tribes; W.P. CLARK, *The Indian Sign Language*, . . . (1885, reprinted 1959), an early study, but one of the most complete, of this system of visual communication; JESSIE CORNPLANTER, *Legends of the Longhouse* (1938), oral traditions of the Seneca as set down and illustrated by an Iroquois artist-writer; GEORGE W. CRONYN (ed.), *The Path of the Rainbow: An Anthology of Songs and Chants from the Indians of North America*, new ed. (1934; reprinted as *American Indian Poetry*, 1970), a volume of Indian poetry from many tribes; A. GROVE DAY, *The Sky Clears: Poetry of the American Indians* (1951), a compilation of American Indian poetry, including more than 200 poems and lyrics from 40 tribes; WALTER DYK, *The Son of Old Man Hat:*

A Navaho Autobiography (1938, reprinted 1967), a classic work recounting a Navajo's life story in his own words; HORATIO HALE (ed.), *The Iroquois Book of Rites* 1883, reprinted 1963), ancient ceremonies as revealed by two aboriginal "manuscripts" discovered at Grand River, with insights into Iroquois social and political life; CHARLES HAYWOOD, *A Bibliography of North American Folklore and Folksong*, 2nd rev. ed., 2 vol. (1961), a remarkable compilation, extremely valuable to anyone interested in American Indian oral literature; ARLENE B. HIRSCHFELDER, *American Indian Authors: A Representative Bibliography* (1970), an extensive listing of oral and written literature authored by persons of Indian descent; MELVILLE JACOBS, *The Content and Style of an Oral Literature: Clackamas Chinook Myths and Tales* (1959), a discussion of a method by which oral literature can be understood in terms of its own content; LOUIS T. JONES, *Aboriginal American Oratory* (1965), a collection of Indian speeches and orations; GARRICK MALLERY, *Picture-Writing of the American Indians* (1893), an exhaustive consideration of the visual forms of communication adopted by many tribes, particularly strong in Plains Indian research. GUY MARY-ROUSSELIERE, *Beyond the High Hills* (1971), a sensitive collection of poems from the Hudson Bay Eskimo people, illustrated by photographs; KAREN PETERSEN, *Howling Wolf: A Cheyenne Warrior's Graphic Interpretation of His People* (1968), a pictorial history of the Cheyenne Indians, based on a collection of drawings by an artist-historian; PAUL RADIN, *The Road of Life and Death* (1945), a translation of the sacred rituals of the Winnebago, from their origin to their death and reincarnation; LEO W. SIMMONS (ed.), *Sun Chief: The Autobiography of a Hopi Indian* (1942), a revealing life story depicting the contrast of cultures within the experience of a single individual; STANDS IN TIMBER, JOHN and MARGOT LIBERTY, *Cheyenne Memories* (1967), a systematic collection of tribal history recording early Cheyenne life, by an Indian historian; SARAIN STUMP, *There Is My People Sleeping* (1970), a book of poems by a young Cree-Shoshoni artist; STITH THOMPSON (ed.), *Tales of the North American Indians* (1929, reprinted 1966), one of the earlier and more complete studies of American Indian legend; JUDITH C. ULLOM, *Folklore of the North American Indians* (1969), a collection of titles largely of popular versions but including some excellent analysis of folktales, their distribution, and place in the culture, with special attention given to children's literature; W.C. VANDERWERTH (comp.), *Indian Oratory: Famous Speeches by Noted Indian Chieftains* (1971), a collection of orations by 37 individuals, recorded from 1750 to 1910; JAMES WELCH, *Riding the Earthboy 40* (1971), poems by a Blackfoot youth, reflecting sound knowledge of his people, as related in vibrant terms. (Mexico, Central America, and South America): MIGUEL LEON-PORTILLA, *Las literaturas precolombinas de México* (1964; Eng. trans., *Pre-Columbian Literatures of Mexico*, 1969), a selection of myths, hymns, poetry, and prose accounts from Aztec, Maya, Mixtec-Zapotec, and Otomí peoples of Mexico recorded and discussed in depth; ADRIAN RECINOS (trans.), *Popol Vuh: The Sacred Book of the Ancient Quiché Maya* (1950), a complete version of the most important example of Maya literature to survive the conquest; FRANCES GILLMOR, *Flute of the Smoking Mirror: A Portrait of Nezahualcoyotl, Poet-King of the Aztecs* (1949, reprinted 1968), a sensitive portrayal of a major Nahuatl ruler, reflecting the thought processes of the Aztec as expressed through ancient graphic documents; RALPH L. ROYS (trans.), *The Book of Chilam Balam of Chumayel*, new ed. (1967), an account by the prophet of Chumayel village recorded in 1782, rich in Mayan ritual and oral traditions.

Music: PAUL COLLAER (ed.), *Amerika: Eskimo und indianische Bevölkerung*, 2 vol. (1967; Eng. trans., *Music of the Americas: An Illustrated Ethnology of the Eskimos and American Indian Peoples*, 1971), a magnificently illustrated study of the forms and instruments of the aborigines of the New World. (North America—United States and Canada): FREDERICK R. BURTON, *American Primitive Music* (1909, reprinted 1969), an important book because of its early exposition of the little known Garden River Reserve area in Ontario and for its transcriptions of Indian hymnody; WALLACE L. CHAFE, *Seneca Thanksgiving Rituals* (1961), a painstaking transcription of texts and melodies by a musically trained linguist; NATALIE CURTIS-BURLIN (ed.), *The Indians' Book* (1907), a pioneering collection of many tribal tunes, written down by ear and lucidly presented; FRANCES DENSMORE, *The American Indians and Their Music* (1926), one of the first major studies of the subject that combined anthropological knowledge with sound musical training to produce a well-organized ethnomusicology.

Chippewa Music, 2 vol. (1910–13); *Teton Sioux Music* (1918); *Menominee Music* (1932); and *Music of Santo Domingo Pueblo, New Mexico* (1938), particularly important books by Densmore, a pioneer who spent a lifetime salvaging the lore of one tribe after another, transcribing tunes from recordings—early cylinders, then discs, of poor fidelity but of inestimable cultural value; CHARLES HAYWOOD (op. cit.), an exhaustive

volume, with remarkably detailed consideration of the various areas of American Indian music; GEORGE HERZOG, *Research in Primitive and Folk Music in the United States* (1936), a useful survey by a pioneer musicologist; GERTRUDE P. KURATH, *Iroquois Music and Dance* (1964), transcription and analysis of many Seneca songs, from recordings by William N. Fenton and Martha Huot, with dance diagrams and interpretations from the author's field work; and "Dogrib Choreography and Music," in JUNE HELM MACNEISH and NANCY O. LURIE, "The Dogrib Hand Game," *Bull. Natn. Mus. Can.*, no. 205, pp. 13–28 (1966), transcription, analysis, and choreography; BERNARD S. MASON, *Drums, Tomtoms and Rattles* (1938), a practical book on North American instruments; DAVID P. MCALLESTER, *Peyote Music* (1949), transcription and interpretation of the songs used in this semi-Christian, nativistic cult; and *Enemy Way Music* (1954), one of the few books with musical scores of a Navajo curative rite, with valuable material on native aesthetic concepts; ALAN P. MERRIAM, *Ethnomusicology of the Flathead Indians* (1967), an exhaustive study of the music of a Montana tribe, with musical scores, analyses, and historical notes by an anthropologist; BRUNO NETTL, *Music in Primitive Culture* (1956), and *North American Indian Musical Styles* (1954), representative works by a prolific ethnomusicologist with anthropological as well as musical training, including selected musical scores and bibliographies. HELEN H. ROBERTS, *Musical Areas in Aboriginal North America* (1936), one of the earliest attempts to divide American Indian into its geographical subdivisions; and with DIAMOND JENNESS, *Songs of the Copper Eskimos* (1925); and with MORRIS SWADESH, *Songs of the Nootka Indians of Western Vancouver Island* (1955), two painstaking works with detailed musical scores and background notes by collaborators; FRANK G. SPECK, *Ceremonial Songs of the Creek and Yuchi Indians* (1911), and *Penobscot Man* (1940), two reliable books by an anthropologist, with musical scores by JACOB SAPIR (also contains comments on dance). (Mexico, Central America, and South America): GILBERT CHASE, *A Guide to the Music of Latin America*, 2nd ed. rev. (1962), an indispensable bibliography; RAOUL and M. D'HARCOURT, *La Musique des Incas et ses survivances*, 2 vol. (1925), still one of the most exhaustive studies of the ancient Inca and his music, and its present-day place in South America; KARL GUSTAV IZIKOWITZ, *Musical and Other Sound Instruments of the South American Indians* (1935), a remarkable compilation of facts on the forms and functions of instruments; SAMUEL MARTI, *Canto, danza y música precortesianos* (1961), a well-illustrated study of the subject by one of Mexico's foremost ethnomusicologists; and *Instrumentos musicales precortesianos* (1955), a valuable description of native instruments, past and present, with excellent photographs, scales of prehistoric flutes, and notations of native South American and Middle American tunes; CHARLES W. MEAD, *The Musical Instruments of the Inca* (1924), an illustrated examination of various Peruvian examples, largely from the American Museum of Natural History collections; SEGUNDO L. MORENO, *La música de los Incas* (1957), a well-rounded survey, written by an Ecuadorean ethnomusicologist, of the ancient and contemporary Inca musical world; ROBERT STEVENSON, *Music in Aztec and Inca Territory* (1968), a major survey of attitudes toward ancient music, its instrumentation, and social position in the two areas at the time of the conquest.

Recordings are available in vast numbers. The public has access to the commercial albums of the Library of Congress, Ethnic Folkways, Canyon Records, and to vast archives, such as the National Museum of Canada, the Wenner-Gren Foundation for Anthropological Research, the American Philosophical Society, and Indiana University.

Dance: (North America—Canada and the United States): JULIA M. BUTTREE-SETON, *The Rhythm of the Red Man* (1930), choreographies, some music; FREDERICK J. DOCKSTADER, *The Kachina and the White Man: A Study of the Influences of White Culture on the Hopi Kachina Cult* (1954), a survey on the origin of Pueblo masked dances and their development among the Hopi people of Arizona; BESSIE and MAY G. EVANS, *American Indian Dance Steps* (1931), descriptions of steps, six choreographies, and music; WILLIAM N. FENTON and GERTRUDE P. KURATH, *The Iroquois Eagle Dance: An Offshoot of the Calumet Dance* (1935), history, choreographies, music, analysis, photographs, and bibliography; ERNA FERGUSSON, *Dancing Gods* (1931), an evaluation of ceremonial dances of the Indians of the Southwest; ALICE C. FLETCHER, *Indian Games and Dances with Native Songs* (1915), a combined study of games, songs, and dances, useful to younger readers; CHARLES HAYWOOD (op. cit.), bibliography primarily of mythology and music, with a considerable section devoted to works on the dance; GERTRUDE P. KURATH, *Michigan Indian Festivals* (1966), history, choreography, music, photographs, and bibliography; *Iroquois Music and Dance* (1964), diagrams, choreography, music, analysis, and photographs; and *Music and Dance*

of the Tewa Pueblos (1970), background, choreography, music, photographs, and bibliography; BERNARD S. MASON, *Dances and Stories of the American Indian* (1944), almost entirely concerned with North American Indian dance steps, forms, and costumes (well illustrated); VIRGINIA M. ROEDIGER, *Ceremonial Costumes of the Pueblo Indians* (1941), a superbly illustrated volume, dealing with all Pueblo tribes and their ritual dress, including dance costumes; CURT SACHS, *Eine Weltgeschichte des Tanzes* (1933; Eng. trans., *World History of the Dance*, 1937, reprinted 1963), includes several sections on various Indian tribal dance performances; FRANK G. SPECK and LEONARD BROOM, *Cherokee Dance and Drama* (1951), a specialized study of Eastern Cherokee dances and related ritual; JOHN L. SQUIRES and ROBERT E. MCLEAN, *American Indian Dances* (1963), a volume intended primarily for hobbyist readers. (*Mexico, Central America, and South America*): AUGUSTE GENIN, *Notes on the Dances, Music, and Songs of the Ancient and Modern Mexicans* (1922), a comparison of pre-Columbian with contemporary folk dances; LISA LEKIS, *Folk Dances of Latin America* (1958), exhaustive bibliography, with historical notes and descriptions; SAMUEL MARTI, *Canto, danza y música precortesianos* (1961), thoroughly illustrated, with equal sections given to an examination of musical instruments, songs, and the forms of the dance in pre-Columbian times; and with GERTRUDE P. KURATH, *Dances of Andhuac: The Choreography and Music of Precortesian Dances* (1964), a thorough and well-illustrated analysis of the subject; ROBERT STEVENSON, *Music in Aztec and Inca Territory* (1968), includes a large amount of valuable material on the dance in pre-Columbian times, although primarily involved with music, singing, and the vocal arts; FRANCES TOOR, *A Treasury of Mexican Folkways* (1947), a volume on folklore, including the dance, by a long-time resident of Mexico; CARLOS VEGA, *Las danzas populares argentinas* (1952), authoritative history, choreography, and some music.

Visual arts: FERDINAND ANTON and FREDERICK J. DOCKSTADER, *Das Alte Amerika* (1967; Eng. trans., *Pre-Columbian Art and Later Tribal Arts*, 1968), a popular treatment that covers the Western Hemisphere, extremely valuable for the many illustrations, most of which are in colour; FRANZ BOAS, *Primitive Art* (1927; new ed., 1955), an old-time classic with considerable discussion of the place of native arts in European society—especially helpful for the section on Northwest Coast art; G.H.S. BUSHNELL, *Ancient Arts of the Americas* (1965), a general treatment of the Western Hemisphere, with greater attention given to Latin America; MIGUEL COVARRUBIAS, *The Eagle, the Jaguar and the Serpent* (1954), a splendid volume on the arts of the Americas, with many line drawings and colour plates by the author, a major Mexican artist, and *Indian Art of Mexico and Central America* (1957), a continuation of the above and one of the best single treatments on the formative centuries of ancient Mexican civilization; HANS D. DISSELHOFF and S. LINNE, *Alt-Amerika* (1960; Eng. trans., *The Art of Ancient America*, 1961), a well-illustrated volume that concentrates primarily upon the prehistoric cultures of Central and South America, and largely ignores North American Indian art; FREDERICK J. DOCKSTADER, *Indian Art in America: The Arts and Crafts of the North American Indian*, 3rd ed. (1966), a survey of the native arts of the United States and Canada, *Indian Art in Middle America: The Arts and Crafts of the Indians of Mexico, Central America and the Caribbean* (1964), extending the study to the southern boundary of Panama, with particular emphasis on the lesser known tribes

of the region, and *Indian Art in South America: Pre-Columbian and Contemporary Arts and Crafts* (1967), the final volume in this series, completing a survey of the entire range of aboriginal art of the New World; ALVIN M. JOSEPHY, JR., *The Indian Heritage of America* (1968), one of the few volumes to discuss the Indian from North to South—a sound introduction to the New World native, although written from the historical point of view; PAL KELEMEN, *Art of the Americas, Ancient and Hispanic* (1969), a well-illustrated study of the earlier periods of the Americas, particularly valuable for its inclusion of the colonial influences on Indian aesthetics; and *Medieval American Art*, 3rd rev. ed., 2 vol. (1969), a rich sourcebook of illustrations that includes the entire hemisphere; GORDON R. WILLEY, *An Introduction to American Archaeology*, 2 vol. (1966–71), a profusely illustrated, comprehensive survey of the prehistory of the New World, by one of its leading archaeologists. (*North America—United States and Canada*): CHARLES A. AMSDEN, *Navaho Weaving: Its Technic and History* (1934, reprinted 1964); MARIUS BARBEAU, *Totem Poles* . . . , 2 vol. (1929–30); ROBERT T. DAVIS, *Native Arts of the Pacific Northwest* (1949); FREDERIC H. DOUGLAS and RENE D'HARNONCOURT, *Indian Art of the United States* (1941, reprinted 1969); DOROTHY DUNN, *American Indian Painting of the Southwest and Plains Areas* (1968); WOLFGANG HABERLAND, *The Art of North America* (1964); ROBERT B. INVERARITY, *Art of the Northwest Coast Indians* (1950); WILLIAM C. ORCHARD, *Beads and Beadwork of the North American Indians*, 2nd rev. ed. (1972), the most complete single study of Western Hemisphere bead artistry; CLARA LEE TANNER, *Southwest Indian Craft Arts* (1968). (*Mexico, Central America, and the West Indies*): MIGUEL COVARRUBIAS, *Indian Art of Mexico and Central America* (1957); ANDRE EMMERICH, *Art Before Columbus* (1963); JESSE W. FEWKES, *A Prehistoric Island Culture Area of America* (1922); PAL KELEMEN, *Medieval American Art*, 3rd rev. ed., 2 vol. (1969); GEORGE KUBLER, *The Art and Architecture of Ancient America: The Mexican, Maya, and Andean Peoples* (1962); SAMUEL K. LOTHROP, *Pottery of Costa Rica and Nicaragua*, 2 vol. (1926); IGNACIO MARQUINA, *Arquitectura Prehispánica* (1951); SYLVANUS G. MORLEY, *The Ancient Maya*, 3rd ed. (1956); TATIANA PROSKOURIAKOFF, *An Album of Maya Architecture* (1946); DONALD ROBERTSON, *Mexican Manuscript Painting of the Early Colonial Period* (1959); MARSHALL H. SAVILLE, *The Goldsmith's Art in Ancient Mexico* (1920); HERBERT J. SPINDEN, *A Study of Maya Art* (1913; rev. as *Maya Art and Civilization*, 1957); J. ERIC THOMPSON, *The Rise and Fall of Maya Civilization* (1954); GEORGE C. VAILLANT, *The Aztecs of Mexico*, rev. ed. (1962); HASSO VON WINNING, *Pre-Columbian Art of Mexico and Central America* (1968); MURIEL P. WEAVER, *The Aztecs, Maya, and Their Predecessors* (1972). (*South America*): WENDELL C. BENNETT, *Ancient Arts of the Andes* (1954); JUNIUS B. BIRD and LOUISA BELLINGER, *Paracas Fabrics and Nazca Needlework, 3rd Century B.C.—3rd Century A.D.* (1954); G.H.S. BUSHNELL, *Peru*, rev. ed. (1963); RAOUL D'HARCOURT, *Les Textiles anciens du Pérou, et leurs techniques* (1934; Eng. trans., *Textiles of Ancient Peru and Their Techniques*, 1934); ANDRE EMMERICH, *Sweat of the Sun and Tears of the Moon: Gold and Silver in Pre-Columbian Art* (1965); PAL KELEMEN, *Art of the Americas, Ancient and Hispanic* (1969); SAMUEL K. LOTHROP, *Treasures of Ancient America* (1964); J. ALDEN MASON, *Ancient Civilizations of Peru* (1957); BETTY J. MEGGERS, *Ecuador* (1966); G. REICHEL-DOLMATOFF, *Colombia* (1965); ALAN R. SAWYER, *Ancient Peruvian Ceramics* (1966).

American Literature

Like other national literatures, American literature was shaped by the history of the country that produced it. For almost a century and a half, America was merely a group of colonies scattered along the eastern seaboard of the North American continent—colonies from which a few hardy souls tentatively ventured westward. After a successful rebellion against the motherland, America became the United States, a nation. By the end of the 19th century this nation extended southward to the Gulf of Mexico, northward to the 49th parallel, and westward to the Pacific. By the end of the 19th century, too, it had taken its place among the powers of the world—its fortunes so interrelated with those of other nations

that inevitably it became involved in two world wars and, following these conflicts, with the problems of Europe and the Far East. Meanwhile, the rise of science and industry, as well as changes in ways of thinking and feeling, wrought many modifications in people's lives. All these factors in the development of the United States molded the literature of the country.

The 17th century

American literature at first was naturally a colonial literature, by authors who were Englishmen and who thought and wrote as such. John Smith, a soldier of fortune, is credited with initiating American literature. His chief books included *A True Relation of . . . Virginia . . .* (1608) and *The generall Historie of Virginia, New England, and the Summer Isles* (1624). Although these volumes often glorified their author, they were avowedly written to explain colonizing opportunities to Englishmen. In time, each colony was similarly described: Daniel Denton's *Brief Description of New York* (1670), William Penn's *Brief Account of the Province of Pennsylvania* (1682), and Thomas Ashe's *Carolina* (1682) were only a few of many works praising America as a land of economic promise for English colonists.

Such writers acknowledged British allegiance, but others stressed the differences of opinion that spurred the colonists to leave their homeland. More important, they argued questions of government involving the relationship between church and state. The attitude that most authors attacked was jauntily set forth by Nathaniel Ward of Massachusetts Bay in *The Simple Cobar of Aggawam in America* (1647). Ward amusingly defended the status quo and railed at colonists who sponsored newfangled notions. A variety of counter-arguments to such a conservative view were published. John Winthrop's *Journal* (written 1630–49) told sympathetically of the attempt of Massachusetts Bay Colony to form a theocracy—a state with God at its head and with its laws based upon the Bible. Later defenders of the theocratic ideal were Increase Mather and his son Cotton. William Bradford's *History of Plymouth Plantation* (through 1646) showed how his pilgrim Separatists broke completely with Anglicanism. Even more radical than Bradford was Roger Williams, who, in a series of controversial pamphlets, advocated not

only the separation of church and state but also the vesting of power in the people and the tolerance of different religious beliefs.

The utilitarian writings of the 17th century included many sorts—biographies, treatises, accounts of voyages, and sermons. There were few achievements in drama or fiction, since there was a widespread prejudice against these forms, but more in the field of poetry. Bad but popular poetry appeared in the *Bay Psalm Book* of 1640 and in Michael Wigglesworth's summary in doggerel verse of Calvinistic belief, *The Day of Doom* (1662). There was some poetry, at least, of a higher order. Anne Bradstreet of Massachusetts wrote some lyrics published in *The Tenth Muse* (1650), which movingly conveyed her feelings concerning religion and her family. Ranked still higher by modern critics is a poet whose works were not discovered and published until 1939: Edward Taylor, an English-born minister and physician who lived in Boston and Westfield, Massachusetts. Less touched by gloom than the typical Puritan, Taylor wrote lyrics that showed his delight in Christian belief and experience.

All 17th-century American writings were in the manner of British writings of the same period. John Smith wrote in the tradition of geographical literature, Bradford echoed the cadences of the King James Bible, while the Mathers and Roger Williams wrote bejewelled prose typical of the day. Anne Bradstreet's poetic style derived from a long line of British poets, including Spenser and Sydney, while Taylor was in the tradition of such Metaphysical poets as George Herbert and John Donne. Both the content and form of the literature of this first century in America were thus markedly English.

Theocratic
 writings

The 18th century

In America in the early years of the 18th century, some writers, such as Cotton Mather, carried on the older tra-

ditions. His huge history and biography of Puritan New England, *Magnalia Christi Americana*, in 1702, and his vigorous *Manuductio ad Ministerium*, or introduction to the ministry, in 1726, were defenses of ancient Puritan convictions. Jonathan Edwards, initiator of the Great Awakening, a religious revival that stirred the eastern seacoast for many years, eloquently defended his burning belief in Calvinistic doctrine—of the concept that man, born totally depraved, could attain virtue and salvation only through God's grace—in his powerful sermons and most notably in the philosophical treatise *Freedom of Will* (1754). He supported his claims by relating them to a complex metaphysical system and by reasoning brilliantly in clear and often beautiful prose.

But Mather and Edwards were defending a doomed cause. Liberal New England ministers such as John Wise and Jonathan Mayhew moved toward a less rigid religion. Samuel Sewall heralded other changes in his amusing *Diary*, covering the years 1673–1729. Though sincerely religious, he showed in daily records how commercial life in New England replaced rigid Puritanism with more worldly attitudes. The *Journal* of Mme Sara Knight comically detailed a journey that lady took to New York in 1704. She wrote vividly of what she saw and commented upon it from the standpoint of an orthodox believer, but a quality of levity in her witty writings showed that she was much less fervent than the Pilgrim founders had been. In the South, William Byrd of Virginia, an aristocratic plantation owner, contrasted sharply with gloomier predecessors. His record of a surveying trip in 1728, *The History of the Dividing Line*, and his account of a visit to his frontier properties in 1733, *A Journey to the Land of Eden*, were his chief works. Years in England, on the Continent, and among the gentry of the South had created gaiety and grace of expression, and, although a devout Anglican, Byrd was as playful as the Restoration wits whose works he clearly admired.

The wrench of the American Revolution emphasized differences that had been growing between American and British political concepts. As the colonists moved to the belief that rebellion was inevitable, fought the bitter war, and worked to found the new nation's government, they were influenced by a number of very effective political writers, such as Samuel Adams and John Dickinson, both of whom favoured the colonists, and Loyalist Joseph Galloway. But two figures loomed above these—Benjamin Franklin and Thomas Paine.

Franklin, born in 1706, had started to publish his writings in his brother's newspaper, the *New England Courant*, as early as 1722. This newspaper championed the cause of the "Leather Apron" man and the farmer and appealed by using easily understood language and practical arguments. The idea that common sense was a good guide was clear in both the popular *Poor Richard's* almanac, which Franklin edited between 1732 and 1757 and filled with prudent and witty aphorisms purportedly written by uneducated but experienced Richard Saunders, and in the author's *Autobiography*, written between 1771 and 1788, a record of his rise from humble circumstances that offered worldly wise suggestions for future success.

Franklin's self-attained culture, deep and wide, gave substance and skill to varied articles, pamphlets, and reports that he wrote concerning the dispute with Great Britain, many of them extremely effective in stating and shaping the colonists' cause.

Thomas Paine went from his native England to Philadelphia and became a magazine editor and then, about 14 months later, the most effective propagandist for the colonial cause. His pamphlet "Common Sense" (January 1776) did much to influence the colonists to declare their independence. "The American Crisis" papers (December 1776–December 1783) spurred Americans to fight on through the blackest years of the war. Based upon Paine's simple Deistic beliefs, they showed the conflict as a stirring melodrama with the angelic colonists against the forces of evil. Such white and black picturings were highly effective propaganda. Another reason for Paine's success was his poetic fervour, which found expression in impassioned words and phrases long to be remembered and quoted.

THE NEW NATION

In the postwar period some of these eloquent men were no longer able to win a hearing. Thomas Paine and Samuel Adams lacked the constructive ideas that appealed to those interested in forming a new government. Others fared better—for example, Franklin, whose tolerance and sense showed in addresses to the constitutional convention. A different group of authors, however, became leaders in the new period—Thomas Jefferson and the talented writers of *The Federalist* papers, a series of 85 essays published in 1787 and 1788 urging the virtues of the proposed new constitution. They were written by Alexander Hamilton, James Madison, and John Jay. More distinguished for insight into problems of government and cool logic than for eloquence, these works became a classic statement of American governmental, and more generally of republican, theory. At the time they were highly effective in influencing legislators who voted on the new constitution. Hamilton, who wrote perhaps 51 of the *Federalist* papers, became a leader of the Federalist Party and, as first secretary of the treasury (1789–95), wrote messages that were influential in increasing the power of national government at the expense of the state governments.

Thomas Jefferson was an influential political writer during and after the war. The merits of his great summary, the Declaration of Independence, consisted, as Madison pointed out, "in a lucid communication of human rights . . . in a style and tone appropriate to the great occasion, and to the spirit of the American people." After the war he formulated the exact tenets of his faith in various papers but most richly in his letters and inaugural addresses, in which he urged individual freedom and local autonomy—a theory of decentralization differing from Hamilton's belief in strong federal government. Though he held that all men are created equal, Jefferson thought that "a natural aristocracy" of "virtues and talents" should hold high governmental positions.

NOTABLE WORKS OF THE PERIOD

Poets and poetry. Poetry became a weapon during the American Revolution, with both Loyalists and Continentals urging their forces on, stating their arguments, and celebrating their heroes in verse and songs such as "Yankee Doodle," "Nathan Hale," and "The Epilogue," mostly set to popular British melodies and in manner resembling other British poems of the period.

The most memorable American poet of the period was Philip Freneau, whose first well-known poems, Revolutionary War satires, served as effective propaganda; later he turned to various aspects of the American scene. Although he wrote much in the stilted manner of the Neoclassicists, such poems as "The Indian Burying Ground," "The Wild Honey Suckle," "To a Caty-did," and "On a Honey Bee" were romantic lyrics of real grace and feeling that were forerunners of a literary movement destined to be important in the 19th century.

Drama and the novel. In the years toward the close of the 18th century, both dramas and novels of some historical importance were produced. Though theatrical groups had long been active in America, the first American comedy presented professionally was Royall Tyler's *Contrast* (1787). This drama was full of echoes of Goldsmith and Sheridan, but it contained a Yankee character (the predecessor of many such in years to follow) who brought something native to the stage.

William Hill Brown wrote the first American novel, *The Power of Sympathy* (1789), which showed authors how to overcome ancient prejudices against this form by following the sentimental novel form invented by Samuel Richardson. A flood of sentimental novels followed to the end of the 19th century. H.H. Brackenridge followed Cervantes' *Don Quixote* and Henry Fielding with some popular success in *Modern Chivalry* (1792–1815), an amusing satire on democracy and an interesting portrayal of frontier life. Gothic thrillers were to some extent nationalized in Charles Brockden Brown's *Wieland* (1798), *Arthur Mervyn*, and *Edgar Huntly* (1799). But all such works were more interesting as beginnings than as outstanding artistic achievements.

The 19th century

EARLY 19TH-CENTURY LITERATURE

After the American Revolution, and increasingly after the War of 1812, American writers were exhorted to produce a literature that was truly native. As if in response, four authors of very respectable stature appeared. William Cullen Bryant, Washington Irving, James Fenimore Cooper, and Edgar Allan Poe initiated a great half century of literary development.

Bryant, a New Englander by birth, attracted attention in his 23rd year when the first version of his poem "Thanatopsis" (1817) appeared. This, as well as some later poems, was written under the influence of English 18th-century poets. Still later, however, under the influence of Wordsworth and other Romantics, he wrote nature lyrics that vividly represented the New England scene. Turning to journalism, he had a long career as a fighting liberal editor of *The Evening Post*. He himself was overshadowed, in renown at least, by a native-born New Yorker, Washington Irving.

Irving and
Cooper

Irving, youngest member of a prosperous merchant family, joined with ebullient young men of the town in producing the *Salmagundi* papers (1807–08), which took off the foibles of Manhattan's citizenry. This was followed by *A History of New York* (1809), by "Diedrich Knickerbocker," a burlesque history that mocked pedantic scholarship and sniped at the old Dutch families. Irving's models in these works were obviously Neoclassical English satirists, from whom he had learned to write in a polished, bright style. Later, having met Sir Walter Scott and having become acquainted with imaginative German literature, he introduced a new Romantic note in *The Sketch Book* (1819–20), *Bracebridge Hall* (1822), and other works. He was the first American writer to win the ungrudging (if somewhat surprised) respect of British critics.

James Fenimore Cooper won even wider fame. Following the pattern of Sir Walter Scott's "Waverley" novels, he did his best work in the "Leatherstocking" tales (1823–41), a five-volume series celebrating the career of a great frontiersman named Natty Bumppo. His skill in weaving history into inventive plots and in characterizing his compatriots brought him acclaim not only in America and England but on the continent of Europe as well.

Edgar Allan Poe, reared in the South, lived and worked as an author and editor in Baltimore, Philadelphia, Richmond, and New York City. His work was shaped largely by analytical skill that showed clearly in his role as an editor: time after time he gauged the taste of readers so accurately that circulation figures of magazines under his direction soared impressively. It showed itself in his critical essays, wherein he lucidly explained and logically applied his criteria. His gothic tales of terror were written in accordance with his findings when he studied the most popular magazines of the day. His masterpieces of terror—"The Fall of the House of Usher" (1839), "The Masque of the Red Death" (1842), "The Cask of Amontillado" (1846), and others—were written according to a carefully worked out psychological method. So were his detective stories, such as "The Murders in the Rue Morgue" (1841), which historians credited as the first of the genre. As a poet, he achieved fame with "The Raven" (1845). His work, especially his critical writings and carefully crafted poems, had perhaps a greater influence in France, where they were translated by Charles Baudelaire, than in his own country.

Poe's
Gothic
tales

Two Southern novelists were also outstanding in the earlier part of the century: John Pendleton Kennedy and William Gilmore Simms. In *Swallow Barn* (1832), Kennedy wrote delightfully of life on the plantations. Simms's forte was the writing of historical novels like those of Scott and Cooper, which treated the history of the frontier and his native South Carolina. *The Yemassee* (1835) and Revolutionary romances show him at his best.

AMERICAN RENAISSANCE

The authors who began to come to prominence in the 1830s and were active until about the end of the Civil War—the humorists, the classic New Englanders, Herman

Melville, Walt Whitman, and others—did their work in a new spirit, and their achievements were of a new sort. In part, this was because they were in some way influenced by the broadening democratic concepts that in 1829 triumphed in Andrew Jackson's inauguration as president. In part, it was because, in this Romantic period of emphasis upon native scenes and characters in many literatures, they put much of America into their books.

Particularly full of vivid touches were the writings of two groups of American humorists whose works appeared between 1830 and 1867. One group created several down-east Yankee characters who used commonsense arguments to comment upon the political and social scene. The most important of this group were Seba Smith, James Russell Lowell, and Benjamin P. Shillaber. These authors caught the talk and character of New England at that time as no one else had done. In the old Southwest, meanwhile, such writers as Davy Crockett, Augustus Baldwin Longstreet, Johnson J. Hooper, Thomas Bangs Thorpe, Joseph G. Baldwin, and George Washington Harris drew lively pictures of the ebullient frontier and showed the interest in the common man that was a part of Jacksonian democracy.

democracy
reflected in
humorous
writing

New England Brahmins. Although Lowell for a time was one of these writers of rather earthy humour, his lifelong ties were to a group of New England writers associated with Harvard and Cambridge, Massachusetts—the Brahmins, as they came to be called—at an opposite extreme. Henry Wadsworth Longfellow, Oliver Wendell Holmes, and Lowell were all aristocrats, all steeped in foreign culture, all professors at Harvard. Longfellow adapted European methods of storytelling and versifying to narrative poems dealing with American history, and a few of his less didactic lyrics perfectly married technique and subject matter. Holmes, in occasional poems and his "Breakfast Table" series (1858–91), brought touches of urbanity and jocosity to a perhaps oversober polite literature. Lowell, in poems descriptive of the out-of-doors in America, put much of his homeland into verse. His odes—particularly the "Harvard Commemoration Ode" (1865)—gave fine expression to noble sentiments.

The Transcendentalists. Concord, Massachusetts, a village not far from Cambridge, was the home of leaders of another important New England group. The way for this group had been prepared by the rise of a theological system, Unitarianism, which early in the 19th century had replaced Calvinism as the faith of a large share of the New Englanders. Ralph Waldo Emerson, most famous of the Concord philosophers, started as a Unitarian minister but found even that liberal doctrine too confining for his broad beliefs. He became a Transcendentalist who, like other ancient and modern Platonists, trusted to insights transcending logic and experience for revelations of the deepest truths. His scheme of things ranged from the lowest objects and most practical chores to soaring flights of imagination and inspired beliefs. His *Essays* (1841–44), *Representative Men* (1850), and *English Traits* (1856) were thoughtful and poetic explanations of his beliefs; and his roughhewn lyrics, packed with thought and feeling, were as close to 17th-century Metaphysical poems as any produced in his own time.

An associate of Emerson with a salty personality of his own and an individual way of thinking, Henry David Thoreau, a sometime surveyor, labourer, and naturalist, was closer to the earthy and the practical than even Emerson was. He also was more of a humorist—a dry Yankee commentator with a flair for paradoxical phrases and sentences. Finally, he was a learned man, widely read in Western classics and books of the Orient. These qualities gave distinction to *A Week on the Concord and Merrimack Rivers* (1849) and to *Walden* (1854). The latter was a record of his experiences and ponderings during the time he lived in a hut by Walden Pond—a defense of his belief that modern man should simplify his demands if need be to "suck out all the marrow of life." In his essay "Civil Disobedience" (1849), Thoreau expounded his anarchistic views of government, insisting that if an injustice of government is "of such a nature that it requires injustice to another [you should] break the law [and] let your life be a counter friction to stop the machine."

individual-
ism

Associated with these two major figures were such minor Transcendentalists as Bronson Alcott, George Ripley, Orestes Brownson, Margaret Fuller, and Jones Very. Fuller edited *The Dial*, the chief Transcendental magazine, and was important in the feminist movement.

New England reformers and historians. A worldwide movement for change that exploded in the revolutions of 1848 naturally attracted numerous Americans. Reform was in the air, particularly in New England. At times even Brahmins and Transcendentalists took part. William Lloyd Garrison, ascetic and fanatical, was a moving spirit in the fight against slavery; his weekly newspaper, *The Liberator* (1831–65), despite a small circulation, was its most influential organ. A contributor to the newspaper—probably the greatest writer associated with the movement—was John Greenleaf Whittier. His simple but emotional poems on behalf of abolition were collected in such volumes as *Poems Written During the Progress of the Abolition Question* . . . (1837), *Voices of Freedom* (1846), and *Songs of Labor, and Other Poems* (1850). The outstanding novelist of the movement—so far as effect was concerned—was Harriet Beecher Stowe. Her *Uncle Tom's Cabin* (1852) combined the elements of contemporary humour and sentimental fiction to dramatize the plight of the Negro.

One other group of writers—and a great novelist—contributed to the literature of New England in this period of its greatest glory. The group consisted of several historians who combined scholarly methods learned abroad with vivid and dramatic narration. These included George Bancroft, author of *History of the United States* (completed in 12 volumes in 1882), and John Lothrop Motley, who traced the history of the Dutch Republic and the United Netherlands in nine fascinating volumes (1856–74). The leading member of the group was Francis Parkman, who, in a series of books (1851–92), wrote as a historian of the fierce contests between France and England that marked the advance of the American frontier and vividly recorded his own Western travels in *The Oregon Trail* (1849).

Hawthorne, Melville, and Whitman. History also figured in tales and romances of Nathaniel Hawthorne, the leading New England fictionist of the period. Many tales and longer works—for example, his masterpiece, *The Scarlet Letter* (1850)—were set against a background of colonial America with emphasis upon its distance in time from 19th-century New England. Others, such as *The House of the Seven Gables* (1851), dealt with the past as well as the present. Still others, such as *The Marble Faun* (1860), were set in distant countries. Remote though they were at times from what Hawthorne called “the light of common day,” they showed deep psychological insight and probed into complex ethical problems.

Another great American fiction writer, for a time a neighbour and associate of Hawthorne, was Herman Melville. After relatively little schooling, Melville went to sea; a whaling ship, as he put it, was his “Yale College and his Harvard.” His first books were fiction in the guise of factual writing based upon experiences as a sailor—*Typee* (1846) and *Omoo* (1847); so were such later works as *Redburn* (1849) and *White-Jacket* (1850). Between 1846 and 1851, however, Melville's reading in philosophy and literary classics, as well as in Hawthorne's allegorical and symbolic writings, gave him new interests and aims. The first sign of this interest was *Mardi* (1849), an uneven and disjointed transitional book that used allegory after the model of Rabelais to comment upon ideas afloat in the period—about nations, politics, institutions, literature, and religion. The new techniques came to fruition in *Moby Dick; or, The Whale* (1851), a richly symbolical work, complex but brilliantly integrated. Only in short stories, “Benito Cereno”—a masterpiece of its genre—and others, in the psychological novel *Pierre* (1852), and in the novelette *Billy Budd* (written 1890?) was Melville later to show sporadic flashes of the genius that created *Moby Dick*.

An ardent singer of the praise of Manhattan, Walt Whitman saw less of the dark side of life than Melville did. He was a believer in Jacksonian democracy, in the splendour of the common man. Inspired by the Romantic concept of a poet as prophet and also by the Transcendental phi-

losophy of Emerson, Whitman in 1855 published the first edition of *Leaves of Grass*. As years passed, nine revised and expanded editions of this work were published. This autobiography in verse was intended to show the ideas, beliefs, emotions, and experiences of the common man in a great period of American individualism. Whitman had a hard time winning a following because he was frank and unconventional in his Transcendental thinking, because he used free verse rather than rhymed or regularly metred verse, and because his poems were not conventionally organized. Nevertheless, he steadily gained the approval of critics and in time came to be recognized as one of the great poets of America.

The slow growth of Whitman's reputation

FROM THE CIVIL WAR TO 1914

Like the Revolution and the election of Andrew Jackson, the Civil War was a turning point in U.S. history and a beginning of new ways of living. Industry became increasingly important, factories rose and cities grew, and agrarian pre-eminence declined. The frontier, which before had always been an important factor in the economic scheme, moved steadily westward and toward the end of the 19th century vanished. The rise of modern America was accompanied, naturally, by important mutations in literature.

Literary comedians. Although they continued to employ some devices of the older American humorists, a group of comic writers that rose to prominence was different in important ways from the older group. Charles Farrar Browne, David Ross Locke, Charles Henry Smith, Henry Wheeler Shaw, and Edgar Wilson Nye wrote, respectively, as Artemus Ward, Petroleum V. (for Vesuvius) Nasby, Bill Arp, Josh Billings, and Bill Nye. Appealing to a national audience, these authors forsook the sectional characterizations of earlier humorists and assumed the roles of less individualized literary comedians. The nature of the humour thus shifted from character portrayal to verbal devices such as poor grammar, bad spelling, and slang, incongruously combined with Latinate words and learned allusions. Most that they wrote wore badly, but thousands of Americans in their time and some in later times found these authors vastly amusing.

Fiction and local colorists. The first group of fiction writers to become popular—the local colorists—took over to some extent the task of portraying sectional groups that had been abandoned by writers of the new humour. Bret Harte, first of these writers to achieve wide success, admitted an indebtedness to prewar sectional humorists, as did some others; and all showed resemblances to the earlier group. Within a brief period, books by pioneers in the movement appeared—Harriet Beecher Stowe's *Oldtown Folks* (1869) and Sam Lawson's *Oldtown Fireside Stories* (1871), delightful vignettes of New England; Bret Harte's *Luck of Roaring Camp, and Other Sketches* (1870), humorous and sentimental tales of California mining camp life; and Edward Eggleston's *Hoosier Schoolmaster* (1871), a novel of the early days of the settlement of Indiana. Down into the 20th century, short stories (and a relatively small number of novels) in patterns set by these three continued to appear. In time, practically every corner of the country had been portrayed in local-colour fiction. Additional writings were the depictions of Louisiana Creoles by George W. Cable, of Virginia Negroes by Thomas Nelson Page, of Georgia Negroes by Joel Chandler Harris, of Tennessee mountaineers by Mary Noailles Murfree (Charles Egbert Craddock), of tight-lipped folk of New England by Sarah Orne Jewett and Mary E. Wilkins Freeman, of people of New York City by Henry Cuyler Bunner and William Sydney Porter (“O. Henry”). The avowed aim of some of these writers was to portray realistically the lives of various sections and thus to promote understanding in a united nation. The stories as a rule were only partially realistic, however, since the authors tended nostalgically to revisit the past instead of portraying their own time, to winnow out less glamorous aspects of life, or to develop their stories with sentiment or humour. Touched by romance though they were, these fictional works were transitional to Realism, for they did portray common folk sympathetically; they did concern themselves with dialect

of Mark
Twain

and mores; and some at least avoided older sentimental or romantic formulas.

Samuel Langhorne Clemens (Mark Twain) was allied with literary comedians and local colorists. As a printer's apprentice, he knew and emulated the prewar sectional humorists. He rose to prominence in days when Artemus Ward, Bret Harte, and their followers were idols of the public. His first books, *The Innocents Abroad* (1869) and *Roughing It* (1872), like several of later periods, were travel books in which affiliations with postwar professional humorists were clearest. *The Adventures of Tom Sawyer* (1876), *Life on the Mississippi* (1883), and *The Adventures of Huckleberry Finn* (1884), his best works, which recreated the life of the Mississippi Valley in the past, were closest to the work of older humorists and local colorists. Even in his best work, however, he succumbed now and then to the temptation to play the buffoon or sink into burlesque. Despite his flaws, he was one of America's greatest writers. He was a very funny man. He had more skill than his teachers in selecting evocative details, and he had a genius for characterization.

Born and raised in Ohio, William Dean Howells was an effective advocate of a new realistic mode of fiction writing. At the start, Howells conceived of Realism as truthful portrayal of ordinary facets of life—with some limitations; he preferred comedy to tragedy, and he tended to be reticent to the point of prudishness. The formula was displayed at its best in *Their Wedding Journey* (1872), *A Modern Instance* (1882), and *The Rise of Silas Lapham* (1885). Howells preferred novels he wrote after he encountered Tolstoy's writings and was persuaded by them, as he said, to "set art forever below humanity." In such later novels as *Annie Kilburn* (1888) and *A Hazard of New Fortunes* (1890), he chose characters not only because they were commonplace but also because the stories he told about them were commentaries upon society, government, and economics.

The Naturalists. Other American writers toward the close of the 19th century moved toward Naturalism, a more advanced stage of Realism. Hamlin Garland's writings exemplified some aspects of this development when he made short stories and novels vehicles for philosophical and social preachments and was franker than Howells in stressing the harsher details of the farmer's struggles and in treating the subject of sex. His *Main-Travelled Roads* (1891) and *Rose of Dutcher's Coolly* (1895) displayed Garland's particular talents. These and a critical manifesto for the new fiction, *Crumbling Idols* (1894), were influential contributions to a developing movement.

Other U.S. authors of the same period or slightly later were avowed followers of French Naturalists led by Émile Zola. Theodore Dreiser, for instance, treated subjects that had seemed too daring to earlier Realists and, like other Naturalists, illustrated his own beliefs by his depictions of characters and unfolding of plots. Holding that men's deeds were "chemical compulsions," he showed characters unable to direct their actions. Holding also that "the race was to the swift and the battle to the strong," he showed characters defeated by stronger and more ruthless opponents. His major books included *Sister Carrie* (1900), *Jennie Gerhardt* (1911), *The Financier* (1912), *The Titan* (1914), and—much later—*An American Tragedy* (1925).

Dreiser did not bother with—or did not care for—niceties of style or elaborate symbolism such as were found in French Naturalistic works; but Stephen Crane and Frank Norris were attentive to such matters. In short novels, *Maggie: A Girl of the Streets* (1893) and *The Red Badge of Courage* (1895), and in some of his short stories, Crane was an impressionist who made his details and his setting forth of them embody a conception of man overwhelmed by circumstance and environment. Frank Norris, who admired Crane's "aptitude for making phrases—sparks that cast a momentary gleam upon whole phases of life," himself tried to make phrases, scenes, and whole narratives cast such gleams in *McTeague* (1899), *The Octopus* (1901), and *The Pit* (1903). Both Crane and Norris died young, their full abilities undeveloped but their experiments foreshadowing later achievements in the 20th-century novel.

Henry James. In the books of Henry James, born in

New York but later an expatriate in England, fiction took a different pathway. Like Realists and Naturalists of his time, he thought that fiction should reproduce reality. He conceived of reality, however, as twice translated—first, through the author's peculiar experiencing of it, and, second, through his unique depicting of it. Deep insight and thorough experience were no more important, therefore, than the complicated and delicate task of the artist. *The Art of Fiction* (1884), essays on novelists, and brilliant prefaces to his collected works showed him struggling thoroughly and consciously with the problems of his craft. Together, they formed an important body of discussion of fictional artistry.

An excellent short-story writer, James nevertheless was chiefly important for novels in which his doctrines found concrete embodiment. Outstanding were *The American* (1877), *The Portrait of a Lady* (1881), *The Spoils of Poynton* (1897), *What Maisie Knew* (1897), *The Wings of the Dove* (1902), *The Ambassadors* (1903), and *The Golden Bowl* (1904). The earliest of these were international novels wherein conflicts arose from relationships between Americans and Europeans—each group with its own characteristics and morals. As time passed, he became increasingly interested in the psychological processes of his characters and in a subtle rendering of their limited insights, their perceptions, and their emotions.

Critics of the gilded age. Writers of many types of works contributed to a great body of literature that flourished between the Civil War and 1914—literature of social revolt. Novels attacked the growing power of business and the growing corruption of government, and some novelists outlined utopias. Political corruption and inefficiency figured in Henry Adams' novel *Democracy* (1880). Edward Bellamy's *Looking Backward* (1888) was both an indictment of the capitalistic system and an imaginative picturing of a utopia achieved by a collectivist society in the year 2000. Howells' *Traveler from Altruria* (1894) pleaded for an equalitarian state in which the government regimented men's lives. The year 1906 saw the publication of Upton Sinclair's *Jungle*, first of many works by him that criticized U.S. economic and political life and urged Socialism as the remedy.

Two poets embodied criticisms in songs. Edwin Markham's "Man with the Hoe" (1899) was a protest against the exploitation of labour and vaguely threatened revolution; it immediately stimulated nationwide interest. A year later William Vaughn Moody's "Ode in Time of Hesitation" denounced growing U.S. imperialism as a desertion of earlier principles; his "On a Soldier Fallen in the Philippines" (1901) developed the same theme even more effectively.

With the rise of journalistic magazines, a group of journalists became notable as critics of America—the group dubbed "the muckrakers" by Theodore Roosevelt. Ida M. Tarbell's *History of the Standard Oil Company* (1904) and Lincoln Steffens' *Shame of the Cities* (1904) were typical contributions by two members of a large group of journalistic crusaders.

Henry Adams. One of the most devastating and most literate attacks on modern life was an autobiography of a scion of an ancient New England family, the Adamsses. Educated at Harvard and abroad, Henry Adams was a great teacher and historian (*History of the United States* [1889–91] and *Mont-Saint-Michel and Chartres* [1904]). *The Education of Henry Adams* (printed privately 1906; published 1918), however, complained that a lifelong hunt for some sort of order in the world, some sort of faith for man, left him completely baffled. The quiet, urbane style served well to underline, in an ironic way, the message of this pessimistic book.

Poets of the era. The latter 19th century and early years of the 20th century were a poor period for American poetry; yet (in addition to William Vaughn Moody) two poets of distinction wrote songs that survived long after scores of minor poets had been forgotten. One was Southern-born Sidney Lanier, a talented musician who utilized the rhythms of music and the thematic developments of symphonies in such fine songs as "Corn" (1875), "The Symphony" (1875), and "The Marshes of Glynn"

of Zola on
Dreiser

(1878). Distressed, like many of his contemporaries, by changes in American life, he wove his doubts, fears, and suggestions into his richest poems.

The other poet was a New Englander, Emily Dickinson. A shy, playful, odd personality, she allowed practically none of her writings to be published during her lifetime. Not until 1890, four years after her death, was the first book of her poems published, to be followed at intervals by other collections. Later poets were to be influenced by her individual techniques—use of imperfect, or eye, rhymes, avoidance of regular rhythms, and a tendency to pack brief stanzas with cryptic meanings. Like Lanier, she rediscovered the value of conceits for setting forth her thought and feeling. Such poems as “The Snake,” “I Like to See It Lap the Miles,” “The Chariot,” “Farther in Summer than the Birds,” and “There’s a Certain Slant of Light” represented her unusual talent at its best.

The 20th century

WRITING FROM 1914 TO 1945

Important movements in drama, poetry, fiction, and criticism took form in the years before, during, and after World War I. The eventful period that followed that war left its imprint upon books of all kinds, for it was a time when writers were much involved with interpreting life about them. Literary forms of the period were extraordinarily varied, and in drama, poetry, and fiction leading authors tended toward radical technical experiments.

Experiments in drama. Although drama in the 19th century had not been a preeminent form, no type of writing embodied wider experimentation than a new drama that arose as a result of rebellion against the glib commercial stage. In the early years of the 20th century, Americans travelling abroad found a vital theatre flourishing in Europe; returning home, some of them became active in founding a Little Theatre movement in every corner of their country. Freed from commercial limitations, playwrights experimented with dramatic forms and methods of production, and in time producers, actors, and dramatists appeared who had been trained in college classrooms and community playhouses. Some Little Theatre groups became commercial producers; for example, the Washington Square Players, founded in 1915, which became the Theatre Guild (first production in 1919). The drama that resulted was marked by a spirit of innovation and by a new seriousness and maturity.

Eugene O'Neill, the most admired dramatist of the period, was a product of this movement. He worked with the Provincetown Players before his plays were commercially produced. His dramas are remarkable for their range. *Beyond the Horizon* (first performed 1920), *Anna Christie* (1921), *Desire Under the Elms* (1924), and *The Iceman Cometh* (1946) were Naturalistic works, while *The Emperor Jones* (1920) and *The Hairy Ape* (1922) made use of the Expressionistic techniques developed in German drama in the period 1914–24. He also employed a stream-of-consciousness form in *Strange Interlude* (1928) and produced a work of subtle psychological analysis in *Mourning Becomes Electra* (1931).

No other dramatist was as generally praised as O'Neill, but many others wrote plays of a high order that reflected the growth of a serious and varied drama. Marc Connelly wrote touching fantasy in a Negro folk biblical play, *The Green Pastures* (1930). Like O'Neill, Elmer Rice made use of both Expressionistic techniques (*The Adding Machine* [1923]) and Naturalism (*Street Scene* [1929]). Beginning as a Realist, Maxwell Anderson turned to verse drama in plays such as *Elizabeth the Queen* (1930) and *Winterset* (1935) and then to musical comedy satire in *Knickerbocker Holiday* (1938). Robert Sherwood produced a distinguished body of work, writing comedy (*Reunion in Vienna* [1931]) and tragedy (*There Shall Be No Night* [1940]). Clifford Odets, in *Waiting for Lefty* (1935), a plea for labour unionism, utilized auditorium as well as stage for action and in *Awake and Sing* (1935) wrote in the vein of Naturalism. Thornton Wilder used stylized settings and poetic dialogue in *Our Town* (1938) and turned to fantasy in *The Skin of Our Teeth* (1942).

The new poetry. Poetry ranged between traditional types of verse and experimental writing that departed radically from the established forms of the 19th century. Two New England poets, Edwin Arlington Robinson and Robert Frost, who were not noted for technical experimentation, both won critical as well as popular acclaim in this period. Robinson, whose first book appeared in 1896, found sonnets, ballad stanzas, and blank verse satisfactory to his thought. In the 1920s he won three Pulitzer Prizes—for his *Collected Poems* (published 1921), *The Man Who Died Twice* (1925), and *Tristram* (1927). Like Robinson, Frost used traditional stanzas and blank verse in volumes such as *A Boy's Will* (1913), his first book, and *North of Boston* (1914), *New Hampshire* (1923), *A Further Range* (1936), and *A Masque of Reason* (1945). The best known poet of his generation, Frost, like Robinson, saw and commented upon the tragic aspects of life and the complexities of human existence and was skeptical of pat solutions.

Just as modern U.S. drama had its beginnings in little theatres, modern U.S. poetry took form in little magazines. Particularly important was *Poetry: A Magazine of Verse*, founded by Harriet Monroe in Chicago in 1912. The surrounding region soon became prominent as the home of three poets: Vachel Lindsay, Carl Sandburg, and Edgar Lee Masters. Lindsay's blend of legendary lore and native oratory in irregular odelike forms was well adapted to oral presentation, and his lively readings from his works contributed to the success of such books as *General William Booth Enters into Heaven, and Other Poems* (1913) and *The Congo, and Other Poems* (1914). Sandburg wrote of life on the prairies and in Middle Western cities in Whitmanesque free verse in such volumes as *Chicago Poems* (1916) and *The People, Yes* (1936). Masters' very popular *Spoon River Anthology* (1915) consisted of free-verse monologues by village men and women, most of whom spoke bitterly of their frustrated lives.

Writing traditional sonnets and brief, personal lyrics, Edna St. Vincent Millay and Sara Teasdale were innovative in being unusually frank (according to old standards) for women poets. Three fine Negro poets—James Weldon Johnson, Langston Hughes, and Countee Cullen—also found old molds satisfactory for dealing with new subjects, specifically the problems of their race. In general, however, the range of experimentation was great. While Conrad Aiken experimented with poetical imitations of symphonic forms often mingled with stream-of-consciousness techniques, e.e. cummings used typographical novelties to produce poems that had surprisingly fresh impact. Marianne Moore invented and brilliantly employed a kind of free verse that was to make her one of the most distinguished voices in modern U.S. poetry. Stephen Vincent Benét, in *John Brown's Body* (1928), produced a stirring novel in verse. Robinson Jeffers used violent imagery and modified free or blank verse to express perhaps the most bitter views voiced by a major poet in this period.

Except for a period after World War II, when he was confined in St. Elizabeth's Hospital, Washington, D.C., Ezra Pound lived outside the United States after 1908. He had, nevertheless, a profound influence on 20th-century writing in English, both as a practitioner of verse and as a patron and impresario of other writers. His most controversial work remained *The Cantos*, the first installment of which appeared in 1925 and the latest in 1959 (*Thrones: 96–109 de los cantares*).

Like Pound, to whom he was much indebted, T.S. Eliot lived abroad most of his life, becoming a British citizen in 1927. His first volume, *Prufrock and Other Observations*, was published in 1917. In 1922 appeared *The Waste Land*, the poem by which he first became famous. As a poet and critic, Eliot exercised a strong influence, especially in the period between World Wars I and II. In what some critics regard as his finest work, *Four Quartets* (1943), Eliot explored through images of great beauty and haunting power his own past, the past of the human race, and the meaning of human history.

Eliot was the acknowledged master of many members of a varied group of poets whose work was indebted to 17th-century English Metaphysical poets, especially to John Donne. Eliot's influence was clear in the writings of

Robinson and Frost

The poetic techniques of Emily Dickinson

The plays of Eugene O'Neill

Pound, Eliot, and the influence of the 17th-century Metaphysical poets

Archibald MacLeish, whose earlier poems were similar in both manner and thought to *The Waste Land*. In later poems MacLeish voiced a positive belief in social advance that contrasted with the religious attitude advocated by Eliot. A number of Southern poets showed a loose affiliation with Metaphysical influence; among them were John Crowe Ransom and Allen Tate. Hart Crane had a similar Metaphysical manner but a subject matter of his own. Other American Metaphysicals having individual qualities of thought and method were Louise Bogan, Muriel Rukeyser, Delmore Schwartz, and Karl Shapiro.

The
influence
of the little
magazines

Fiction. The little magazines that helped the growth of the poetry also contributed to a development of the fiction of the era by printing material that diverged from older patterns and by attacking conventional writing and established writers. The most powerful of the little magazines were two edited by the journalist-critic H.L. Mencken—*The Smart Set* (editorship 1914–23) and *American Mercury* (which he coedited between 1924 and 1933). One of Mencken's favourites, James Branch Cabell, sprang to fame with *Jurgen* (1919), a novel that attacked America's orthodoxies and institutions. Other authors whom Mencken favoured launched "a revolt against the village," an attack on the narrow, provincial quality of much rural American life. The most distinguished of these was Sherwood Anderson, who dealt with the subject in two collections of short stories, *Winesburg, Ohio* (1919) and *Triumph of the Egg* (1921).

In 1920 a new school of fiction rose to prominence with the success of books such as F. Scott Fitzgerald's *This Side of Paradise* and Sinclair Lewis' *Main Street*. Thereafter, writers tended toward Realism and Naturalism—frank portrayals of contemporary life. In the decades that followed, fiction voiced reactions to changing times: novels of the 1920s expressed disillusionment with established institutions and ideologies. Some from the 1930s protested against the economic and political system.

Critics of society. F. Scott Fitzgerald's *This Side of Paradise* (1920) showed the disillusionment and moral disintegration of post-World War I America. His masterpiece, *The Great Gatsby* (1925), was a more poignant and unified development of the same theme. Like Fitzgerald, Sinclair Lewis was best as social critic. His onslaught against the "village virus" (*Main Street* [1920]); against average businessmen (*Babbitt* [1922]); against materialistic scientists (*Arrowsmith* [1925]); and against the racially prejudiced (*Kingsblood Royal* [1947]) were satirically sharp and thoroughly documented. Similar careful documentation characterized James T. Farrell's Naturalistic "Studs Lonigan" trilogy (1932–35). Richard Wright protested against the plight of the Negro in *Uncle Tom's Children* (1938) and *Native Son* (1940). Particularly admired as a novelist of protest was John Dos Passos, who first attracted attention with an anti-World War I novel, *Three Soldiers* (1921). His *Manhattan Transfer* (1925) and the "U.S.A." trilogy (*The 42nd Parallel*, *Nineteen Nineteen*, and *The Big Money* [1930–36]) employed various narrative innovations to attack society from the left. His later books, attacks on leftists, had less merit. A bitter vision of an inhuman and brutal world and a black-comedy style distinguish Nathanael West's novels, particularly *Miss Lonelyhearts* (1933) and *The Day of the Locust* (1939).

Hemingway, Faulkner, and Steinbeck. Three Nobel laureates whose writings showed a shift from disillusionment were Ernest Hemingway, William Faulkner, and John Steinbeck. Hemingway's early short stories and first novels, *The Sun Also Rises* (1926) and *A Farewell to Arms* (1929), were full of the disillusionments of the postwar years, but the Spanish Civil War led him to believe in the possibility of collective action, embodied in his novels *To Have and Have Not* (1937), *For Whom the Bell Tolls* (1940), and *The Old Man and the Sea* (1952).

William Faulkner brilliantly handled point of view, stream-of-consciousness techniques, and complex plots in a body of work concerned chiefly with a mythical Mississippi county, Yoknapatawpha. Such novels as *The Sound and the Fury* (1929), *As I Lay Dying* (1930), *Light in August* (1932), and *The Hamlet* (1940) presented a generally grim picture of the human condition, though more opti-

mistic convictions emerged in *Intruder in the Dust* (1948) and *The Reivers* (1962).

Steinbeck's career, marked by uneven achievements, began with a historical novel, *Cup of Gold* (1929), wherein he voiced the glorification of the anarchistic individualist typical of the rebellious 1920s. Later, however, a belief in collectivist action was implied in *In Dubious Battle* (1936) and *The Grapes of Wrath* (1939).

Lyric fictionists. An interesting development in fiction was a movement toward poetry. The tendency to select details and endow them with symbolic meaning, to stress thoughts and emotions, and to use rhythmical prose gave fiction more of a lyrical quality. In varied ways, Hemingway, Steinbeck, and Faulkner all showed the trend. Lyricism was prominent in such writings of Willa Cather as *My Antonia* (1918) and *Death Comes for the Archbishop* (1927). Katherine Anne Porter, writing more in the style of the Metaphysical poets, used the stream-of-consciousness method in *Flowering Judas* (1930) and *Pale Horse, Pale Rider* (1939) with the complexity and the symbolic sophistication of poetry. Another leading poetic fictionist was Thomas Wolfe, the author of four novels that were a lyrical recording of his life: *Look Homeward, Angel* (1929), *Of Time and the River* (1935), *The Web and the Rock* (1939), and *You Can't Go Home Again* (1940).

Literary criticism. The first half of the 20th century was noteworthy for its achievements in literary criticism. The period began with a battle between the New Humanists—who supported the older values in judging literature—and a group who urged that new standards be adopted. The Humanists were led by Irving Babbitt, who attacked the tendency toward Naturalism as a vicious influence. The leader of the opposition was the pugnacious H.L. Mencken, who, notably in *Prejudices* (1919–27), claimed that the duty of writers was to present "the unvarnished truth." In the end, the progress of Naturalism was assured, and literature was liberated from a number of ancient restrictions.

The New
Humanists
and their
opponents

In this period of social change, it was natural for a number of critics to consider literature's relationships to society and politics. They consistently judged books as reflections of society or as expressions of social truth. Van Wyck Brooks and Vernon Parrington wrote greatly admired studies that embodied such an approach. Two outstanding critics, Kenneth Burke and Edmund Wilson, stressed social influences less and illuminated literary works by analyzing them and relating them to their creators' sensibility. (Wa.B.)

AFTER WORLD WAR II

Literary historian Malcolm Cowley described the years between the two world wars as a "second flowering" of American writing, and significant works by several major figures from those decades were published after 1945. Faulkner, Hemingway, Steinbeck, and Katherine Anne Porter wrote memorable fiction; and Frost, Eliot, Wallace Stevens, Marianne Moore, e.e. cummings, William Carlos Williams, and Gwendolyn Brooks published important poetry. Eugene O'Neill's most distinguished play, *Long Day's Journey into Night*, appeared posthumously in 1956. Robert Penn Warren's *All the King's Men*, one of the best American political novels, won the 1947 Pulitzer Prize. Henry Miller's fiction, influential primarily because of its frank exploration of sexuality, first appeared in the United States in the 1960s. Still, there was a gradual changing of the guard in American letters after World War II.

The novel and short story. Two distinct groups of novelists responded to the cultural impact, and especially the technological horror, of World War II. Norman Mailer's *The Naked and the Dead* (1948) and Irwin Shaw's *The Young Lions* (1948) were realistic war novels. Using a Naturalistic technique, James Jones documented the war's tragic legacy in an ambitious trilogy, *From Here to Eternity* (1951), *The Thin Red Line* (1962), and *Whistle* (1978). Younger novelists found the Realistic-Naturalistic tradition inadequate for treating the war's nightmarish implications. Joseph Heller, in *Catch-22* (1961), satirized the military mentality with surrealist black humour; and Kurt Vonnegut, Jr., in *Slaughterhouse-Five* (1969), de-

War

Novels of
satire and
protest

scribed the U.S. firebombing of Dresden, Germany, within a larger context of dark fantasy.

In part because of the atomic bomb, American writers of fiction turned increasingly to black humour and absurdist fantasy. A highly self-conscious fiction, which imitated earlier fiction rather than social reality, emerged. Russian-born Vladimir Nabokov and the Argentine writer Jorge Luis Borges were strong influences on this new "metafiction." Nabokov, who became a U.S. citizen in 1945, produced a body of highly sophisticated fiction distinguished by linguistic and formal innovation. His novels *Lolita* (1955), *Invitation of a Small Animal* (1957), *Pale Fire* (1962), and *Invitation of a Small Animal* (1962), and *Invitation of a Small Animal* (1962), and *Invitation of a Small Animal* (1962) were particularly important. In a major 1967 essay, "The Literature of Exhaustion," John Barth declared himself an American disciple of Nabokov and Borges. Barth described his own work as "novels which imitate the form of the novel, [written] by an author who imitates the role of Author." In his most ambitious work, he simultaneously imitated and parodied conventional forms—the historical novel in *The Sot-Weed Factor* (1960), Greek and Christian myth in *Giles Goat-Boy* (1966), and the epistolary novel in *Letters* (1979). Similarly, Donald Barthelme mocked the fairy tale in *Snow White* (1967) and Freudian fiction in *The Dead Father* (1975).

Thomas Pynchon emerged as the major American practitioner of the absurdist fable. He investigated elaborate "conspiracies" in *V* (1963), *The Crying of Lot 49* (1966), and *Gravity's Rainbow* (1973). The underlying assumption of Pynchon's fiction was the inevitability of entropy—the disintegration of physical and moral energy. In *Naked Lunch* (1959) and other novels, William Burroughs used a drug addict's consciousness to depict a hideous modern landscape. Vonnegut, Terry Southern, and John Hawkes were other major practitioners of black humour and the absurdist fable.

Inevitably, such writers as Barth, Barthelme, and Pynchon rejected the novel's traditional function as a mirror reflecting society. Still, a significant number of contemporary novelists were reluctant to abandon social realism. Highly conscious of the contemporary nightmare, 1976 Nobel laureate Saul Bellow nevertheless rejected despair. In such novels as *The Victim* (1947), *The Adventures of Augie March* (1953), *Herzog* (1964), *Mr. Sammler's Planet* (1970), and *Humboldt's Gift* (1975), Bellow proclaimed the necessity of "being human." His mystical vision, derived from sources as diverse as Judaism and American Transcendentalism, was affirmative. Three other Jewish writers—Bernard Malamud, Philip Roth, and Isaac Bashevis Singer—treated the human condition with humour and forgiveness. Malamud's gift for comedy was especially evident in his short-story collection *The Magic Barrel* (1958). Roth's most lasting achievement was his three-volume account of the misadventures of a controversial Jewish novelist—*The Ghost Writer* (1979), *Zuckerman Unbound* (1981), and *The Anatomy Lesson* (1983). The Polish-born Singer won the Nobel Prize for Literature in 1978 for his stories written originally in Yiddish. The sexual and moral confusion of the American middle class were the focus of John Updike's *Rabbit, Run* (1960), *Couples* (1968), and *Rabbit Redux* (1971) as with the fiction of J.D. Salinger. John Cheever created in his short stories and novels a gallery of memorable eccentrics. In sharp contrast, Nelson Algren (*The Man with the Golden Arm* [1949]) and Hubert Selby, Jr. (*Last Exit to Brooklyn* [1964]), documented lower-class urban life with brutal frankness. Similarly, John Rechy portrayed America's urban homosexual subculture in *City of Night* (1963).

Post-World War II Southern writers inherited Faulkner's rich legacy. Three women—Eudora Welty, Flannery O'Connor, and Carson McCullers—further advanced Southern fiction. O'Connor, writing from a deeply religious perspective, provided new directions for Southern Gothicism in her short stories. Always a brilliant stylist, Welty received the 1973 Pulitzer Prize for her novel *The Optimist's Daughter*. Initially known for his lyrical portraits of Southern eccentrics (*Other Voices, Other Rooms* [1948]), Truman Capote published *In Cold Blood*, a classic work of documentary realism, in 1966. In two am-

bitious works, William Styron fictionalized the dark side of human history—*The Confessions of Nat Turner* (1967) depicted an antebellum slave revolt, while *Sophie's Choice* (1979) attempted to capture the horror of the Holocaust. *The Moviegoer* (1961) and *The Last Gentleman* (1966) established Walker Percy as an important voice in Southern fiction. Inspired by Faulkner and Mark Twain, William Humphrey wrote two powerful novels set in Texas, *Home from the Hill* (1958) and *The Ordways* (1965).

Postwar black writers found alternatives to the Richard Wright tradition of social protest. In *Go Tell It on the Mountain* (1953) and *Just Above My Head* (1979), James Baldwin attempted to portray the diversity of the black community. Ralph Ellison combined Afro-American history with Western myth to produce a modern classic, *Invisible Man* (1952). Later, two black women novelists published some of the most important postwar American fiction. In *The Bluest Eye* (1970), *Sula* (1973), and *Song of Solomon* (1977), Toni Morrison created a strikingly original fiction drawing from influences as diverse as Afro-American history, African and Western mythology, the Western fairy tale, and black folk culture. Alice Walker received the 1983 Pulitzer Prize for her black feminist novel *The Color Purple*.

It is impractical to generalize about postwar American fiction. Reality itself seemed inaccessible, and writers of novels and short stories were under unprecedented pressure to discover, or invent, new and viable kinds of fiction. A brief discussion of two of the most fascinating contemporary writers, Norman Mailer and Joyce Carol Oates, will perhaps illustrate this search for new directions. In his 1948 World War II novel, *The Naked and the Dead*, Mailer wrote in the Dos Passos tradition of social protest. Yet, it was only when he turned to "nonfiction fiction" or "fiction as history" in *The Armies of the Night* (1968) that Mailer discovered his truest voice. He further refined this approach in the 1980 Pulitzer Prize "true life novel" *The Executioner's Song*. Later, Mailer published a long, mystical novel set in ancient Egypt, *Ancient Evenings* (1983). In her early work, especially *A Garden of Earthly Delights* (1967) and *them* (1969), Joyce Carol Oates worked primarily out of the Naturalistic tradition. Incredibly prolific, she later experimented with surrealism in *Wonderland* (1971) and Gothic fantasy in *Bellefleur* (1980). While Mailer and Oates refused to surrender the novel's obligation to capture reality, both were compelled to expand new fictional forms in order to fulfill that obligation.

Poetry. As with fiction, new voices emerged in postwar poetry. Robert Lowell, for example, produced distinguished dramatic poetry in *Lord Weary's Castle* (1946) and *For the Union Dead* (1964), while Theodore Roethke revealed a genius for ironic lyricism in *The Lost Son, and Other Poems* (1948). Along with Lowell, Roethke, Gwendolyn Brooks, and Robert Penn Warren, such diverse voices as John Berryman (*77 Dream Songs* [1964]), Randall Jarrell (*Losses* [1948]), Louis Simpson (*At the End of the Open Road, Poems* [1963]), Richard Wilbur (*Things of This World* [1956]), W.D. Snodgrass (*Heart's Needle* [1959]), and W.S. Merwin (*The Carrier of Ladders* [1970]) ultimately formed a new establishment in American poetry.

The poet-critic Yvor Winters inspired a Pacific school of writers of moral focus and plain style, among them his friend J.V. Cunningham and such later poets as N. Scott Momaday and Edgar Bowers. Charles Olson and Robert Creeley were associated with a group inspired by William Carlos Williams and known as the Black Mountain school. The 1950s saw the emergence of the San Francisco "beatniks" (Allen Ginsburg, Lawrence Ferlinghetti, and Gregory Corso). Gary Snyder, in *Turtle Island* (1974), continued the American tradition of nature poetry; while Galway Kinnell's poetry was shaped by a mythic consciousness. Like James Dickey, Kinnell was often fascinated by nature at its most primitive and brutal.

A number of important new women poets appeared. Before her suicide in 1963, Sylvia Plath wrote idiosyncratic, and often painfully introspective, poetry. Adrienne Rich was an important voice in poetry as well as feminist thought. Often as emotional and intimate in subject mat-

ter and tone as Plath, Anne Sexton won the 1967 Pulitzer Prize for *Live or Die*, while English-born Denise Levertov published several volumes of poetry after moving to the United States in 1948.

Drama. Two post-World War II playwrights established reputations comparable to O'Neill's. In essays, Arthur Miller eloquently defended his belief in a modern, democratic concept of tragedy; and *Death of a Salesman* (1949) came close to vindicating this belief. *All My Sons* (1947) and *The Crucible* (1953) were protest plays that reflected Miller's liberal idealism. Though his work was decidedly uneven, Tennessee Williams must be viewed as a more important playwright than Miller. Williams brought a passionate poetry and a tragic Southern vision to such plays as *The Glass Menagerie* (1944), *A Streetcar Named Desire* (1947), *Cat on a Hot Tin Roof* (1955), and *The Night of the Iguana* (1961).

Until the 1960s, Miller and Williams so dominated the postwar theatre that no other playwright emerged to challenge them. Then, in 1962, Edward Albee's reputation was secured by the stunning power of *Who's Afraid of Virginia Woolf?* A master of absurdist theatre, Albee has since emerged as the third major figure in postwar American drama. After the centre of American drama shifted from Broadway to off- and off-off-Broadway, American playwrights were increasingly free to write radical and innovative plays with some realistic hope of seeing them produced. David Rabe's *The Basic Training of Pavlo Hummel* (produced in 1971) and *Sticks and Bones* (1972) satirized America's militaristic nationalism and cultural shallowness. David Mamet won a 1976-77 New York Drama Critics Award for *American Buffalo*. Imamu Amiri Baraka (LeRoi Jones) and Ed Bullins inspired an angry black nationalist theatre. Baraka's *Dutchman* and *The Slave* (1964) communicated anger through experimental techniques, while Bullins' *In the Wine Time* (1968) made use of "street" lyricism. A clear indication of off-Broadway's ascendancy in American drama came in 1979 when Sam Shepard, a prolific and experimental playwright, won the Pulitzer Prize for *Buried Child*. Other important new voices in American drama were Lanford Wilson, the 1980 Pulitzer winner for *Talley's Folly*, and Ntozake Shange, whose "choreopoem," *For Colored Girls Who Have Considered Suicide/When the Rainbow Is Enuf*, moved to Broadway in 1976.

Literary and social criticism. Until his death in 1972, Edmund Wilson solidified his reputation as one of America's most versatile and distinguished men of letters. Later, Gore Vidal emerged as a potential heir to Wilson's legacy. Like Wilson, Vidal wrote important literary criticism, fiction, history, and social commentary. In *A Second Flowering* (1973) and *The Dream of the Golden Mountains* (1980), Malcolm Cowley investigated the effects of social and political change on 20th-century American literature. Alfred Kazin wrote literary history (*Bright Book of Life* [1973]) and autobiography (*New York Jew* [1978]); while Irving Howe produced literary theory and social criticism. The iconoclastic literary criticism of Leslie Fiedler was distinguished by its wit and creativity. Fiedler's *Love and Death in the American Novel* (1960) remains the most important Freudian study of American literature. Lionel Trilling, in *The Liberal Imagination* (1950) and other works, rejected V.L. Parrington's concept of literature as social reportage but insisted on its humanistic role. In *The Way of the New World* (1975), Addison Gayle, Jr., defended his theory that black literature must promote a sense of militant nationalism.

Despite the insistence by Wilson, Cowley, Trilling, and others that literature has a social function, the New Criticism of Robert Penn Warren and Cleanth Brooks remained a dominant influence in postwar literary studies. In addition, scholars published important biographies of several major American novelists. Leon Edel's exhaustive study of Henry James appeared in five volumes: *Henry James: The Untried Years, 1843-1870*; *The Conquest of London, 1870-1881*; *The Middle Years, 1882-1895*; *The Treacherous Years, 1895-1901*; and *The Master, 1901-1916* (1953-72). Mark Schorer's *Sinclair Lewis, An Amer-*

ican Life (1961), Carlos Baker's *Ernest Hemingway: A Life Story* (1969), Michel Fabre's *The Unfinished Quest of Richard Wright* (1973), and Joseph Blotner's *Faulkner: A Biography* (1974) were uniquely perceptive biographies. The impressive *Harvard Guide to Contemporary American Writing*, edited by Daniel Hoffman, appeared in 1979.

One positive result of the accelerating complexity of postwar life was a body of distinguished journalism and social commentary. John Hersey's *Hiroshima* (1946) was a deliberately controlled, unemotional account of atomic holocaust. In *Notes of a Native Son* (1955), *Nobody Knows My Name* (1961), and *The Fire Next Time* (1963), black novelist James Baldwin published a body of the most eloquent essays written in America. Norman Mailer's "new journalism" proved especially effective in capturing the drama of political conventions. Novelist Joan Didion published two collections of incisive social and literary commentary, *Slouching Towards Bethlehem* (1968) and *The White Album* (1979). The title essay of the first collection was the first truly detached and honest investigation of the forces behind, and the implications of, the 1960s counterculture. Robert M. Pirsig's *Zen and the Art of Motorcycle Maintenance* (1974) defied all classification. In it, Pirsig equated the emotional collapse of his central character with the disintegration of American workmanship and cultural values.

The emergence in academic circles of two sharply contrasting critical movements illustrated the complexity of the time. First, the French-inspired school of Structuralism reached the United States. Centred primarily at Yale, the American disciples of Jacques Derrida and Roland Barthes practiced an abstract criticism based on linguistic and philosophic innovation. For them, criticism often supplanted literature as the focus of attention. In sharp contrast, feminist literary criticism often emphasized the social, even the political, function of literature. Tillie Olsen's *Silences* (1978) exemplified a feminist criticism stressing androgyny. (J.R.G.)

Amphibians

The Amphibia constitute a class of vertebrate animals that occupy a position in the evolutionary series midway between that of the fishes and that of the reptiles. Living amphibians include the frogs and toads, the salamanders and sirens, and the caecilians. The amphibians are of primary interest to students of evolution

because they were the first vertebrates to make their way from the primeval aquatic environment onto the land and because the group includes among its extinct members the ancestors of all the other terrestrial vertebrates—the reptiles, birds, and mammals.

This article is divided into the following sections:

AMPHIBIANS: CLASS AMPHIBIA

GENERAL FEATURES

Economic importance. The amphibians are of little direct economic importance to man. Toads of the genus *Bufo* have long been noted as avid devourers of insect pests. Large species have been introduced into such places as Florida, Jamaica, and Hawaii to help control pests in the cane fields. There is some demand for frog legs as table delicacies.

Amphibians are of great importance to biologists. Most students have their first introduction to vertebrate anatomy through the dissection of a frog. Salamanders have contributed to knowledge of embryology and of tissue regeneration.

Size range and diversity of structure. In size the living amphibians range from the tiny frog *Sminthillus limbatus* of Cuba, less than 12 millimetres ($1/2$ inch) in length, to the giant salamander *Andrias* of eastern Asia, which reaches a total length of 160 centimetres (about 63 inches). There are fewer species of amphibians than of any other terrestrial vertebrate class; they show a great diversity of structure, however, ranging from the elongated, legless, wormlike caecilians to the short-bodied, tailless, long-legged frogs.

Distribution and abundance. The amphibians are concentrated in the tropics; some families and many genera are confined to these regions. As a group, though, the amphibians have a worldwide distribution. The salamanders are primarily animals of the North Temperate Zone, although the range of one family extends into Central America and northern South America, where it has evolved a large number of species. Frogs of the family Hylidae range as far north as the swamplands of northwestern Canada; and the family of true frogs, Ranidae, is found on all major landmasses except Antarctica, New Zealand, and Greenland. The caecilians occur throughout the tropics and the sirens only in the southeastern United States and northeastern Mexico.

Members of this class, for the most part, are found as isolated individuals; but many of the frogs, particularly in the temperate zones, assemble in large breeding choruses during the spring and summer.

NATURAL HISTORY

Life cycle. The amphibians are so named because most members have aquatic larval stages that metamorphose (transform) into terrestrial adults—*amphi* is the ancient Greek word for “both” and *bios* means “life.” A few extant species remain aquatic as adults. Yet many species

of salamanders and frogs and all egg-laying caecilians deposit their eggs away from open water, and some species lack the aquatic larval stage. Because no amphibian has a shelled egg, eggs must be deposited in a moist place—soil, rotting wood, a foam nest constructed by the parent, or the skin of the mother’s back.

Behaviour. Because their life history involves both land and water, most amphibians have behaviour patterns built around a seasonal movement between breeding sites and other places. For the caecilians and sirens the breeding site

Drawing by S. Jones

Figure 1: Representative amphibians.

Fertiliza-
tion and
egg laying

is probably essentially the same as the nonbreeding site. Although this is also true for some salamanders, others must undertake annual journeys, perhaps from a relatively dry hillside to some pond or stream in a valley. Evidence indicates that they are guided on such journeys by chemical stimuli as well as by physical characteristics of the land (e.g., slope). In frogs and toads that have voices, the calls of the males that have located a suitable breeding site attract other males and females, often from one-fourth to one-half mile away. It has been demonstrated that some amphibians are able to use celestial bodies for orientation.

Reproduction. Fertilization is internal in the caecilians and most salamanders. In caecilians, sperm are introduced into the female's body by means of a protrusible portion of the male's cloaca (i.e., the lower end of the digestive tract), which is modified to form a copulatory organ. The male salamander deposits his sperm in a gelatinous structure (spermatophore) consisting of a stalk on which rests a little cap containing the sperm. The female manoeuvres the cap into her cloaca, where the gelatinous material dissolves, and the sperm are freed to fertilize the eggs as they descend through her reproductive tubes. It is not yet known whether fertilization is internal or external in the sirens.

With few exceptions, the frogs and toads have external fertilization. The male clasps the female and releases sperm over the eggs as the female extrudes them.

Most caecilians deposit their eggs on land; the aquatic forms bear living young. Sirens and many salamanders lay eggs in water. Other salamanders lay them on land, in burrows, in rotten logs, or under debris where they will remain moist. Frogs have various means of caring for the eggs after deposition. In the North Temperate regions most species abandon their eggs in a pool or stream; many tropical species have developed other, sometimes bizarre, techniques of egg care. Some lay eggs in a hole on land; after the eggs hatch into tadpoles, the male transports them on his back to water. In other species the mother has a special pouch on her back in which she carries the eggs until they hatch.

Ecology. The primary element in the ecology of amphibians is their need for a moist environment. With their soft, scaleless, glandular skins, they are very susceptible to drying out. Although a few species spend their entire lives in water, most live at least part of the time on land, either under moist debris or not far from water. A few, such as the toads, have become quite terrestrial, but even they are not entirely independent of moisture. The familiar garden toads, often seen at night, live where there is moisture near the surface; during the day, when water evaporates rapidly, they tend to remain in their burrows.

FORM AND FUNCTION

Structure. The major groups of living amphibians differ markedly from one another in structure. Caecilians are slender, wormlike animals without limbs or limb girdles, with practically no tail, and with a simple intestine. The minute eyes are buried in the smooth skin, and there are no eyelids. The largest grow to about 135 centimetres (about 53 inches). Because caecilians use their heads to burrow in the soil of the forest floor and in the mud along riverbanks, the skull is compact. The cloaca of the male is modified into a protrusible copulatory organ. The body is segmented into circular folds, called annuli, separated by shallow grooves. The more primitive species have tiny scales imbedded in the skin. Some aquatic forms have a dorsal fin fold. All caecilians have tentacles, small sensory structures that lie buried in pits near each eye and are protrusible in many species. Several series of teeth are arranged on different bones around the jaws.

The sirens, or trachystomes, which lack hindlimbs and pelvic girdles, are elongated, aquatic animals, with an anterior pectoral girdle to which the upper bones of the front legs are attached. The tiny front legs have three or four toes on each foot. Gills are present. Sirens also breathe by gulping the surface air. The eyes are lidless and are buried in the smooth glandular skin, which is lacking in scales and annuli, although so-called costal folds are present along each side of the body. A horny claw caps each toe,

and a horny sheath covers part of each jaw. Except for the tiny splenial bones, the bones of the jaws lack teeth; but teeth are present on the bones forming the roof of the mouth. The well-developed tail has dorsal and ventral fin folds. Sinuous body motions and the tail fins are used for locomotion.

The salamanders, which have forelegs and hindlegs, retain a tail throughout life. A distinct neck is present between the head and body. The smooth skin lacks scales, and the eyes of terrestrial forms have lids. Teeth are present on the jaws and roof of the mouth. Although fertilization is internal in most species, the male lacks a copulatory organ, sperm transfer occurring via spermatophores (sperm capsules). Some species never metamorphose but remain in the water as permanent larvae, retaining gills throughout life.

The largest group of amphibians are the familiar frogs and toads. The one characteristic that clearly distinguishes this group from others is the presence in the hindleg of a segment formed by two elongated tarsal bones, the astragalus and calcaneum. In salamanders these bones are small, merely forming part of the ankle. The elongated hindleg of frogs and toads is an adaptation for hopping or swimming. Adults lack a tail; and teeth, although usually found on the upper jaw, are (except in one tropical species) absent from the lower jaw. The tympanic membranes, used for hearing, are on the sides of the head, behind the eyes. Males of species with well-developed voices have resonating pouches, called vocal sacs, in the throat region. The glandular skin, which lacks scales, is usually smooth and soft; in some terrestrial forms, however, it is rather dry and rough.

Physiology and biochemistry. The amphibians have not evolved an impermeable skin. They have, therefore, special problems involving the maintenance of internal water balance and the removal of the nitrogenous wastes that are the by-products of metabolism. They take in water through the skin and excrete it, along with the nitrogenous wastes, through the kidneys.

Most larval amphibians and permanently aquatic adult

Leg bones
of frogs
and toads

forms live in fresh water. Water, which flows constantly into the body, removes nitrogenous wastes in the form of ammonia. The kidneys produce copious amounts of very dilute urine, thereby eliminating both excess water and waste products. Terrestrial forms, lacking an unlimited supply of water, cannot excrete such dilute urine; instead, they convert their nitrogenous wastes into urea, which, because it is less toxic than ammonia, can be excreted in a much more concentrated form. As a result, less water is lost through excretion.

A physiological mechanism also controls urine production in relation to temperature. As temperature rises, water flows more rapidly through the skin, and urine flow increases; conversely, water flow and urine production decrease with a decline in temperature. In experiments with the green frog (*Rana clamitans*) it has been found that no urine was formed at 2.5° C (36.5° F), although some water moved into the body.

EVOLUTION

Fossil remains of the earliest known amphibians have been found in freshwater beds of the Upper Devonian (about 370,000,000 years old). The amphibians evolved from the lobe-finned fishes (Crossopterygii), which were abundant and diversified during the Devonian. These fishes had muscular fins supported by bony elements comparable to the bones of amphibian limbs; functional lungs; and, in certain species, passages leading from the nasal sacs to openings (internal nares) in the roof of the mouth, an arrangement characteristic of all terrestrial vertebrates. The crossopterygian skull was divided transversely into front and back parts that were slightly movable on each other. Early crossopterygians had teeth with an infolding of the enamel surface. Similar teeth were also present in the primitive amphibians.

The amphibian ancestor was able to take air into the mouth and lungs through the nasal passages and internal nostrils when the mouth was closed and only the external nostrils were above water. The question of why the ancestral amphibian went from an aquatic environment to a terrestrial one has been much debated. One suggestion is that in times of drought these animals, with their muscular fins and well-developed lungs, would have been able to heave themselves out of the drying pools and travel overland in search of other bodies of water. It has also been proposed that, since the crossopterygians were carnivorous, they probably preyed on the young of various species, including their own. Small individuals may have remained in shallow water inaccessible to larger fish or they may have fled to the land in order to escape a predator. Perhaps they later spent more time on shore, especially at night when the humidity was high, returning to water to feed during the day; gradually, they could have supplemented their diet with primitive terrestrial arthropods, and so become less dependent on water except for breeding purposes.

The earliest amphibians of the Upper Devonian are the ichthyostegians. The best known member of the group, *Ichthyostega* from freshwater beds of Greenland, was a fairly large animal with a skull 150 millimetres (about six inches) or more in length. Instead of fins it had short, stubby limbs with five toes; its tail was something like that of a modern lungfish, with a caudal, or tail, fin supported by fin rays. Small, bony scales were present on the belly and tail. The vertebrae were like those of crossopterygians, the skull more amphibian-like. *Ichthyostega* probably spent most of its time in water, but the well-developed limbs indicate that it must have been capable of walking on land. In many ways the ichthyostegians were intermediate between the crossopterygians and the later amphibians, but they had some specializations that suggest they represent a sideline rather than the main stock from which the later amphibians evolved. One of the bones of the skull, the intertemporal, which is present in many fossil amphibians, had been lost by the ichthyostegians.

Fossil remains of amphibians are rare in deposits of Mississippian age (325,000,000 to 345,000,000 years ago), but during the Pennsylvanian (280,000,000 to 325,000,000 years old), amphibians were abundant and diversified.

They were divided into three major stocks: temnospondyls, anthracosaurs, and lepospondyls. The earliest temnospondyls were probably aquatic, but some later members of the group were well adapted to life on land. They were a widespread and flourishing stock, showing considerable morphological diversity. Almost all the large amphibians of the Permian (225,000,000 to 280,000,000 years ago) belonged to this group. *Eryops* of the Lower Permian (about 250,000,000 to 280,000,000 years ago) was about 150 centimetres (about 60 inches) long. As the reptiles spread over the land during the Late Paleozoic (about 225,000,000 to 325,000,000 years ago), the terrestrial amphibians declined. The temnospondyls of the Triassic Period (about 190,000,000 to 225,000,000 years ago) were aquatic animals with reduced limbs. Some were very large. *Mastodonsaurus*, with a skull length of over 90 centimetres (about three feet), was the largest known amphibian. The temnospondyls were extinct by the end of the Triassic.

The centrum (base) of the vertebra in primitive anthracosaurs was formed of a crescent-shaped intercentrum and two pleurocentra shaped like half rings. In more advanced forms the intercentrum was reduced and the pleurocentra became enlarged, joining to form a complete ring around the notochord (*i.e.*, the skeletal rod passing through the centre of the vertebral column). The anthracosaurs, though less numerous and diversified than the temnospondyls, also included both aquatic and terrestrial forms. The fish-eating *Pteroplax* of the Pennsylvanian reached an estimated length of more than 450 centimetres (nearly 15 feet). The anthracosaurs are of interest because the reptiles evolved from them. They became extinct during the Permian.

Lepospondyls of the Paleozoic Era were of modest size; many were eel-like or snakelike in appearance and had lost their limbs. They were aquatic or semi-aquatic; a few may have been fossorial—*i.e.*, burrowing forms. They were present in the Lower Mississippian, flourished during the Pennsylvanian, and disappeared in the Lower Permian.

From A.S. Romer, *Vertebrate Paleontology*, Copyright 1966 by the University of Chicago Press, all rights reserved

Figure 3: A primitive amphibian, *Cacops*.

The modern orders of amphibians cannot be positively traced to any of the Paleozoic groups. No fossil caecilians are known. The trachystomes have been found in the Cretaceous and the salamanders in the Jurassic. Both groups seem to have evolved in the Northern Hemisphere; in fact, only recently have members of one family of salamanders (Plethodontidae) invaded the Southern Hemisphere in South America. The earliest remains of frogs, on the other hand, have all been found in southern landmasses. It has been suggested that certain footprints in the Permian of South Africa may have been made by a form ancestral to the frogs. *Triadobatrachus* of the Lower Triassic (about 210,000,000 to 225,000,000 years ago) of Madagascar had a skull like that of a frog, elongated hindlegs, and a short tail. Frogs were undoubtedly present in the Lower Jurassic (about 160,000,000 to 190,000,000 years ago) in the southern part of South America.

CLASSIFICATION

Distinguishing taxonomic features. The method of formation of the vertebral centrum (*i.e.*, the heavy ventral, or bottom, part that connects with the adjacent vertebra) is important in the classification of the amphibians, particularly of fossil forms. The recent orders are distinguished by general body structure and by the presence or absence of limbs and tail. The structure of the sound-transmitting mechanism of the ear is also an important clue to identification. Adult frogs have an otic notch on either side of the

Evolution
from water
to land

Origin of
modern
orders

skull that houses the tympanic membrane, or eardrum. Salamanders, caecilians, and sirens lack the otic notch, eardrum, and middle-ear cavity. Sound transmission in salamanders is by way of the forelimb and shoulder blade to a muscle (opercularis) that passes from the shoulder blade to the operculum, a bone in the ear. Some fossil amphibians have the otic notch; presumably, many also possessed an eardrum and middle-ear cavity. Others lack the otic notch.

Annotated classification. The classification of the amphibians has not yet been satisfactorily established. The lack of critical fossil material prevents the establishment of clear-cut relationships between the major groups. The arrangement below is based on that of A.S. Romer (1966) and Coleman J. and Olive B. Goin (1971). Groups indicated by a dagger (†) are extinct and known only from fossils.

CLASS AMPHIBIA

Vertebrate animals without hair, feathers, or horny scales of epidermal origin (epidermis is the outer cell layer of the integument); small bony scales of dermal origin (dermis is the inner cell layer of the integument) occasionally present; skin soft and glandular; ectothermic (*i.e.*, dependent on external sources for body heat); fertilization external or internal; eggs usually laid in water; typically an aquatic larval stage; about 2,400 living species.

†Superorder Ichthyostegalia

Fossils only; Upper Devonian to Lower Mississippian; Europe, North America, Greenland; with limbs and fishlike tail; otic notch present; size to about 90 cm; probably largely aquatic.

†Superorder Temnospondyli

Fossils only; centrum primitively formed of wedge-shaped blocks; otic notch present; no more than 4 toes on front feet.

Order Rhachitomi

Upper Mississippian through Lower Triassic; worldwide distribution; intercentrum (crescent-shaped structure of centrum) not forming a complete ring, pleurocentra (semicircular structures of centrum) bony; size to 150 cm; aquatic and terrestrial.

Order Stereospondyli

Middle Permian to Upper Triassic; worldwide distribution; intercentra sometimes forming complete disks, pleurocentra reduced or absent; includes largest known amphibian, *Mastodonsaurus*; all forms aquatic.

Order Plagiosauria

Upper Permian to Upper Triassic; Europe and Africa; centrum closed cylinder; body broad and flat; scales present; size to about 90 cm; aquatic.

Superorder Lepospondyli

Centrum a bony cylinder around notochord; body more or less elongated; otic notch usually absent; limbs frequently reduced or absent.

†Order Aistopoda

Fossils only; Lower Mississippian to Lower Permian; North America and Europe; elongated body form, limbs absent; ribs attached to vertebrae by one head; length about 75 cm; possibly fossorial (burrowing).

†Order Nectridea

Fossils only; Lower Mississippian to Lower Permian; Europe and North America; body elongated or broad and flat; limbs reduced or absent; caudal vertebrae with expanded fan-shaped neural (dorsal) spines and hemal (ventral) spines; otic notch sometimes present, though small; some with cranium extended into posterior "horns"; length to about 60 cm (about 2 feet); aquatic, some possibly fossorial.

Order Trachystomata (sirens)

Lower Cretaceous to Recent; North America; eel-like forms, hindlimbs absent, forelimbs minute; expanded spines on caudal vertebrae; ribs 2-headed; length to 90 cm; 3 living species, all aquatic.

†Order Microsauria

All fossil; Lower Mississippian to Lower Permian; Europe and North America; body somewhat elongated, limbs rather small; caudal vertebrae without expanded spines; ribs 2-headed; small forms, probably most were semi-aquatic.

Order Gymnophiona (caecilians)

Recent; worldwide in tropics; wormlike burrowing forms without limbs or limb girdles; eyes reduced; fertilization internal, with copulation; length to about 135 cm (about 53 inches) but most much smaller; burrowing or aquatic; about 160 living species.

Order Urodela (Caudata) (salamanders)

Jurassic to Recent; worldwide in Northern Hemisphere, 1 family widely distributed in northern South America; vertebral centrum develops by direct development of bone tissue around notochord; ribs 2-headed; fertilization external or internal by means of spermatophore; size to 160 cm (about 63 inches) but most much smaller; terrestrial or aquatic; about 300 living species.

Superorder Salientia (frogs and their possible Triassic predecessor)

Triassic to Recent; worldwide.

Order Proanura

One fossil form from Triassic of Madagascar; skull like that of a frog; tail short; hindlegs elongated.

Order Anura (frogs and toads)

Jurassic to Recent; worldwide; hindlegs elongated, body short and stout, tail absent; centrum preformed in cartilage; otic notch present; fertilization usually external, no spermatophore; body length to 30 cm (about one foot); terrestrial or aquatic; about 1,900 living species.

†Superorder Anthracosauria

Fossils only; elements of centrum primitively crescent-shaped, pleurocentra later fuse to form main body of centrum, intercentrum reduced; otic notch present; 5 toes on front feet.

Order Schizomeri

Upper Mississippian, Europe; pleurocentra paired half rings, intercentrum large and crescent-shaped; trunk elongated, limbs reduced; length to about 120 cm (about 4 feet); probably aquatic.

Order Embolomeri

Upper Mississippian to Lower Permian; Europe and North America; intercentrum and pleurocentrum complete disks, body elongated, tail powerful, limbs reduced; length to over 450 cm (about 15 feet); probably aquatic eaters of fish.

Order Seymouriamorpha

Upper Pennsylvanian to Upper Permian; North America, Europe, Australia; intercentrum reduced and crescent-shaped, pleurocentrum ring-shaped; limbs well developed, body stout; otic notch very large; length to 300 cm (about 10 feet); terrestrial.

Order Diplomeri

Middle Pennsylvanian; Europe and North America; intercentrum large and crescentic, pleurocentrum disk-shaped; limbs well developed; otic notch present, skull otherwise like that of a primitive reptile; presumably represents stock from which reptiles evolved; body length (without tail) about 10 cm (about 2.5 inches); terrestrial.

Critical appraisal. There is no agreement among herpetologists that the amphibians evolved from a single stock. It has been suggested that the fossil lepospondyls and the salamanders are derived from one group of crossopterygians (porolepiforms) and that the ichthyostegids, temnospondyls, anthracosaurs, and frogs are derived from another (osteolepiforms). For alternate classification of Caudata (salamanders) see the *Annotated classification* in *Urodela* that follows.

A.S. Romer and others divide the amphibians into three subclasses: Labyrinthodontia for the ichthyostegals, temnospondyls, and anthracosaurs; Lepospondyli for the fossil orders of lepospondyls; and Lissamphibia for the modern amphibians. The labyrinthodonts include those extinct forms whose teeth were covered by a series of surface folds (labyrinthine folds); most species superficially resembled salamanders, with weak limbs and a well-developed tail. The lepospondyls had teeth lacking folds; these extinct species were either four-legged (resembling salamanders) or legless (resembling snakes). The combination of ichthyostegals, temnospondyls, and anthracosaurs into one subclass is based in large part on the assumption that the three-part centrum found in primitive members of the last two groups is derived from the crossopterygian-type centrum of *Ichthyostega*. It has been suggested that this assumption is false and that the divided centrum of the temnospondyls and anthracosaurs represents a new, tetrapod structure.

Whether the modern amphibians should be placed in one suborder is another much-debated question, which will probably not be answered unless and until sufficient fossil material is found to allow the modern orders to be traced to their Paleozoic ancestors. (C.J.G.)

MAJOR AMPHIBIAN GROUPS

The following sections of this article consist of a detailed discussion of two important orders of living amphibians, the salamanders and sirens (Urodela) and the frogs and toads (Anura). The remaining living members of the class Amphibia, such as the caecilians (Gymnophiona), are treated individually in the *Micropædia*. Additional information about extinct groups (designated in the *Annotated classification* by a dagger [†]) is contained in the *Macropædia* article FOSSIL RECORD.

Urodela (salamanders and sirens)

Salamanders and sirens, constituting the order Urodela (Caudata), together with frogs (order Anura) and caecilians (order Gymnophiona) are major living groups of the class Amphibia. The relatively small and inconspicuous salamanders are important members of north temperate and some tropical animal communities. They are important as subjects of experimental studies in embryology, developmental biology, physiology, anatomy, biochemistry, genetics, and behaviour. Convenient size, low food requirements, low metabolic rate, and hardiness make them good laboratory animals.

GENERAL FEATURES

Size range and diversity of structure. The most typical salamanders are short-bodied, four-legged, moist-skinned vertebrates about 100 to 150 millimetres (about four to six inches) long. The tail is usually about as long as the body. There is much variation in size, and terrestrial salamanders range from 40 to nearly 350 millimetres (about 1.6 to 14 inches) in length. Some live in moist places on land but must go to water to breed. Others are completely terrestrial. Wholly aquatic salamanders attain larger sizes than do terrestrial ones, the former reaching a maximum of 180 centimetres (about six feet). Salamanders may retain gills throughout life, lose the gills but retain a spiracle (breathing pore) or gill slit, or completely metamorphose (*i.e.*, alter radically in structure and appearance) and lose both gills and gill slits. Many aquatic species resemble their terrestrial relatives in body form, but aquatic genera such as *Siren* and *Pseudobranchius* lack hindlimbs, and *Amphiuma* has an extremely elongated body, short tail, and diminutive legs; several cave-dwelling forms (*Proteus*, *Haideotriton*, *Typhlomolge*) are blind and almost without pigment.

Distribution and abundance. Salamanders are classic examples of animals with a Holarctic distribution (*i.e.*, in the north-temperate regions of both the Eastern and Western hemispheres); eight of the nine families (see below *Annotated classification*) are found almost entirely in northern regions that lie outside the tropics. Typically, they occur in moist, forested habitats, where they are often common in aquatic and terrestrial communities. Members of the family Salamandridae extend south to extreme northern Africa, the southern foothills of the Himalayas, northern Vietnam, and the island of Okinawa. Some ambystomatids reach the southern margins of the Mexican Plateau, but only the lungless salamanders (plethodontids) have truly entered the tropics. One group of plethodontids, which occupies a wide variety of tropical habitats in the New World—from northern Mexico to southern Brazil and central Bolivia—contains nearly half of all recognized species of salamanders, an indication that the plethodontids have been highly successful in the tropical environment. Other areas in which salamanders have been successful include temperate North America (Appalachian and Ozark uplands; Pacific coast areas with a moist habitat), western Europe, Japan, and China.

NATURAL HISTORY

Life cycle and reproduction. Most salamanders are terrestrial or semiterrestrial as adults, but many return to aquatic habitats to breed. Courtship, which is simple or nonexistent in hynobiids and cryptobranchids, is increas-

ingly elaborate and prolonged in the more highly evolved families. In primitive species comprising the suborder Cryptobranchioidea, fertilization of the egg is external. The females deposit sacs or strings of eggs that may be grasped by the male, who then sheds milt (which contains the sperm) over them. Nothing is known of courtship in sirens, but they, too, may have external fertilization, for the males lack the cloacal glands that produce the spermatophore, or sperm case, in species with internal fertilization, and the females lack spermathecae—chambers inside the cloaca used for sperm storage. All other species of salamanders have more complex courtship behaviour—often differing in details between species—and internal fertilization. The male deposits from one to many spermatophores on the ground or other surface. These consist of a gelatinous base, which is produced by cloacal glands, and a so-called sperm cap at the tip. The female moves by herself or is led by the male onto the spermatophore, and she takes the sperm mass into her cloaca. Breeding often occurs in ponds, but some salamandrids and most plethodontids breed on land. Egg deposition may take place shortly after mating but in many plethodontids may be delayed for several months, the eggs being fertilized by stored sperm. Eggs are laid in masses in streams or ponds, often in the shallows near shore. In most plethodontids and in some species of other families, eggs are laid singly, in short strings, or in small groups in terrestrial sites—*e.g.*, under surface objects, in rotting logs, or underground. Some species deposit eggs in tree cavities, and tropical species may deposit them in bromeliad plants, the leaves of which are arranged so that they often hold water. Frequently, the female stays with the eggs until they hatch, a period of several weeks. The number of eggs varies greatly and is correlated with adult size. Aquatic forms deposit as many as 400 eggs; terrestrial forms, as few as five or six.

Typical salamanders undergo an aquatic larval stage that lasts for a period ranging from a few days to several years. A short period of metamorphosis usually occurs before the terrestrial phase of the life cycle begins. The newly metamorphosed salamander is usually very small, and from one to several years elapse before it achieves sexual maturity.

Some salamander species never metamorphose and thus retain most of their larval characteristics. In other species, individuals or populations may occasionally fail to metamorphose. Still other species undergo partial metamorphosis. This phenomenon, known as paedomorphosis—*i.e.*, retention of larval or juvenile features by adults—characterizes all salamanders to a degree but is particularly evident in species such as *Necturus maculosus* (mudpuppy) and *Ambystoma mexicanum* (axolotl), which retain gills and other larval structures throughout life. These animals breed in what is essentially a larval state. This extreme condition, which characterizes the Proteidae, Necturidae, and Sirenidae, is also found in several species of the Plethodontidae and Ambystomatidae. In most species the permanent larval state is determined by heredity, but in some it is induced by environmental factors, such as unfavourable terrestrial conditions resulting from drought or cold. The most complete metamorphosis is found in the families Hynobiidae, Salamandridae, Ambystomatidae, and Plethodontidae.

Most species of the family Plethodontidae develop entirely on land, with no aquatic larval stage. The hatchling has either rudimentary gills that soon disappear or none at all and, in virtually all respects, is a miniature of the adult.

Females of the genus *Salamandra* (Salamandridae) may retain the fertilized eggs in the reproductive tract for a varying time. The fire salamander (*Salamandra salamandra*) deposits a relatively advanced larva in the water. In the Alpine salamander (*Salamandra atra*) and some other *Salamandra* species, fully metamorphosed individuals are born. One individual develops from the first egg in each oviduct, the tube leading from the ovary to the outside. Initially, the young salamander lives on its own yolk sup-

Fertiliza-
tion

Paedomor-
phosis

Figure 4: Principal types of urodele larvae.

Adapted from G.K. Noble, *The Biology of the Amphibia*, copyright 1931; used with permission of McGraw-Hill Book Co.

ply; later it eats the yolk of the other eggs, and finally it develops enlarged gills that form an intimate association with the walls of the oviduct to convey nutrients to itself. The gills are lost shortly before birth. Such salamanders are the only live-bearing members of the order.

Larval salamanders are exclusively aquatic. They may occur in a variety of habitats, from temporary ponds to permanent swamps, rivers, slow-moving streams, mountain brooks, springs, and subterranean waters. In all habitats they are exclusively carnivorous, feeding primarily on aquatic invertebrates. In most salamander larvae, feeding is accomplished by a "gape and suck" method, in which the throat is expanded, or gaped, to produce a suction that draws water and prey into the opened mouth. Skin flaps around the mouth direct the water movement. The larvae are well equipped with teeth, which aid in holding and shredding prey. Pond larvae have a high fin on the upper side of the tail that extends far anteriorly (toward the head) and large gills. Limbs are rather slow to develop. By contrast, stream larvae have a low, short tail fin, small gills, and limbs that develop early.

Metamorphosis, although a period of major reorganization, is not so dramatic as that in frogs. In the final stages, metamorphosis is usually a rapid process; it is mediated by several hormones (*i.e.*, chemical substances that serve to regulate the function of various organs) produced by the thyroid and pituitary glands. The following typically occur during metamorphosis: loss of the gills; closure of the gill slits; appearance of a tongue pad and reorganization of the gill skeleton and musculature to produce a tongue; enlargement of the mouth and eyes; development of eyelids; and major changes in the structure of the skull and skin.

Locomotion. Locomotion is by means of limbs and by sinuous body movements. Some very elongated species of the genera *Phaeognathus*, *Batrachoseps*, *Oedipina*, and *Lineatriton* have reduced limbs and rely mainly on body movements for rapid locomotion. Species of the genus *Aneides* have arboreal (*i.e.*, tree-climbing) tendencies, and their long legs and digits, expanded toe tips, and prehen-

sile (grasping) tails make them effective climbers. Some salamanders of the genera *Pseudoeurycea* and *Chiropterotriton*, found in the New World tropics, are similarly adapted. Others, members of the genus *Bolitoglossa*, have extensively webbed forefeet and hindfeet with indistinct digits, allowing them to move across moist leaves and other smooth surfaces.

Behaviour and ecology. Adult salamanders are nearly all nocturnal (*i.e.*, active mainly at night) animals. They may be highly seasonal, remaining hidden underground until the breeding season, or they may emerge from hiding places on any evening when moisture and temperature are at the proper levels. Fallen logs, rocks, crevices in soil, and surface litter commonly provide daytime refuge. Home ranges of salamanders are small, often less than three or four square metres (30 to 40 square feet), and, in favourable areas, some of the smaller species can be very abundant, occasionally numbering thousands per acre.

Insects are by far the most important food of salamanders. Primitive salamanders seize their prey by a combination of jaw and tongue movements. Some members of the Salamandridae and Plethodontidae, however, have evolved highly specialized tongue protrusion mechanisms. These are especially well developed in the tropical plethodontids, many of which are arboreal. The tongue can be extended from the mouth for a considerable distance and retracted almost instantaneously, with the prey attached to the sticky tongue pad.

Most terrestrial species live near the surface of the ground, often in thick leaf litter and rock piles. Some enter subterranean retreats, sometimes by way of burrows made by mammals and invertebrates. Caves are often occupied during cold or dry periods. Climbing species live on rock faces and in crevices, in trees, on broad-leaved herbs and shrubs, and in bromeliads. Many species are semi-aquatic, frequenting streamside and spring habitats throughout their lives. The terrestrial species that have direct development have been able to free themselves entirely from reliance on standing or flowing water. Among one group of plethodontids, species are found in habitats ranging from true deserts and frigid Alpine areas to tropical rain forests and from sea level to elevations of more than 4,000 metres (13,000 feet).

FORM AND FUNCTION

Skin and external features. The most distinctive and important feature of amphibians in general and salamanders in particular is their smooth, moist skin. This organ consists of an epidermis, or surface tissue, that is several layers thick and a rather thick dermis containing mucus and poison glands as well as pigment cells. The integument, or skin, is highly vascular and serves a major respiratory function. The poison glands of some species produce some of the most virulent toxins known. The fleshy tongue pad contains many mucus-secreting glands.

Most species are drab gray or brown; but many species, especially the more poisonous ones, are spectacularly coloured, with bright spots, blotches, or streaks on a

Larval
feeding
habits

Habitat

Figure 5: Representative urodeles.

contrasting dark background. The few integumentary specializations include keratinized (*i.e.*, infused with a tough, horny material: keratin) skins of the terrestrial stages of many salamandrids; keratinized claws in stream-dwelling hynobiids; and so-called hedonic glands (believed to stimulate sexual activity of the opposite sex) that are variously distributed in many species. Cryptobranchids have large, lateral folds of skin that serve respiratory functions.

Bones and cartilage. The rather weak skull of adults is comprised of various paired bones. These bones may fuse or be lost in different groups, and their presence and arrangement are important in classification. Much of the fusion and loss of skull bones is frequently associated with a trend toward tongue feeding. Small, double-cusped teeth line the margins of the jaw and spread over parts of the palate. They are important in holding but not chewing the prey.

Cartilage plays an important role in the urodele head, especially in supportive structures in the throat region. These are ossified (bony) to different degrees, with more cartilage in the more highly evolved groups. Species that display tongue protrusion often have flexible, cartilaginous tongue skeletons. In larvae and permanently gilled species the tongue is not developed.

The vertebrae comprising the spinal column are generalized with centrums (*i.e.*, ventral, or lower, sections connecting with the adjacent vertebrae) that are rather poorly developed. The notochord (*i.e.*, a resilient, flexible cord of specialized cells passing through the vertebral column) is usually persistent in adults. An intervertebral cartilage forms the articulation between vertebrae. If it remains cartilaginous, the vertebrae are said to be amphicoelous (biconcave, or depressed on both the anterior and posterior sides), but, if it mineralizes or ossifies, the vertebrae are termed opisthocelous (bulged on the anterior side and depressed on the posterior side). There is one cervical vertebra with a characteristic projection called the odontoid process and two large facets for articulation with the skull. There may be from 11 (*Ambystoma talpoideum*) to 60 (*Amphiuma*) dorsal, or trunk, vertebrae, all but the last one or two usually bearing ribs. Most salamanders have from 14 to 20 trunk vertebrae. One sacral vertebra, two to four caudosacral vertebrae, and from about 20 to over 100 (*Oedipina*) caudal, or tail, vertebrae complete the column. Many plethodontids are capable of autotomizing, or dropping off, the tail, a valuable defense mechanism in the event that the tail is grasped or bitten by a predator. These salamanders have various specialized features associated with the last caudosacral and the first caudal vertebrae, between which the break usually occurs.

The limbs and girdles are similar to those of generalized vertebrates. The pectoral, or chest, girdle, supporting the forelimbs, is relatively reduced; all elements are fused and remain largely in a cartilaginous condition. An ypsiloid cartilage, used in exhalation, is present in several groups, especially ambystomatids and salamandrids. Digits and digital bones have been lost in many different groups. There are never more than four fingers, but nearly all species have five toes.

Nervous system and sense organs. The nervous system is the simplest found in any four-legged animal. The generalized brain is rather small. The relatively large cerebrum (collectively, the two large anterior lobes of the brain) is associated with the large and important olfactory and vomeronasal organs, both of which are used for smelling. The eyes, usually large and well developed, are reduced and nearly lost in some cave-dwelling species. Certain parts of the inner ear are large and well developed. Hearing mechanisms of the salamander are not fully understood. There is no middle ear cavity and no external ear. One middle ear bone rests in the structure known as the vestibular fenestra. The other bone of the middle ear rests in the posterior part of the fenestra and is joined by muscles to the pectoral girdle. The elements are variously fused or lost in different groups. The spinal cord and the peripheral nervous system—*i.e.*, the paired cranial and spinal nerves—are generalized in their structure, and there are distinct brachial and sacral plexuses, both of which are important nerve networks supplying the limbs.

Muscles and organ systems. The generalized musculature of the trunk exhibits little differentiation. The abdominal muscles show increasing degrees of differentiation in the higher groups. The hyobranchial and branchiomic muscles and some abdominal muscles (rectus abdominis) are highly specialized in those species that use the tongue to capture prey.

The simple digestive system includes a short, nearly straight gut. The lungs are relatively simple, saclike organs in primitive groups. In stream-dwelling members of several families, the lungs are greatly reduced; they are entirely absent in all plethodontids.

The circulatory system is characterized by a highly developed vascularization of the body surface. The heart is simple, with one ventricle (*i.e.*, a chamber that pumps blood out of the heart) and two atria (chambers that receive blood from the rest of the body); separation between the two atria is not distinct in lungless forms.

The urogenital system consists of an elongated kidney with a distinct sexual segment and a posterior concentration of large renal units, which filter urine from the blood. Testes, the male sex glands, are small and compact, increasing in size with age. Ovaries of females are thin sacs. The cloaca is relatively complex in highly evolved groups with a spermatheca in females and several sets of cloacal glands in both sexes.

Gonads

EVOLUTION AND CLASSIFICATION

Paleontology. Fossils have contributed little, as yet, to the understanding of salamander evolution. The earliest definitive salamander is one of unknown affinities from the Jurassic Period (about 136,000,000 to 190,000,000 years ago). Several ambystomatoid families (Prosirenidae, Scapherpetonidae, Batrachosauroididae) are known only from fossils. The relationships of urodeles to other living and fossil amphibians are unclear, but recent workers consider the three living groups to form the subclass Lissamphibia.

Distinguishing taxonomic features. The features used to establish the limits of the order and of the groups within it include: general body size and organization—*e.g.*, presence or absence of external gills, numbers and relative proportions of limbs and digits, number and arrangement of skull bones; organization of the hyobranchial apparatus (cartilage in the throat region); structure and distribution of the teeth; structure of the vertebrae and intervertebral articulations; numbers of vertebrae; number and organization of the hand and foot elements; anatomy of the pelvic girdle; anatomy of external structures, such as hedonic (sex-attractant) glands, body and tail fins, webbing of hands and feet, and cloacal glands. Distinctive also is the general way of life, whether permanently aquatic, semi-aquatic, or terrestrial.

Annotated classification. The classification below is based on that of A.H. Brame, Jr. (1967). There is as yet no widely accepted scheme for classification below the order level. The plethodontids of the New World tropics remain poorly known, taxonomically.

ORDER URODELA (OR CAUDATA)

Tailed amphibians with 2 or 4 legs; moist, usually smooth, glandular skin; the most generalized of the living amphibians not only in structure but also in way of life; about 320 species.

Suborder Cryptobranchioidea

The most primitive salamanders; external fertilization; angular bone separate from the prearticular bone in the lower jaw; 2 pairs of limbs; no external gills; aquatic, semi-aquatic, and terrestrial.

Family Hynobiidae (Asiatic salamanders)

Generalized, medium-sized (to about 250 mm, or about 10 in.), semi-aquatic and terrestrial; lacrimal and septomaxillary bones present in skull; vomerine teeth not parallel to marginal teeth; Paleocene (?) (54,000,000–65,000,000 years ago) to present; northern Asia from Ural Mountains to Japan and Taiwan; about 30 species.

Family Cryptobranchidae (giant salamanders and hellbender)

Very large, to about 180 cm (about 6 ft), aquatic; no lacrimal or septomaxillary bones in skull; vomerine teeth parallel to marginal teeth; Oligocene (26,000,000–38,000,000 years ago) to present; Japan, China, and eastern United States; 3 species.

Fingers
and toes

Suborder Sirenoidea

Mode of fertilization unknown; angular bone fused with prearticular bone in lower jaw; only anterior pair of limbs present; external gills; aquatic.

Family Sirenidae (sirens and dwarf sirens)

Small to very large, to about 100 cm (about 40 in.), predators; inhabitants of lowland waters; Late Cretaceous (65,000,000–90,000,000 years ago) to present; southeastern United States from South Carolina to Tamaulipas, Mexico; 3 species.

Suborder Salamandroidea

Fertilization internal; angular bone fused with prearticular bone in lower jaw; no septomaxillary bones in skull; tooth replacement of vomerine teeth from medial side in metamorphosed forms; 2 pairs of limbs; external gills in a few species; aquatic, semi-aquatic, and terrestrial.

Family Proteidae (olms)

Blind; lacking pigment, cave-dwelling; elongated body, length to 30 cm (about 1 ft), and slender limbs (3 fingers, 2 toes); external gills present; Pliocene (2,500,000–7,000,000 years ago) to present; 1 species, native to Yugoslavia.

Family Necturidae (mud puppies)

Small to moderately large, to 45 cm (about 1½ ft), permanently aquatic, lake and stream dwellers; eyes and skin pigmentation present; 4 fingers and 4 toes; external gills present; no fossil record; eastern North America; 5 species, of genus *Necturus*.

Family Amphiumidae (congo eels)

Large, to over 100 cm (about 40 in.); very elongated, aquatic to semi-aquatic; predaceous, with powerful jaws and teeth; limbs diminutive, 1 to 3 fingers and toes; external gills absent, but spiracle open; Late Cretaceous to present; eastern North America; 3 species, of genus *Amphiuma*.

Family Salamandridae (salamanders and newts)

Generalized form and habit; moderate size, to 32 cm (about 13 in.); limbs with 4 fingers, 4 to 5 toes; usually no external gills or spiracle; Upper Cretaceous (?) to present; Europe, North Africa; Middle East; Afghanistan to Japan, China, and northern Vietnam; eastern and western North America; about 42 species.

Suborder Ambystomatoidea

Fertilization internal; angular bone fused with prearticular bone in lower jaw; septomaxillary bones present primitively in skull; tooth replacement of vomerine teeth from posterior or lateral direction; 2 pairs of limbs; external gills in some species; aquatic, semi-aquatic, or terrestrial.

Family Ambystomatidae (mole salamanders and others)

Small to moderate size, to 35 cm (about 14 in.); usually with well developed lungs; no nasolabial grooves; ypsiloid cartilage present; Paleocene to present; North America; about 33 species, including *Ambystoma*.

Family Plethodontidae (lungless salamanders)

Very small to moderate size, 4 to about 30 cm (about 1.6 to 12 in.); includes the most specialized and most terrestrial salamanders, and the only truly tropical species; lungless; nasolabial grooves present; no ypsiloid cartilage; Pliocene to present; North America, Central America, and most of South America; 2 species in Europe (Sardinia, southern France, and north central Italy); more than 200 species.

Critical appraisal. Some controversy exists concerning the classification of salamanders below the ordinal level. Some authorities place the sirenids in a separate order, Trachystomata, while others separate the Necturidae from the Proteidae, but neither scheme has been widely accepted. Chromosomal evidence of proteidnecturid similarity has recently been presented. Close association of Ambystomatidae and Plethodontidae is now accepted, but placement of Amphiumidae remains controversial.

Anura (frogs and toads)

Frogs and toads comprise the order Anura (Salientia of some authors) of the vertebrate class Amphibia and because of their wide distribution are known by most people around the world. The name frog is commonly applied to those forms with long legs and smooth, mucus-covered skins, toad being used for a variety of robust, short-legged anurans, especially those with rough skins. The name toad is applied so unevenly that one member of a family may be called a toad and a closely related member a frog. The familiar members of the family Bufonidae may be distinguished as “true toads.” In this article, “frog” is applied

generally to members of the Anura and “toad” to those for which it has traditionally been used. Many school children catch and keep frogs as pets and obtain one of their first biology lessons by rearing the larvae, known as tadpoles or pollywogs, in science classes. College students become familiar with frog anatomy and embryology in biology courses. People in various parts of the world eat frog legs, and some kinds of toads are used in insect control. Certain South American Indians use the poisonous secretions of some kinds of frogs for poison arrows, and now biochemists are studying the possible medical uses of the constituents of the poison. The biologist interested in evolution finds a vast array of interesting, and often perplexing, problems in the study of frogs, a highly specialized group of amphibians.

GENERAL FEATURES

Size range and diversity of structure. Although all frogs are readily recognizable, there are great varieties of sizes and of structural modifications. Many frogs are tiny animals; the smallest is the Cuban *Sminthillus limbatus*, adults of which do not exceed 12 millimetres (½ inch) in body length (with legs drawn in), whereas the African giant frog, *Conraua goliath*, has a body length of nearly 300 millimetres (slightly less than one foot). Many anurans have smooth, moist skins. Toads of the genus *Bufo* are familiar as “warty” amphibians, the skin being highly glandular and covered with tubercles. Frogs of many other families have rough, tubercular skins, usually an adaptation for life in the less humid environments. The opposite extreme is found in the small arboreal frogs of the tropical American family Centrolenidae, in which the skin on the under side is thin and transparent, and the heart and viscera can be seen through the skin.

Most frogs move by leaping. The long and powerful hind limbs are straightened rapidly from the crouching position, propelling the frog through the air into water or to a distant place on the ground. Many arboreal frogs, especially members of the family Hylidae, have adhesive discs on the ends of the fingers and toes and leap from branch to branch or from leaf to leaf. Members of the families Bufonidae, Rhinophrynidae, and Microhylidae and certain burrowing species in other families have relatively short hindlimbs and move forward by series of short hops. Some bufonids actually walk instead of hopping. Highly modified members of the hylid subfamily Phyllomedusinae have opposable digits on the hands and feet and walk slowly along branches, deliberately grasping the branch in the manner of tiny lemurs. Many kinds of frogs have membranous webbing between the fingers and toes; in the aquatic species the webbing on the feet aids in swimming. The extreme in this specialization is seen in the aquatic family Pipidae. Members of that family normally never leave the water. In regions of the earth subjected to long dry periods, frogs must seek cover in order to avoid desiccation and have behavioral and structural adaptations to conserve water.

Although many frogs are unimpressively coloured, some species are brilliantly marked. The most common colours are brown, gray, green, and yellow. Uniformly coloured frogs are the exception rather than the rule. The markings of a frog may seem bold when observed out of the natural habitat, but they usually are concealing or disruptive when the frog is in its environment.

Distribution and abundance. Because of their morphological and physiological adaptations, frogs are able to inhabit most regions of the world except the extremely cold land masses at high latitudes and some oceanic islands that they have been unable to colonize due to the barriers provided by saltwater. Frogs live in desert regions below sea level and in montane areas up to elevations above 4,560 metres (15,000 feet). Some members of the genus *Rana* live north of the Arctic Circle. Although widely distributed on the earth, frogs are most diverse and abundant in the tropics, and 7 of the 17 families are restricted to the tropics. In most temperate areas of the world, the number of species of frogs at any one locality is usually less than ten; but in the tropics, especially in rain forests, the number of species is much greater. At one locality in

the upper Amazon Basin in eastern Ecuador, 83 species are known to occur, about the same number as is known for all of the United States.

In a complex environment, such as the tropical rain forest, the large number of species of frogs partition the environmental resources in a variety of ways. In the humid tropics, frogs can be active throughout the year, but many species are seasonal in their breeding activity. Various kinds of sites and different seasons are used for calling and egg laying; such temporal and spatial separation avoids interspecific competition. Frogs feed mostly on insects and other invertebrates, and the abundance of food in tropical rain forests probably places no competitive restrictions on this aspect of environmental resources. Some large species eat vertebrates, including small rodents and other frogs.

NATURAL HISTORY

Breeding behaviour. The breeding behaviour is one of the most distinctive attributes of the Anura. Since the eggs can develop only under moist conditions, most frogs place their eggs in bodies of fresh water. Many species congregate in large numbers at temporary pools for short breeding seasons. Mating calls serve to attract males and females to breeding sites. Other frogs breed along the mountain streams where they live year round. In the

Mating
calls

Figure 6: Frogs (*Rana*) in copulatory embrace.

latter species and in those that breed on the land, there is no great concentration of breeding individuals at one place. In all cases, the mating call produced by the male attracts the females. It has been observed in the field and experimentally in the laboratory that the females can discriminate between mating calls of their own species and those of other species. At a communal breeding site, such as a pond, swamp, or stream, differences in specific calling sites of the males help the frogs to maintain their identities. Differences in mating calls, however, constitute the principal premating isolating mechanism preventing hybridization of closely related species living in the same area and breeding at the same time and place. Frogs have rather simple vocal cords, in most species a pair of slits in the floor of the mouth opening into a vocal pouch. Air is forced from the lungs over the vocal cords, causing them to vibrate and thus produce sound of a given pitch and pulsation. The air passes into the vocal pouch, which, when inflated, acts as a resonating chamber emphasizing the same frequency or one of its harmonics. In this manner, different kinds of frogs produce different calls.

Females move toward and locate calling males. Once the male clasps the female, a copulatory embrace called amplexus, she selects the site for depositing the eggs. In the primitive frogs (superfamilies Discoglossoidea, Pipioidea, and Pelobatoidea), the male grasps the female from above and around the waist (inguinal amplexus); whereas in the advanced frogs (superfamilies Bufonoidea and Ranoidea), the position is shifted anteriorly to the armpits (axillary amplexus). The latter position brings the cloacae of the

amplectic pair into closer proximity and presumably insures more efficient fertilization.

Most frogs deposit their eggs in quiet water as clumps, surface films, strings, or as individual eggs. The eggs may be freely suspended in the water or attached to sticks or submergent vegetation. Some frogs lay their eggs in streams, characteristically firmly attached to the lee sides or under sides of rocks where they are not subject to the current. The large pond-breeding frogs of the genus *Rana* and toads of the genus *Bufo* apparently produce more eggs than any other frogs. More than 10,000 eggs have been estimated in one clutch of the North American bullfrog, *Rana catesbeiana*. The habit of spreading the eggs as a film on the surface of the water apparently is an adaptation for oviposition in shallow temporary pools and allows the eggs to develop in the most highly oxygenated part of the pool. This type of egg deposition is characteristic of several groups of tree frogs, family Hylidae, in the American tropics, one of which, *Smilisca baudinii*, is known to lay more than 3,000 eggs. Frogs breeding in cascading mountain streams lay far fewer eggs, usually no more than 200.

The problem of fertilization of eggs in rapidly flowing water has been overcome by various modifications. Some stream-breeding hylids have long cloacal tubes so that the semen can be directed onto the eggs as they emerge. Some other hylids have huge testes, which apparently produce vast quantities of sperm, helping to insure fertilization. Males of the North American tailed frog, *Ascaphus truei*, have an extension of the cloaca that functions as a copulatory organ (the "tail") to introduce sperm into the female's cloaca.

Most frogs are considered to be placid animals, but recent observations have shown that some species exhibit aggressive tendencies, especially at breeding time. Male bullfrogs (*Rana catesbeiana*) and green frogs (*Rana clamitans*) defend calling territories against intrusion by other males by kicking, bumping, and biting. The South American nest-building hylid, *Hyla faber*, has a long, sharp spine on the thumb with which males wound each other when wrestling. The small Central American *Dendrobates pumilio* calls from leaves of herbaceous plants. Intrusion into a territory of one calling male by another results in a wrestling match that terminates only after one male has been thrown off the leaf. Males of the Central American dendrobatid *Colostethus inguinalis* have calling sites on boulders in streams. The intrusion by another male results in the resident uttering a territorial call, and if the intruder does not leave, the resident charges him, attempting to butt him off the boulder. Females of the Venezuelan *Colostethus trinitatus* wrestle in defense of territories in a stream bed.

Aggressive
behaviour

Males of at least three South American species of *Hyla* build basin-like nests, 25–30 centimetres (10–12 inches) wide and 2–5 centimetres (1–2 inches) deep, in the mud of riverbanks. Water seeps into the basin providing a medium for the eggs and young. Calling, mating, and oviposition take place in the nest, and the tadpoles undergo their development in the nests.

Some frogs in the families Leptodactylidae, Ranidae, and Microhylidae build froth nests. The small toadlike leptodactylids of the genus *Physalaemus* breed in small, shallow pools. Amplexus is axillary, and the pair floats on the water; as the female exudes the eggs, the male emits semen and kicks vigorously with his hind legs. The result is a frothy mixture of water, air, eggs, and semen, which floats on the water. This meringue-like nest is about 7.5–10.0 centimetres (3–4 inches) in diameter and about 5 centimetres (2 inches) deep. The outer surfaces exposed to the air harden and form a crust covering the moist interior, in which the eggs are randomly distributed. Upon hatching, the tadpoles wriggle down through the decaying froth into the water.

Most frogs have an aquatic, free-swimming larval stage (tadpole). After a period of growth, the tadpole undergoes a striking change (metamorphosis) in which the tail is lost and limbs appear. These are only two of the most obvious changes that take place. Tadpoles have a cartilaginous skeleton, thin nonglandular skin, and a long, coiled intestine;

Metamor-
phosis

they lack jaws, lungs, and eyelids. Among the first changes that take place is the appearance of hindlimb buds, which grow and develop into differentiated hindlimbs, complete with toes, webbing, and tubercles. Much later, the front limbs emerge through the skin; in contrast to the hindlimbs, the forelimbs develop before they emerge. At the time of emergence of the forelimbs, the tail begins to shrink, being absorbed by the body. The tadpole mouth begins to change; as the horny denticles and papillae, if present, disappear, the jaws and true teeth develop. The eyelids develop, and mucous glands form in the skin. The vertebral column and limb bones ossify, and the adult digestive system differentiates as the long, coiled intestine shrinks to the short, thick-walled, folded intestine of the adult. These radical changes are equalled in the animal kingdom only by the metamorphosis found in insects.

Just how and where the changes from larva to adult take place is highly varied and is one of the most fascinating aspects of the study of frogs. The differences in modes of life history reflect varied environmental conditions. In various evolutionary lines in frogs, there is a strong tendency toward an escape from the ties that bind the less advanced frogs to the water for breeding.

The tadpoles of the pond breeders characteristically have rather large bodies and deep caudal (tail) fins, which in some have a terminal extension, as do the familiar sword-tail fishes. The mouths are relatively small, either at the end of the snout or on the underside, and usually contain rather weak denticles (small toothlike projections). These tadpoles swim easily in the quiet water and feed

on attached and free-floating vegetation, including algae. In contrast, the stream tadpoles have depressed bodies, long muscular tails, and shallow caudal fins. The mouth is relatively large and usually contains many rows of strong denticles. In highly modified stream tadpoles, the mouth is ventral and modified as an oral sucker, with which the tadpole anchors itself to stones in the stream. Such tadpoles move slowly across stones, gnawing off moss or algae as they move. It is conceivable that a tadpole can complete its larval life on a single large stone.

Most tadpoles complete their development in two or three months, but there are notable exceptions. Tadpoles of spadefoot toads, genus *Scaphiopus*, develop in temporary rain pools in arid parts of North America, where it is imperative for the tadpoles to complete their development before the pools dry up. Some *Scaphiopus* tadpoles metamorphose about two weeks after hatching. In the northern part of its range in North America, the tadpoles of the bullfrog *Rana catesbeiana* require three years to undergo their development.

Some tree frogs of the family Hylidae deposit their eggs in water in trees. Several tropical species of *Hyla* lay their eggs in the water held in the overlapping bases of leaves of epiphytic bromeliads high in trees. Their tadpoles, which are slender with long muscular tails, develop in small quantities of water high above the ground. The Mexican hylid, *Anotheca spinosa*, lays its eggs in bromeliads or water-filled cavities in trees. The small tadpoles, like those of *Hyla*, feed on aquatic insect larvae, such as mosquitoes, but the larger tadpoles of *Anotheca* apparently feed only on the eggs of frogs.

A modification of the basic behaviour of aquatic eggs and aquatic tadpoles is the habit of depositing eggs on vegetation above water; this pattern occurs in some arboreal hylids and ranids and in all species in the family Centrolenidae. *Hyla ebraccata*, a small Central American tree frog, deposits its eggs in a single layer on the upper surfaces of horizontal leaves just a few inches above the pond. Upon hatching, the tadpoles wriggle to the edge of the leaf and drop into the water. The Mexican *Hyla thorectes* suspends 10–14 eggs on ferns overhanging cascading mountain streams. The phyllomedusine hylids in the American tropics suspend clutches of eggs from leaves or stems above ponds. Males call from trees; once a female has been attracted and amplexus takes place, the male placidly hangs onto the back of the female as she descends to the pond and absorbs water. This accomplished, she climbs into a tree, selects an oviposition site, and deposits eggs until her water supply is depleted. She again descends to the pond and repeats the performance at a different site until the entire complement of eggs is deposited. Upon hatching, the tadpoles drop into the pond below. Most of the tree frogs of the family Centrolenidae are less than one inch long. Males call from leaves of trees or bushes over cascading mountain streams in the American tropics. Individuals return to the same leaf night after night. Attracted females are clasped on the leaf, and egg deposition takes place there immediately. A highly successful male may have three or four egg clutches on his leaf, each consisting of only about two dozen eggs. Upon hatching, the tadpoles drop into the stream bed; and if the tadpole lands on a stone, it flips about vigorously until it falls into the water, where it hides in the loose gravel on the bottom of the stream. Many kinds of frogs lay their eggs on land and subsequently transport the tadpoles to water. The ranid genus *Sooglossus* of the Seychelle Islands and all members of the family Dendrobatidae in the American tropics have terrestrial eggs. Upon hatching, the tadpoles adhere to the backs of adults, usually males. The exact means of attachment is not known. The frogs carry the tadpoles to streams, bromeliads, or pools of water in logs or stumps, where the tadpoles complete their development. The most unusual example of tadpole care known is that exhibited by the mouth-breeding frog, or Darwin's toad, *Rhinoderma darwinii*, in southern South America. An amplexic pair deposits 20–30 eggs on moist ground. Several males gather around the eggs, and when the eggs are about ready to hatch, with the embryos moving, each male picks up some eggs with his tongue. The eggs pass

Parental care

Figure 7: Specializations of tail (left) and mouth (right) in tadpoles.
(A) For pelagic life in ponds. (B) For bottom life in ponds.
(C) For life in running water.

through the vocal slits in the floor of the mouth and into the vocal sac. The eggs hatch, and the larvae complete their development in the large vocal sac. Upon metamorphosis, the young frogs emerge from the male's mouth.

The European midwife toad, *Alytes obstetricans*, displays a peculiar breeding habit. Inguinal amplexus takes place on land; at the time of oviposition the female extends her legs to form a receptacle for the string of 20–60 eggs. After fertilizing the eggs, the male moves forward on the back of the female and pushes his legs into the string of eggs until they are wound around his waist and legs. Then the female departs. The male carries the eggs with him on land until they are ready to hatch, at which time he moves to a pond, where the eggs hatch and complete their development.

The hylid *Gastrotheca marsupiata* lives in the high Andes of South America, one of several so-called marsupial frogs, so named because of a brood pouch in the back of the female. In amplexus the male exudes a quantity of semen, which flows into the pouch. The female extrudes eggs, a few at a time; these are pushed into the pouch by the male who uses the hindfeet to catch and push the eggs. The eggs are fertilized in the pouch, where they hatch and the tadpoles begin their development. Subsequently, the female moves to a pond, where the tadpoles emerge from the pouch and complete their development in the water.

In each of the above instances of parental care, there is a trend away from the aquatic environment. Far fewer eggs (less than 50) are laid in comparison with those species depositing eggs in the water. The bonds with the aquatic environment have been partially broken, for, although the tadpoles must develop there, the eggs are effectively terrestrial, but not truly so, lacking the necessary embryonic membranes (allantois and amnion) to maintain physiological balance and lacking a shell. Consequently, if they are to survive and develop, the eggs must be maintained in moist places, such as damp soil or a part of the parental body. Water and waste products are transported through the membranes by osmosis.

The next evolutionary step in mode of life history is the elimination of the larval stage, thereby completely severing the ties with the aquatic environment. Direct development of the egg, in which the larvae undergo their development within the egg membranes and emerge as tiny froglets, occurs in many species, scattered in seven families (Leiopelmatidae, Pipidae, Leptodactylidae, Bufonidae, Brachycephalidae, Hylidae, and Microhylidae). Typical direct development of terrestrial eggs occurs in the many species of the leptodactylid genus *Eleutherodactylus* of Central and South America and the West Indies. During axillary amplexus, the female deposits a clutch of eggs in a moist place (beneath a log or stone, amidst leaf litter, in a rotting stump, in moss, or in a bromeliad). The parents depart, leaving the eggs to develop and subsequently hatch. In some *Eleutherodactylus* and in the New Zealand leiopelmatid *Leiopelma hochstetteri*, the hatching froglet still has a tail. In *Leiopelma*, at least, vigorous thrusts of the tail are used to rupture the egg membranes. Soon after hatching, the tail is completely absorbed.

Brooding of terrestrial eggs is known in a few species. Females of two species of *Eleutherodactylus* that lay their eggs on leaves of bushes or trees sit on the eggs. Apparently this brooding serves to prevent desiccation of the eggs by dry winds. Females of the Papuan microhylid *Sphenophryne* lay their few eggs beneath stones or logs and sit on top of them until they hatch.

Direct development occurs in several genera of hylid marsupial frogs (*Gastrotheca* and *Amphignathodon*) living in mountain rain forests in northwestern South America. In these frogs, amplexus is axillary, and the female raises her cloaca so that the eggs, which are extruded one at a time, roll forward on her back and into the pouch. There the eggs develop into frogs. Large, external, gill-like structures envelop the developing embryo. These structures, which are attached to the throat of the embryo by a pair of cords, apparently function in respiration. These frogs live high in trees and complete their life cycle without descending to the ground. Thus they are rare in collections, and their biology is poorly known.

Some other South American genera of Hylidae also exhibit the phenomenon of direct development of eggs carried on the backs of the females. In *Flectonotus* and *Fritziana*, the eggs are contained in one large basin-like depression in the back, whereas in others each egg occupies its own individual depression. In *Hemiphractus*, gill-like structures and cords similar to those in *Gastrotheca* are present. At hatching, the expanded gill adheres to the

Marsupial
frogs

modified skin of the maternal depression and is attached to the young by the pair of cords. The female carries the young until they are sufficiently well developed to care for themselves. The manner of detachment of gill from female and young is unknown.

The strictly aquatic Surinam toad *Pipa pipa* of northern South America also has direct development, in this case in the water. Eggs are carried in individual depressions in the back of the female. Amplexus is inguinal, and the pair rests on the bottom of the pond. The female initiates vertical circular turnovers, at the height of which she extrudes a few eggs. These are fertilized, fall against the belly of the then upside down male, and are pushed forward onto the female's back, where they adhere and subsequently become enclosed in tissue. Upon completion of development, the young frogs emerge from the skin of the female's back.

The most advanced form of reproduction known in frogs takes place in the small African bufonids of the genus *Nectophrynoides*. By some unknown means, fertilization is internal, and the young are born alive. It is noteworthy that the evolution of live birth has taken place independently in all three living orders of amphibians, for this phenomenon also occurs in salamanders and caecilians.

Feeding habits. The great majority of frogs feed on insects, other small arthropods, or worms, but some larger species eat vertebrates. The South American leptodactylid *Ceratophrys varia* and the large bufonid *Bufo marinus* eat other frogs and small rodents. The superficially similar Solomon Island ranid, *Ceratobatrachus guentheri*, and the South American hylids, *Hemiphractus*, eat other frogs. Large North American bullfrogs, *Rana catesbeiana*, have been reported to consume other frogs, mice, small snakes, and even small turtles.

FORM AND FUNCTION

Adult anurans are easily recognized, by layman and specialist alike, by the short body and elongated hindlimbs, the absence of a visible neck, and the absence of a tail. The compact body has been attained by a reduction of the number of trunk vertebrae and the fusion of tail vertebrae into a single rodlike bone, the coccyx or urastyle. The lengthening of the hindlimbs has been attained, in part, by the elongation of two bones (astragalus and calcaneum) in the foot. Considering the variety of habitats occupied by anurans, there is remarkably little gross variation in body plan. The female is usually larger than the male. In most frogs the tympanic membrane (eardrum) is visible as a prominent disc on each side of the head. Correlated with a sound-oriented existence, the larynx is also well developed, often accompanied by single or paired inflatable resonating sacs.

Poisons

All frogs have poison glands in the skin, well developed in many diverse groups. In the Dendrobatidae, the skin secretions are especially toxic. *Dendrobates* and *Phyllobates* are small, diurnal frogs living in Central and South America, brilliantly coloured, solid red, yellow, or orange, or patterned with bold stripes or cross bars. These bright patterns are believed to act as warning colours to ward off predators. One nonpoisonous South American leptodactylid, *Lithodytes lineatus*, mimics the dendrobatid *Phyllobates femoralis*, thus gaining protection from predation (see also MIMICRY).

The biochemical properties of amphibian skin toxins are highly varied, most being complex nitrogenous compounds. The toxically active ingredients are of various types, from local irritants to convulsants, hallucinogens, neurotoxins (nerve poisons), and vasoconstrictors (acting to narrow blood vessels). The medical importance of these ingredients is now being investigated. Although these skin secretions irritate human skin and mucous membranes, they do not cause warts.

The skin toxins of most frogs do not provide security from predators; in fact, frogs are a basic food for many snakes, birds, and mammals. Edible anurans rely on modifications of shape, skin texture, and colour, supplemented by behaviour, to escape detection. These modifications may reach remarkable extremes. Hylids of the South American genus *Hemiphractus* live on the forest floor

among leaf litter and have flattened bodies that enable them to blend well with dead leaves. Several tree frogs, rough skinned and greenish-gray, resemble lichens when flattened out on tree trunks. The coloration of many frogs changes from night to day. In most species the colour is darker and the pattern more distinct by day than by night, but the reverse is true for some tree frogs inhabiting semi-arid regions. Colour change is brought about through the stimuli of light and moisture, which create a physiological change and result in contraction or expansion of the melanophores (pigment cells) in the skin.

Coloration

More difficult to comprehend is the striking array of colours on the hidden surfaces of frogs. Many frogs that are rather dull or uniformly coloured when in a resting position have bright colours or patterns on the flanks, groin, posterior surfaces of the thighs, and belly. For example, the South and Central American hylid, *Agalychnis saltator*, when observed sleeping by day, is nothing more than a green bump on a leaf. The eyes are closed, the hindlimbs drawn in close to the body, and the hands folded beneath the chin. Upon moving, the frog creates a striking appearance, previously hidden surfaces showing a deep golden orange, interrupted by vertical black bars on the flanks and thighs. These so-called flash colours are common in frogs and are thought to serve in species recognition or in confusing predators. Some colour patterns obviously do confuse predators. The South American leptodactylids of the genus *Eupsophus* have a pair of brightly coloured "eyespot" on the rump. When approached by a potential predator, the frog lowers its head and elevates the rump, thus confronting the predator with a seemingly much larger head.

Structural modifications allow certain specialized frogs to survive dry periods. Some arboreal frogs hide in bromeliad plants (various genera of the family Bromeliaceae), which hold water in the axils of their leaves. Among the Hylidae are genera that have the head modified into a bony casque ("helmet") and the skin co-ossified with the underlying bone. The head is used by some species to plug the constricted base of the bromeliads and by others to plug up holes in trees, the frogs surviving the dry season by utilizing what little moisture is trapped in the cavity.

Most toads of the genus *Bufo* and many genera in the families Rhinophrynidae, Pelobatidae, Myobatrachidae, Leptodactylidae, Hylidae, Ranidae, and Microhylidae burrow in sand, soil, or mud. Many of these species have the tubercles on the middle (metatarsal) part of each foot modified into a spade-shaped digging organ. The animals are highly resistant to desiccation and conserve water in the body by the mucous skin secretions that tend to make the skin impermeable. This modification is carried to the extreme in some Australian myobatrachids, which secrete a cocoon formed of hardened mucus.

CLASSIFICATION

Distinguishing taxonomic features. The superfamilies and families of the Anura are based on anatomical, developmental, and behavioral characteristics. Important anatomical features include: the type of vertebrate present, especially with respect to the articulating surfaces, which may be concave on the anterior end of each vertebra (procoelus), on the posterior side (opisthocoelus), or concave on both ends (amphicoelus); the presence or absence of intercalary cartilages (between the terminal and penultimate bones of the digits); whether the pectoral girdle is firmisternal (*i.e.*, with the cartilages of the two epicoracoid bones fused together) or arciferal (with these cartilages separate and overlapping); the presence or absence of an anterior projection, the omosternum, on the pectoral girdle; the presence or absence of teeth on the maxillary bone; and the presence or absence of Bidder's organ (a rudimentary ovary) in the male. The type of egg and anatomy of the tadpole are often important. The key behavioral characteristics are primarily those involved with reproduction, such as the type of amplexus and method of egg deposition.

Annotated classification. The classification presented here is an amalgamation of recent views by various specialists, none of whom has surveyed the entire order. A scanty record of meaningful fossils and inadequate knowledge of

the morphology and mode of life history of many kinds of frogs result in inconclusive evidence for any classification of the families; consequently, the following classification must be considered to be tentative.

ORDER ANURA

Amphibians lacking a tail in the adult stage; 6 to 9 presacral vertebrae; postsacral vertebrae (posterior to the pelvis) fused into a bony coccyx; hindlimbs elongated, modified for jumping; fertilization normally external; eggs laid in water or not; an aquatic larval stage (tadpole) present in most; males usually with vocal cords, vocal sac (resonating chamber), and a voice. About 2,660 species.

Superfamily Discoglossoidea

Vertebrae amphicoelous with labile centra (*i.e.*, joined by rings of cartilage); pectoral girdle arciferous; ribs present on anterior vertebrae; amplexus inguinal; larvae with single median spiracle (respiratory opening) and complex mouthparts or with direct development (froglet hatching directly from the egg).

Family Leiopelmatidae

No fossil record. Nine presacral vertebrae (*i.e.*, anterior to the pelvic girdle); parahyoid and caudalipuboischiotibialis ("tail-wagging") muscles present; direct development (*Leiopelma*) or stream-adapted tadpoles (*Ascaphus*). New Zealand and northwestern North America; 2 genera, 4 species. Adult length about 5 cm.

Family Discoglossidae (fire-bellied and midwife toads)

Eocene to present. Usually 8 presacral vertebrae; parahyoid tongue muscle and caudalipuboischiotibialis muscle absent. Still-water tadpoles. Eurasia, North Africa, and Philippine Islands; 4 genera, 8 species. Adult length to about 10 cm.

Superfamily Pipoidea

Vertebrae opisthocelous; pectoral girdle arciferous; ribs absent or fused to transverse processes of vertebrae; amplexus inguinal; larvae with paired spiracles and simple mouthparts or with direct development.

Family Rhinophrynidae (burrowing toad)

Oligocene to present. Eight presacral vertebrae; ribs absent; coccyx free, with 2 articulating surfaces; tongue free and protrusible; body robust; burrowing; aquatic larvae present. Mexico and Central America, 1 species; adult length to about 7 cm.

Family Pipidae (tongueless frogs)

Cretaceous to present; 5 to 8 presacral vertebrae; ribs present and free in larvae, but fused to transverse processes of vertebrae in adults; coccyx fused to sacrum or free and monocondylar (*i.e.*, with 1 articulation); tongue absent; body flattened. Aquatic, direct development or aquatic larvae present. Africa south of Sahara and tropical South America, east of Andes; 6 genera, 14 species; adult length 5–20 cm.

Superfamily Pelobatoidea

Vertebrae procoelous with labile centra; pectoral girdle arciferous; ribs absent; amplexus inguinal; larvae with single spiracle on the left, and complex mouthparts.

Family Pelobatidae (spadefoots)

Eocene to present. Eight presacral vertebrae; coccyx fused to sacrum or free and monocondylar. Ten genera, 59 species; adult length 4 to about 15 cm. Three subfamilies: Megophryinae (Southeast Asia, Indo-Australian Archipelago, Philippine Islands), Pelodytinae (southwestern Europe and southwestern Asia), Pelobatinae (Europe and North America).

Family Myobatrachidae

Eocene to present. Eight presacral vertebrae; coccyx free, bi-condylar. Eighteen genera, 76 species; adult length to about 10 cm. Three subfamilies: Myobatrachinae (New Guinea and Australia), Cyclorhinae (New Guinea and Australia), Heleophryinae (South Africa).

Superfamily Bufonoidea

Vertebrae procoelous; pectoral girdle arciferous (in some, secondarily firmisternal); ribs absent; amplexus axillary; larvae usually with single spiracle, on the left, and complex mouthparts, or with direct development.

Family Rhinodermatidae (mouth-breeding frog)

No fossil record. Eight presacral vertebrae, 1st and 2nd fused; pectoral girdle partly firmisternal; maxillary teeth, intercalary cartilages, and Bidder's organ absent; omosternum cartilaginous. Southern South America; 1 species; adult length 2.5 cm.

Family Leptodactylidae

Eocene to present. Eight presacral vertebrae; pectoral girdle arciferous; maxillary teeth present; Bidder's organ and intercalary cartilages absent; omosternum cartilaginous or ossified. Thirty-nine genera, about 625 species; adult length 2 to about 20 cm. Four subfamilies: Ceratophryinae (South America), Telmatobiinae (South and Central America, West Indies), Elosiinae

(South America), Leptodactylinae (South and Central America).

Family Bufonidae (true toads)

Oligocene to present. Five to 8 presacral vertebrae; pectoral girdle arciferous, or partly or even completely firmisternal; intercalary cartilages and omosternum absent; Bidder's organ present; maxillary teeth present or absent; aquatic larvae, direct development, or live birth (*Nectophrynoides* only). Worldwide, except eastern part of Indo-Australian Archipelago, Polynesia, Madagascar; *Bufo marinus* introduced into Australia and some Pacific islands; 13 genera, about 234 species; adult size 2 to about 25 cm.

Family Brachycephalidae

No fossil record. Seven presacral vertebrae, pectoral girdle partly firmisternal; intercalary cartilages and omosternum absent; Bidder's organ present; maxillary teeth present; direct development. Southeastern Brazil; 1 species; adult length 2 cm.

Family Dendrobatidae (arrow-poison frogs)

No fossil record. Eight presacral vertebrae; pectoral girdle completely firmisternal; intercalary cartilages absent; omosternum present; Bidder's organ absent; maxillary teeth present or absent. Larvae carried on backs of adults. Central and South America; 3 genera, about 70 species; adult length 1.5–5 cm.

Family Pseudidae

No fossil record; 8 presacral vertebrae; sacral diapophyses round; pectoral girdle arciferous; intercalary cartilages present, ossified; omosternum present; Bidder's organ absent; maxillary teeth present; aquatic larvae (which grow to a much larger size than the adult). South America east of Andes; 2 genera, 5 species; adult length 2–5 cm, larval length to 25 cm.

Family Centrolenidae

No fossil record; 8 presacral vertebrae; pectoral girdle arciferous; intercalary cartilages present; omosternum absent; Bidder's organ absent; maxillary teeth present; terminal phalanges T-shaped; astragalus and calcaneum bones of the foot fused. Stream-adapted larvae. Central and South America; 2 genera, about 45 species; adult length 2–6 cm.

Family Hylidae (tree frogs)

Miocene to present; 8 presacral vertebrae; pectoral girdle arciferous; intercalary cartilages present; omosternum absent; Bidder's organ absent; maxillary teeth usually present; terminal phalanges claw-shaped; astragalus and calcaneum not fused; aquatic larvae or direct development; adult length 1.3 to about 12 cm. Four subfamilies: Phyllomedusinae (Central and South America), Hemiphractinae (Central and South America), Amphignathodontinae (Central and South America), Hylinae (North and South America, Europe, Asia except Indian subregion, Africa north of Sahara and Australasia).

Superfamily Ranoidea

Pectoral girdle firmisternal; ribs absent; amplexus axillary; larvae with single sinistral spiracle and complex mouthparts, single median spiracle and simple mouthparts, lacking spiracle or undergoing direct development.

Family Ranidae (true frogs)

Miocene to present. Vertebral column diplasiocoelous (mixed amphicoelous and procoelous); intercalary cartilages present or absent; larvae with single spiracle, on left, and complex mouthparts. About 55 genera and 842 species, adult length about 2–25 cm. Nine subfamilies: Raninae (worldwide except for southern South America, southern and central Australia, New Zealand, and eastern Polynesia), Astylosterninae (Africa), Scaphiophryninae (Madagascar), Rhacophorinae (Africa, Madagascar, southeastern Asia, Indo-Australian Archipelago), Arthroleptinae (Africa), Cacosterninae (Africa), Hyperoliinae (Africa, Madagascar, Seychelles), Hemisinae (Africa), Petropedetinae (Africa).

Family Sooglossidae

No fossil record. Vertebrae procoelous; sacral diapophyses dilated; intercalary cartilages absent; larvae lacking spiracle. Seychelle Islands; 2 genera, 3 species; length about 4 cm.

Family Microhylidae

No fossil record. Vertebrae procoelous or diplasiocoelous; intercalary cartilages usually absent; larvae with single median spiracle and simple mouthparts, or undergoing direct development. Eight subfamilies: Cophylinae (Madagascar), Dyscophinae (Malay Peninsula, western Indo-Australian Archipelago, Madagascar), Asterophryninae (New Guinea and Sulu Islands), Sphenophryninae (Philippine Islands, eastern Indo-Australian Archipelago, New Guinea, northern Australia), Brevicipitinae (Africa), Microhylinae (North and South America, Southeast Asia, Sri Lanka, western Indo-Australian Archipelago, Philippine and Riu Kiu Islands), Melanobatrachinae (east-central Africa, India), Phrynomerinae (Africa).

Critical appraisal. Modern authorities do not agree on all aspects of anuran classification, and further study is needed to clarify the relationships of certain groups. The most widely used classification above the family level is that established by G.K. Noble in 1931, in which five suborders were recognized, based on vertebral characteristics. The superfamilies given above are not exactly equivalent to the suborders of Noble, the following modifications being most noteworthy: (1) The names Ascaphidae and Leiopelmatidae are interchangeable, the first being used by most American authorities, the latter by most others. (2) The family Myobatrachidae includes what were formerly recognized as Old World members of the Leptodactylidae, a family now considered restricted to the New World. (3) The Brachycephalidae, as recognized by Noble, included the dendrobatids and the peculiar mouth-breeding frog (*Rhinoderma*), now considered distinct families, as well as several genera (e.g., *Atelopus*) currently placed in the Bufonidae. Most authorities now restrict the family Brachycephalidae to the single genus *Brachycephalus*. (4) The family Atelopodidae (sometimes spelled Atelopodidae) of many authors is now relegated to the Bufonidae. (5) *Rhinoderma*, which other authors have placed in the Atelopodidae, Leptodactylidae, and Bufonidae, is now given family status. (6) The relationships of the Microhylidae are uncertain, and their placement in the suborder Ranoidea must be considered tentative. This family may have had an evolutionary history entirely independent from the ranoids. (W.E.D.)

Amsterdam

To the scores of tourists who visit each year, Amsterdam is known for its historical attractions, for its collections of great art, and for the distinctive colour and flavour of its old sections, which have been so well preserved. The visitor to the city, which celebrated its 700th anniversary in 1975, also sees an overcrowded metropolis beset by the familiar urban afflictions of environmental pollution, traffic congestion, and housing shortages. It is easy to describe Amsterdam as a living museum of a bygone age and to praise the eternal beauty of the centuries-old canals, the ancient patrician houses, and the atmosphere of freedom and tolerance, but the modern city has yet to work out its own solutions to the pressing urban problems that confront it.

Amsterdam is the nominal capital of The Netherlands but not the seat of government, which is at The Hague. The royal family, for example, is only occasionally in residence at the Royal Palace on the Dam square in Amsterdam. The city lacks the monumental architecture found in other capitals. There are no wide squares suitable for big parades, nor are there triumphal arches or imposing statues. Amsterdam's intimate character is best reflected

in the narrow, bustling streets of the old town, where much of the population still goes about its business. There are reminders of the glorious past—the gabled houses, the noble brick facades clad with sandstone, the richly decorated cornices, the towers and churches, and the music of carillons and barrel organs—but the realities of life in the modern city often belie this romantic image.

The inner city is divided by its network of canals into some 90 "islands," and the municipality contains approximately 1,300 bridges and viaducts. Amsterdam is the main wholesale, retail, and industrial centre of The Netherlands. Nevertheless, tradition persists alongside innovation. Although the first part of a new rapid transit system opened in 1977, about 20 percent of the work force still rely on the time-honoured bicycle for transportation. The city continues to be famous for its countless Chinese and Indonesian restaurants and the hundreds of houseboats that line its canals. Since the mid-1960s the city, now sometimes called "Swinging Amsterdam," has been known for a permissive atmosphere, attracting numerous persons seeking an alternative life-style.

THE LANDSCAPE

The city layout. Amsterdam is situated at the mouth and on the south side of the IJ, an inland arm of the former Zuiderzee, now IJsselmeer, and connected by canal with the North Sea. It is divided by the canalized Amstel River into two main sections.

The medieval town lies on either side of the Amstel at the city's centre, enclosed by the semicircular Singel (ditch or moat). Outside the Singel are the three main canals dating from the 17th century: the Herengracht (Heren Canal), Keizersgracht, and Prinsengracht. Within this area smaller canals run north and south. One tower (the Schreierstoren) of the old fortifications still stands.

The old part of Amsterdam has many ancient buildings, among which the Old Church (Oude Kerk), built in the 13th century, and the New Church (Nieuwe Kerk), begun in the 15th century, are outstanding. Next to the New Church is the 17th-century town hall, now the Royal Palace, built in classical Palladian style. Other notable buildings include the Mint Tower (Munttoren), with a 17th-century upper part superimposed on a medieval gate; the South Church (Zuiderkerk, 1611); the West Church (Westerkerk, 1631), where Rembrandt is buried; the Trippenhuis, housing the Royal Netherlands Academy of Arts and Sciences; and the Old Man's House Gate (Oudemanshuispoort), now the entrance to one of the University of Amsterdam's main buildings. The Sint Nicolaas Church (1886), the Central Station (1889), the Beurs (the bourse, or Commercial Exchange Building, 1903), and the Shipping House (1916) are more modern in style. The former Jewish quarter, in the east of the old town, is the location of the Portuguese Synagogue (1670) and the Rembrandt House (Rembrandthuis), which is now a museum. The old town's three main squares are the Dam, the Leidseplein (Leidse Square), and the Rembrandtsplein. Fine

17th- and 18th-century patrician houses line the canals.

In the 17th century the Buitensingel (Outer Moat), today called the Singelgracht (Singel Canal), enclosed the three main canals. Along it now run three quays: the Nassaaukade (Nassau Quay), Stadhouderskade, and Mauritskade. Buildings outside the Singelgracht date from the late 19th century onward and include the Rijksmuseum (State Museum, 1876–85); the Concertgebouw, or Concert Hall (home of the Concertgebouw Orchestra); the Stedelijk, or Municipal, Museum (1895); the Olympic Stadium (1928); and the Amstel Station (1939).

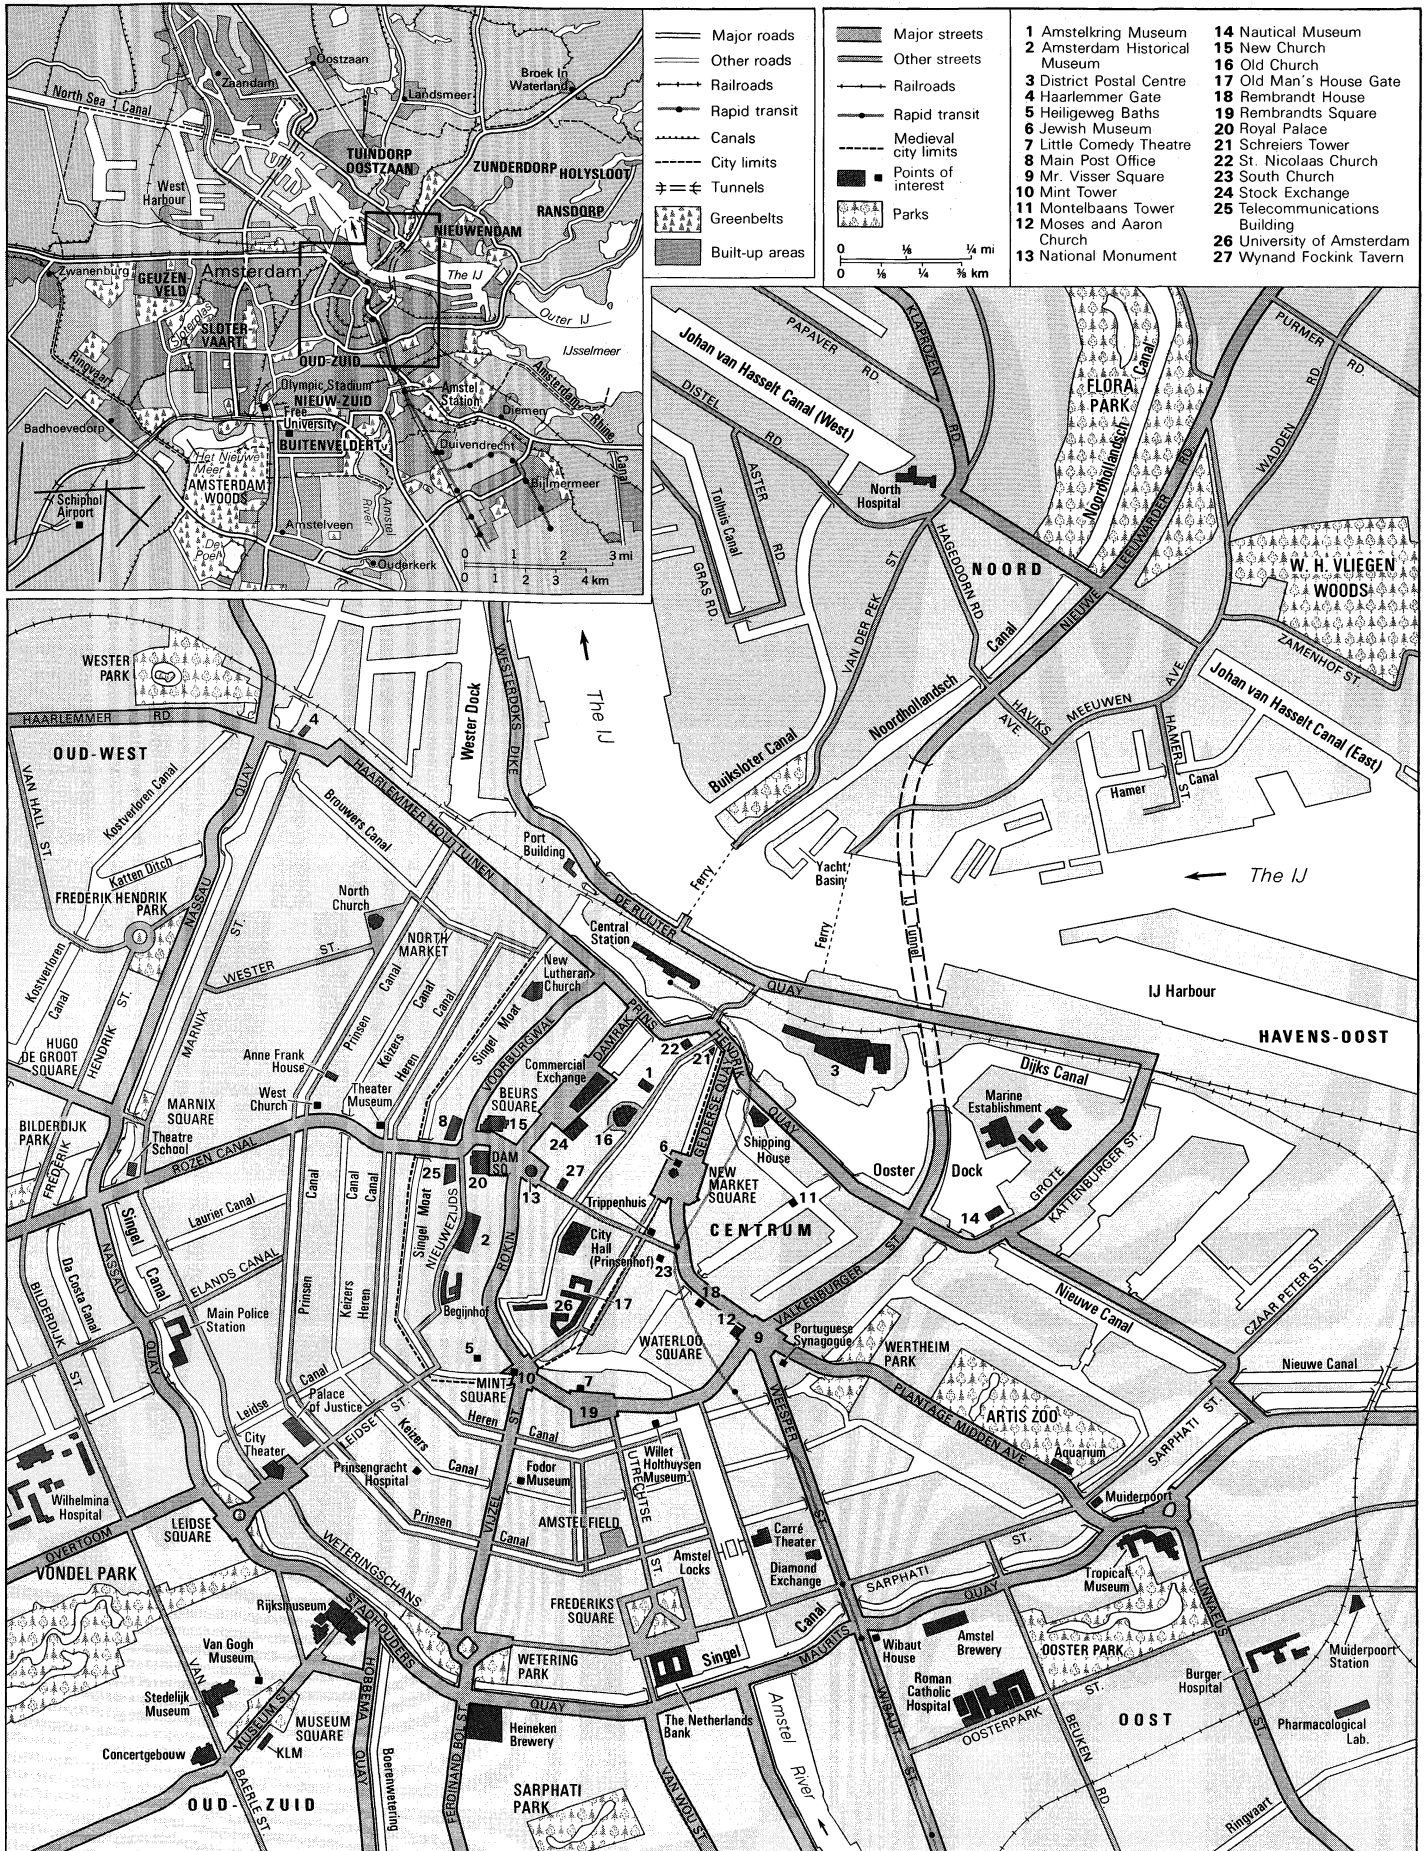

City planning. A development plan, called the General Extension Plan, was realized after World War II when the urgent need for houses was an incentive to build as quickly as possible. Simultaneously, a further detail of the master plan was realized: Forest Park, in the southwestern part of the city, situated more than 13 feet (four metres) below sea level, was developed into a recreation centre.

Soon after World War II certain developments made it necessary to revise the General Extension Plan: it became obvious that the existing residential areas were inadequate. Further space, moreover, was required for traffic and parking as well as for schools, service industries, and recreation. In addition, the urban renewal of the old city, including the 19th-century residential areas, required much replacement space in the outer areas for dwellings and businesses that were razed in the inner areas.

Amsterdam's planning problems differ little from those of any major city in the world; the particular problem has been that the city, with many areas more than 300 years old, must integrate its growth with the existing features of the area. The streets are narrow, for example, and the great concentration of employment in the city produces heavy radial traffic flows. Public transportation carries a large part of the passenger load and private cars only a relatively small part. As the metropolitan area has grown, and because large radial highways from the outer areas

The old
own

The
General
Extension
Plan

to the city are not desirable, the continual need to expand the public transport system is a primary concern. An expansion of the rapid transit system was planned as one solution to the problem, but it was abandoned in the 1980s after much local protest.

Town expansion since 1945 has resulted in the building of tens of thousands of dwellings, but this has meant at the same time a doubling of the urban area. There still will remain a considerable housing shortage for the foreseeable future. The main problem for years to come will be the renewal of further tens of thousands of dwellings in the 19th-century area. A very large number of the additional dwellings needed cannot be built in Amsterdam itself, and, therefore, development is being extended to other neighbouring centres, such as Purmerend and Hoorn, about 10 and 20 miles (16 and 32 kilometres) northward, respectively. At the same time, new cities have been and continue to be constructed in the polders (land reclaimed from the sea) of the former Zuiderzee, east of Amsterdam. The General Extension Plan of 1935 came to be regarded as only a modest beginning when it was realized, and a more complete renewal of the city will take until the year 2000 or beyond.

THE PEOPLE

In 1947 the urban district of Amsterdam covered an area of 14,100 acres, while the number of inhabitants was 800,000. Nearly 18 years later the area had expanded to 27,000 acres, but the population had only grown to 866,000; however, by the mid-1980s the area had increased to some 41,000 acres and the population had decreased to about 675,000, a phenomenon common to many older cities of western Europe.

The birthrate went down after 1946, while the death rate increased. Population changes resulting from migration have shown negative figures since 1951, while, typically, the metropolitan area has shown a steady increase. The city has a large school-age population and a large population of old people. The renewal of residential districts in the centre of the city by the affluent has displaced many of the poor, forcing them to outlying districts. Housing shortages in the late 1970s and the 1980s led to a well-organized and militant squatting movement. During the

same period thousands of foreign workers were attracted to Amsterdam because of the city's chronic manpower shortage. By the mid-1980s a little more than 12 percent of the city's population was made up of foreign nationals, and in addition there were sizable communities originating from The Netherlands' former colonies (notably Indonesia and Suriname). The city's increasing cosmopolitanism and traditional liberalism present a sharp contrast with the more conservative attitudes generally prevalent elsewhere in The Netherlands.

THE ECONOMY

Finance. Although Amsterdam is a major manufacturing centre, the city is even more important as a centre for financial transactions. The origins of most of these activities can be traced back several hundred years. The Amsterdam Exchange Bank, founded in 1609, became the largest clearinghouse in Europe and made the city an international financial centre. Earlier, in 1602, the Dutch East India Company was founded, and the lively trade in shares laid the basis for modern stock dealings. More foreign securities are now quoted in Amsterdam than in any other exchange in Europe; and as the home exchange for leading Dutch securities, it ranks with the great financial centres of New York City, London, and Zürich. The main banks and insurance companies in The Netherlands have their roots in Amsterdam, and much of the nation's banking and insurance business originates there.

Trade. In wholesale trade Amsterdam has played an important role since the 14th century, and its importance as a staple market reached its zenith in the 17th century. In the past the port was mainly a harbour for tropical products (coffee, tobacco, tea, and rubber), but, after the waterway connections with Germany were improved following World War II and the ties with the former Indonesian colonies were severed in 1949, the port developed into a transit port for bulk cargo (ore, coal, cereals, timber, and oil). By 1968 the harbour mouth at IJmuiden (on the coast some 15 miles west-northwest of Amsterdam) had been thoroughly modernized, and the port gave access to ships weighing up to 85,000 tons. In addition to this, large areas of deepwater-fronted industrial sites were developed for occupation by modern process industries.

Migration
from the
inner city

Changing
role of the
port

In civil aviation Amsterdam occupies a prominent place because of the importance and proximity of Schiphol Airport (linked by a five-mile railway to the city centre) and because of KLM Royal Dutch Airlines' large share of international air transport. Schiphol, which began operation in 1967, now ranks among the top European airports in volume of passenger and freight traffic.

Industry. Amsterdam is the largest industrial city in The Netherlands. The city accounts for an important part of the production value of the printing and publishing business, of the chemical and petrochemical industries, of textile manufacturing, of metal goods and mechanical engineering, and of the conveyance industry. A special attraction for tourists is the diamond industry, introduced to Amsterdam in the 1570s when refugees from Antwerp settled there. Two thousand diamond workers of Jewish origin were deported and murdered during World War II by the Germans, and large quantities of precious stones disappeared during the occupation. With foreign assistance and government support, the industry was rebuilt, and now there are several diamond factories. Most (by weight) of the total world production of industrial diamonds is processed there.

Tourism. The tourist trade is one of Amsterdam's most important sources of employment and revenue and is served by the city's numerous hotels and its many boardinghouses, youth hostels, restaurants, and retail businesses. The principal attractions for tourists include the Rijksmuseum, the Artis Zoo, and sight-seeing trips on the canals. Amsterdam is also an important centre for international conferences and exhibitions.

ADMINISTRATION

According to the constitution, every municipality in The Netherlands is headed by a council, the size of which depends on the number of inhabitants. The Amsterdam City Council has 45 members, who are elected for a four-year period. The Executive Committee consists of the burgomaster and nine elected aldermen. The burgomaster is not an elected official: he is appointed by the crown for a period of six years, and, though he presides at the meetings of the council, he is not a member of this institution. The council has no say in his appointment, but he usually represents the largest political group in the council. Since the end of World War II, the Socialists have dominated the council, and the burgomasters have been members of the Socialist Party. The council, however, is made up of members of many different political persuasions, including the Communists.

The aldermen are chosen by and from the members of the council. They, too, have a four-year period of office and receive an income, in contrast to the council members, who get only an attendance fee.

As a rule the council meetings are open to the public. The meeting place has been the old city hall—the Prinsenhof, formerly the Admiralty Court. In the 15th century this was a convent, but after alteration in 1578 it was converted into a suitable "inn for Princes and High Personages." From 1655 to 1808 the seat of the council was at the Dam square, where the medieval town hall was replaced by a new building designed by Jacob van Campen. When Louis Bonaparte, the French king of Holland, chose this as his residence in 1808 and converted it into what is now the Royal Palace, the council moved to the Prinsenhof. In the mid-1980s a new city hall and opera house were built on the north bank of the Amstel. In 1926 Herengracht 502, which was built for a director of the Dutch East India Company in 1672, became the burgomaster's official residence.

The various tasks of the municipality cover a wide range of activities. These include public transport, public works (including acquisition and allocation of grounds and buildings), public health, housing, electricity and gas, the port, markets, police, fire brigade, cleaning, social services, waterworks, education, old people's welfare work, and churchyards. The city has its own clearing bank, credit bank, advertising department, printing shop, swimming pools, theatre, archive department, museums, slaughterhouse, and orphanage.

CULTURAL LIFE

As a centre of art, Amsterdam has much to offer. The Rijksmuseum is famous for its collection of 17th-century Dutch masterpieces. The museum has about 1,100,000 art objects, including some 7,000 paintings, displayed in more than 150 rooms. The Stedelijk Museum is a leading international centre of modern art, representing such artists as the Spanish Pablo Picasso, the Russian-born Marc Chagall, the French Henri Matisse, the Dutch Karel Appel, the Dutch-American Willem de Kooning, and the American Robert Rauschenberg. The Van Gogh Museum, opened in 1972, is dedicated to the work of Vincent van Gogh and his contemporaries. Among the many other museums is the notable Amsterdam Historical Museum, located in the former Sint Lucien Convent built around 1420.

The city's Concertgebouw Orchestra has an international reputation, and Amsterdam is also a home for hundreds of painters, sculptors, authors, musicians, and actors. There are scores of curio and antique shops. Institutions of higher learning include the University of Amsterdam (founded 1632) and the Free (Vrije) University (founded 1880).

The city is situated in a region with many opportunities for recreation. In addition to the Amsterdam Woods, outdoor recreation, including water sports, is offered at the seaside resort of Zandvoort to the west, Sloter Lake (Sloterplas) in the heart of the western suburbs, the neighbourhood of the former Zuiderzee, and many smaller lakes to the south and the north of the city.

History

EARLY SETTLEMENT AND GROWTH

Although modern historians do not exclude the possibility that during the Roman period some form of settlement existed at the mouth of the Amstel River, evidence of such has never been found. So far as is known, Amsterdam originated as a small fishing village in the 13th century AD. To protect themselves from floods, the early inhabitants had to build dikes on both sides of the river, and in about 1270 they built a dam between these dikes.

Even then, merchant ships from Amsterdam sailed as far as the Baltic Sea and laid the foundation of the future trade centre, acting as a link between northern countries and Flanders (roughly modern Belgium). The city was under the jurisdiction of the counts of Holland, one of whom, Count Floris V, granted the *homines manentes apud Amestelledamme* ("the people living near the Amsteldam") a toll privilege in 1275. In this document the name Amsterdam is mentioned for the first time, though a full charter was not granted until 1306. The city rapidly extended its business, and in 1489, as a sign of gratitude for the support given by the city to the Burgundian-Austrian monarchs, Emperor Maximilian I allowed Amsterdam to adorn its armorial bearings with the imperial crown. By then Holland's greatest commercial town and port, as well as the granary of the northern Netherlands, Amsterdam had become a centre of wealth and influence in Europe.

In the 16th century there was religious and political resistance in the Netherlands against Spanish oppression. Amsterdam hesitated to accept the leadership of William I the Silent, prince of Orange, but in 1578 there was a bloodless revolution. The magistrates, together with the majority of Roman Catholic priests, were deported, the religious communities were secularized, and the Roman Catholic Church underwent reform.

Amsterdam was still a small town with no more than about 30,000 inhabitants, but things changed quickly, especially when, in 1585, Antwerp (in modern Belgium) was recaptured by Spanish troops, and the Scheldt (Schelde) River was closed. Antwerp's fall led to a wholesale influx of mainly Protestant refugees into the towns of the northern Netherlands, principal among them Amsterdam. Their arrival enriched the city's intellectual, cultural, and commercial life. Banking and shipbuilding especially flourished. Much of the trade formerly concentrated in Antwerp then moved to Amsterdam, and with the Flemish merchantmen soon came hundreds of Jews expelled from Portugal, followed by their coreligionists from the area of modern Germany and eastern Europe. The city soon became a

Development as a trading centre

Methods of political appointment

trading metropolis, whose population more than trebled between 1565 and 1618; merchant ships from Amsterdam not only sailed to the Baltic and the Mediterranean but also plied the long sea route to the East Indies and established colonies in South America and southern Africa.

At this time, the still outwardly medieval town developed into a big city, and in 1612 the City Council decided upon a new extension—the Three Canals Plan. Furthermore, the city needed a new and stately town hall, and the architect Jacob van Campen was commissioned to build one in the Dam square in the shadow of the New Church. In 1632 the Athenaeum Illustre (which became the University of Amsterdam in the 19th century) was erected. When, in 1648, the Treaty of Münster ended the Eighty Years' War (1568–1648) with Spain, Amsterdam was the financial, trading, and cultural centre of the world, lending money to foreign kings and emperors and thus exerting political influence internationally.

Conflict between the City Council and other political forces in the Dutch Republic was inevitable because the country was effectively no longer ruled by the States General in The Hague but by a small elite of burgomasters and merchants in Amsterdam. This situation led to political difficulties with William II, prince of Orange, who in 1650 planned to besiege the city. Amsterdam, nevertheless, maintained its dominant position for many years. Decline gradually came in the 18th century; London and Hamburg surpassed Amsterdam as trade centres, but the city remained the financial heart of Europe. Amsterdam was occupied in 1787 by the Prussians who backed the policy of William V, prince of Orange. The French, welcomed as liberators in 1795, brought freedom, but within a few years trade and shipping nearly stopped because of Napoleon's embargo on trade with Britain. In 1806 Napoleon proclaimed the Netherlands a kingdom, with Amsterdam as its capital, but by 1810 the country was incorporated into the French Empire. Russian Cossacks entered the town in 1813, and, on March 30, 1814, William VI, prince of Orange, was inaugurated as William I, king of The Netherlands, in Amsterdam's New Church.

THE MODERN CITY

Several attempts to restore prosperity to the city failed outwardly because of the harbour's disastrous condition. Economic rehabilitation came only after the digging of the North Sea Canal from 1865 to 1876. The population expanded rapidly (to 500,000 by 1900), with the East

Indian trade remaining the backbone of its economic activities. A sudden end to prosperity came in 1940, when the German Army occupied the country. Allied bombers attacked industrial areas several times during World War II, but the city's severest loss was the deportation of about 70,000 Jewish inhabitants. In May 1945 Amsterdam was liberated by Canadian troops, and, on March 29, 1946, Queen Wilhelmina granted the town the right to add to its armorial bearings the device "Heroic, Resolute, Compassionate," in recognition of the citizens' attitude during the German occupation. In the latter part of the 20th century the city's traditional individualism and resistive attitude found an outlet in movements that called attention to issues such as nuclear disarmament, world peace, and the environment.

BIBLIOGRAPHY. One of the earliest descriptions of Amsterdam may be found in LODOVICO GUICCIARDINI, *The Description of the Low Countreys and of the Provinces Thereof* (1593, reprinted 1976; originally published in Italian, 2nd ed., 1581). More exact details are in JOHANNES PONTANUS, *Historische beschrijvinghe der seer wijt beroemde coop-stadt Amsterdam* (1614; originally published in Latin, 1611); PHILIPP VON ZESEN, *Filips von Zesen Beschreibung der Stadt Amsterdam* (1664); and in JAN WAGENAAR, *Amsterdam, in zyne opkomst, aanwas, geschiedenissen, voorregten, koophandel, gebouwen, kerkenstaat, scholen, schut-terye, gilden en regeeringe*, 23 vol. (1760–1801). See also JOHN J. MURRAY, *Amsterdam in the Age of Rembrandt* (1967, reissued 1972). A modern history of the city was written by HAJO BRUGMANS, *De geschiedenis van Amsterdam van den oorsprong af tot heden*, 8 vol. in 4 (1930–33). The rise of the city during the Netherlands' Golden Age is covered by VIOLET BARBOUR, *Capitalism in Amsterdam in the Seventeenth Century* (1950, reissued 1963). Many details of cultural life in the 17th century are presented by PIERRE DESCARGUES in *Rembrandt et Saskia à Amsterdam* (1965). Works dealing with specific aspects are A. VAN DER HEYDEN and BEN KROON, *The Glory of Amsterdam: An Explorer's Guide* (1975; originally published in Dutch, 1975); and IDS HAAGSMA et al., *Amsterdamse gebouwen, 1880–1980* (1981), on architecture; J.J. VAN DER VELDE, *Stadsontwikkeling van Amsterdam 1939–1967*, also with an English summary (1968); AMSTERDAM, TOWN PLANNING SECTION, *Amsterdam, Planning and Development: Rise, Spatial Development, Structure, and Design* (1975), on town planning in modern times; and G.H. KNAP, *The Port of Amsterdam* (1970; originally published in Dutch, 1969). The best guides for tourists are HENDRIK F. WIJNMAN, *Historische gids van Amsterdam* (1971); BRYCE ATTWELL, *Amsterdam* (1968), with parallel English, Dutch, German, and French texts; GEOFFREY COTTERELL, *Amsterdam: The Life of a City* (1972); and *Baedeker's Amsterdam* (1982), a guide in English. ic era

Analysis (in Mathematics)

Analysis is one of the main divisions of mathematics, the others being history and foundations, algebra, combinatorics and number theory, geometry, topology, and applied mathematics. In extent, analysis is the largest of these, comprising subdivisions that are nearly autonomous and easier to describe than the division as a whole. Analysis may be defined as that part of mathematics concerned with smooth abstract objects such as sets of numbers, sets of geometric points, or sets of functions that map numbers into numbers or points into points and with the processes, called limit processes, that depend on a measure of closeness between numbers, points, or functions. Analysis developed initially out of ad hoc arguments in which curves, geometric bodies, and physical motions were analyzed by an informal process of decomposition into infinitesimal parts.

Limit and approximation processes, the usefulness of which was discovered during this early period of development, came to be used systematically in the 17th and

18th centuries in the differential and integral calculus of Sir Isaac Newton and Gottfried Wilhelm Leibniz. Limit processes were applied by their followers and by 19th-century French and German schools of analysts to sequences of values of a single function. Differential and integral calculus, ordinary differential equations, and the calculus of variations have thus arisen from mechanics; so-called Fourier series from acoustics and thermodynamics; complex analysis from optics, hydrodynamics, and electricity; and partial differential equations from elasticity, hydrodynamics, and electrodynamics. Even mathematical probability, although born from problems of gambling and human chance, drew much of its syllogistic strength in the 19th century from statistical theories of mechanics and thermodynamics. (Ed.)

REAL ANALYSIS

Origins and concepts of analysis

EARLY STAGES OF DEVELOPMENT

The concept of number. The concept "number" has changed its meaning repeatedly throughout history, as new demands on mathematics have required a broader view of the nature of numbers. The main number systems used

in analysis are those of the real numbers and the complex numbers, for it is in these systems, that ideas of continuity and limiting processes can be given rigorous meaning.

The simplest number system comprises the natural numbers (0, 1, 2, 3, . . . ; some mathematicians exclude 0) and is used for counting. The incorporation of negative numbers (−1, −2, −3, . . .) leads to the integers. The system

Number systems

that includes all fractions p/q in which p and q are integers and q is not zero comprises the rational numbers. However, the ancient Greeks discovered that some naturally occurring geometric lengths, such as the diagonal of a unit square, cannot be expressed as rational numbers. This discovery led eventually to the notion of irrational numbers (numbers that cannot be expressed as a ratio of integers) and real numbers, which include both rational and irrational numbers and can most simply be defined as numbers whose decimal expansion may not terminate—for example, the number π , whose decimal expansion 3.14159... goes on forever. The final step in this series of extensions of the number concept was the invention of the complex number system, in which there exists a number i whose square is -1 (or $i = \sqrt{-1}$). Problems now recognized as being part of the prehistory of analysis have played a major role in the evolution of today's main number systems.

Irrational numbers. In the 5th and 4th centuries BC the Greeks gave the first known satisfactory solution to a problem in analysis. In a square the side of which has length equal to 1, the diagonal has a length equal to $\sqrt{2}$. The decimal expansion of $\sqrt{2}$ is a nonterminating quantity, 1.4142..., so that the value $\sqrt{2}$ is determined as the sum of an infinite series (see Box, sum 1), each term of which is an integer times a (nonpositive) power of 10. The Greeks proved that $\sqrt{2}$ is not a rational number—that is, not a quotient p/q of any integers p and q . But they apparently found for $\sqrt{2}$ an approximate representation by certain rational numbers, or rather they found for the diagonal of the square approximations by line segments that are commensurate with the side of the square. The approximate numbers were later called the partial sums of the continued fraction for $\sqrt{2}$, and apparently from the study of this problem there evolved the so-called Euclidean algorithm, a chain of operations (indicated by equations) for finding the largest integer that divides two given integers.

$$\begin{aligned} (1) \quad & 1 + \frac{4}{10} + \frac{1}{100} + \frac{4}{1,000} + \frac{2}{10,000} + \cdots \\ (2) \quad & \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} + \cdots + \frac{1}{2^n} + \cdots \end{aligned}$$

General theory of irrational numbers

The most profound achievement in this entire context was the development of a general theory of irrational numbers, or of incommensurate ratios of certain types of “magnitudes” and of proportions between ratios. This achievement was the work of Eudoxus of Cnidus of the 4th century BC but was recorded by Euclid.

Areas and volumes. The Greeks also investigated the number $\pi = 3.14159\dots$, which is the area of a circle the radius of which is 1, and the problem of squaring the circle that was widely known to the Athenian public. Computations of other areas and volumes and of centres of masses are known from the works of Archimedes, and these results taken cumulatively can be viewed as a precursor to the 17th-century theory of integration. But these “direct” Greek calculations of many particular areas and volumes by circumscribed and inscribed approximating figures, when compared with the procedures of the integral calculus proper, are rather awkward and tedious.

Limit processes. The Greeks were also puzzled by the fact that the ordinary number 1 is the sum of the geometric series (see 2) composed of the numbers $\frac{1}{2}$, the square of $\frac{1}{2}$, the cube of $\frac{1}{2}$, and so forth, and this was for them part of a range of problems relating to the concepts “infinitely small” and “infinitely large.” The preoccupation with such problems is reflected in the paradox of Achilles and the Turtle put forward by Zeno of Elea and in the distinction between potential and actual infinite as proposed by Aristotle.

FROM CALCULUS TO ANALYSIS

Analytic geometry. The Greek achievements in analysis were but a prelude. A notable step was taken in the

14th century by the French bishop Nicole d'Oresme, who discovered the logical equivalence between tabulation and graphing, more or less, and, in a way, proposed the use of a graph for plotting a variable magnitude the value of which depends on that of another.

The systematic theoretical basis for this possibility, however, evolved only later from the work of a leading French philosopher and mathematician, René Descartes, who in 1637 laid the foundation for analytic geometry—that is, a geometry in which everything is reduced to numbers. In this geometry a point is defined as a set of numbers called its coordinates. A figure is viewed as an aggregate of points, but it is usually described by formulas, equations, and inequalities. This approach to geometry is the basis for the maps, graphs, and charts that have penetrated into all walks of life and for the mathematical concept of a function or rule of correspondence identifying with each value of x at most one value of y , which, first intended only for analysis, eventually penetrated into all corners of mathematics and into all areas of rational thinking as well.

Later in the 17th century the culminating event took place simultaneously in England and Germany when Sir Isaac Newton and Gottfried Wilhelm Leibniz introduced derivatives and laid the foundation for calculus and mechanics. Archimedes had been groping for the concept of a derivative but hit upon it only dimly in his book on spirals. Archimedes' methods, comparable to those of the 16th and 17th centuries, were in fact analytical in the modern sense of the term. The 17th and 18th centuries produced much mathematics in all directions, but analysis was the underlying theme.

The concept of the derivative. Greek mathematics was largely geometric. It initiated some durable topics of analysis, but the organized creation of analysis began only around 1600. Geometry deals with spaces and configurations; topology with spatial deformations; algebra with the general nature of the basic operations of addition, subtraction, multiplication, and division; and arithmetic with additive and multiplicative properties of general integers—that is, natural numbers and negative forms of these. Analysis also deals with specific operations, namely with differentiation and integration. It is more appropriate to say, however, that it deals with the mathematical infinite in many of its aspects, such as those of an infinite multitude, the infinitely large, infinitely small, infinitely near, and infinitely subdivisible. Its first objects and concepts, introductory and basic, are infinite sequence; infinite series; a function such as $y = f(x)$; continuity of a function, which is a property of a function in an infinitely small neighbourhood of a point; derivative of a function such as $y' = df/dx$; and integral of a function, both of which can be defined in terms of infinite limits. The derivative is a master concept, one of the most creative in analysis as well as in all of human cognition. Without it there would be no proper expression of such fundamental properties in physics as velocity, acceleration, density, gradient, and potential. The wave equation would not exist, and, indeed, physics as a discipline would be vastly different if the concept were unavailable. The formal textbook definition of the derivative took more than 150 years to evolve, and it is rewarding to begin with Newton's own description of it under the name of “ultimate ratio”:

Concern of analysis for the infinite

For those ultimate ratios with which quantities vanish are not truly the ratios of ultimate quantities, but [they are] limits towards which the ratios of quantities, decreasing without a limit, do always converge: and to which they approach nearer than by any given difference, but never go beyond, nor in effect attain to, until the quantities have diminished in infinitum.

Newton's generation was able to listen to a recondite mathematical definition, all in words, without symbols; and the Marquise du Châtelet, woman of the world, could undertake to translate Newton's formidable *Principia* from Latin into French, ultimate ratios and all.

The introduction of rigour. The techniques introduced by Newton and Leibniz revolve around various “limiting” processes, involving quantities that are infinitely small or infinitely large. As George Berkeley pointed out with some force in 1734, there was then no adequate logical basis

for the use of such quantities. However, Newton's ideas of 1704 are very close to the modern view: "I consider mathematical quantities not as consisting of very small parts, but as described by a continual motion." In his *Cours d'analyse de l'École Royale Polytechnique* of 1821, the French mathematician Baron Augustin-Louis Cauchy based all of analysis on the notion of a limit and defined it thus: "When the successive values attributed to a variable approach indefinitely a fixed value so as to end by differing from it by as little as one wishes, this last is called the limit of all the others." This definition is not totally satisfactory because the words "end" and "last" suggest that the limit has to be reached. Newton was in some ways nearer to the modern view because he realized that the limit need only be approached indefinitely closer.

The notion of limit was finally provided with a firm logical basis in the mid-19th century by Bernhard Bolzano of Prague and, definitively, by the German Karl Weierstrass. In effect, Weierstrass made Cauchy's definition quantitative by assigning two real numbers, ε and δ , to measure how closely the dependent and independent variables differ from their limits. In his definition a function $f(x)$ tends to the limit l as x tends to some value a if, given any positive number ε , there always exists a positive number δ such that, whenever the difference between x and a is less than δ , the difference between $f(x)$ and l is less than ε . This rather cumbersome "epsilon-delta" style of reasoning became the cornerstone of analysis and remains the accepted approach.

In 1961, however, the logician Abraham Robinson discovered a new extension of the number concept in which infinitesimals and infinite quantities exist and can be subjected to rigorous calculations. This idea provides an alternative foundation for analysis, and the approach is generally known as nonstandard analysis. It has useful applications for research mathematicians and is in many respects simpler than the epsilon-delta approach, but it has not yet become established as a standard technique.

The basic number systems

Number as quantity. Mankind was early led to the concept of a real number by the need for symbols to represent such geometric quantities as length, area, and volume and such physical quantities as weight and (more recently) electric charge.

Characteristics of geometric quantities

The characteristic features of such quantities are that (1) two quantities of the same kind can be added by some obvious geometric or physical operation (such as laying two segments next to each other on a straight line) and (2) any quantity can be divided into parts. The second feature, of infinite divisibility, is the crudest way of expressing the principle that the real-number system is continuous and not discrete like the system of positive integers.

The laws of addition are frequently intuitively obvious from the physical definition of this operation. In the case of lengths, it is obvious that $a + (b + c) = (a + b) + c$ because both represent the sum of three segments of lengths a , b , and c in order on a line (see Figure 1). It is also obvious that $a + b = b + a$ because the segment $a + b$ can be transformed into the segment $b + a$ by rotating the segment through 180° .

In representing geometric or physical quantities by numbers, it is usually necessary to choose first an arbitrary unit, such as a foot, a square inch, or a pound. This unit of quantity is assigned arbitrarily the numerical value 1, and exact multiples of this quantity (*i.e.*, sums of an integral number of unit quantities) are assigned corresponding

integral values. Because the entire addition table for positive integers can be constructed from the law for positive integers, which states that the sum of an integer a and an integer $(b + 1)$ is the same as the sum of the integers $(a + b)$ and 1, the sum of two such quantities must be represented by the sum of the corresponding positive integers.

Multiplication; number as ratio. A simple definition of the product of two quantities is not always possible. If the product of two lengths a and b is defined as the area of the rectangle with sides a and b , it may logically be objected that this is a quantity of a different kind.

To get around this logical difficulty, the Greeks suggested that a number should be considered as representing the ratio between a certain quantity and the unit quantity and never as representing the quantity itself. Thus, 160 pounds is a weight; the number 160 is the ratio of this weight to the weight of a pound.

This idea that numbers are dimensionless ratios has wide applicability: it leads to plausible "proofs" of the laws of multiplication. For example, the hypothesis that $a \times (b \times c) = (a \times b) \times c$ for all real numbers is given substantial support by the fact that both quantities may be regarded as representing the volume of a box of sides a , b , and c . These laws $a \times b = b \times a$ and $a \times (b + c) = (a \times b) + (a \times c)$ can be given similar plausible geometric interpretations in terms of areas. But these plausible arguments are not proofs in any rigorous sense. They depend not only on postulates for geometry but also on definitions of area and volume.

Numbers as dimensionless ratios

The only known way of getting rid of these difficulties is to define real numbers abstractly in terms of the system of positive integers, deducing all properties of real numbers by pure logic from these definitions and properties of the positive integers and using geometric and physical concepts only to suggest possible postulates and definitions. In this way the properties of real numbers may be made to depend on pure logic and the concept of a class alone (see MATHEMATICS, THE FOUNDATIONS OF). This abstract procedure will be followed henceforth.

Rational numbers. If it be assumed that division (except by zero) and subtraction are always possible, the system of positive integers then leads to a system of rational numbers (positive and negative fractions and integers, as well as zero). For the fundamental laws of arithmetic, see ARITHMETIC. The assumption that every equation $by = a$ in which a and b are positive integral coefficients has a solution corresponds to the idea that a quantity, a , can be divided into any positive whole number, b , of equal parts. The fundamental laws of arithmetic and the cancellation law for multiplication, which states that, if $a \times m = a \times n$, then $m = n$, can all be preserved.

By the cancellation law for multiplication, $by = a$ can have only one solution, which is written a/b . It may be shown that the usual rules for adding and multiplying fractions must hold. For example, if $by = a$ and $dz = c$, then $bdy = ad$, $bdz = bc$; and so $bd(y + z) = bdy + bdz = ad + bc$, which proves the rule for adding fractions having different denominators. It can also be proved that division by fractions as well as by integers is possible in the new system.

Conversely, it can be proved that the rules for adding and multiplying fractions do give a system in which the laws of arithmetic, as well as the cancellation law for multiplication and certain other basic laws, are valid.

A more thorough study would reveal that a considerable reduction in the number of postulates (fundamental laws needed to imply the others) is possible. All the laws for positive fractions thus can be deduced from the associative law for addition; the distributive laws, $a \times (b + c) = (a \times b) + (a \times c)$ and $(a + b) \times c = (a \times c) + (b \times c)$; and the unit laws, $a \times 1 = 1 \times a = a$ and $1 + 1 \neq 1$.

Irrational numbers. Fractions were used as early as 1700 BC by the ancient Egyptians, but it was not until Pythagoras (530 BC) that the need for other numbers, such as $\sqrt{2}$, was discovered. The need for such irrational numbers is corroborated in modern mathematical analysis, in which they play a fundamental role in the integral calculus, trigonometry, and other fields. Pythagoras showed

Figure 1: The associative law of addition. The length $a + (b + c)$ is the same as $(a + b) + c$ because both represent the sum of three segments of lengths a , b , c in order on a line.

Pythagorean theorem

that the ratio x of the diagonal of an isosceles right triangle to the length of a side must satisfy the equation $x^2 = 2$ (Pythagorean theorem). No fraction m/n , however, can satisfy $(m/n)^2 = 2$; that is, $m^2 = 2n^2$ has no solution among the integers, because 2 divides m^2 an even number of times, and it divides $2n^2$ an odd number of times.

Eudoxus of Cnidus pointed out in about 367 BC that, although $\sqrt{2}$ could not be represented exactly by any one fraction, it could be represented as a limit of a sequence of fractions. Thus, $\sqrt{2}$ can be represented in the form of an infinite decimal: $\sqrt{2} = 1.4142 \dots$; this amounts to specifying $\sqrt{2}$ as the limit of the sequence of decimal fractions.

The clear exposition of these ideas from the modern point of view is due to Georg Cantor (1871). Real numbers, including both rational and irrational numbers, are defined by Cantor as infinite sequences, $x = (x_1, x_2, x_3, \dots)$, $y = (y_1, y_2, y_3, \dots)$, \dots , of fractions x_n, y_n, \dots , that converge in the sense that $(x_m - x_n), (y_m - y_n), \dots$, approach zero as m and n increase indefinitely. Here x is regarded as the limit of the sequence (x_1, x_2, x_3, \dots) .

Real numbers. Equality is defined by making $x = y$ mean that $(x_n - y_n)$ approaches zero as n increases indefinitely. Addition and multiplication are defined by adding and multiplying corresponding terms (see 3). Laws valid for rational numbers can be extended to all real numbers by the principle of continuity. Each approximating term $(x + y)_n = x_n + y_n$ of $x + y$, for example, is equal to the corresponding approximation $(y + x)_n = y_n + x_n$ of $y + x$; hence, $(x + y)_n - (y + x)_n = 0$ for all n , and $x + y = y + x$ by definition of equality. In general, the principle of continuity holds that laws involving continuously varying functions like $x + y$ and $x \times y$ that are valid for arbitrarily good approximations x_n, y_n, \dots of x, y, \dots must be valid also for the limit values x, y, \dots .

Another interesting definition of real numbers was made by the 19th-century German mathematician Richard Dedekind: by a section in the class R of fractions is meant a division of all fractions into two classes L and U , such that $x \leq y$ for every x in L and every y in U . Each fraction (rational number) determines a section: L consists of the $x \leq a$ and U of the $y \geq a$. The other sections define the irrational numbers; thus, the section dividing the fractions into the $x < \sqrt{2}$ and the $y > \sqrt{2}$ (more precisely, the positive y with $y^2 > 2$) may be regarded as defining $\sqrt{2}$. Dedekind's definition is in fact equivalent to Cantor's.

The real numbers defined by this process have so far been found adequate for the mathematical treatment of most geometric and physical quantities such as length, area, weight, electric charge, and the like. Not only are the fundamental laws of arithmetic, the cancellation laws, and the order properties true, but division (except by zero) and subtraction are always possible. Finally, there is the property of any increasing sequence $x_1 < x_2 < x_3 < \dots$ the terms of which are all bounded above by a fixed constant c tending to a limit.

Complex numbers. The equation $x^2 = -1$ can have no real solution because the square of any real quantity is either positive or zero. But $i = \sqrt{-1}$ can be introduced as an imaginary number, and those laws of addition and multiplication that do not involve the relation $a \geq b$ may thus be preserved. To do this, all combinations $a + bi = a + b \times \sqrt{-1}$ must be introduced; these are the so-called complex numbers. If addition and multiplication of complex numbers are defined appropriately (see 4), the basic laws familiar from the properties of real numbers will be satisfied. It can be verified by substitution, for example, that the equation $(c + di)z = (a + bi)$ has a solution (see 5). Furthermore, any quadratic equation $Ax^2 + Bx + C = 0$ with real coefficients has complex roots (see 6), because, even if $B^2 - 4AC = -D$ is negative, the roots (see 7) can be found as complex numbers.

This is a special case of a fundamental theorem of algebra that asserts that any polynomial equation $x^n + a_1x^{n-1} + \dots + a_n = 0$ with real or complex coefficients has a complex root. From a strictly algebraic standpoint, no further generalization is called for.

Although the theory of algebraic equations is greatly simplified by the use of complex numbers, it is necessary to sacrifice the properties of order. That is, if z_1, z_2, \dots, z_n are a collection of n distinct complex numbers, it is generally not possible to order these such that, say, $z_1 < z_2 < \dots < z_n$. This is in contrast to the corresponding case of a collection of n distinct real numbers, for which such an ordering is always possible.

Complex numbers are useful not only in pure mathematics (theory of equations and function theory) but also throughout the physical sciences. (Ed.)

Functions and differential calculus

FUNCTIONS

The concept of a function. A concept central to analysis is that of a function. Mathematics contains numerous instances of a variable y depending in some fixed manner on another variable x . For example, y may be the square of x , the reciprocal, the cube, the sine, the inverse hyperbolic tangent, or some more complicated expression that can be calculated if the value of x is known. In this case y is said to be a function of x . In the traditional terminology x is the independent variable and y is the dependent variable.

Classically, the notion of function was mixed up with that of continuity, and both were confused with representation as a formula. For example, there was considerable debate on whether the absolute value $|x|$, which is x when x is positive but $-x$ when x is negative, is "really" a function, because it cannot be defined by a single formula and because its slope changes abruptly from -1 to 1 at the origin.

The current notion of function is extremely general. Given two sets X and Y , a function f is a well-defined rule that assigns to each element x of X a unique element $y = f(x)$ of Y . Thus, X might be the set of all circles, Y the real numbers, and $f(x)$ the radius of the circle x . The geometric concept of radius becomes a function entirely analogous to square or sine. There is a more technical definition that replaces the word rule by a mathematical construction in set theory.

If both variables are real numbers, as is often the case in analysis, then a function may be represented geometrically by its graph. This is a collection of points in a plane, formed by plotting the dependent variable on the vertical axis against the independent variable on the horizontal axis. The graph of a general function may appear extremely complicated, but for the traditional functions of analysis the graph forms a smooth curve. This is because the functions employed in analysis are very special. They are generally required to possess properties such as continuity (the graph does not break up into disconnected pieces) or differentiability (the graph has no sharp corners).

Special types of function. A function in general, as just described, is not sufficiently tangible for statements to be made concerning it, even if X and Y are real numbers (except if one of them is a finite set). Rather, in order to start, it is necessary to impose on the functions some

 \end{aligned}$$

restrictions or qualifications—that is, to single out classes of functions with some particular features that may be analyzed. Together with the general notion of function, certain overall descriptive properties also began to emerge by means of which classes of functions could be characterized: continuity, differentiability, integrability, bounded variation, and others. Earlier, however, especially in the 17th century, it had been taken for granted, expressly or not, that a function is a “formula” or “expression” that is a tangible prescription for finding y if x is given. Certain functions, then familiar, were taken as being basic, as it were—for instance, x , x^2 , \dots , $\sin x$, $\tan x$, $\arctan x$, e^x , $\log x$ —and a formula arose by taking one or several such functions and performing a finite number of “natural” operations, primarily the four arithmetical basic operations but including also extraction of roots and, what is important, the substitution of one function into another.

There soon appeared in these manipulations, however, certain expressions involving an infinite, or unending, succession of operations: certain infinite series, infinite products, and infinite continued fractions. Of these, the infinite series proved the most important by far, and two types of such series have advanced into positions of leadership and command that no phase of development has seriously impaired since, although there have been cases of evasion from authority, half in mathematical sport and a little in earnest. These two are the power series and the Fourier series (named after the 19th-century French mathematician and Egyptologist Jean-Baptiste-Joseph Fourier).

Infinite
series

DIFFERENTIAL CALCULUS

The derivative. The derivative of a function represents the rate at which the dependent variable changes relative to the independent variable. Graphically, it is the slope of the tangent to the graph. Rates of change are highly important in science; for example, velocity is the rate of change of position, and acceleration is the rate of change of velocity. The idea of rate of change is given mathematical precision as follows.

The
difference
quotient

If $f(x)$ is a real-valued function of a real variable and x_0 a real number, consider the difference quotient constructed by taking the ratio of the difference $f(x_0 + h) - f(x_0)$ to h , in which h is any real number except zero. If this difference quotient approaches a number as h approaches zero, this number is called the derivative of the function $f(x)$ at the point x_0 . If $f(x) = x^2$ and $x_0 = 1$, for example, the difference quotient is, by a direct calculation (see 8), seen to be $2 + h$. As h approaches zero, the difference quotient approaches the number 2. The function thus has for its derivative the value 2 at the point 1.

$$(8) \quad \frac{f(1+h) - f(1)}{h} = \frac{(1+h)^2 - 1^2}{h} = \frac{2h + h^2}{h} = 2 + h$$

$$(9) \quad \frac{f(0+h) - f(0)}{h} = \frac{h - 0}{h} = 1$$

$$(10) \quad \frac{f(0+h) - f(0)}{h} = \frac{-h - 0}{h} = -1$$

On the other hand, there exist functions that fail to have a derivative at some given point. A simple example is the following: Let $f(x) = x$ if x is positive or zero and $f(x) = -x$ if x is negative (that is, $f(x) = |x|$, the absolute value of x) and choose x_0 to be 0. It follows that, if h is positive, the difference quotient is the number 1, as shown by calculation (see 9); whereas, if h is negative, the quotient is -1 (see 10). Thus, $f(x)$ does not have a derivative at $x_0 = 0$ because, arbitrarily close to 0, the difference quotient assumes the values 1 and -1 ; i.e., this difference quotient does not approach one unique number as h approaches zero.

The derivative of $f(x)$ at x_0 (if it exists) is usually denoted by the symbol $f'(x_0)$ or $(df/dx)(x_0)$.

Figure 2: Geometric representation of the concept of the derivative (see text).

Geometric interpretation. Perhaps the quickest way to obtain some insight into the concept of the derivative is to consider its geometric interpretation. For example, if $f(x) = x^2/2$ and $x_0 = 1$, then inspection of the graph of this function near the point $P = [x_0, f(x_0)] = (1, 1/2)$ shows that the difference quotient, the ratio of $f(x_0 + h) - f(x_0)$ to h , is equal to the ratio QM/PM (see Figure 2). But, as is well known from analytic geometry, this ratio is the slope of the line passing through the two points P and Q ; that is, it is the trigonometric tangent of the angle, symbolized by the Greek letter theta followed by an inferior h , θ_h , made by this line and the x -axis. Now, if L be the line tangent to the graph of $f(x)$ at the point P , then, as h approaches zero, the point Q moves along the graph of $f(x)$ toward the point P , and the angle θ_h approaches the angle θ made by the line L and the x -axis. Consequently, the trigonometric tangent of θ_h approaches the trigonometric tangent of θ . The latter, by definition, is the slope of the line L . On the other hand, by the definition of the derivative, this slope must also be the derivative of $f(x)$ at x_0 . The derivative of $f(x)$ at x_0 , therefore, is the slope of the line tangent to the graph of $f(x)$ at the point $[x_0, f(x_0)]$.

This geometric interpretation and the argument justifying it extend equally well to other functions, provided that their graphs are sufficiently smooth—i.e., smooth enough to guarantee the existence of a unique tangent line passing through the point in question. Conversely, if the graph of $f(x)$ fails to satisfy this condition at a point, then the derivative fails to exist; it has already been shown that the function $f(x) = |x|$ fails to have a derivative at $x_0 = 0$. This is reflected geometrically by the fact that the graph of $f(x)$ has a “corner” at the point $[x_0, f(x_0)] = (0, 0)$ (see Figure 3).

Non-
existence
of a
derivative

Instantaneous velocity. An important physical application of the derivative is embodied in the concept of instantaneous velocity. In fact, a precise definition of the velocity of a moving particle at a given time, t , involves exactly the same limiting process that occurred in the definition of the derivative, as will now be shown.

If, for simplicity, a particle is considered to be moving along a straight line and in a fixed direction, then its position as a function of time can be represented in the

Figure 3: Graph of $f(x) = |x|$ showing the absence of a derivative for the function at $x_0 = 0$.

particle
velocity
and freely
falling
bodies

following way. If some point along the particle's path of motion is selected, then the particle's position at time t is completely determined by the distance, $f(t)$, between the particle and the chosen point, and no other dimension is needed to locate the particle.

Using this notation, the average velocity of the particle during an interval of time h , beginning at time t_0 , is defined to be the ratio of $f(t_0 + h) - f(t_0)$ to h , as in the nontemporal case; that is, the distance traveled during this interval of time divided by the length of the interval.

On the other hand, a little reflection will show that, whatever meaning is attached to the concept of the instantaneous velocity of the particle at time t_0 , it should, first of all, be a number, and, second, the average velocities of the particle during small intervals of time starting at time t_0 should approximate this number. Comparison of the ratio just considered with the difference quotient shows that these considerations make it obligatory to define this instantaneous velocity to be the derivative $f'(t_0)$.

An important example of this situation is given by a freely falling body. It is an experimentally established law that, if a body is allowed to fall from rest, it will traverse, in time t , a distance that is proportional to t^2 (provided the medium through which it falls offers no resistance). This law can also be expressed by asserting that the distance traveled by the body is a function of time, the expression having the form $f(t) = ct^2$ (in which the constant c depends on the units used in measuring distance and time). Thus, the average velocity of the body during an interval of time h , beginning at time t_0 , is by calculation (see 11) found to be $c(2t_0 + h)$. The limiting value of this ratio, as h approaches zero, is $2ct_0$. Thus, the instantaneous velocity of the freely falling body at time t_0 is $2ct_0$ and also $f'(t_0) = 2ct_0$.

$$(11) \quad \frac{f(t_0 + h) - f(t_0)}{h} = \frac{c(t_0 + h)^2 - ct_0^2}{h} = \frac{2ct_0h + ch^2}{h} = c(2t_0 + h)$$

Maxima and minima. It is now possible to discuss one of the more important applications of elementary differential calculus: the location of the maxima and minima of a function. If a function $f(x)$ of a real variable, x , is at least as large at \bar{x} as it is at all other values of x throughout an interval about \bar{x} , then $f(x)$ is said to have a relative maximum, $f(\bar{x})$, at $x = \bar{x}$. If, on the other hand, $f(\bar{x})$ does not exceed the values $f(x)$ when x ranges throughout an interval about \bar{x} , then $f(x)$ is said to have a relative minimum at $x = \bar{x}$. In Figure 4, x_1 and x_3 are the locations of minima, while x_2 and x_4 specify the locations of maxima.

Now, if $f(x)$ has a derivative $f'(x)$ for all values of x satisfying $a < x < b$, then the tangent to the graph of $f(x)$ passing through a point $[x, f(x)]$ corresponding to either a maximum or a minimum must be horizontal, and the slope of the tangent must be zero (see Figure 4). (It has been assumed here that $a < \bar{x} < b$.) The rigorous proof of this fact is not difficult: For, assuming $f(x_0)$ to be a maximum, it is seen that, if h is positive and sufficiently small, the difference quotient cannot be positive, because $f(x_0) \geq f(x_0 + h)$ if $x_0 + h$ is near enough to x_0 ; similarly, for h negative but of small absolute value, the difference quotient cannot be negative (because in this case both the numerator and the denominator are negative). The number $f'(x_0)$, therefore, must be arbitrarily close to numbers that cannot be negative and to numbers that cannot be positive. The only number having this property, however, is zero; hence, $f'(x_0) = 0$. Obvious changes in this argument will show that the result is equally valid for the case in which $f(x_0)$ is a minimum.

It has just been shown that, if $f(x)$ is either a maximum or a minimum, then $f'(x) = 0$. Simple examples show that the converse of this statement is not always true. The value of the positive result just obtained, however, lies in the fact that, if it is desired to locate a maximum or a minimum of a function $f(x)$, it is necessary only to deter-

Figure 4: Maxima and minima of a function.

mine those numbers x for which $f'(x) = 0$. In general, this greatly simplifies the task.

Consider a simple but illuminating example. Suppose that 100 feet of fence is available to enclose a rectangular pasture. What dimensions should the pasture have in order to contain the maximum possible area? If x denotes one length of the rectangle, then $50 - x$ must be the other length. Thus, the area of the pasture is $(50 - x)x = 50x - x^2$. The problem, then, reduces to finding the largest value (hence, a maximum) of the function $f(x) = 50x - x^2$, $0 \leq x \leq 50$. It is found by calculation (see 12) that the difference quotient is $50 - 2x - h$; therefore $f'(x) = 50 - 2x$. A maximum must satisfy, thus, the equation $f'(x) = 50 - 2x = 0$; therefore, $x = 25$. The area is largest when $x = 25$; that is, when the rectangle is a square of side 25 feet.

Computation of derivatives. It has already been shown that, if $f(x) = x^2$, then $f'(x) = 2x$. This is just a special case of one of several formulas for differentiation that are obtained in elementary calculus. It follows from the definition of the derivative that, if $n = 1, 2, 3, \dots$ is any positive integer and $f(x) = x^n$, then $f'(x) = nx^{n-1}$.

In fact, by means of an appropriate limiting process, it can be shown that, for each real number n , the expression x^n for positive x has a natural definition as a real number (for example, $n = 1/2$ gives the familiar square root function: $x^{1/2} = \sqrt{x}$). The formula for differentiation extends to include all functions of the form $f(x) = x^n$.

Many other well-known functions have simple expressions for their derivatives. The trigonometric functions, for example, have derivatives that are expressible in terms of other trigonometric functions (see 13).

In addition to such specific formulas, several general rules for differentiation are derived from the definition of

$$(12) \quad \frac{f(x + h) - f(x)}{h} = \frac{50h - 2xh - h^2}{h} = 50 - 2x - h$$

$$(13) \quad \begin{cases} (\sin x)' = \cos x \\ (\cos x)' = -\sin x \\ (\tan x)' = \sec^2 x \\ (\cot x)' = -\csc^2 x \end{cases}$$

$$(14) \quad [af(x) + bg(x)]' = af'(x) + bg'(x)$$

$$(15) \quad [f(x)g(x)]' = f(x)g'(x) + f'(x)g(x) \quad (\text{Leibniz' rule})$$

$$(16) \quad \left[\frac{f(x)}{g(x)} \right]' = \frac{f'(x)g(x) - f(x)g'(x)}{[g(x)]^2}$$

$$(17) \quad h'(x) = f'[g(x)] \cdot g'(x)$$

$$(18) \quad p(x) = a_0 + a_1x + \dots + a_kx^k$$

$$(19) \quad p'(x) = a_1 + 2a_2x + \dots + ka_kx^{k-1}$$

Meaning
of zero
derivative

the derivative. The four most basic of these rules will now be referred to.

Suppose that $f(x)$ and $g(x)$ are two functions and a and b are two constants. Whenever $f'(x)$ and $g'(x)$ exist, rules can be derived for the derivative of the sum (see 14), or linear combination, of $f(x)$ and $g(x)$, for the product (see 15), and for the ratio (see 16) of $f(x)$ to $g(x)$, provided $g(x) \neq 0$.

The chain rule

The fourth basic rule, the chain rule, may be stated in the following way. Suppose that, for each real number x for which $g(x)$ is defined, the number $g(x)$ is such that $f[g(x)]$ is defined. The composite function $h(x) = f[g(x)]$ can then be formed. The chain rule asserts that, if both $g'(x)$ and $f'[g(x)]$ exist, then $h'(x)$ exists and equals (see 17) the product of the former two derivatives.

These four rules, together with formulas for the derivatives of the powers of x and the basic trigonometric functions of x , permit the computation of the derivatives of a large class of functions. These include the derivative of the most general polynomial (see 18 and 19).

In addition, a formula for the derivative of the most general rational function (i.e., the quotient of two polynomials) can be obtained.

Measure and integral calculus

HISTORICAL DEVELOPMENT

The abstract concepts of measure and of integration are best understood in the light of the historical evolution and growth of the problem of measure. This problem always has been present in everyday life as well as in science. It pertains to measures of such properties as the length of a curve (rectification), area of a surface (quadrature), volume of a solid (cubature), mass or weight or electric charge of a body, probability of a random event, and so on. Yet the abstract concept of measure, of which the preceding measures are but particular concrete cases, was not isolated until the 20th century. The corresponding evolution may be loosely divided into several periods, each characterized by its particular attitude toward the problem of measure.

Babylonian and Egyptian knowledge

The empirical period. The purely empirical period began with prehistory and lasted until the 6th century BC. The most advanced organized knowledge of this era was that of the ancient Babylonians and Egyptians, providing precise and correct rules for finding areas and volumes of such geometric figures as the triangle, trapezoid, and circle. For the Babylonians, π equaled 3 (this value of π is also found in the Old Testament), and for the Egyptians π equaled $256/81$ ($\approx 3.160 \dots$). They also had correct rules for the volumes of the parallelepiped, prism, pyramid, and circular cylinder, thought of in concrete terms—mainly as storage containers for grain. The ancient Egyptians even had a correct rule for measuring the frustum of a square pyramid—i.e., the part next to the base and formed by cutting off the top by a plane parallel to the base.

Apparently these rules were discovered empirically. To become proved mathematical propositions, deduced from a set of definitions and postulates, they had to await the “Greek miracle”: the emergence of organized abstract thinking in Greece, which includes the earliest known treatment of mathematics as a deductive discipline. Available information prompts some historians to attribute the birth of abstract mathematics to Thales of Miletus (6th century BC), one of the Seven Wise Men of ancient Greece.

The Greek period. This period began with Thales of Miletus and lasted until about 200 BC. By the 5th century BC, problems of quadrature and cubature were so popular that Aristophanes in his satiric comedy *The Birds* alludes to the quadrature of circles, and the problem of duplication of cubes is attributed to the Delphic oracle. The first abstract proofs of rules for finding some areas and volumes are said to have been developed by Eudoxus of Cnidus in about 367 BC. About a century later, his method of approximation was developed and exploited by Archimedes, called the greatest mathematician of antiquity. This procedure, called the method of exhaustion in the 17th century AD, was at the root of all further developments of the mathematical problem of measure. The method culminated in the 19th-century isolation of

the concept of Riemann integration, defined by means of approximating Riemann sums (which, in all justice, could be called Eudoxus or Archimedes sums or, as will be seen below, Cauchy sums).

In modern terms, the method of exhaustion applied to surfaces, for example, may be stated as follows: if S is a surface of unknown area s , then one may choose another surface of known area s' contained in S , and yet another surface S'' of known area s'' containing S ; thus $s' < s < s''$. The approximating surfaces S' and S'' are polygons or sums of slices, mainly trapezoidal or rectangular, selected by Eudoxus and by Archimedes according to the particular figure S . In fact, sums of rectangular slices (the areas of which are particularly simple to compute) were to become predominant from the 16th century AD on. To complete the proof, Archimedes used the following proposition: if a known area a is such that for every positive ε there exist surfaces S' and S'' with $s' < a < s''$ and $s'' - s' \leq \varepsilon$, then $s = a$. Archimedes did not isolate this proposition. He proved it, in concrete geometric terms for every particular figure that he considered, by a double *reductio ad absurdum* (double, because negative numbers were not available to him): If $s < a$, then $\varepsilon < a - s$ is taken; but, if $s > a$, then the choice $\varepsilon < s - a$ is made. In either case, a contradiction is reached, so that $s = a$. The method does not specify how the value of a is to be found.

The period of indivisibles. This period extended from 1615 to about 1670, heavily influenced by Archimedes, whose works had become available in 1544 in Greek and in Latin. The concept of integration (see below *Integral calculus*) gradually emerged, but neither in Archimedean nor in modern dress—especially in England; there, integration became for a time not a primary operation but the inverse of differentiation.

After the efforts of the Dutch mathematician and physicist Simon Stevin and other followers of Archimedes came the pioneering work of the German astronomer Johannes Kepler, *Nova Stereometria Doliorum Vinariorum* (1615; “Solid Geometry of a Wine Barrel”). From then on and until the 19th century, Archimedean rigour was abandoned in favour of an intuitive “infinitesimal” reasoning. For Kepler, the circle consisted of an “infinity” of infinitesimal triangles with a common vertex at the centre, the sphere consisted of an “infinity” of pyramids, and so on. Nevertheless, he obtained more than 80 new results for certain areas and volumes. The language of infinitesimals, or method of indivisibles, was then codified by the Italian mathematician Bonaventura Cavalieri in 1635, in his *Geometria Indivisibilibus Continuum Nova Quadam Ratione Promota* (“A Certain Method for the Development of a New Geometry of Continuous Indivisibles”). For the first time in the history of the problem of measure, instead of measures of specific geometric figures, general principles for quadratures and cubatures were announced. While not proved rigorously, the principles were at least justified in the language of infinitesimals.

During this period, the method of indivisibles yielded a very large number of special integrals as quadratures, cubatures, and centres of gravity. Most were formulated geometrically. Yet more abstract algebraic formulations were already apparent: Pierre de Fermat of France and Cavalieri integrated x^n for rational values of $n \neq -1$; the French mathematician Grégoire de Saint-Vincent integrated it for $n = -1$ in a geometric form that is readily recognized as the logarithmic function; and Pascal integrated $\cos x$. Fermat, Pascal, and the Scottish mathematician James Gregory geometrically manipulated changes of variables and integrations by parts. In fact, geometric methods, formulations, and results were gradually made analytic. Pascal first discussed the types of sums that he would need and then only computed them in the concrete geometric case under consideration. The English mathematician John Wallis in *Arithmetica Infinitorum* (1655; “Infinitesimal Algebra”) started straight from algebraic grounds, introducing infinite series and infinite products, and Nicolaus Mercator, a German mathematician, discovered the series expansion of $\log(1+x)$.

The impetus and the tools for abstraction were provided by the growth of algebra, the birth of analytic geom-

Pioneering work of Kepler

The birth of analytic geometry

etry with René Descartes's *Géométrie* (1637), Fermat's *Isagoge* (written before 1636), and the birth and growth of kinematics, the consideration of motion leaving aside considerations of mass and force. Consideration of time as a concept in kinematics, and the notion of abscissa (the horizontal coordinate of a point in a plane Cartesian coordinate system), led to a gradual emergence of the idea of independent variable. Velocities and slopes of tangents led to the concept of differentiation. Performance of rectifications, such as that of parabolic arcs, forged a first link between differentiation and integration, because the rectification of curves $y=f(x)$ was reduced to the quadrature of $\sqrt{1+[f'(x)]^2}$, where $f'(x)$ is the derivative of $f(x)$. In fact, integration lost its predominant role in favour of differentiation. The basic link was provided by the recognition that differentiation and integration are inverse operations, to be found in the English mathematician Isaac Barrow's *Lectiones Geometricae* of 1670. Although a crowning of the period of indivisibles, Barrow's work also represented the dying spirit of that period. He began with kinematic considerations that seemed to lead at once to the basic link. The relation between differentiation and integration, however, was given only much later in two widely spaced propositions and in geometric terms: the derivative in terms of slopes of tangents, and the integral in terms of areas.

The calculus period. This period extended from about 1670 to the beginning of the 19th century, beginning with the creation of the calculus by Leibniz and Newton.

Newton, influenced by his teacher Barrow and his preoccupation with dynamics—dealing with forces and their relation, primarily to motion—used a universal independent variable conceived primarily as time; thus, he had no concept of functions of several variables and hence none of partial derivatives. The primary concept was that of fluxion (derivative) and arose from kinematic considerations. The concept of integral was not isolated, and no symbol for integration was introduced. His first basic problem was to find fluxions. Integration was treated in a geometric form as a search for fluents (antiderivatives, primitives, indefinite integrals), functions the fluxions of which are given.

Newton depended mainly on the fact that the derivative of a variable area $F(x)$ under a curve is the ordinate $f(x)$ of this curve. For Newton, moreover, integration was only a particular case of his second basic problem: given an equality containing fluxions, find the corresponding relation for fluents (solve ordinary differential equations). He solved this problem formally by means of series.

Leibniz, influenced by Pascal, conceived the derivative as the slope of a tangent and the integral as *summa omnium linearum* ("the sum of all lines"). The main purpose of his activity was to devise a universal language—that is, a general formalism for the acquisition and organization of knowledge. He largely succeeded in the creation of such a formalism for the calculus, and the present formalism is still essentially and properly his, including the integral symbol (a stylized form of the letter S standing for *summa omnium*). His also are the terms constant, variable, parameter, and (with the help of the Swiss mathematician Johann Bernoulli) function and integral.

The heroic years of the calculus at the end of the 17th century saw the constant flow of new results from Leibniz and his school, as embodied in the work of Jakob Bernoulli, Johann Bernoulli, and G.F.A. de l'Hospital. During the 18th century, the Scottish mathematician Colin Maclaurin pursued and developed Newton's ideas and attempted to clarify them in his *Treatise of Fluxions* (1742), while the Swiss mathematician Leonhard Euler pursued further the ideas of Leibniz and his school in his *Introductio in Analysin Infinitorum* of 1748 and attempted to found the calculus upon an obscure passage to the limit, starting with the calculus of differences.

Mathematicians of the 18th century devoted little effort to the shaky foundations of the calculus, apparently happy with the powerful tools at their disposal, the fecundity of the methods, the beauty and consistency of the results. Discussions about the metaphysics of calculus were left to philosophers and theologians, among whom the Irish-born

Anglican Bishop George Berkeley figured prominently. The whole subject of metaphysics of calculus vanished into thin air, however, with the French mathematician Jean Le Rond d'Alembert's two articles on "Limite" and "Différentielle" in the *Encyclopédie* (1751–65). At last the concept of limit was isolated, a concept that had run as an almost invisible thread in the fabric of infinitesimals as woven since Stevin and others at the turn of the 17th century. The concept of differentiation, too, was finally defined rigorously in terms of limits. (Yet, after d'Alembert, Lagrange still tried to define integration in terms of Newton's conception of a function as a power series.)

The analysis period. A new era opened in France with Augustin-Louis Cauchy's *Résumé des leçons sur le calcul infinitésimal* (1823), the basis of which was the concept of limit. Differentiation was defined by a passage to the limit. At last, the integral was defined directly and in purely analytic terms by returning to the very essence of the method of exhaustion as follows: Given a bounded function $f(x)$ defined for $a \leq x \leq b$, the interval $[a, b]$ may be divided into n subintervals by means of points $a = x_0 < x_1 < \dots < x_n = b$, and the Eudoxus-Archimedes-Cauchy sums (see 20; nowadays called Riemann sums) may be formed by adding n terms, each composed of a product of a value of f and the length of a subinterval, with f evaluated at an intermediate point of the subinterval. The limit of these sums, as the largest length of the subintervals converges to zero, is, by definition, the integral of the function f on $[a, b]$, provided that this limit exists and is independent of the choice of the t_k , the intermediate point in the subinterval at which f is evaluated.

The concept of limit as a basis

$$(20) \quad \sum_{k=0}^{n-1} f(t_k)(x_{k+1} - x_k), \quad x_k \leq t_k \leq x_{k+1}$$

$$(21) \quad \sum_{k=0}^{n-1} M_k(x_{k+1} - x_k), \quad \sum_{k=0}^{n-1} m_k(x_{k+1} - x_k)$$

A new way of thinking was thus born; existence of integrals as well as of derivatives was no longer a question of faith but a problem to be studied. Cauchy gave an incomplete proof of the existence of integrals of continuous functions, a proof that was completed only in 1875 by the French mathematician Gaston Darboux. Meanwhile, Riemann in 1854 (published in 1867) gave necessary and sufficient conditions for the existence of the integral called the Riemann integral and showed that continuous and piecewise monotone functions satisfy these conditions. Instead of Riemann sums, Darboux introduced the upper and lower Darboux sums (see 21), replacing the value of f at an intermediate point in an interval by M_k and m_k , which, respectively, denote the least upper and the greatest lower bounds of $f(x)$, as x varies between x_k and x_{k+1} . The passage to the limit yields the upper and lower Darboux integrals. These two integrals coincide if and only if the bounded function f is Riemann-integrable on $[a, b]$.

INTEGRAL CALCULUS

The definite integral. As mentioned earlier in this article, the integral is a limit concept. The geometric aspects of this concept will now be explored. First, consider two real numbers, a and b , and a function $f(x)$ defined for all x satisfying $a \leq x \leq b$. For the sake of simplicity it will be further supposed, for the moment, that the values $f(x)$ are never negative. The basic problem of integral calculus can then be stated, based on Figure 5, as follows: What is the meaning (and numerical value) of the area of the region below the graph of $f(x)$ and above the interval (a, b) on the x -axis?

Geometric aspects of the integral

Other basic assumptions are that it is known what is meant by "area" in case the region is a rectangle and also that, if a region can be subdivided into a finite number of nonoverlapping rectangles, then its area is the sum of the areas of these rectangles. Having made these assumptions,

Development by Newton and Leibniz

Figure 5: Representation of the area under a curve that underestimates the integral value.

the question raised may be answered using the following.

Estimation
of the
integral
value

First, the interval (a, b) is to be subdivided into n subintervals by choosing consecutive points $a = x_0, x_1, x_2, \dots, x_n = b$. In each of the subintervals $I_i = (x_{i-1}, x_i)$, a point ζ_i ($i = 1, 2, \dots, n$) is chosen such that the value $f(\zeta_i)$ is smallest among the values assumed by the function in I_i (if such a point ζ_i exists). The rectangle with base I_i and height $f(\zeta_i)$ (see Figure 5, in which $n = 4$ and $\zeta_i = x_{i-1}$) then lies below the graph of $f(x)$. It is reasonable to assume, therefore, that the area in question should be a number exceeding the sum of the areas of the rectangles that have been constructed (that is, the area of the shaded region in Figure 5). This can be expressed algebraically (see 22) in terms of A , in which A denotes the area below the graph of $f(x)$ and above the interval (a, b) .

$$(22) \quad A \geq f(\zeta_1)(x_1 - x_0) + f(\zeta_2)(x_2 - x_1) + \dots + f(\zeta_n)(x_n - x_{n-1})$$

$$(23) \quad A \leq f(\mu_1)(x_1 - x_0) + f(\mu_2)(x_2 - x_1) + \dots + f(\mu_n)(x_n - x_{n-1})$$

Next, using a similar construction, instead of choosing the point ζ_i in the subinterval I_i , a point μ_i (if it exists) may be chosen such that the value $f(\mu_i)$ is the largest among the values assumed by the function in I_i (see Figure 6, in which $\mu_i = x_i$ and, again, $n = 4$). An inequality between the area A and a sum of rectangles can, again, be expressed algebraically (see 23).

A sum of the type in which the smallest value of $f(x)$ in each subinterval I_i is used is called a lower sum (with respect to the given subdivision); a sum of the type in which the largest value of $f(x)$ in each subinterval is used is called an upper sum. The area in question should be a number, A , less than or equal to any upper sum and greater than or equal to any lower sum. If the notion of area as used here is to have a unique meaning, however, there should exist only one number with this property.

It will be noted that the restriction $f(x) \geq 0$, which was made only in order to obtain a better grasp of the geometric aspects of the construction, can be dropped without necessitating any change in the above definition. Dropping the restriction, however, implies that regions below the x -axis and above the graph of a negative-valued function will have negative areas.

The area that has just been defined is usually called the Riemann integral (or the definite integral, for reasons that will be shown) of the function $f(x)$ over the interval (a, b) .

Integrable and nonintegrable functions. It is natural, at

this point, to attempt to determine what classes of functions have a Riemann integral. It can be shown that, if $f(x)$ is continuous—roughly speaking, this means that, whenever x_1 and x_2 are close, then $f(x_1)$ and $f(x_2)$ are close—then it is (Riemann) integrable. In fact, this restriction is not only sufficient but comes close to being also a necessary condition for this type of integrability.

Two simple examples of functions that are not integrable are the following: Suppose $a = 0$ and $b = 1$. Let $f(x) = 1/x$ for $0 < x \leq 1$, and let $f(0) = 0$. Then it can be seen that the upper sums of this function are not defined (for, in the first interval, I_1 , of any subdivision, there is no number μ_1 such that the value $f[\mu_1]$ is the largest among the values that may be assumed by the function in I_1).

In the second case, again, let $a = 0$ and $b = 1$, and suppose $f(x) = 0$ if x is rational, but $f(x) = 1$ if x is irrational. It is then easy to check that each upper sum is 1 and each lower sum is 0. In this case there does not exist a unique number less than or equal to any upper sum but greater than or equal to any lower sum.

Fundamental theorem of calculus. The connection between the two basic concepts, the derivative and the integral, is perhaps the most important feature of calculus. This connection can be summarized roughly by saying that integration and differentiation are inverse operations; if first one of these operations and then the other is applied to a function, the original function is obtained (this is analogous to the operation of addition, and then subtraction, with a given number).

In order to describe this more precisely, the concept of the indefinite integral must be introduced. Suppose that $f(x)$ is continuous (hence, integrable) in some interval I , and let a and y be two points of this interval. If the number a is fixed, then a function of y , $F(y)$, can be formed by letting $F(y)$ be the integral of f from a to y ; if $y < a$, $F(y)$ is equal to the negative of the integral from y to a . The function $F(y)$ is called an indefinite integral of the function $f(x)$.

The connection between differentiation and integration can then be stated in the following way: the function $F(y)$ (as defined above) is differentiable, and $F'(y) = f(y)$; furthermore, if $G(y)$ is any other differentiable function satisfying $G'(y) = f(y)$ for all y in I , then the difference $F(y) - G(y)$ is constant. This statement is known as the fundamental theorem of the integral calculus.

A function such as $G(y)$, satisfying $G'(y) = f(y)$, is called an antiderivative of $f(y)$. If a constant is added to an antiderivative of $f(y)$, another antiderivative of the same $f(y)$ is obtained (because the derivative of a constant is zero). The fundamental theorem of the integral calculus can then be paraphrased by saying that the most general antiderivative of $f(y)$ can be obtained by adding a constant function to an indefinite integral of $f(y)$.

The anti-
derivative

Figure 6: Representation of the area under a curve that overestimates the integral value.

The
Riemann
integral

One of the immediate, and most important, consequences of the fundamental theorem is that the integrals of a large class of functions can be obtained merely by inverting the formulas already developed for differentiation. For example, it can be found that $\sin x$ is an antiderivative of $\cos x$. Thus, $F(y)$ is the integral from 0 to y of the cosine function and must differ from $\sin y$ by a constant; that is, $F(y) = \sin y + C$. The constant C is easily determined, because it follows from the definition of the integral that $F(0) = 0$. Hence, $0 = F(0) = \sin 0 + C = C$. It has been shown, therefore, that the sine is the indefinite integral of the cosine, for all y (see 24).

$$(24) \quad \sin y = \int_0^y \cos x \, dx$$

$$(25) \quad A = \left[\frac{x^2}{2} - \frac{x^3}{3} \right]_0^1 = \frac{1}{2} - \frac{1}{3} = \frac{1}{6}$$

The power of the fundamental theorem can be appreciated once it is realized that explicit formulas for integration, such as the formula for the integral of the cosine, are by no means easy to obtain by working directly from the definition of the integral. Unlike the case of differentiation, however, there are many functions that can be expressed by simple formulas but that do not have simple expressions for their antiderivatives.

Applications. Areas. The method of computing areas under curves has already been indicated in the formal definition of integral. As a further illustration, the area bounded by the curve $y = x^2$ and by the line $y = x$ will be found (see Figure 7). The points of intersection of the curve and the line are $(0, 0)$ and $(1, 1)$. The strip of width Δx and height $x - x^2$ has an area approximated by the product $(x - x^2)\Delta x$. This is the element of area ΔA . Summation of these elements, and subsequent passage to the limit by letting Δx approach zero, leads to the formula for the area as the integral of $x - x^2$. An antiderivative of $x - x^2$ is the function $x^2/2 - x^3/3$. Hence, the integral becomes $1/6$ (see 25).

Volumes of solids of revolution. If a plane region is rotated about a line in the plane, the resulting figure is called a solid of revolution. The volume of this solid is readily represented in the form of an integral. As an example, the volume generated by revolving the plane region bounded by the curve $y = \sqrt{x}$, the x -axis, and the lines $x = 0$ and $x = 5$ will be calculated (see Figure 8). When this plane figure is rotated about the x -axis, the strip of width Δx and height \sqrt{x} generates a thin disk (or cylinder) of radius \sqrt{x} and thickness Δx . The volume of this cylinder is approximately given by the area of the base times the thickness. Thus, the element of volume of the solid of revolution is $\Delta V = \pi(\sqrt{x})^2 \Delta x = \pi x \Delta x$. Summation of these elements leads to the formula for the volume of the solid: V (see 26). It follows from this example that, in general, if the equation of the curve is $y = f(x)$ and if the plane figure bounded by this curve, the x -axis, and the lines $x = a$ and $x = b$ is rotated about the x -axis, then the volume of the resulting solid can be expressed by an integral (see 27).

Lengths of curves. The arc length Δs from P to Q (see Figure 9) is approximately given by the distance from

Figure 7: The curve $y = x^2$, the line $y = x$, and an element of area (strip) between them.

$$(26) \quad V = \int \pi x \, dx = \pi \left[\frac{x^2}{2} \right]_0^5 = 12.5\pi$$

$$(27) \quad V = \int_a^b \pi [f(x)]^2 \, dx$$

General formula for the length of a curve:

$$s = \int_a^b \sqrt{1 + \left(\frac{dy}{dx} \right)^2} \, dx$$

$$(28) \quad \left\{ \begin{array}{l} \text{The length of the curve } y = \frac{2}{3}x^{3/2}, \text{ between } x = 0 \text{ and } \\ x = 3, \text{ is given by } S = \int_0^3 \sqrt{1+x} \, dx. \text{ An antiderivative} \\ \text{of } \sqrt{1+x} \text{ is } \frac{2}{3}(1+x)^{3/2}, \text{ so that} \end{array} \right.$$

$$S = \left[\frac{2}{3}(1+x)^{3/2} \right]_0^3 = \frac{2}{3}(8-1) = \frac{14}{3}.$$

$$(29) \quad S = \int_a^b 2\pi y \sqrt{1 + \left(\frac{dy}{dx} \right)^2} \, dx$$

$$(30) \quad \left\{ \begin{array}{l} S = \int_0^3 4\pi \sqrt{x} \sqrt{1 + \left(\frac{1}{x} \right)^2} \, dx \\ = 4\pi \int_0^3 \sqrt{1+x} \, dx = \frac{56\pi}{3} \end{array} \right.$$

$$(31) \quad W = \int_0^2 100x \, dx = 100 \left[\frac{x^2}{2} \right]_0^2 = 200 \text{ lb-in.}$$

$$(32) \quad M_x = \int \int y \, dx \, dy$$

$$(33) \quad \left\{ \begin{array}{l} \int_{\frac{1}{2}(y^2-1)}^{y+1} y \, dx = y \int dx \\ = y \left[x \right]_{\frac{1}{2}(y^2-1)}^{y+1} = [(y+1) - \frac{1}{2}(y^2-1)] \end{array} \right.$$

$$(34) \quad M_x = \int_{-1}^3 y[(y+1) - \frac{1}{2}(y^2-1)] \, dy$$

P to Q if these two points are sufficiently close to each other. Thus, the element of arc length Δs is approximately $\sqrt{(\Delta x)^2 + (\Delta y)^2}$, which can also be written in a form with the common factor Δx . Summation of these arc lengths, and passage to the limit, yields the formula for the length of the curve between the points A , B (see 28), in which a and b are the abscissas of the points A , B . The length of a specific curve has therefore been obtained by calculation (see 28).

Areas of solids of revolution. If the plane region of Figure 9 is rotated about the x -axis, the lateral area of the thin slab bounded by the segment PQ is given by the circumference of the cross section times the slant height, or $2\pi y$ times length of PQ . Since the arc length from P to Q is approximated by the length of the segment from P to Q , the element of surface area of the solid of revolution is given by $\Delta S = 2\pi y \Delta s$. With Δs approximated by $\sqrt{(\Delta x)^2 + (\Delta y)^2}$, subsequent passage to the limit gives the surface area (see 29). For example, if $y = 2\sqrt{x}$, $a = 0$, and $b = 3$, then $s = 56\pi/3$ (see 30).

Work done by a force. If a constant force F is directed along the x -axis and acts on a particle, displacing it through a distance x , then the work done by the force is given

Figure 8: The plane region bounded by the curve $y = \sqrt{x}$, the x -axis, and the lines $x = 0$ and $x = 5$; when the plane figure is rotated about the x -axis to generate a solid of revolution, the strip of width Δx and height \sqrt{x} generates a thin disk of radius \sqrt{x} and thickness Δx , which is an element of volume.

by the product of the force and the distance: $W = Fx$. If the force is not constant, the formula for the work done is represented by an integral. The element of work ΔW is given by $F(x)\Delta x$, in which $F(x)$ is the value of the force at x , and Δx is a small displacement from x to $(x + \Delta x)$. Summation of the elements of work, followed by passage to the limit, leads to the formula in which W equals the integral from a to b of $F(x)$.

Figure 9: The arc length Δs from P to Q is approximated by the distance from P to Q if these two points are sufficiently close together.

Work
required to stretch
a spring

For example, the force required to stretch a spring is proportional to the amount of stretch: $F(x) = kx$ (see Figure 10). For a certain spring it is found that a force of 50 pounds is required to extend it by 0.5 inch. The constant of proportionality k , therefore, has the value 100, and $F(x) = 100x$. If the unstretched length of the spring is 10 inches, the work required to stretch the spring to a length of 12 inches is $W = 200$ lb-in. (see 31). If the upper limit of integration (that is, 2) is replaced by 0.5, the same formula (31) indicates that the work required to extend the spring by 0.5 inch is only 12.5 lb-in.

Figure 10: A 10-inch spring displaced to length $10 + x + \Delta x$.

Moments and centroids. The moment of an element of area about an axis (perpendicular to the plane of the area) is defined as the product of the element of area by its distance from the axis. In particular, the moment of ΔA about the x -axis is $y\Delta A$, and the moment about the y -axis

is $x\Delta A$ (see Figure 11). Summation of these elements over the whole area and a passage to the limit lead to formulas for the moment of the plane area A expressed as double integrals: the moment about the x -axis is the double integral of y with respect to A ; the moment about the y -axis is the double integral of x with respect to A .

The evaluation of these integrals is achieved by the computation of successive single integrals whose limits are determined by the boundary of the region. The centroid of the plane area A is defined as the point (\bar{x}, \bar{y}) at which $\bar{x} = M_y/A$, $\bar{y} = M_x/A$. For example, if the area is bounded by the curve $y^2 = 2x + 1$ and the line $y = x - 1$ (see Figure 12), the points of intersection are $(0, -1)$ and $(4, 3)$. Using the methods previously discussed, the area is

Figure 11: For a plane area A , the moment of an element of area ΔA about the x -axis is $y\Delta A$, and the moment about the y -axis is $x\Delta A$.

found to be $A = 16/3$. With the element of area written as $\Delta x \Delta y$, the moment about the x -axis can be written (see 32, in which the inner integral is taken with respect to x , keeping y fixed). From the diagram it is seen that the lower and upper limits of integration for this integral are $x = 1/2(y^2 - 1)$, and $x = y + 1$. Thus, the inner integral is calculable (see 33). The moment is also obtainable (see 34, in which the limits are determined by the points of intersection of the curve and straight line). Evaluation of the integral yields $M_x = 16/3$.

A similar evaluation for the moment about the y -axis gives $M_y = 129/20$. The centroid is therefore located at $(387/320, 1)$. (Hy.K./Ed.)

Figure 12: The area bounded by the curve $y^2 = 2x + 1$ and the line $y = x - 1$. The points of intersection are $(0, -1)$ and $(4, 3)$.

Infinite series

History of series. The origin of the modern theory of series precedes that of the calculus and can be associated in the 17th century with the names of Bonaventura Cavalieri, John Wallis, James Gregory, and others. In the same century, the discovery of the calculus by Leibniz and Newton gave a very strong impulse to the theory; the 18th century witnessed considerable progress in the work of Jakob and Daniel Bernoulli, Jean Le Rond d'Alembert, Leonhard Euler, and others. Much of this work was of purely formal character, and mathematical rigour was not the primary concern of the investigators.

Origin and
develop-
ment of
the theory

Though Newton and Leibniz avoided divergent series, formal and uninhibited use of them brought such mathematical rewards that the temptation was too much to withstand, and divergent series became—mostly through the work of Euler—an accepted tool of investigation. Mathematical instinct of the great mathematicians of the 18th century prevented them, however, from making mistakes, and their results, properly interpreted, can now be proved rigorously. Rigorous foundations for the theory of infinite series were laid in the first half of the 19th century by the French mathematician Augustin-Louis Cauchy and Norwegian mathematician Niels Henrik Abel; their definitions and proved results can be found in all textbooks of calculus. Their attitude toward divergent series, however, was purely negative. (Abel wrote in 1828: “Divergent series are the invention of the devil, and it is shameful to base on them any demonstration whatsoever.”) The respect commanded by the work of Cauchy and Abel banished divergent series from mathematics for more than half a century. Their work on the foundations of the theory of series was continued by others in the 19th century, in particular by Peter Gustav Lejeune Dirichlet, Bernhard Riemann, and Karl Weierstrass. By the last decade of the 19th century, the effects of Abel’s anathema began to disappear, and the work of Ernesto Cesàro, Émile Borel, Leopold Fejér, and others showed that the theory of divergent series can be put on a rigorous basis and is a source of great progress in mathematics. In the 20th century the work of the British mathematicians Godfrey Harold Hardy and John Edensor Littlewood brought major breakthroughs and extended the field in depth. Important progress in Tauberian theorems (of the Slovak mathematician Alfred Tauber) was made by Norbert Wiener.

Sequences and series. The notion of a series has a close connection with that of a sequence, a set of numbers arranged in order. The simplest example of a sequence is that of the positive integers $1, 2, 3, \dots, n, \dots$. A sequence may be finite or infinite, depending on whether the number of terms is limited or unlimited. An infinite sequence of numbers exists if every positive integer $1, 2, 3, \dots, n, \dots$ is assigned a number; in what follows, the expression “sequence” means an infinite sequence of numbers.

Some examples of sequences are as follows: a sequence of squares of positive integers (see sequence 35), an alternating sequence of the integers one and zero (see 36), an alternating sequence of integers (alternating means that the sign of each term is opposite to that of the preceding term; see 37), and a sequence of fractions each with numerator one and with denominators ascending in integer value (see 38).

The numbers constituting a sequence are called the terms of the sequence (such as the first, the second, \dots , the

n th, \dots). It is customary to denote a sequence by using a single letter with a subscript (called the index) to indicate the position of the term—for example, $a_1, a_2, a_3, a_4, \dots, a_n, \dots$. An abbreviated notation $\{a_n\}$ is also used. It is assumed here that the terms are real numbers (natural numbers, their ratios, negatives, and limits); the case of sequences of complex numbers is considered later.

A series is the indicated sum of a sequence of numbers; for example, $a_1 + a_2 + a_3 + \dots + a_n + \dots$. A series can also be finite or infinite, depending on the sequence. It is customary to denote a series by using the Greek letter sigma Σ , to indicate summation. For example, $a_1 + a_2 + a_3 + \dots + a_n + \dots$ is written $\sum_{n=1}^{\infty} a_n$, or simply Σa_n .

The properties of series are related to the properties of sequences. If every term in a sequence is less than or equal to the following term, the sequence is said to be increasing (or nondecreasing). In other words, if, in $\{a_n\}$, a_n is less than or equal to a_{n+1} for every n , then $\{a_n\}$ is increasing. If each term is less than the following one (that is, if $a_n < a_{n+1}$), the sequence is strictly increasing. On the other hand, if, for a sequence $\{a_n\}$, a_n is greater than or equal to a_{n+1} , the sequence is decreasing (or nonincreasing); if $a_n > a_{n+1}$, it is strictly decreasing.

Sequences that are either increasing or decreasing are called monotone (monotonically increasing or monotonically decreasing, as the case may be; see 35 and 38). Some sequences are not monotone (see 36 and 37). If all the terms of the sequence a_n are less than a given number M (in symbols, $a_n < M$ for some M and all n), the sequence is said to be bounded above. If all a_n exceed a certain number, $\{a_n\}$ is said to be bounded below (see 35). Sequences bounded both above and below are simply called bounded (see 36). Some sequences are not bounded either above or below (see 37).

Convergence. A sequence $\{a_n\}$ is said to converge (or tend) to the limit a if the terms a_n approach a indefinitely as n increases (see 39). A precise definition is as follows: a_n tends to the limit a if, given any positive number (no matter how small) symbolized by the Greek letter epsilon, ϵ , the magnitude of the difference, $|a_n - a|$, is less than ϵ for all n large enough. If $\{a_n\}$ tends to a limit, the sequence is said to be convergent; otherwise it is divergent. The following type of divergence is important: $\{a_n\}$ is said to diverge to infinity, or the limit of a_n as n approaches infinity is positive infinity (see 40), if for any number M (no matter how large) a_n is greater than M for all n large enough; divergence of a sequence to negative infinity is defined in a similar way.

Of the sequences mentioned above, one (see 38) converges to the limit 0; others (see 35 and 36) diverge. Whether a given sequence converges and, if so, toward what limit is not always easy to decide. The following facts, however, can be helpful.

I. If $a_n \rightarrow a$ and $b_n \rightarrow b$, then the limit of the sum, the product, and the ratio of a_n and b_n is the sum, the product, and the ratio of a and b , respectively (see 41), the last relation requiring, however, the additional assumption that b is not equal to (\neq) 0.

II. Every convergent sequence is necessarily bounded; an example (see 36) shows that the converse is not true: a bounded sequence need not converge.

III. If a sequence is increasing and bounded above or decreasing and bounded below, it converges.

IV. If a sequence converges, then its terms, coming arbitrarily close to the limit, must also come arbitrarily close to each other, provided the indices are large enough. The converse of this is also true, though less easy to prove, and the result is the following important theorem of the 19th-century French mathematician Augustin-Louis Cauchy: a sequence $\{a_n\}$ converges if and only if it has the following property: for any positive number ϵ (no matter how small) $|a_m - a_n| < \epsilon$ for all m and n large enough.

Starting with a sequence $a_1, a_2, \dots, a_n, \dots$, a new sequence $s_1, s_2, \dots, s_n, \dots$ is formed by the following rule: a sequence of partial sums is generally labeled s_n and defined as a sum of the first n of its terms (see 42). If $\{s_n\}$ converges to limit s , then it is said that the infinite series, an infinite sum of a_k (see 43), converges to sum s .

$$(36) \quad 1, 0, 1, 0, 1, \dots$$

$$(37) \quad 1, -2, 3, -4, 5, -6, \dots$$

$$(38) \quad 1, \frac{1}{2}, \frac{1}{3}, \dots, \frac{1}{n}, \dots$$

Note: (35), (36), (37), and (38) are examples of sequences.

$$(39) \quad \lim_{n \rightarrow \infty} a_n = a, \quad \text{or} \quad a_n \rightarrow a$$

$$(40) \quad \lim_{n \rightarrow \infty} a_n = +\infty, \quad \text{or} \quad a_n \rightarrow +\infty$$

$$(41) \quad a_n + b_n \rightarrow a + b, \quad a_n b_n \rightarrow ab, \quad \frac{a_n}{b_n} \rightarrow \frac{a}{b}$$

The numbers s_n are called the partial sums of the series Σa_n , and the relation $s_n \rightarrow s$ is also written $\Sigma a_n = s$. The numbers a_n are the terms of the series Σa_n .

For any sequence $b_1, b_2, \dots, b_n, \dots$, there is always an associated series that is a sum of differences constructed of b_k and with typical term b_n minus b_{n-1} (see 44), the partial sums of which are $b_1, b_2, b_3, \dots, b_n, \dots$. Hence, every series is represented by a sequence (that of its partial sums) and, conversely, every sequence by a series. It follows that every statement about series can be given in a form bearing on sequences, and conversely (but usually, in individual cases, one form may be preferable to the other). For example, Cauchy's theorem stated above and pertaining to sequences assumes, in the case of series, the following form:

V. A series Σa_n converges if, and only if, given any positive number ε , $|a_{m+1} + a_{m+2} + \dots + a_n| < \varepsilon$ for all m large enough and any n greater than m . In particular (taking $n = m + 1$), the terms of a convergent series must necessarily tend to 0.

For example, if a is any number and q is any number of absolute value less than 1, the series $a + aq + aq^2 + \dots + aq^{n-1} + \dots = \Sigma aq^{n-1}$ (called a geometric series) converges, and its sum is $a/(1 - q)$.

The series $\Sigma 1/n = 1 + 1/2 + 1/3 + \dots$, called the harmonic series, diverges.

If the terms of a series are positive numbers, the series is called positive. The partial sums of a positive series form a strictly increasing sequence and, in view of proposition III, a positive series converges if its partial sums are bounded above. If the partial sums of a positive series are not bounded above, the series diverges to $+\infty$. Proposition III also shows the following:

VI. If Σa_n and Σb_n are positive series and if $a_n \geq b_n$ for all n , then the convergence of Σa_n implies convergence of Σb_n and, equivalently, the divergence of Σb_n implies that of Σa_n . This result, which is usually called the comparison test, is very useful because the knowledge of convergence or divergence of some positive series can be used to obtain information about other series.

For example, from the fact that the geometric series Σaq^{n-1} converges if a is positive and q is positive and less than 1, it is possible to deduce the following corollaries for positive series.

VII. If $a_{n+1}/a_n \rightarrow l$, then, if $l < 1$, the series Σa_n converges; if $l > 1$, the series diverges. This is known as the ratio test.

VIII. If $a_n^{1/n} \rightarrow l$ and if $l < 1$, the series Σa_n converges; if $l > 1$, the series diverges. This is known as the root test.

If the limit l in VII or VIII exists but is equal to 1, the test fails (the case $l = 1$ can occur for both convergent

and divergent series) and other tests are sought. There are many of them, but the most useful is the following one based on the notion of the integral.

IX. If $f(x)$ is a function defined for x positive, itself positive and steadily decreasing to 0 as x increases indefinitely, then the series $\Sigma f(n) = f(1) + f(2) + f(3) + \dots$ converges or diverges according as the $\int_1^\infty f(x)dx$ is finite or not. This is known as the integral test.

When applied to the function $f(x) = x^{-k}$, in which k is a fixed positive constant, the test shows that the series that is a sum of reciprocals of k th powers of positive integers (see 45) converges if $k > 1$ and diverges in all other cases. The result is not deducible from either the ratio or root test, because, for the series $\sum_{n=1}^\infty n^{-k}$, l is

equal to 1 both in VII and VIII.

Of interest among series that are not positive is a type called alternating series; this name is given to series $a_1 - a_2 + a_3 - a_4 + \dots$ in which the numbers a_n themselves are of constant sign. It can be shown that such a series converges if (a_n) decreases monotonically to 0. For example, the series $1 - 1/2 + 1/3 - 1/4 + \dots$ converges.

A series Σa_n is said to converge absolutely if $\Sigma |a_k|$ converges. Cauchy's theorem for series shows that, if a series converges absolutely, then it converges in the ordinary sense; but the example of the convergent alternating series $1 - 1/2 + 1/3 - \dots$ shows that a series may converge without converging absolutely. It follows that absolutely convergent series form a special class among all convergent series. Because series $\Sigma |a_k|$ have positive or zero terms, the problem of whether a given series converges absolutely can be solved by applying one of the tests for the convergence of positive series. In many cases the simplest way of proving that a certain series converges is by showing that the series converges absolutely, and this shows the importance of positive series for the general theory of series. Absolutely convergent series have a number of properties that are not shared by all convergent series. The most important of these properties is the fact that if a series converges absolutely, then arbitrary changes in the order of the terms of the series affect neither the convergence nor the sum of the series.

The situation is completely different for series that converge but do not do so absolutely (such series are called conditionally convergent); by a suitable change of the order of the terms, such a series can be made to converge to any prescribed sum or can even be made divergent. This is a theorem of the 19th-century German mathematician Bernhard Riemann. Hence, unlike the case of absolutely convergent series, a conditionally convergent series has no intrinsic sum and everything depends on the order of the terms.

The number of important series that occur in mathematics is enormous. A few basic convergent series are given in five examples of series the sums of which are known and are expressed in terms of the natural logarithm and the numbers π and e (see 46).

Series of functions. If $\Sigma u_n(x)$ is a series the terms $u_1(x), u_2(x), \dots, u_n(x), \dots$ of which are functions defined in an interval of the real variable x and if $\Sigma u_n(x)$ converges at each point of the interval, then the series is said to converge pointwise in the interval; $f(x)$ denotes the sum, and $S_n(x)$ the partial sums, of the series. Pointwise convergence means that for any positive ε there is an index n_0 , depending in general on ε and x , in symbols $n_0 = n_0(\varepsilon, x)$, such that $|f(x) - S_n(x)| < \varepsilon$ for $n > n_0$. If for each $\varepsilon > 0$ an n_0 can be found independent of x , the series is said to converge uniformly in the interval considered; geometrically this means that for each $n > n_0$ the graph of the curve $y = S_n(x)$ and that of the curve $y = f(x)$ differ by less than ε in the whole interval under consideration. Pointwise convergence in general does not preserve properties of the terms of the series. For example, if the functions $u_n(x)$ are continuous and $\Sigma u_n(x)$ converges pointwise, the sum $\Sigma u_n(x)$ need not be continuous. A simple example is provided by the series $(1 - x) + x(1 - x) + x^2(1 - x) + \dots$, which converges at each point of the interval $0 \leq x \leq 1$ and the sum of which is equal to 0 for $x = 1$ and equal to 1 at the remaining points of the interval. Similarly,

$$(42) \quad \begin{cases} s_1 = a_1, & s_2 = a_1 + a_2, & s_3 = a_1 + a_2 + a_3, & \dots \\ s_n = a_1 + a_2 + \dots + a_n \end{cases}$$

$$(43) \quad a_1 + a_2 + a_3 + \dots + a_n + \dots$$

$$(44) \quad b_1 + (b_2 - b_1) + (b_3 - b_2) + \dots + (b_n - b_{n-1}) + \dots$$

$$(45) \quad 1^{-k} + 2^{-k} + 3^{-k} + \dots + n^{-k} + \dots = \sum_{n=1}^\infty n^{-k}$$

$$(46) \quad \begin{cases} 1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \frac{1}{5} - \dots = \ln 2 \\ 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \dots = \frac{1}{4}\pi \text{ (Leibniz' series)} \\ 1 + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \frac{1}{5^2} + \dots = \frac{1}{6}\pi^2 \\ 1 + \frac{1}{3^2} + \frac{1}{5^2} + \frac{1}{7^2} + \frac{1}{9^2} + \dots = \frac{1}{8}\pi^2 \\ 1 + \frac{1}{1} + \frac{1}{1 \times 2} + \frac{1}{1 \times 2 \times 3} + \frac{1}{1 \times 2 \times 3 \times 4} + \dots \\ \quad \quad \quad = e = 2.7182818 \dots \end{cases}$$

These series converge to known values as shown.

if the $u_n(x)$ are integrable over an interval and the series $\sum u_n(x)$ converges pointwise, the sum of $\sum u_n(x)$ need not be integrable. The significance of the notion of uniform convergence is that the sum of a uniformly convergent series of functions inherits many important properties of the terms—in particular their continuity and integrability. Not all properties, however, are preserved by uniform convergence; for example, the sum of a uniformly convergent series of differentiable functions need not be differentiable. As a matter of fact, examples of continuous and nowhere differentiable functions are usually given as sums of uniformly convergent series of differentiable functions. The three theorems that now follow about uniformly convergent series are particularly useful.

X. If the functions $u_n(x)$ are continuous in an interval and if the series $\sum u_n(x)$ converges uniformly in the interval, the sum of the series is continuous in the interval.

XI. If the $u_n(x)$ are integrable over a finite interval (a, b) and if $\sum u_n(x)$ converges uniformly in (a, b) , then the sum $f(x)$ of $\sum u_n(x)$ is integrable over (a, b) and a definite integral of the function f is written as a sum of integrals of functions u_n (see 47).

XII. If each term of the series $\sum u_n(x)$ has a continuous derivative in a finite interval (a, b) , if the series $\sum u'_n(x)$ of derivatives converges uniformly in (a, b) , and if the series $\sum u_n(c)$ converges for one point c in (a, b) , then the series $\sum u_n(x)$ also converges uniformly in (a, b) , its sum $f(x)$ is differentiable, and $f'(x) = \sum u'_n(x)$.

There are no special tests for the pointwise convergence of series because pointwise convergence simply means ordinary convergence at each point x separately. There are tests for the uniform convergence of a series of functions, among which the following, usually called Weierstrass' M-test, is particularly useful.

XIII. If there are positive constants $M_1, M_2, \dots, M_n, \dots$ such that the series $\sum M_n$ converges and if $|u_n(x)| \leq M_n$ for each n and all x of an interval, then the series $\sum u_n(x)$ converges uniformly in the interval.

Only the uniform convergence of series has been considered. There are parallel definitions and results for the uniform convergence of sequences. One can also consider the uniform convergence of double series and sequences. Special types of series of functions are particularly important for various branches of analysis (as in the Fourier series described later). The convergence of series $\sum u_n(z)$ the terms of which depend on a complex variable $z = x + iy$ may be considered. The most important among them is the case of power series.

Power series. Power series are of the form with coefficients a_n (see 48), in which the a_n are constants (in general, complex) and $z = x + iy$ is a complex variable; in

the symbol $\sum a_n z^n$ the index n ranges through the values $0, 1, 2, \dots, n, \dots$. Each power series has a circle of convergence; this is a circle (disk) with the centre at the point $z = 0$ and the following properties: the series converges at each point interior to the circle and diverges at each point exterior to the circle. As to the behaviour on the circumference of the circle of convergence, $\sum a_n z^n$ may converge at some points, diverge at others. The intersection of the circle of convergence with the real axis is an interval $(-R, R)$; and the series $\sum a_n x^n$, a power series of the real variable x , converges in the interior of this interval and diverges in the exterior. The radius R of the circle of convergence is called the radius of convergence of the power series. The circle of convergence can degenerate to a point; each power series $\sum a_n z^n$ necessarily converges at the point $z = 0$ but may converge at no other point: the series $\sum n! z^n$ is an example of this ($n!$ —factorial n —is the product $n(n-1)(n-2) \cdots 1$). The circle of convergence may also cover the whole complex plane, as in the series $\sum z^n/n!$. Finally, the radius of convergence may have any prescribed positive value R because the radius of convergence of the geometric series $\sum (z/R)^n$ is precisely R .

At each point interior to the circle of convergence, the power series not only converges but converges absolutely. What is very important is that, in each circle concentric with the circle of convergence but of smaller radius, the power series converges uniformly. Series of the form $a_0 + a_1(z-b) + a_2(z-b)^2 + \cdots = \sum a_n(z-b)^n$, in which b is a fixed complex number, are called power series with centre b . Their study does not require the introduction of new concepts because by replacing $z-b$ with a new variable Z the series is reduced to the previously discussed case $\sum a_n Z^n$. It follows that $\sum a_n(z-b)^n$ also has its circle of convergence, but this time the circle has its centre at the point b . Functions representable by power series have very important properties. Listed above are a few basic power series, considering for simplicity only real values of z (see 49).

Vector and tensor analysis

Many physical quantities, such as temperature, pressure, and mass, have only magnitude. The numbers representing them are called scalars and obey the simple rules of arithmetic. On the other hand, quantities such as velocity, force, or position in two or more dimensions relative to a fixed point have both magnitude and direction and can be represented mathematically by two or more numbers that constitute what is called a vector. Geometrically, a vector is drawn as a line in a specific direction with a length equal to its magnitude (Figure 13).

The earliest knowledge of how to manipulate vector quantities dates from the time of Galileo, who in the course of his studies in the 17th century first formulated the simple parallelogram law for combining forces. If two forces act on a body, their resultant force can be obtained from a parallelogram in which two adjacent sides have lengths and directions representing the forces. The two forces acting together are equivalent to a single force represented, in magnitude and direction, by the diagonal of the parallelogram. This is equivalent to the rule that two or more vectors can be added by putting their geometric representations end to end, so to speak.

A vector can be multiplied by a positive number by simply multiplying its magnitude by that number (it has the same direction). To multiply a vector by a negative number, its direction is reversed and its magnitude multiplied. The process of multiplication by numbers is called scalar multiplication. An example of its application to physical quantities is the process of multiplying the mass of a body by its velocity to give its momentum. The momentum of a body is, thus, a vector quantity having the same direction as the velocity and a magnitude equal to the product of the magnitudes of its mass and its velocity.

Vectors in three dimensions may be expressed in the following way. A set of three mutually perpendicular vectors each of unit length is chosen, and any vector may be represented uniquely as a combination of these. If these vectors are written i, j , and k (it should be noted that vectors in

physical applications are often printed in boldface type), then any vector can be represented by $a_1\mathbf{i} + a_2\mathbf{j} + a_3\mathbf{k}$. The numbers a_1 , a_2 , and a_3 are called the components of the vector. By Pythagoras' theorem, the length of $a_1\mathbf{i} + a_2\mathbf{j} + a_3\mathbf{k}$ is the square root of the sum of the squares of the components. The magnitude of an arbitrary vector \mathbf{v} is written $\|\mathbf{v}\|$.

Vectors may be multiplied together in two ways. The scalar product of two vectors (also called the dot product) is, in two dimensions only, defined to be the product of their lengths multiplied by the cosine of the angle between their directions. A physical example concerns the work done if a force \mathbf{F} moves in a straight line that has magnitude and direction \mathbf{d} . If the force moves along the direction of \mathbf{d} , the work is $\|\mathbf{F}\| \|\mathbf{d}\|$; if it acts at an angle θ to that direction, it is $\|\mathbf{F}\| \|\mathbf{d}\| \cos \theta$. If the force acts at right angles to the direction, the work done is zero.

In three dimensions, two vectors can be multiplied to give a third. The vector product of \mathbf{a} and \mathbf{b} is written as $\mathbf{a} \times \mathbf{b}$ and is also called the cross product. It is a vector perpendicular to \mathbf{a} and \mathbf{b} with length $\|\mathbf{a}\| \|\mathbf{b}\| \sin \theta$, θ being the angle between them. When an electric charge moves in a magnetic field, for example, it experiences a force that is mutually perpendicular to the field and the direction of motion, hence the principle from which it is inferred that the wire moving in the magnetic field of a generator will carry electrical current.

Many physical quantities take the form of mappings (or correspondences) from one collection of vectors to another. For example, the stress at a point in a fluid is the relation between two vectors. The stress is an example of a tensor, which has a general mathematical definition that will be presented below. It will be seen that the tensor concept depends upon ideas involving more than one vector—in fact, collections of vectors that are called vector spaces. The idea of vectors and tensors was suggested by particular needs in problems of mathematical physics.

Once the concepts of vector and tensor are known from the study of particular physical or mathematical questions, it becomes natural, by the route of mathematical reasoning, to express individual vectors or tensors as members of an appropriate space. By doing so, a setting of generality is established and the properties of these entities can be studied without reference to particular representatives that might have been encountered first historically or that might have been important in special cases. Therefore, with the advantage of historical maturity, discussion will begin here with the treatment of a vector space. (Ed.)

VECTOR ALGEBRA AND ANALYSIS

Vector space: history and basic ideas. The germinal idea of an abstract vector space that is not limited to applications grew out of investigations of the mathematicians Sir William Rowan Hamilton and Hermann Günther Grassmann during the early 1840s. In that era mathematicians still regarded complex numbers that involve the square root of -1 with a mixture of mysticism and suspicion, although by 1800 Caspar Wessel had suggested representing the complex number $a_1 + ia_2$, in which i is the square root of -1 , concretely by a point in a plane (specifically, by the point $[a_1, a_2]$ so that a_1 and a_2 become distances to the point measured along straight lines parallel to two rectilinear axes). In 1831 Carl Friedrich Gauss showed that complex numbers can be regarded as ordered pairs of real numbers for which the operations of addition and multiplication are defined (see equations 50) in terms of the component parts of the pairs. The resulting algebra of pairs is a perfect replica of the algebra of complex numbers, without any reference to complex numbers or to the symbol i . This algebra proved to be useful in describing rotations in the plane.

Unaware of Gauss's work, Hamilton discovered the same device six years later and continued to search for a comparable algebraic description of rotations in three-dimensional space. His early efforts were thwarted, however, by an algebraic dogma that insisted on certain familiar properties of addition, subtraction, and multiplication growing out of centuries of exclusive concern with familiar numbers. Each of the number systems known was an example

$$(50) \quad \begin{cases} (a_1, a_2) + (b_1, b_2) = (a_1 + b_1, a_2 + b_2) \\ (a_1, a_2) \cdot (b_1, b_2) = (a_1b_1 - a_2b_2, a_1b_2 + a_2b_1) \end{cases}$$

$$(51) \quad \begin{aligned} (a_1, a_2, \dots, a_n) + (b_1, b_2, \dots, b_n) \\ = (a_1 + b_1, a_2 + b_2, \dots, a_n + b_n) \end{aligned}$$

$$(52) \quad c(a_1, a_2, \dots, a_n) = (ca_1, ca_2, \dots, ca_n)$$

of an algebraic system that in today's terminology is called a field. Formally, a field is a set of elements and two operations, called addition and multiplication, satisfying well-defined postulates, as discussed fully in the article ALGEBRA: *Fields*.

Hamilton's eventual success came from his willingness to discard the notion that any useful and consistent algebraic system must satisfy all of the field postulates. His new algebra provided a means of describing rotations in three-dimensional space by an algebraic system that satisfies all the field postulates except the commutative law for multiplication, which identifies the products $a \cdot b$ and $b \cdot a$ as equal. In Hamilton's algebra $a \cdot b = -b \cdot a$. Thus, Hamilton provided the first example of a noncommutative field, which is now called a division ring. The elements of his algebra were called quaternions.

The realization that useful algebraic systems could be constructed by replacing some traditional postulates proved to be as liberating to algebra as the corresponding discovery had been to geometry only a few years before, when the parallel postulate of Euclidean geometry had been replaced by Gauss and the Hungarian and Russian discoverers of non-Euclidean geometry, János Bolyai and Nikolay Ivanovich Lobachevsky. Mathematical heresy apparently was in the air in those days. In 1844 Grassmann independently developed a theory that was far more imaginative and comprehensive than Hamilton's, providing an algebraic mechanism for n -dimensional space and allowing for various definitions of multiplication. At the same time in England, Arthur Cayley invented matrix algebra, which includes the quaternions invented by Hamilton as a very special case.

The contemporary concept of a vector is a natural or closely related abstraction and extension of the observation that an ordered pair of real (not complex) numbers (a_1, a_2) represents a unique point in the Cartesian plane (that for which pairs of numbers are identified with numbers as described above); similarly, an ordered triple of numbers (a_1, a_2, a_3) represents a point in three-dimensional Cartesian space (Figure 13), and an ordered n -tuple of numbers (a_1, a_2, \dots, a_n) represents a point in Cartesian n -dimensional space.

Addition of two n -tuples is defined by the parallelogram law, which states (see 51) that components of the n -tuples are added to form components of a new n -tuple called the sum. Multiplication of an n -tuple by a number is defined by extending the multiplication (by the number) to each

component (see 52). The laws of addition and multiplication are illustrated in Figures 14 and 15.

The resulting algebraic system is a particular example of a vector space, and the example is general enough to suggest an axiomatic formulation of the concept of a vector space. To begin with, observe that two types of objects are involved in this example: numbers (which are called scalars and will be denoted here by lower case letters) and n -tuples of numbers (which are called vectors and will be denoted here by capital letters). Normally the set of scalars is assumed to be a field, although a comparable theory of vector spaces exists for the case in which the scalars form only a division ring. It need not be assumed that a vector is an n -tuple of scalars; in general, the set V of vectors can be any set of objects that can be combined according to specific laws. Because the laws make specific references to a field of scalars, the term vector space over a field is used. Two of the most important fields that appear in this context are the field \mathfrak{R} of real numbers and the field \mathfrak{C} of complex numbers.

In the familiar notation used for many years for vectors in three-dimensional real space \mathfrak{R}^3 , the vectors along the three mutually perpendicular axes are denoted i , j , and k . Then an arbitrary vector v is written $v = xi + yj + zk$, thus designating the point (x, y, z) in \mathfrak{R}^3 . This particular basis is called the standard basis for \mathfrak{R}^3 , and much of the late-19th-century work in vector analysis and vector calculus, developed by the American physicist J. Willard Gibbs and the English physicist Oliver Heaviside, was expressed in this form. One of the great advantages of the abstract approach to vector space algebra is that it emphasizes coordinate-free methods and thereby avoids long arithmetic computations for properties that are intrinsic, and therefore it is independent of the choice of coordinates.

It is important to observe that the definition of a vector space describes only the algebraic operations of vector sum and scalar multiple of a vector. Special types of vector spaces can be obtained by superimposing additional operations on a vector space. The most glaring omission up to this point concerns metric concepts or concepts that define distance. In itself a vector space provides no means for measuring distance, or angle, or area, or any of the usual concepts needed for geometry and most applications. Therefore, in particular, the reference in the previous paragraph to mutually perpendicular axes was intuitive and premature.

Products: scalar and vector. To attribute to a vector space \mathfrak{L} the usual metric properties, a way must be found to define the length of a vector and the angle between vectors. Length is by nature a function from \mathfrak{L} into the nonnegative real numbers, in the same sense that to each vector in \mathfrak{L} there is assigned a number, the length. Angle is a function in

Figure 15: Multiplication of an n -tuple by a number c (see text).

a similar sense from the space of all ordered pairs of vectors into the real numbers between 0 and π . Therefore, the real numbers are needed for such computations; for simplicity the scalar field can be chosen to be the complex numbers \mathfrak{C} , which include the real scalar field as a special case. Accordingly, the complex conjugate \bar{z} of a complex number $z = x + iy$ is defined by $\bar{z} = x - iy$. It follows that $\bar{z}_1 + \bar{z}_2 = \overline{z_1 + z_2}$, and $\bar{z}_1 \bar{z}_2 = \overline{z_1 z_2}$. The magnitude $|z|$ of z is defined by $|z| = \sqrt{x^2 + y^2}$.

$$\begin{aligned}

 (60) \quad & d(A, B) = \|A - B\| \\
 (61) \quad & d(A, B) \leq d(A, C) + d(C, B) \\
 (62) \quad & \frac{|p(A, B)|}{\|A\| \|B\|} \leq 1 \text{ if } A \neq 0 \neq B \\
 (63) \quad & \cos\{\psi(A, B)\} = \frac{p(A, B)}{\|A\| \|B\|} \text{ for } 0 \leq \psi(A, B) \leq \pi \\
 (64) \quad & \begin{cases} \|A\| = \sqrt{a_1^2 + \dots + a_n^2} \\ d(A, B) = \sqrt{(a_1 - b_1)^2 + \dots + (a_n - b_n)^2} \\ A \cdot B = \|A\| \|B\| \cos\{\psi(A, B)\} \end{cases} \\
 (65) \quad & (a_1, a_2, a_3) \times (b_1, b_2, b_3) \\
 & \quad = (a_2 b_3 - a_3 b_2, a_3 b_1 - a_1 b_3, a_1 b_2 - a_2 b_1) \\
 (66) \quad & \begin{cases} A \times B = -B \times A \\ (A + B) \times C = (A \times C) + (B \times C) \\ (cA) \times B = c(A \times B) \\ A \cdot (A \times B) = 0 \\ \|A \times B\|^2 = \|A\|^2 \|B\|^2 - (A \cdot B)^2 \end{cases}
 \end{aligned}$$

If a vector space \mathfrak{L} is defined so that vectors multiply with members of the field \mathfrak{C} of complex numbers, a scalar product (or inner product) on \mathfrak{L} is a function p with certain properties that maps pairs of vectors into complex numbers. The properties of the function p are those that define the inner product (see 53). Examples of inner products are the following: First, on the space of n -tuples of complex numbers (see 54), p maps the pair $(a_1, \dots, a_n), (b_1, \dots, b_n)$ into $a_1 \bar{b}_1 + \dots + a_n \bar{b}_n$. Second, on the space of n -tuples of real numbers (see 55), the value of the function at $(a_1, \dots, a_n), (b_1, \dots, b_n)$ becomes $a_1 b_1 + \dots + a_n b_n$. Third, on the infinite-dimensional space of complex valued functions continuous on the interval of real numbers between a and b (see 56), the

basis
for \mathfrak{R}^3

pair of functions (f, g), is mapped into the limit of a sum, namely, the value of an integral.

The central fact about any scalar product is expressed in the Schwarz inequality, first employed by the German mathematician Hermann Amandus Schwarz (see 57). The length $\|A\|$ of a vector A is defined (see 58) in terms of inner product, and it has the usual properties of Euclidean length (see 59). Distance between points (vectors) A and B is then defined in terms of length (see 60). Distance is symmetric—that is, independent of the order of the vectors in the pair (A, B)—positive if $A \neq B$ and satisfies the triangle inequality (see 61).

In the case of the space of all real n -tuples with the inner product defined as in the examples above, these concepts of length and distance coincide with the usual Euclidean distance. Hence, any real inner product space is called a Euclidean space. Any complex inner product space is called a unitary space.

A major distinction between Euclidean and unitary spaces occurs in the definition of angle. In either case the Schwarz inequality assumes the same form (see 62). In the Euclidean case there is precisely one number $\psi(A, B)$ the cosine of which corresponds to the intuitive notion of the cosine between two directed line segments (see 63). Thus $\psi(A, B)$ is defined to be the angle between vectors A and B . In a unitary space $p(A, B)$ is a complex number, in general, and so the real definition of angle cannot apply. The important case of perpendicularity (orthogonality) of A and B , however, can be defined by $p(A, B) = 0$ in a unitary space, just as in a Euclidean space.

The standard basis in terms of which all other vectors can be expressed for n -dimensional Euclidean or unitary space is a set of n vectors, each of unit length and each pair orthogonal. Such a basis is called orthonormal. Relative to an orthonormal basis, any inner product on an n -dimensional space assumes the first form given in the examples above (54). This form is also called the dot product because of the notation frequently used, $A \cdot B = p(A, B)$, in which $A = (a_1, \dots, a_n)$ and $B = (b_1, \dots, b_n)$ are expressed relative to an orthonormal basis for n -dimensional unitary space. The same form is valid in the Euclidean case, because $\bar{b} = b$ whenever b is real. The metric concepts assume familiar forms (see 64).

Quite a different form of product of vectors is used extensively in studying the geometry of Euclidean three-dimensional space and its physical applications. As contrasted with the scalar (or dot) product $A \cdot B$, which is a scalar, the vector (or cross) product $A \times B$ is a vector. Geometrically, $A \times B$ is the vector that, first, is perpendicular to both A and B ; second, that is of length $\|A\| \|B\| \sin \psi(A, B)$, which numerically equals the area of the parallelogram having A and B as adjacent sides; and, third, that extends from the origin in the direction of travel of a right-hand screw when it is rotated from A to B through ψ , which is the smaller of the two possible angles.

An expression for $A \times B$ in terms of components is essential for computations and precise reasoning (see 65). The basic algebraic properties satisfied by $A \times B$ are important to compare with those of the inner product (see 66). The first of these properties shows that a cross product is anticommutative (or alternating), as first described by Hamilton for quaternions. The last of these properties relates $A \times B$ to the Schwarz inequality.

Unlike the concept of scalar product, the existence of a vector product having the properties listed above depends critically upon the dimension n of the vector space on which it is defined. Except for the trivial cases ($n = 0$ and $n = 1$), such a vector product exists only for $n = 3$ and $n = 7$. This odd fact is closely related to long-standing problems in algebra, originating in the work of Hamilton and Cayley but only fully solved in the 1960s. (D.T.F.)

Field theory. A particle moving in three-dimensional space can be located at each instance of time t by a position vector r drawn from some fixed reference point O . Because the position of the terminal point of r depends on time, r is a vector function of t . Its components in the directions of Cartesian axes, introduced at O , are the coefficients of i, j , and k in the representation that identifies these three vectors with vectors of unit length

$$(67) \quad r = x(t)i + y(t)j + z(t)k$$

$$(68) \quad \frac{dr}{dt} = \frac{dx}{dt}i + \frac{dy}{dt}j + \frac{dz}{dt}k = v$$

$$(69) \quad \frac{d^2r}{dt^2} = \frac{d^2x}{dt^2}i + \frac{d^2y}{dt^2}j + \frac{d^2z}{dt^2}k = a$$

$$(70) \quad \overrightarrow{PP'} = \Delta r$$

$$(71) \quad \frac{u(P') - u(P)}{|\Delta r|}$$

$$(72) \quad \nabla u = i \frac{\partial u}{\partial x} + j \frac{\partial u}{\partial y} + k \frac{\partial u}{\partial z}$$

$$(73) \quad \frac{\int_S v \cdot n d\sigma}{\tau}$$

$$(74) \quad \operatorname{div} v = \frac{\partial v_1}{\partial x} + \frac{\partial v_2}{\partial y} + \frac{\partial v_3}{\partial z}$$

$$(75) \quad v = i v_1 + j v_2 + k v_3$$

$$(76) \quad \operatorname{curl} v(P) = \lim_{\tau \rightarrow 0} \frac{\int_S n \times v d\sigma}{\tau}$$

$$(77) \quad \operatorname{curl} v = i \left(\frac{\partial v_3}{\partial y} - \frac{\partial v_2}{\partial z} \right) + j \left(\frac{\partial v_1}{\partial z} - \frac{\partial v_3}{\partial x} \right) + k \left(\frac{\partial v_2}{\partial x} - \frac{\partial v_1}{\partial y} \right)$$

along the three mutually perpendicular axes (see 67). If the components are differentiable functions, the derivative of r with respect to t is defined by a formula (see 68) that represents the velocity v of the particle. The Cartesian components of v appear as coefficients of i, j , and k . If these components are also differentiable, the acceleration $a = dv/dt$ is obtained by differentiation (see 69). It may also be verified that the rules for differentiating products of scalar functions remain valid for derivatives of the dot and cross products of vector functions, and suitable definitions of integrals of vector functions allow the construction of the calculus of vectors. Such calculus has become a basic analytic tool in physical sciences and technology.

Applications of vector calculus to problems of continuum mechanics (e.g., fluid mechanics, aerodynamics) call for a consideration of scalar and vector functions specified at each point of some region. A region of space with each point of which a scalar function is associated is called a scalar field, while a region in which a vector function is determined is a vector field. Examples of scalar fields are regions at each point of which the temperature or density of a body can be determined. A region in the vicinity of a charged body in which the electric-intensity vector is determined is an example of a vector field. A scalar function $u(P)$ determined at each point P of a scalar field is called a scalar point-function, while a vector function $v(P)$ specified in a vector field is a vector point-function.

Gradient of a scalar field. If there is a scalar point-function $u(P)$ at a point P and another scalar point-function $u(P')$ at a nearby point P' , the vector from P to P' being expressed as Δr (see 70), then the ratio (see 71) of the difference between u at P and u at P' relative to Δr represents the average space rate of change of $u(P)$ in the direction of Δr . The limit of this ratio as $|\Delta r| \rightarrow 0$, when this limit exists, represents the space rate of change of $u(P)$ in the direction of Δr . The vector in that direction for which the space rate of change of $u(P)$ is a maximum

Geo-
metric
meaning
of vector
cross
product

Examples
of scalar
fields

is called the gradient of $u(P)$ and is denoted by $\text{grad } u$ or ∇u . It can be shown that in Cartesian coordinates the vector components of the gradient are partial derivatives of u —that is, derivatives of u , obtained by holding all but one variable fixed and differentiating with respect to the unrestricted variable (see 72). Thus, with each point of a scalar field, in which ∇u exists, there can be associated a vector field. If $u(P)$ is the temperature, then ∇u gives the direction of the heat-flow vector in the field.

Divergence of a vector field. On the other hand, two important fields can be associated with each continuously differentiable vector point-function $\mathbf{v}(P)$: one is a scalar field and the other a vector field. If $\mathbf{v}(P)$ is defined in some region T bounded by a sufficiently smooth surface S , then the component of $\mathbf{v}(P)$ (which for the sake of concreteness can be thought to represent velocity \mathbf{v} of fluid particles moving in T) in the direction of the unit vector \mathbf{n} that is exterior (directed away from) and normal to the surface S is $\mathbf{v} \cdot \mathbf{n}$. The amount of fluid issuing from S then is given by $\int \mathbf{v} \cdot \mathbf{n} d\sigma$, in which the integration symbol represents the summation of $\mathbf{v} \cdot \mathbf{n}$ over the elements of area $d\sigma$ of the surface S .

The flux of fluid per unit volume is thus equal to a ratio of the integral referred to, relative to τ , in which τ is the volume of T (see 73). The limit of this ratio as $\tau \rightarrow 0$, so that S shrinks toward some point P in T , is an important scalar called the divergence of $\mathbf{v}(P)$. Thus, the divergence of $\mathbf{v}(P)$, written $\text{div } \mathbf{v}(P)$, represents the rate of fluid flow from P . If $\text{div } \mathbf{v}(P)$ is positive at P , then P is a source of fluid; if it is negative, then P is a sink. If $\text{div } \mathbf{v}(P) = 0$, then no fluid issues from P .

In Cartesian coordinates $\text{div } \mathbf{v}(P)$ is given by a formula (see 74) that is the sum of partial derivatives of vector components of the velocity vector \mathbf{v} (see 75).

Curl of a vector field. Associated with $\mathbf{v}(P)$ is an important vector field in which the vector called curl of $\mathbf{v}(P)$ is defined by a formula that expresses, in the limit of small volume, the ratio of $\int \mathbf{n} \times \mathbf{v} d\tau$ relative to that volume, in which the integral is calculated over the surface S (see 76). This vector provides a measure of the angular velocity of the fluid at any point P in the field. In Cartesian coordinates $\text{curl } \mathbf{v}$ is given by an especially convenient formula in which the vector components are differences of partial derivatives (see 77). When $\text{curl } \mathbf{v} = 0$ at every point of the region, the field is said to be irrotational, and, when $\mathbf{v}(P)$ is such that $\text{div } \mathbf{v} = 0$, the field is solenoidal. The importance of these two special fields stems from the fact that every continuously differentiable vector function $\mathbf{v}(P)$ defined in a region τ (subject to mild restrictions) can be expressed as a sum of two vector functions $\mathbf{f}(P)$ and $\mathbf{g}(P)$ such that $\mathbf{f}(P)$ is solenoidal and $\mathbf{g}(P)$ is irrotational. The possibility of such decomposition greatly simplifies the study of many velocity and force fields occurring in physics.

TENSOR ANALYSIS

Tensors, or generalizations of vectors, as characterized at the beginning of this article, were invented to express geometric entities arising in the study of manifolds—that is, spaces that resemble Euclidean space in small regions but which may be curved in an arbitrary manner. Originally these small regions were used to define coordinate systems on the manifold, and tensors were expressed in terms of functions involving many indices that obey certain transformation laws when the coordinate system is changed. Subsequently, a global study of manifolds resulted in an invariant treatment of tensors and their algebraic rules of combination. This is the subject of tensor or multilinear algebra.

The concept of tensors and the knowledge of some of their properties can be traced back to the work of Gauss and to the work of his younger countrymen Bernhard Riemann and Elwin Bruno Christoffel as well. Their algebra and analysis eventually were shaped into a systematic method by the Italians Gregorio Ricci-Curbastro and Tullio Levi-Civita, who coined for this powerful branch of mathematics the name absolute differential calculus. It is now known as tensor analysis. The chief aim of tensor analysis is to construct and discuss relations of laws that are generally covariant—that is, laws that remain valid

in passing from one to any other system of coordinates. Thus, the method of tensor analysis is of prime importance for differential geometry. It became the object of widespread interest after the advent of general relativity theory, in which a principal requirement is precisely such unrestricted covariance of physical laws. There are many useful applications of tensor analysis—both finite and infinite dimensional—to classical mechanics, quantum mechanics, fluid mechanics, and other fields.

Consider a continuous n -dimensional manifold or space S_n (see GEOMETRY: *Topological groups and Differential topology*), the element or point $P(x_i)$ of which is determined by assigning the values of n real independent variables or coordinates x_i . Let $Q(x_i + dx_i)$ be another point of S_n . Then the ordered point-pair P, Q or the set of differentials dx_i is a vector. To begin with, the idea of size or length is foreign to this concept, as S_n thus far is a nonmetrical manifold. If the x_i be transformed into any other system of n coordinates x'_i , the former being continuous functions of the latter with continuous derivatives $\partial x_i / \partial x'_k$ and nonvanishing, finite Jacobian $J = \partial x_i / \partial x'_k$; then dx_i are transformed into differentials dx'_i by a linear transformation in which the coefficients are partial derivatives (see 78). (The convention will be adopted that every term in which an index occurs twice is to be summed over all its values.) Any set of n magnitudes A_i , functions of the x_i , that are transformed by this rule, that is, by the rule of transformation that governs differentials (see 79), forms a contravariant tensor of rank 1, the A_i being its n components. For contravariant tensors upper indices are used, except for dx_i , the prototype of all such tensors. Next, any n magnitudes A_i that are transformed as the differentiators $\partial / \partial x_i$, which are arrived at by formally inverting the partial derivatives that constitute the coefficients (see 80), form a covariant tensor of rank 1; lower indices are used for such tensors. These two kinds of tensors, or rank 1, are also termed vectors—e.g., three-vectors, four-vectors (such as the relativistic four-velocity or four-potential, in space-time, S_4) and so on, according as $n = 3, 4, \dots$. Similarly, any n^2 magnitudes A_{ik} transformable by a natural generalization of the rank 1 covariant tensor transformation (see 81) form a covariant, and any A'^i transformable by a natural generalization of the rank 1 contravariant tensor transformation (see 82) form a contravariant tensor of rank 2. Again, n^2 magnitudes A'^{ik} transformable by a linear transformation in which coefficients are products of coefficients from rank 1 covariant and contravariant tensor transformations (see 83) are said to form a mixed tensor of rank 2, covariant in i and contravariant in k .

Tensor
transformation
and rank

$$(78) \quad dx'_i = \frac{\partial x'_i}{\partial x_a} dx_a$$

$$(79) \quad A'_i = \frac{\partial x'_i}{\partial x_a} A^a$$

$$(80) \quad A'_i = \frac{\partial x_a}{\partial x'_i} A_a$$

$$(81) \quad A'_{ik} = \frac{\partial x_a}{\partial x'_i} \frac{\partial x_b}{\partial x'_k} A_{ab}$$

$$(82) \quad A'^{ik} = \frac{\partial x'_i}{\partial x_a} \frac{\partial x'_k}{\partial x_b} A^{ab}$$

$$(83) \quad A'^{ik} = \frac{\partial x_a}{\partial x'_i} \frac{\partial x'_k}{\partial x_b} A^{ab}$$

$$(84) \quad (A'^{ik \dots})' = \frac{\partial x_a}{\partial x'_i} \frac{\partial x_b}{\partial x'_k} \dots \frac{\partial x'_i}{\partial x_a} \frac{\partial x'_k}{\partial x_b} \dots A^{ab \dots}$$

The extension to any rank is obvious. Any $n^{r_1+r_2}$ magnitudes $A^{ik\dots}$, with r_1 lower and r_2 upper indices, which are transformed according to a generalized rule (see 84), form a mixed tensor of rank $r = r_1 + r_2$. This is the most general concept of a tensor. A tensor of rank zero, called also a scalar, is a single function of the x_i , invariant with respect to any transformations of coordinates, $f' = f$. A_{ik} is symmetrical if $A_{ik} = A_{ki}$ and is antisymmetrical or a skew tensor if $A_{ik} = -A_{ki}$, implying $A_{ii} = 0$. Similarly for A^{ik} . Analogous definitions hold for mixed tensors and for higher ranks. Symmetry and antisymmetry are invariant properties.

Differentiation. The differentiation of tensors with respect to the coordinates yields, in certain circumstances, further tensors. If f is a scalar function of the x , or scalar field, $\partial f / \partial x_i = f_i$ is a covariant vector, the gradient of f (but $\partial^2 f / \partial x_i \partial x_k$ is not a tensor; again, if du is an invariant, dx_i / du is, but $d^2 x_i / du^2$ is not a vector). Further, if A_i is a vector, $B_{ik} = \partial A_i / \partial x_k - \partial A_k / \partial x_i$ is a skew tensor, the rotation of A_i . Finally, if A_{ik} is antisymmetric, $B_{ik\alpha} = \partial A_{ik} / \partial x_\alpha + \partial A_{\alpha k} / \partial x_i + \partial A_{\alpha i} / \partial x_k$ is again such a tensor, the expansion of A_{ik} .

In what precedes only such properties of tensors were treated as are independent of any metrical considerations; the space S_n thus far is a nonmetrical, amorphous manifold. Its metrics may now be fixed by laying down the line element, a quadratic differential form (see 85) to be considered as invariant and to serve as the measure of the (squared) size or length of the vector dx_i . In the differential form there are coefficients $g_{ik} = g_{ki}$ that are prescribed functions of x . It follows that, because dx_i is contravariant, g_{ik} is covariant. Equivalently, it may be said that a certain symmetrical tensor g_{ik} is impressed upon S_n as the fundamental or metrical tensor, converting it into a metrical manifold called a Riemannian space.

The minors g^{ik} of $g = |g_{ik}|$, divided by g , form again a symmetrical tensor, the contravariant metrical tensor, to be used along with g_{ik} . The outer product and contraction can be used in raising and lowering tensor indices. Thus, $g^{ik} A_k = A^i$ and $g_{ik} B^k = B_i$.

The angle θ between two (copunctal) vectors A^i and B^i is defined by the invariant $\cos \theta = g_{ik} A^i B^k / AB$, where A, B defines their sizes. The unit vector $x_i = dx_i / ds$ determines, locally, a direction in S_n . The angle between two directions \dot{x}_i, \dot{y}_i is given by $\cos \theta = \dot{g}_{ik} \dot{x}_i \dot{y}_k$.

Integrals. The integral $\int dx_1, \dots, dx_n$, briefly $\int dx$, extended over a region of S_n , is transformed into $\int J dx'$, and the determinant g into $g' = J^2 g$. Consequently, $\int \sqrt{g} dx$ is an invariant metrically impressed upon that region's size or volume (area, if $n = 2$). This concept is readily extended to any submanifold of S_n characterized by x_i as functions of $m < n$ parameters p_a , the role of metrical tensor is taken over by a linear transformation of it (see 86). If, by a proper choice of the coordinate system, all components g_{ik} are reducible to constants, the metric space S_n is Euclidean or homaloidal (flat). This is but a very special case of Riemannian space. In general, such a reduction is not possible, and S_n is non-Euclidean.

Differentiation of tensors, aided by metrics, yields an unlimited number of new tensors. The oldest of such is Riemann's set of four-index symbols of 1861. The simplest metrically differential tensor, however, was discovered in 1869 by Christoffel. This is the covariant derivative of a vector A , (see 87) in which certain terms $[ik, \mu]$ are Christoffel's symbols (not forming a tensor) (see 87). Again, the generalization of this is a mixed tensor (see 88). Detailed symbolism is necessary to express the covariant derivatives of C^{ik} and C_{ik} (see 89, 90). The covariant derivative of g_{ik} itself vanishes identically. Noteworthy for their applications are the vector divergence of a skew A^{ik} and the scalar divergence of A^k (see 91); e.g., one group of the 19th-century Scottish physicist James Clerk Maxwell's equations is represented by $\text{div}(F^{ik}) = C^i$, where C^i is the four-current and F^{ik} the electromagnetic skew tensor (six vector); the second group is expressed by equating to zero the expansion of $F_{ik} = g_{ia} g_{kb} F^{ab}$.

Geodesics, null lines. The most characteristic curves of the metric S_n are its null or minimal lines, $ds = 0$, and shortest curves or geodesics defined by $\delta \int ds = 0$, with

fixed terminals. The equations of a geodesic are second-order differential equations expressed in terms of Christoffel symbols and \dot{x} , in which $\dot{x} = dx/ds$ (see 92). They determine—e.g., in the case of space-time—the motion of a free particle in the metric, and gravitational, field g_{ik} . The null lines are imaginary or real, depending on whether the form (85) expressing the square of the differential of the line element is a definite or nondefinite form. The definite form holds in the case of spaces proper as contemplated by the pure geometer, and the nondefinite form characterizes space-time with one positive and three negative g_{ik} . The null lines of space-time represent light propagation. The definiteness or nondefiniteness of the quadratic form and its index of inertia (number of negative g_{ik} terms) are invariant properties.

Parallel displacement of vectors. A fruitful contribution to tensor analysis due to Levi-Civita is the concept of parallel displacement of a vector with respect to a curve. The metric S_n can in general be imagined as imbedded locally in a Euclidean space E of $1/2(n+1)$ dimensions. Levi-Civita defined parallel displacement in S_n as a consequence of a parallel displacement in E . In spite of the ultraspatial construction, parallelism is intrinsic, expressible by the S_n metrics alone.

If $x_i = f_i(s)$ are the parametric equations of any chosen curve C , then there are differential equations along C that with the initial vector $A^i(S_0) = A_0^i$ determine uniquely a contravariant vector A^i at each point of the curve (see 93). The vector A^i at the point corresponding to $s = s$ is said to be obtained by a parallel displacement of the vector A_0^i with respect to the given curve C and is said to be parallel to A_0^i . Any two vectors generated as above, one at each point, are parallel with respect to C . If it be required to construct a curve the tangents of which follow from each other by parallel displacement along the curve itself, the result will be the equations of a geodesic (92), so that the curve is a geodesic. The latter is thus throughout parallel to itself. Accordingly, a vector transferred along a geodesic remains equally inclined to it.

Levi-Civita's concept

$$(85) \quad ds^2 = g_{ik} dx_i dx_k$$

$$(86) \quad h_{ab} = g_{ik} \left(\frac{\partial x_i}{\partial p_a} \right) \left(\frac{\partial x_k}{\partial p_b} \right)$$

$$(87) \quad \begin{cases} A_{i,k} = \frac{\partial A_i}{\partial x_k} - \{ik, \lambda\} A_\lambda \\ \{ik, \lambda\} = g^{\lambda\mu} [ik, \mu] = \{\kappa i, \lambda\} \\ [ik, \mu] = \frac{1}{2} \left(\frac{\partial g_{ik}}{\partial x_\mu} + \frac{\partial g_{\mu i}}{\partial x_k} - \frac{\partial g_{ik}}{\partial x_\mu} \right) \end{cases}$$

$$(88) \quad B_{ik}^\lambda = \frac{\partial B^i}{\partial x_k} + \{ak, i\} B^a$$

$$(89) \quad C_{ik}^\kappa = \frac{\partial C^{ik}}{\partial x^\lambda} + \{\lambda a, i\} C^{ak} + \{\lambda a, k\} C^{ia}$$

$$(90) \quad C_{ik,\lambda} = \frac{\partial C_{ik}}{\partial x^\lambda} - \{i, a\} C_{ak} - \{\kappa \lambda, a\} C_{ia}$$

$$(91) \quad \begin{cases} A^i = \text{div}(A^{ik}) \equiv \frac{1}{\sqrt{g}} \frac{\partial}{\partial x_k} (\sqrt{g} A^{ik}) \\ \text{div}(A^k) \equiv \frac{1}{\sqrt{g}} \frac{\partial}{\partial x_k} (\sqrt{g} A^k) \end{cases}$$

$$(92) \quad \ddot{x}_i + \{a\beta, i\} \dot{x}_a \dot{x}_\beta = 0$$

$$(93) \quad \frac{dA^i}{ds} + \{a\beta, i\} A^a \dot{x}^\beta = 0$$

Differentiation of tensors by metrics

If a vector X' be carried by a parallel displacement along two different paths a, b from O to O' , the two vectors at O' , equal in size, generally differ in direction. One is parallel to X' via a , the other via b . In short, parallelism depends on the route of transfer or is nonintegrable (unless S_n is essentially Euclidean). Thus also, if the vector is carried around a circuit, it returns at O with its direction changed.

The covariant derivative of the vector is the tensor X_{ia} . Its covariant derivative $X_{ia\beta}$ is not symmetric in a and β . A straightforward calculation shows that the difference of the two forms of this covariant derivative involves the important tensor $R_{\kappa\alpha\beta}$ (see 94). This latter tensor is the Riemann-Christoffel, or curvature, tensor (see 95) the vanishing of which is the necessary and sufficient condition for the reducibility of g_{ik} to a constant tensor, or the criterion of a homaloidal space.

Riemann's four-index symbols and curvature. Riemann's own set of four-index symbols is the covariant tensor $(\mu, \lambda\kappa) \equiv R_{\mu\lambda\kappa} = g_{\mu\alpha} R_{\lambda\kappa}^{\alpha}$. Conversely, $R_{\lambda\kappa}^{\alpha} = g^{\mu\alpha} (\mu, \lambda\kappa)$. Like equation (95), the symbols are antisymmetric in κ, λ . Three more linear relations hold between them. This reduces the number of independent symbols to $n^2(n^2 - 1)/12$ —e.g., six for a three-space, 20 for an S_4 , and but one for a surface, say $(12, 12)$. This symbol divided by g is a scalar of the surface, its Gaussian curvature K . If a vector undergoes parallel displacement around a circuit on a surface, it returns with its direction changed by an amount equal to $\int K d\sigma$, the Gaussian curvature of the surface integrated over the surface area enclosed by the circuit. As a consequence, the excess (over π) of the angle sum in any geodesic triangle is $\int K d\sigma$, a theorem proved by Gauss.

When there are three or more dimensions, the curvature properties can no longer be expressed by a single magnitude but require for their description the knowledge of the whole curvature tensor or the associated Riemann symbols. The concept of Gaussian curvature is now replaced by that of Riemannian curvature—i.e., at any point $O(x)$ of S_n , the set of Gaussian curvatures K of geodesic surfaces of all possible orientations laid through O . If $h_{\alpha\beta}$ be the metric tensor of such a surface as submanifold, $K = 1/h(12, 12)_K$, the symbol is calculated with $h_{\alpha\beta}$. This and the determinant h can be expressed in terms of the tensor g_{ik} of the manifold and the vector pair, ξ^i, η^j , fixing the orientation (see 96).

$$(94) \quad X_{i\beta,a} - X_{i,a\beta} = R_{i\alpha\beta}^{\kappa} X_{\kappa}$$

$$(95) \quad R_{i\alpha\beta}^{\kappa} = \frac{\partial}{\partial x_{\alpha}} \{i\beta, \kappa\} - \frac{\partial}{\partial x_{\beta}} \{i\alpha, \kappa\} + \{a\gamma, \kappa\} \{i\beta, \gamma\} - \{\beta\gamma, \kappa\} \{i\alpha, \gamma\}$$

$$(96) \quad K = \frac{(\iota\kappa, \lambda\mu) \xi^{\iota} \eta^{\kappa} \xi^{\lambda} \eta^{\mu}}{(g_{\iota\lambda} g_{\kappa\mu} - g_{\mu\iota} g_{\kappa\lambda}) \xi^{\iota} \eta^{\kappa} \xi^{\lambda} \eta^{\mu}}$$

In general, K will depend on position and on orientation. In other words, with regard to curvature, S_n may be nonhomogeneous and anisotropic (e.g., space-time within or around matter); but, if K is everywhere isotropic, it is also constant throughout S_n (Schur's theorem). By the expression (96) for K in terms of the tensor g_{ik} and the vector pair, ξ^i, η^j , the necessary and sufficient condition for isotropy of Riemannian curvature becomes $(\iota\lambda, \kappa\mu) = K(g_{\iota\kappa} g_{\lambda\mu} - g_{\mu\iota} g_{\kappa\lambda})$ or $R_{\iota\alpha}^{\kappa} = K(\delta_{\kappa}^{\alpha} g_{\iota\lambda} - \delta_{\iota}^{\alpha} g_{\kappa\lambda})$ with constant K . (D.T.F./Ed.)

Measure theory

The classical integral calculus is founded on the concept of the Riemann integral. However, this is not an entirely satisfactory basis. Certain functions that "ought to be" integrable fail to possess a well-defined Riemann integral. Functions that are limits of sequences of Riemann integrable functions may not themselves be Riemann inte-

grable. The search for a more general and better behaved notion of integral led to the subject of measure theory, which among other things has provided the long-sought foundations for the concept of probability.

Beyond the Riemann integral. The general concept of a real-valued function of a real variable that had appeared in a more or less vague or restrictive form throughout the calculus period was finally isolated by Dirichlet in 1829. Dirichlet examined the problem of convergence of Fourier series. Since the coefficients of these series are given by integrals, the knowledge of Fourier series expanded with the evolution of the concepts of integration and of function. From the time of Dirichlet and Riemann on, the knowledge of trigonometric series and, more generally, of harmonic analysis thus gained in depth and in extension.

In fact, modern set theory, which changed the whole outlook on measure and integration, began in 1872 with Cantor's investigation of the structure of some exceptional sets of trigonometric series: sets S such that, if a trigonometric series (see 97) converges to zero except at the points of S , then each coefficient $c_n = 0$. The evolution of set theory between 1872 and 1890, due primarily to Cantor's genius, together with the parallel investigation of the system of reals and of functions of reals by such mathematicians as Richard Dedekind, Karl Weierstrass, and Paul du Bois-Reymond, all of Germany, as well as Ulisse Dini of Italy, brought on the "great mathematical revolution" at the turn of the 20th century.

$$(97) \quad \sum_{n=-\infty}^{+\infty} c_n e^{inx}$$

Measure and content. The problem of foundations was revived but was applied to the tremendous wealth of accumulated knowledge at a level of abstraction far beyond that known to the ancient Greeks. In particular, the problem of measure was no longer confined to a few special sets—the geometric figures available to Eudoxus or Pascal. Moreover, the very nature of the problem was different.

Eudoxus' or Pascal's problem was to find the measure (area, volume) of some specific geometric figure. The existence of this measure was a question of faith, and it was approximated by sums of measures of simple figures. The new problem was to define a measure for as large a class of sets as possible by means of such approximations. The first attempts were made in 1884–85 by the German mathematicians Carl Gustav Axel Harnack, Otto Stolz, and Cantor. They did not succeed because they used only approximations from above; they assigned to any set S the greatest lower bound of sums of ordinary measures of simple sets—intervals, rectangles, parallelepipeds, the finite unions of which cover S .

The outer content so defined does not correspond to the intuitive idea of measure, for it is not additive: in everyday experience as well as in experimental science, the "measure" of a union of two disjoint sets is the sum of their "measures." For example, the volume (or mass) of two disjoint bodies is understood as the sum of their volumes (or masses). This requirement was recognized in Italy and France by Giuseppe Peano and Camille Jordan, who introduced approximations both from above and from below. To a set S , contained in a bounded interval I , they assigned also its inner content (the difference between the ordinary measure of I and the outer content of S). If the inner and outer contents of S are the same, then their common value defines the content of S . This content measure is additive. The most important types of sets encountered in analysis, however, such as the set of all rationals or general open sets, have no content. The content measure is thus of limited use.

Borel measure. The extension (or theory of measure) period began in 1898 with Émile Borel, the modern French Eudoxus. It is characterized by the extension of the idea of measure to wider and more abstract classes of sets and by the parallel extension of the idea of integration to wider and more abstract families of functions until both ideas

The Riemann-Christoffel curvature tensor

Modern set theory

The Borel
sets and
measure

coalesce. It was stimulated by and intricately interwoven with the explosive growth of general topology following Maurice Fréchet's thesis in France in 1902.

At the root of the theory of measure lie a few crucial remarks by Borel in his *Leçons sur la théorie des fonctions* (1898). While studying series of functions, Borel found the need for a measure such that sets whose measure is not zero are not countable. He therefore introduced the Borel measure on the Borel field, prototypes of all measures and all σ -fields considered below.

In the present discussion, the following terminology will be used. Unions of disjoint sets will be called sums, and the symbol \cup for union will be replaced by the Greek letter sigma, Σ . "Countable" will mean finite or denumerable. Countable (or finite) set operations are complementations taking countable (or finite) unions and intersections. A σ -field (or field) of sets is a class of sets closed under countable (or finite) set operations.

Borel began by extending the ordinary measure on intervals to a measure on open sets, as follows. As Cantor had shown that every open set G of reals is a countable sum of open intervals I_j , Borel realized that the "natural" extension consists in assigning to G the sum of ordinary measures of its constituent intervals I_j . Hence, if G is not bounded, this sum may be infinite, but it always exists. By indefinite iteration of countable set operations and using the same extension procedure, he then extended the class of open sets and their measure to the class of Borel sets and their Borel measure. This class is a σ -field (the smallest σ -field containing the class of open sets), and this measure is σ -additive; the measure of a countable sum of sets is the sum of their measures. From then on, the Borel field of Borel sets in any topological space will be the smallest σ -field containing the topology; that is, the class of open sets in the space. (In fact, some authors use the term Borel field as a synonym for σ -field.)

The
"Archimedes of
France"

Lebesgue measure and integration. The Archimedes of the extension period in France was Henri-Léon Lebesgue. He took the decisive step in his thesis *Intégrale, aire, volume* (1902), which he immediately applied to trigonometric series (1903), and pursued further in *Sur l'intégration des fonctions discontinues* (1910). Lebesgue combined the ideas of his immediate predecessors, Jordan and Borel, and created and exploited the powerful tools of modern measure and integration. The evolution of his ideas, methods, and results consisted primarily in the gradual shedding of their extraneous coverings.

The Lebesgue measure is defined by extending the ordinary measure on intervals by means of outer and inner Lebesgue measures, exactly as the Jordan content was defined, except that coverings by countable unions of intervals replace coverings by finite unions. The intervals are one-dimensional or N -dimensional, and the same method applies. Thus, the Lebesgue integral of a function $f \geq 0$, defined on a set, becomes simply the Lebesgue measure of the ordinate set of the function, provided this set is Lebesgue-measurable. As may be expected, every Riemann-integrable function is Lebesgue-integrable, but the converse is not true. Riemann's integrability condition for bounded functions f becomes: the discontinuity set of f is of Lebesgue measure 0. Thus, the famous Dirichlet function $f(x) = 0$ or 1 (according as x is irrational or not), which is Lebesgue-integrable on every bounded interval, is not Riemann-integrable.

Lebesgue's main contribution, however, does not lie in the above concepts. The Lebesgue measure, for example, is simply the completed Borel measure; that is, a Lebesgue-measurable set is a Borel-measurable set up to a subset of a set of Borel-measure 0. What really mattered were Lebesgue's discovery and use of the properties of his concepts of measure and of integration.

Using the Lebesgue approach, the problem of finding a process of integration that includes both that of Leibniz (*summa omnium*) and that of Newton (primitive) was solved by Arnaud Denjoy of France (1912) and also by Oskar Perron of Germany (1914).

The cleaning up of Lebesgue's ideas was essentially achieved in the 15 years or so that followed the publication of his thesis. It yielded a general answer to the problem of

measure for areas, masses, probabilities, and the like and finally isolated its conceptual substance. The answer and the substance, however, were to be formulated in terms far removed from the everyday experience. The steps in the cleaning-up process included the generalization that stemmed from Thomas Jan Stieltjes of France and was due to Johann Radon of Germany and the abstraction that began with Fréchet in 1915 and with Constantin Carathéodory of Germany in 1918.

Conditions for existence of the Riemann integral. The question may now be raised: if a function f is bounded on an interval $a \leq x \leq b$, can a criterion be found that will ensure the integrability, or nonintegrability, of f ? (A function f is bounded on $a \leq x \leq b$ if there exists a number M such that $|f(x)| \leq M$ for all x in the interval. Boundedness, in effect, prevents the function from assuming arbitrarily large values at any points of the interval.)

This question can be concisely answered in terms of the concept of a set of points of measure zero. A set of points is of measure zero if the points can be covered by intervals the sum of whose lengths can be made arbitrarily small. For example, the set of points $x_0, x_1, x_2, \dots, x_k, \dots$, in which $x_0 = 0$, $x_k = 1/k$ ($k = 1, 2, 3, \dots$), is of measure zero because for any positive number ε (no matter how small) x_0 can be covered by an interval of length $\varepsilon/2$; x_1 by an interval of length $\varepsilon/2^2$; \dots ; x_k by an interval of length $\varepsilon/2^{k+1}$; and by the theory of infinite series it can be shown that the sum of these lengths is precisely ε . It should be noted, for the sake of clarity, that any finite set of points is of measure zero.

The following criterion provides a necessary and sufficient condition for Riemann integrability: If a function f is bounded on an interval $a \leq x \leq b$, then the Riemann integral of f on the interval exists if and only if the set of discontinuities of f is of measure zero. The result for piecewise-continuous functions is a special case of this theorem.

The function $f(x) = \sin[1/\sin(\pi/x)]$, for example, is not defined at the points $0, 1, 1/2, 1/3, \dots$. At these points the function can be assigned any values. The resulting function is bounded on the interval $0 \leq x \leq 1$, however, and its only discontinuities in this interval are the above points, which form a set of measure zero. Hence, the integral of f from 0 to 1 exists.

A property that holds at all points of a given set, except for a subset of measure zero, is said to hold almost everywhere on the set. The above theorem therefore states, in effect, that, for the Riemann integral to exist, the function f must be continuous almost everywhere on the specific interval. The extension of the concept of an integral to the Lebesgue integral is designed to cover cases that are not so restricted.

Probability theory. The basic setup of the history of measure also yields the foundations of probability theory. Deserving mention is the concept of stochastic independence, which was, and to a great extent still is, essential to the evolution of probability theory since its inception in 1654 by Blaise Pascal and Pierre de Fermat. It, too, became measure-theoretic with the creation and abstraction of finite and infinite product measures by Lebesgue and by the American mathematician P.J. Daniell.

Recent developments. Since about 1930, when integrals of functions with values in a Banach space were introduced by the Polish-born mathematician Salomon Bochner, a further abstraction began. Measures and functions (hence, integrals) take values in more and more abstract spaces instead of taking numerical values as above, and various types of convergence are used. Of particular importance are the various stochastic integrals. In fact, the foregoing indications concerning the theory of measure and integration have many variants, even in the numerical case. In the final analysis, their conceptual substance is the same, but it is seen from different points of view in various settings, from Eudoxus and Archimedes, through Leibniz and Riemann, to Lebesgue and the present day. The most important fact is the ever-spreading use of the powerful tools that these concepts provide for such areas as differentiation theory, boundary problems, ergodic theory, probability theory, group theory, potential theory, and harmonic analysis. (Hy.K./Ed.)

Sets of discontinuity of measure zero

COMPLEX ANALYSIS

Complex analysis arose from studies of analytic functions of complex variables. A function $f(z)$ is said to be analytic in a two-dimensional region if, at each point of the region, the derivative $f'(z)$ exists. Analytic functions are also called holomorphic, monogenic, regular, or regular-analytic functions. Historical usage and the many varieties of context recommend the different terms for the same concept, as will be seen below.

Cauchy's
contribution

The theory of analytic functions was created by the French mathematician Augustin-Louis Cauchy, who in 1814 began the task of integrating between complex limits (see *Real analysis* above). His results were first made known in 1825. He used his new ideas to lay the foundation for a theory of ordinary and partial differential equations, including applications to mathematical physics. In 1851 Bernhard Riemann of Germany outlined a theory in which the analytic function is defined by a pair of harmonic functions (functions that satisfy Laplace's equation; see *Differential equations: Partial differential equations* below) joined by the Cauchy-Riemann equations. The values of the function form a geometric entity that is called a Riemann surface. In the same paper the idea of conformal mapping (see below) was introduced.

His contemporary Karl Weierstrass took the view that analytic functions are defined by power series (in which each term is a constant multiplied by the independent variable to some power; see *Infinite series* above) that are linked by a method of analytic continuation.

Theory of analytic functions of one complex variable

FOUNDATIONS

Complex numbers and the complex plane. Complex numbers are numbers of the form $a + bi$, in which a and b are real numbers and i is the square root of -1 . They can be written also as ordered pairs of real numbers (a, b) . The complex numbers form a field. The elements of this field are ordered pairs of real numbers (a, b) for which equality, addition, multiplication, and scalar multiplication are defined by well-specified rules involving ordered pairs (see Box, equations 98). The associative, commutative, and distributive laws (see ALGEBRA: *Elementary and multivariate algebra*) hold; $(0, 0)$ acts as zero, $(1, 0)$ as unity. From one of these laws the result that an arbitrary ordered pair can be written as a linear combination of two fixed ordered pairs each having components one or zero in some order (see 99) is obtained, using the classical notation. The numbers $(a, 0)$ are identified with the real numbers a so that the equalities $(1, 0) = 1$ and $(0, 1) = i$ may be written.

The notation (a, b) suggests the geometric representation of the complex number $a + bi$ by the point (a, b) in an ordinary Euclidean plane. The x -axis is then called the real axis, and the y -axis the imaginary one. An alternate representation is by the vector (see *Vector and tensor analysis* above) joining $(0, 0)$ with (a, b) . The length r of this vector is called the absolute value of the complex number $c = a + bi$ and is written $|c| = r$. The angle, symbolized here by the Greek letter theta, θ , that the vector makes with the positive real axis is called the argument, $\theta = \arg c$ (see Figure 16). Thus, an arbitrary complex number can be written in trigonometric or exponential form (see 100). The point $a - bi = \bar{c}$ is called the conjugate of c . In the geometric representation of complex numbers, addition becomes vector addition. The absolute value of a product is the product of the absolute values, and the argument is congruent to the sum of the arguments, modulo 2π .

The plane used for this representation is known as the complex plane. The complex variable is usually denoted by $z = x + iy$. There is an extensive geometry of the complex numbers based on this representation. In its trigonometric form z can be expressed by $z = r(\cos \theta + i \sin \theta)$. Given another complex number z' , it can be shown that the product $z \cdot z'$ accords with the general relationship

$z^n = r^n(\cos n\theta + i \sin n\theta)$, which is known as de Moivre's formula (devised in the 18th century by Abraham de Moivre). It holds for any real number n and can be used to compute the n th roots of a complex number. For the following discussion it is important to realize that the equation $|z - c| = r$ represents a circle with centre at c and radius r and that the inequality, the absolute value of $z - c$ less than r (that is, $|z - c| < r$) defines the interior of the circle, often called a disk.

Functions. The idea underlying the function concept is that of a correspondence, or of a mapping of one set of objects D , called the domain, upon another set of objects R , called the range. If there is a unique definite object Q of R corresponding to every object P of D , then Q is said to be a function of P and is written $Q = f(P)$. If R and D are sets of real numbers, then the function is a function Q of a real variable.

The idea
of corre-
spondence

For functions of complex variables, D and R are sets of complex numbers, and D is usually required to be a domain in a narrower sense, namely, an open connected set. This means that for every point of D there is a small

$$(98) \quad \begin{cases} (a, b) = (c, d) \text{ if and only if } a = c, b = d \\ (a, b) + (c, d) = (a + c, b + d) \\ (a, b) \cdot (c, d) = (ac - bd, ad + bc) \\ c \cdot (a, b) = (ac, bc) \end{cases}$$

$$(99) \quad (a, b) = a \cdot (1, 0) + b \cdot (0, 1) = a + bi$$

$$(100) \quad c = r(\cos \theta + i \sin \theta) = re^{i\theta}$$

$$(101) \quad \frac{f(z) - f(z_0)}{z - z_0}$$

$$(102) \quad U_x = V_y, \quad U_y = -V_x$$

$$(103) \quad F_{xx} + F_{yy} = 0$$

$$(104) \quad \sum_{n=0}^{\infty} a_n(z - a)_n$$

$$(105) \quad \frac{1}{R} = \limsup |a_n|^{1/n}$$

$$(106) \quad F(z) = \sum_{k=0}^{\infty} \frac{F^{(k)}(b)(z - b)^k}{k!}$$

$$(107) \quad \int_C f(z) dz = \int_0^1 f[g(t)] dg(t)$$

$$(108) \quad \int_C f(z) dz = 0$$

$$(109) \quad f(z) = \frac{1}{2\pi i} \int_C \frac{f(t) dt}{t - z}$$

$$(110) \quad f^{(n)}(z) = \frac{n!}{2\pi i} \int_C \frac{f(t) dt}{(t - z)^{n+1}}$$

$$(111) \quad \begin{cases} f(z) = \sum_{n=0}^{\infty} a_n(z - b)^n \\ a_n = (2\pi i)^{-1} \int_C f(t)(t - b)^{-n-1} dt \end{cases}$$

Figure 16: Geometric representation of a complex number $a + bi$ by the vector of length r that joins the origin $(0, 0)$ and the point (a, b) in the x, y plane, making an angle θ with the x -axis. As indicated by the relations shown, $r = \sqrt{a^2 + b^2}$ and $\theta = \arctan b/a$.

neighbourhood that is also in D and that any two points of D may be connected by an unbroken line in D .

A function $f(z)$ defined in D may be continuous there. This means that if z is near to z_0 in D , then $f(z)$ is near to $f(z_0)$ in R . The differentiable functions form a subclass of the continuous functions. In the present case $f(z)$ is said to be differentiable at a point z_0 in D if the ratio (see 101) of the difference of the function evaluated at two points to the difference of the two points approaches a finite limit when z approaches z_0 , the limit being independent of how z approaches z_0 . This limit is known as the derivative of $f(z)$ at $z = z_0$ and is denoted by $f'(z_0)$ (see *Real analysis* above). If $f'(z)$ exists everywhere in D , the function $f(z)$ is said to be holomorphic or analytic in D . The term analytic, however, will be used below in a more general sense.

Holo-
morphic
functions

The formal rules of the calculus apply to complex-valued functions. Thus, sums and products of functions holomorphic in D are also holomorphic in D , although in the case of a quotient the points at which the denominator is zero must be excepted. If n is a positive integer, z^n is holomorphic in the finite plane; this implies that every polynomial is a holomorphic function and that rational functions are holomorphic except at the zeros of the denominators.

If $f(z) = U(x, y) + iV(x, y)$ is holomorphic in D , then the real-valued functions U and V have partial derivatives with respect to x and y that satisfy the Cauchy-Riemann equations relating these partial derivatives (see 102, in which subscripts indicate differentiation with respect to x and y). Conversely, if a pair of real-valued functions has continuous partials in D that satisfy the Cauchy-Riemann equations, then $f = U + iV$ is holomorphic in D . The functions U and V are known as conjugate harmonic or logarithmic potential functions. They satisfy Laplace's equation in which the sum of two second partial derivatives is restricted to equal zero (see 103). This is the two-dimensional analogue of the equation satisfied by the Newtonian potential.

Power series. The basic class of holomorphic functions is formed by the power series (see 104). Such a series converges for a given z if the sequence of partial sums converges to a finite limit. This may happen only for $z = a$ or, at the other extreme, for all values of z . In general, there exists a positive number R , known as the radius of convergence of the series, such that it converges (even absolutely) for $|z - a| < R$ and diverges for every z outside the circle $|z - a| = R$, known as the circle of convergence. The value of R is given by a limiting form for its reciprocal (see 105).

The sum of the series in $|z - a| < R$ is a holomorphic function $F(z)$, the derivative of which can be obtained by termwise differentiation of the power series. The resulting power series has the same radius of convergence and may be differentiated as often as desired. Thus $F(z)$ has derivatives of all orders. According to Weierstrass, the power series defines an element of an analytic function. Further elements can be obtained by elementary rearrangements of the power series (see 104).

If $|b - a| < R$, $z - a = (z - b) + (b - a)$ can be written, and the n th power of this expression can be expanded by

the binomial theorem, multiplied by a_n and added. Collection of terms results in Taylor's series (named after the 17th-18th-century English mathematician Brook Taylor); that is, the result of such collection is a power series for f in which the coefficients are constructed from values of derivatives of f (see 106) and that converges at least for $|z - b| < R - |a - b|$. If the radius of convergence exceeds this value, then the new series defines a holomorphic function in a disk that overlaps the old one. In the intersection of the two disks the functions coincide; outside, each function defines the analytic continuation of the other. The new element (see 106) can be rearranged in the same manner and gives rise to further new elements. The totality of such elements (with some adjunctions; see below) constitutes the analytic function defined by the first power series (104). In this process, it is possible to get back to the starting point with an element distinct from this series (104). The number of distinct elements having the same centre $z = a$ is at most countable.

Taylor's
series

It may happen that the power series (104) cannot be continued outside its circle of convergence, which in this case is said to be the natural boundary of the function $F(z)$. In a certain sense this is the rule rather than the exception; the phenomenon is apt to present itself if the coefficients exhibit recurrent nonperiodic irregularities, such as very long gaps between terms, or if the coefficients have only a finite number of distinct values that do not recur periodically.

THE CAUCHY THEORY

Cauchy's integral theorem. A rectifiable curve C is given by $z = g(t)$, for t greater than or equal to zero and less than or equal to unity; that is, $0 \leq t \leq 1$, in which $g(t)$ is continuous and of bounded variation. If $f(z)$ is continuous on C , then the Riemann-Stieltjes integral of $f[g(t)]$ with respect to $g(t)$ (see 107) exists. If D is a simply connected domain with $f(z)$ holomorphic in D and, further, if C is a simple, closed, rectifiable curve in D , then the integral of the function around the curve is zero (see 108).

This basic theorem, announced by Cauchy in 1825, is the source of most of the results in analytic-function theory. First, it gives a representation of $f(z)$ in terms of its boundary values on C . If z is interior to C , then the function evaluated at that point has a representation in terms of an integral extended around the boundary (see 109). The integral can be differentiated with respect to z under the sign of integration as often as desired (see 110). Thus, the existence of a first derivative implies the existence of derivatives of all orders.

Representation theorems. Cauchy's formula (see 109) can also be used to obtain expansions of $f(z)$ in infinite series. The Cauchy kernel $(t - z)^{-1}$ is expanded in a series of the desired type; multiplication by $f(t)$ and termwise integration then gives the corresponding series for $f(z)$. In this manner, for instance, Taylor's series (106), with F replaced by f , which converges in the largest circle with centre at b in which $f(z)$ is holomorphic, is obtained. Laurent's series, named for the French mathematician Pierre Alphonse Laurent, is obtained in an analogous manner (see 111). It is valid in the largest annulus (a ring-shaped region) $0 \leq R_1 < |z - b| < R_2 \leq \infty$ in which $f(z)$ is holomorphic. Various expansions of holomorphic functions in so-called interpolation series are obtainable by the same method.

The
Cauchy
kernel

If in the Laurent series (111) $R_1 = 0$, the point $z = b$ is an isolated singularity of $f(z)$. This singularity is removable if $a_n = 0$ for $n < 0$. It is a pole of order m if $a_{-m} \neq 0$ but a_{-k} is identically equal to zero—that is, $a_{-k} \equiv 0$, for $k > m$; it is an essential singularity in the remaining case. The coefficient a_{-1} is known as the residue of $f(z)$ at $z = b$. In the case of a pole, $|f(z)|$ is uniformly large in the neighbourhood of $z = b$. The function $f(z)$ is assigned the value ∞ (infinity) at $z = b$, and the expansion (111) is adjoined to the elements that define the analytic function.

At an essential singularity no value can be assigned to the function; in fact, $f(z)$ assumes every value infinitely often, with at most one exception, in every neighbourhood of $z = b$ (which was proved by Charles Émile Picard, a French mathematician, in 1879).

Residue theorem. Cauchy's theorem (see 108) must be modified if $f(z)$ is not holomorphic inside C . If the only singularities are isolated and none lies on C , then the integral of the function around the curve is expressed in terms of a sum (see 112), in which the summation extends over the residues of the integrand inside C . This residue theorem of Cauchy also has a large number of applications. Cauchy used it to evaluate definite integrals—a problem of considerable practical importance in electrical engineering, physics, and other fields. He also used his residue theorem for the first rigorous discussion of series expansions arising in boundary value problems of mathematical physics, and this is still a valuable method. The residue theorem also plays a central role in the theory of elliptic functions.

$$(112) \quad \int_C f(z) dz = 2\pi i \sum a_{-1,k}$$

$$(113) \quad \begin{cases} \int \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}} \\ \int \sqrt{\frac{1-k^2x^2}{1-x^2}} dx \\ \int \frac{dx}{(1+nx^2)\sqrt{(1-x^2)(1-k^2x^2)}} \end{cases}$$

$$(114) \quad u = \int_0^x \frac{ds}{\sqrt{(1-s^2)(1-k^2s^2)}}$$

Another important application of the residue theorem is the principle of the argument. Suppose that inside C there are no singularities other than poles of $f(z)$ and that no pole or zero lies on C . If the residue theorem is applied to the logarithmic derivative of $f(z)$, it is found that the change in the argument of $f(z)$ as z describes C in the positive sense equals 2π times the difference in the number of zeros and poles of $f(z)$ inside C .

ENTIRE AND MEROMORPHIC FUNCTIONS

A function $f(z)$ is entire (integral in British terminology) if it is holomorphic in the finite plane. It is transcendental if it does not reduce to a polynomial. In 1876 Weierstrass showed how to construct an entire function of given zeros. An entire function without zeros is of the form $\exp[g(z)]$, where $g(z)$ is also entire. Entire functions are classified according to a quantity called their order, which is closely related to the asymptotic behaviour of the coefficients of the defining power series and imposes an upper bound on the frequency of the zeros.

An entire function takes on every value infinitely often, with at most one exception. This theorem, proved by Picard in 1879 by use of the elliptic modular function, has been in the centre of attention ever since. Elementary proofs have been found by the French mathematician Émile Borel and by the German mathematician Edmund Landau, and the theorem also follows from a mapping theorem due to André Bloch, proved in 1924. It is now a simple consequence of an elaborate theory of the distribution of the values assumed by an entire or meromorphic function developed by Frithiof Nevanlinna and Rolf Nevanlinna of Finland starting in 1924.

A function having only polar singularities is said to be meromorphic. The representation of such a function by partial fractions was given by the Swedish mathematician Magnus Gösta Mittag-Leffler in 1877. (Ed.)

ELLIPTIC FUNCTIONS

One example of analytic functions is the class of functions known as elliptic functions. They have many applications in algebraic geometry, topology, the algebraic theory of numbers, and other fields of mathematics. Also, they have influenced the development of the general theory of functions of complex variables.

Origins. It is a familiar result of elementary calculus that if R is a linear or quadratic function of a variable x , then the integral of any rational function of x and \sqrt{R} is an elementary function. In the next higher case, when R is a cubic or quartic with no repeated factor, no such result is possible. It was gradually recognized by mathematicians of the 18th century that these integrals $\int f(x, \sqrt{R}) dx$, in which f is any rational function of x and \sqrt{R} , were essentially new functions requiring special investigation. They were named elliptic integrals because a special case of such integrals occurred in the problem of finding the length of arc of an ellipse. An important formula connecting such integrals, equivalent to one of what are now called addition theorems, was discovered as early as 1761 by Leonhard Euler of Switzerland. The first systematic treatment of the new integrals, however, is a legacy of Adrien-Marie Legendre, a French mathematician, who proved, among other results, that any elliptic integral can be reduced to the sum of an elementary function and of constant multiples of integrals in three standard forms (see 113) involving the variable x as well as k and n , in which k and n are constants called the modulus and the parameter, respectively. These three integrals are called Legendre's standard (or normal) elliptic integrals of the first, second, and third kinds, respectively.

But before Legendre finished his *Traité des fonctions elliptiques et des intégrales Eulériennes* in 1826, Niels Henrik Abel of Norway, in competition with Karl Gustav Jacob Jacobi of Germany, revolutionized the subject. If a variable u is expressible as an indefinite integral of one of the three standard forms in which k appears (see 114) and if the parameter k is 0 in this integral, then $u = \sin^{-1}x$ or $x = \sin u$. In 1825 Abel recognized this fact and inverted the relation between u and x (for k not necessarily 0) by treating x as a function of u instead of following Legendre in treating the integral u as a function of x . The function x obtained in this manner is denoted by $\operatorname{sn} u$ or, more precisely, by $\operatorname{sn}(u, k)$. Two more functions, $\operatorname{cn} u$ and $\operatorname{dn} u$, are defined similarly; together with $\operatorname{sn} u$ they are called Jacobi's elliptic functions, as distinguished from Legendre's elliptic integrals, which, however, Legendre himself called *fonctions elliptiques*. From the analogy with trigonometric functions, Abel and Jacobi immediately obtained important properties of the new functions: their double periodicity (see below *Properties*) and the addition theorems that express $\operatorname{sn}(u+v)$, etc., as rational functions of $\operatorname{sn} u$, $\operatorname{cn} u$, $\operatorname{dn} u$, and $\operatorname{sn} v$, $\operatorname{cn} v$, $\operatorname{dn} v$. It is now known that many of the fundamental results of Abel and Jacobi had been anticipated, but not published, by Carl Friedrich Gauss, a German mathematician.

Properties. Jacobi's $\operatorname{sn} u$, $\operatorname{cn} u$, $\operatorname{dn} u$ are simple cases of a more general class of functions having the same or similar properties, namely, elliptic functions. Let ω_1, ω_2 be any complex numbers such that $\omega_2/\omega_1 = \tau$ is not real. A function $f(u)$ of a complex variable u is said to be doubly periodic in ω_1, ω_2 if $f(u + \omega_1) = f(u + \omega_2) = f(u)$. An elliptic function is a single-valued doubly periodic analytic function $f(u)$ that has no singularities other than poles for any finite value of u . To obtain the properties of such a function, it is convenient to use the geometric representation of complex numbers by points in a plane (the Argand diagram, named for the Swiss mathematician Jean-Robert Argand). Any parallelogram with vertices at $a, a + \omega_1, a + \omega_1 + \omega_2, a + \omega_2$ (a arbitrary) is called a parallelogram of the periods; if the properties of $f(u)$ are known throughout any one parallelogram, then from the periodicity its properties are known everywhere, so that it suffices to study one parallelogram. The function $f(u)$ may also be considered as an analytic function on the torus obtained by identifying opposite sides of a parallelogram of periods. This interpretation of elliptic functions as functions on tori is the starting point of the modern analytic approach to the theory.

Theta functions. To study the properties of his elliptic functions, Jacobi introduced four allied functions $\theta_j(u, \tau)$, $j = 1, 2, 3, 4$, called theta functions. Jacobi could express his elliptic functions as quotients of θ 's and obtain most of the fundamental properties of elliptic functions by using theta functions.

Abel's
work

$$(115) \quad p(u) = \frac{1}{u^2} + \sum' \left(\frac{1}{(u-\omega)^2} - \frac{1}{\omega^2} \right)$$

$$(116) \quad p'^2(u) = 4p^3(u) - g_2p(u) - g_3$$

$$(117) \quad u = \int_{\infty}^x \frac{ds}{\sqrt{4s^3 - g_2s - g_3}}$$

The Weierstrass theory. Weierstrass founded his theory of elliptic functions on a function $p(u)$ defined by (115) in which the sum is taken over all numbers $\omega \neq 0$ of the form $m\omega_1 + n\omega_2$, $m, n = 0, \pm 1, \pm 2, \dots$, ω_1 and ω_2 being any given complex numbers such that ω_2/ω_1 is not real. The function $p(u)$ is an elliptic function with periods ω_1, ω_2 ; it has poles of order 2 at the points ω and at 0, is regular elsewhere, and satisfies a differential equation that is quadratic in the derivative of the function and cubic in the function itself, coefficients being g_2 and g_3 as well as the constant 4 (see 116), where g_2, g_3 are constants depending only on the periods. Thus, $p(u)$ is the inverse function of the elliptic integral that involves the cubic just mentioned (see 117).

Letting $x = p(u)$, $y = p'(u)$, then $u \leftrightarrow (x, y)$ defines a one-to-one correspondence between points u in a parallelogram of periods and points (x, y) on the plane algebraic curve defined by $y^2 = 4x^3 - g_2x - g_3$, and the elliptic functions with the given periods may be considered as rational functions on this curve. This observation enabled mathematicians to develop the theory of elliptic functions entirely within the realms of algebra and algebraic geometry without recourse to the theory of functions of a complex variable. Thus, the scope of the theory of elliptic functions can be broadened considerably. (K.Iw./Ed.)

Theory of analytic functions of several complex variables

DEVELOPMENT OF COMPLEX ANALYSIS

Complex analysis arose from the study of analytic functions of one or several complex variables. Beginning with Riemann's fundamental discoveries in the middle of the 19th century, there was a gradual but continual shift of emphasis toward the investigation of global properties of analytic functions by topological (see GEOMETRY: *General topology*) and algebro-geometrical methods, with the result that complex analysis became rather intricately interwoven with the other principal mathematical disciplines and could be viewed only against the background of mathematical development as a whole, which is characterized in the 20th century by a remarkable synthesis of ideas.

Analysis of the properties of functions of one complex variable (complex analysis in one dimension) had a remarkable growth during the second half of the 19th century as a result of the brilliant research of Riemann and others. Shortly after 1900 the general principle of uniformization, conceived by Felix Klein of Germany and Henri Poincaré of France, was established by Paul Koebe. These developments were presented as a unified theory in 1913 by Claus Hugo Hermann Weyl, a German-born mathematician who emigrated to the United States in 1933.

During the latter part of the 19th and the beginning of the 20th century, the theory of functions of several complex variables made its appearance, as did algebraic geometry, especially the theory of algebraic surfaces founded by Max Noether of Germany, Charles Émile Picard, Henri Poincaré, and, last but not least, the Italian geometers Guido Castelnuovo, Federigo Enriques, and, somewhat later, Francesco Severi. In 1895 Pierre Cousin investigated certain global properties of analytic functions on domains in complex n -space and brought to the attention of mathematicians two problems that were later to bear his name; the study of these and related problems led to some of the most important developments of complex analysis during the first half of the 20th century.

In the years following the publication of Weyl's book, the

geometric concepts, first introduced into complex analysis by Riemann, were studied for their own sake and vastly generalized as a result of the growth of topology as a branch of mathematics. Solomon Lefschetz, a Russian-born American mathematician, made a profound study of the topological properties of algebraic surfaces in a tract that exerted considerable influence on the later development of complex analysis, topology, and algebraic geometry. Élie-Joseph Cartan, a French mathematician, developed and applied systematically the theory of exterior differential forms that merged with topology in the fundamental theorem proved by the Swiss mathematician Georges de Rham in 1932 and helped give birth to the concept of cohomology in algebraic topology (see ALGEBRA). Stefan Bergman discovered an important type of Hermitian metric on subdomains of complex n -space that was subsequently generalized by Erich Ernst Kähler of Germany and became known as a Kähler metric.

Beginning about 1932, the British mathematician Sir William Vallance Douglas Hodge generalized the theory of harmonic functions on Riemann surfaces to harmonic differential forms on higher dimensional compact Riemannian manifolds, and on complex manifolds that possess Kähler metrics. Hodge's theory was developed and perfected during the 1940s by the Japanese mathematician Kodaira Kunihiko, who also generalized the theory to open manifolds and introduced systematically the method of orthogonal projection in Hilbert space (named after David Hilbert, a German mathematician).

Simultaneous with the development of the theory of harmonic differential forms, an intensive investigation of questions related to the Cousin problems was made by Oka Kiyoshi of Japan, Heinrich Adolf Louis Behnke and Karl Stein of Germany, Henri Cartan of France, and others. Although the methods used by these investigators differed somewhat from those of Hodge, Kodaira, and de Rham, the time was becoming ripe for a remarkable confluence of ideas, and this took place shortly after 1950 with the introduction into complex analysis of new notions from algebraic topology, namely, fibre bundles and cohomology with coefficients in sheaves (see GEOMETRY: *Algebraic topology*).

The idea of a fibre bundle was first recognized during the period 1935–40, while the notion of a sheaf was introduced into topology a few years later by the French mathematician Jean Leray (similar concepts, never precisely defined, had occurred earlier in various special contexts). The introduction of these concepts had an explosive effect on the development of complex analysis during the following years.

A third advance of great importance in complex analysis, which took place during the period 1935–50, was the development, principally by the German mathematician Carl Ludwig Siegel, of the theory of automorphic functions of several complex variables.

HOLOMORPHIC FUNCTIONS

OF SEVERAL COMPLEX VARIABLES

If C denotes the set of all complex numbers, C^n is used to denote the set of n -tuples $z = (z_1, \dots, z_n)$. Here n is an integer and each of z_1, \dots, z_n is a complex number. For any z in C^n , $|z|$ denotes the positive square root of a sum of absolute values of components (see 118); here $z = (z_1, \dots, z_n)$, and $|z_j|$ is the absolute value of the complex number z_j for $j = 1, \dots, n$.

Now, if Ω is a subset of C^n , it is called an open set if, for any point a in Ω , all points of C^n sufficiently close to a actually lie in Ω (that is, there is a positive number ρ such that any z in C^n with $|z - a| < \rho$ belongs to Ω).

$$(118) \quad (|z_1|^2 + \dots + |z_n|^2)^{1/2}$$

$$(119) \quad \sum_{k_1, \dots, k_n} c_{k_1, \dots, k_n} (z_1 - a_1)^{k_1} \dots (z_n - a_n)^{k_n}$$

$$(120) \quad f(z) = (f_1(z), \dots, f_m(z))$$

Harmonic
differential
forms

Functions
of one
complex
variable

An open set Ω is called a domain if it is connected—that is, if any two points of Ω can be joined by an arc lying entirely in Ω .

If a complex-valued function f is defined on the open set Ω [f associates to any point z in Ω a complex number $f(z)$], f is said to be holomorphic on Ω if the following holds:

For any point $a = (a_1, \dots, a_n)$ in Ω , there is a family $\{c_{k_1, \dots, k_n}\}$ of complex numbers, one for each n -tuple (k_1, \dots, k_n) of nonnegative integers, such that, for each z in C^n sufficiently near a , the series of generalized power series type with coefficients from the family of complex numbers (see 119) converges to the value $f(z)$ of the function f at z .

Some basic properties of holomorphic functions are the following:

1. A holomorphic function is continuous; it possesses partial derivatives of any order; and each partial derivative is again a holomorphic function.

2. If f and g are two holomorphic functions on the domain Ω (Ω is open and connected) and if $f(z) = g(z)$ for all z in some neighbourhood of a point of Ω , then f and g are identical.

3. In the maximum principle, f is taken to be holomorphic on Ω , in which Ω is a domain in C^n . Furthermore, there is a point a in Ω such that $|f(a)| \geq |f(z)|$ for any z in Ω . It follows that f is a constant (f is independent of z).

For later use, the following notation is introduced. Ω is an open set in C^n , and $f: \Omega \rightarrow C^m$ is a map of Ω into C^m (n and m are positive integers). For each z in Ω , the value $f(z)$ is a point in C^m , hence is an m -tuple (see 120). This defines m functions f_1, \dots, f_m on Ω . The map $f: \Omega \rightarrow C^m$ is said to be holomorphic if each of f_1, \dots, f_m is a holomorphic function on Ω .

Another basic fact concerning holomorphic functions can be stated as follows:

4. Ω is taken to be open in C^n , and $f: \Omega \rightarrow C^m$ is a holomorphic map. Furthermore, Ω' is taken to be an open set in C^m containing all the points $f(z)$ as z runs over Ω . Finally, φ is a holomorphic function on Ω' . Then the function $\varphi \circ f$ defined on Ω by $\varphi \circ f(z) = \varphi[f(z)]$ is holomorphic on Ω .

A topological space is a set on which the notion of open set is given. Hence, on a topological space, the notion of a continuous function is defined. A map of one topological space onto another is said to be bicontinuous, or to be a homeomorphism, if it is one-one, continuous, and the inverse map is also continuous. Two topological spaces are said to be homeomorphic if they are connected by a homeomorphism. Homeomorphic spaces are topologically equivalent; i.e., their intrinsic topological properties are the same.

A map of one open set of C^n onto another is said to be biholomorphic if it is one-one and holomorphic (which implies that the inverse is also holomorphic). The ball of C^n cannot be mapped biholomorphically onto the polycylinder of C^n if $n > 1$. Thus, topologically equivalent domains are not generally holomorphically equivalent, except under certain circumstances in the case when n is equal to 1.

CONFORMAL MAPS

The study of conformal maps arose from the necessity of constructing geographic maps. Because the surface of the Earth is approximately a sphere, it is readily seen that it cannot be represented on a flat surface with preservation of the proportion of all distances. The next best property to be preserved is the relative shape of configurations in the neighbourhood of each point; this, in a more precise mathematical formulation, amounts to preservation of the

magnitude and sense of angles at each point. Such a map is called conformal. Examples of conformal maps include the familiar Mercator (which was named after Gerardus Mercator, a Flemish mathematician and geographer of the 16th century) and stereographic projections. In a conformal map of one open set of the plane onto another, it is possible to verify that the map is given locally by a biholomorphic transformation of one complex variable.

On the other hand, a biholomorphic map of one open set of C^n onto another is not generally conformal if $n > 1$. Throughout this section it will be supposed that $n = 1$.

The preceding local characterization of a conformal map disposes only of the most trivial aspect of the map because the characterization gives no information concerning the existence of a conformal map of one given plane domain onto another. Because it is impossible, except in the most trivial cases, to construct conformal maps explicitly, attention has centred mainly on the problems of proving their existence and of determining their properties.

A necessary condition in order that there should exist a biholomorphic (one-one conformal) map of one plane domain onto another is that there should exist a bicontinuous map (homeomorphism) of the one domain onto the other, and it is a remarkable fact that this necessary condition is in some cases sufficient.

If D is a domain of C that is not the whole of C , and D is homeomorphic to the unit disk $|z| < 1$, then there exists a unique biholomorphic (one-one conformal) map of D onto the unit disk $|z| < 1$. It has the property that a prescribed point Z_0 of D goes into the centre of the disk, and a given direction at Z_0 transforms into the direction of the positive real axis.

Although the whole plane C is homeomorphic to the unit disk, it is impossible to map it conformally onto the unit disk; this is a consequence of a classical theorem of the 19th-century French mathematician Joseph Liouville.

The symbol S is used to denote the class of functions f of the complex variable z that are holomorphic in the unit disk, that map it one-one conformally onto domains of C , and that are normalized by the condition that their power series in z , convergent for $|z| < 1$, are of the form with lowest power z being 1 and with coefficient of z being 1 (see 121). In his proof of the general uniformization principle (of which the Riemann mapping theorem is a special case), Koebe introduced the class S and studied some of its properties. If the class S is suitably topologized, then, for each integer $n > 1$, the map $F^n: S \rightarrow C^n$, which sends the function f of S into the point $(a_2, a_3, \dots, a_{n+1})$ of C^n , determined by the n coefficients a_2, a_3, \dots, a_{n+1} in the power series development of f , is continuous. If the image of S under the map F is denoted by B^n , then the set B^n , homeomorphic to the closed unit ball $|w^1|^2 + |w^2|^2 + \dots + |w^n|^2 \leq 1$ of C^n , is called the n th coefficient region of S . The structure of the class S is completely determined by a knowledge of these coefficient regions and the maps F^n .

Riemann mapping theorem

$$(121) \quad f(z) = z + a_2 z^2 + a_3 z^3 + a_4 z^4 + \dots + a_n z^n + \dots$$

In 1916 the German mathematician Ludwig Georg Elias Moses Bieberbach proved that B^1 is the region $|a_2| \leq 2$ and, soon thereafter, posed the problem of investigating the regions B^n for all n . He further conjectured that $|a_n| \leq n$ for all n (the Bieberbach conjecture). This problem and conjecture were later followed by an intensive study of the class S . The Bieberbach conjecture was eventually proved in 1984 by Louis de Branges.

(R.Na./Ed.)

DIFFERENTIAL EQUATIONS

Extensive use in science and technology

Differential equations are equations that relate a function f to its derivatives. This type of equation finds widespread application in science and technology because it can be used to express natural laws that describe the behaviour of rates of change of quantities. A well-known example

in physics concerns radioactivity. A radioactive element changes spontaneously into a stable element, a process that is known as radioactive decay or disintegration. The law describing this behaviour states that the rate of decay with time—that is, the amount of a substance changing per

second, say—is proportional to the amount of substance present. Initially, when the material is a pure radioactive element, this rate of decay is high. As the radioactive element changes into a stable element, however, the rate of change falls because there is less radioactive material. Therefore, the rate of decay decreases continuously with time.

In this process the quantity of interest is the amount of substance (n) remaining after a given time—i.e., the number of atoms or the mass. Clearly this quantity will depend in some way on the time that has elapsed; in other words, it is a mathematical function of time and can be denoted by $n(t)$.

A formulation of the law is that dn/dt equals the product of $-\lambda$ and n (see Box, law 122). In this case n represents the amount of radioactive material, λ is a constant, and dn/dt is a notation for the rate at which n increases with time. The minus sign is required because n is decreasing with time and not increasing. The expression dn/dt is known as the derivative of n with respect to t . An idea of the nature of a derivative can be obtained by considering the behaviour of a specific function of x , say x^2 . If x has the value a (a real number), this function has the value a^2 . If this value now changes to $(a+h)$, the value of the function becomes $(a+h)^2$. The change in the value of the function is $(a+h)^2 - a^2$, and this change has occurred as a result of x changing by h . Thus, the rate at which x^2 has changed with respect to the change in x is given by the quotient $\frac{(a+h)^2 - a^2}{h}$. This gives an average rate of change over the value h . If h now becomes smaller and tends to zero, the quotient tends to the value $2a$, because, when the $(a+h)^2$ -term is expanded and the a^2 -term subtracted from it, the division yields $2a+h$ (see 123). $2a$ is the rate of change of x^2 with x at the point a and is known as the derivative of the function. If a is allowed to vary—i.e., to take any values—a new function $2x$ is obtained that for a given value of x expresses the rate of growth of x^2 with x at that value. In general, a function of a single real variable x can be denoted by $u(x)$ and its derivative by $du(x)/dx$ or by $u'(x)$. This process can be repeated: the derivative of $u'(x)$ can be formed and denoted by $u''(x)$ or by $d^2u(x)/dx^2$, and similarly for higher derivatives $u^{(n)}(x)$.

$$(122) \quad \frac{dn}{dt} = -\lambda n$$

$$(123) \quad \frac{(a+h)^2 - a^2}{h} = \frac{a^2 + 2ah + h^2 - a^2}{h} = 2a + h$$

$$(124) \quad a \frac{d^2\theta}{dt^2} = -g \sin \theta$$

$$(125) \quad \frac{d^2x}{dt^2} = 0, \quad \frac{d^2y}{dt^2} = -g$$

$$(126) \quad \kappa = \left[1 + \left(\frac{dy}{dx} \right)^2 \right]^{-3/2} \frac{d^2y}{dx^2}$$

$$(127) \quad \left[1 + \left(\frac{dy}{dx} \right)^2 \right] \frac{d^3y}{dx^3} - 3 \frac{dy}{dx} \left(\frac{d^2y}{dx^2} \right)^2 = \left[1 + \left(\frac{dy}{dx} \right)^2 \right]^{3/2} \psi(x)$$

$$(128) \quad y' = \frac{dy}{dx}, \quad y'' = \frac{d^2y}{dx^2}, \quad y''' = \frac{d^3y}{dx^3}, \quad \dots$$

$$(129) \quad [1 + (y')^2]y''' - 3y'(y'')^2 = [1 + (y')^2]^{3/2}\psi(x)$$

$$(130) \quad [1 + (y')^2]y''' = 3y'(y'')^2$$

$$(131) \quad c^2 \frac{\partial^2 y}{\partial x^2} = \frac{\partial^2 y}{\partial t^2}$$

When the independent variable is time and the dependent variable distance, the first derivative is velocity, the rate at which distance changes with time. The second derivative is acceleration, the rate at which velocity changes.

Returning to the example of radioactive decay, the equation involves a derivative and is one example of a differential equation. The solution of this differential equation is the function $n(t)$, which shows how n depends on t . The problem of solving it is that of finding the function of t the derivative of which is $-\lambda n(t)$.

A common example of a differential equation that involves a second derivative is the equation describing the motion of a simple pendulum under the influence of gravity. The second derivative of the angular displacement from the vertical θ is proportional to the sine of the angular displacement (see 124). The equation involves the length a of the pendulum and g , the acceleration of a falling body under the influence of gravity, called the acceleration of free fall. The equation may be expressed in words as follows. The rate of increase with time of the rate of increase of angular displacement with time (the angular acceleration) is directed toward the vertical position and is inversely proportional to the length of the pendulum and directly proportional to the sine of the angular displacement. This rather complicated verbalization illustrates the economy and precision of the mathematical formulation.

Most physical situations are too complicated to be expressed simply by one variable depending on another. For example, the position of a body in a vertical plane is given by two coordinates x and y , indicating the distances from a vertical and horizontal axis respectively. The motion of a body moving in this plane can be expressed by an equation involving these two coordinates (x, y), each of which depends on the time t .

In particular, if air resistance is neglected, a particle moving under the influence of gravity is described by a pair of differential equations expressed in terms of second derivatives (see 125), in which g denotes the acceleration caused by gravity. There is no acceleration in the horizontal direction because there is no force in this direction.

A further example is provided by geometry. It is shown in calculus that the curvature κ of a curve the equation of which in Cartesian coordinates is $y = y(x)$ is defined in terms of the second derivative of y (see 126). A curve with the property that the rate of change with respect to x of its curvature is a prescribed function $\psi(x)$ therefore has an equation that satisfies the equation $d\kappa/dx = \psi(x)$, which is equivalent to an equation involving a third derivative (see 127). By using the alternative notation of primes denoting differentiation (see 128), it is also possible to write this equation in a more simple form (see 129). For example, a circle has constant curvature so that it has $\psi(x) \equiv 0$; hence, all circles are symbolized by the same differential equation with the term involving $\psi(x)$ set equal to zero (see 130).

The preceding examples are all equations that involve functions of a single variable. Derivatives of such functions are called ordinary derivatives, and, therefore, equations of this type are called ordinary differential equations. The pair of equations involves simultaneously the derivatives of two independent variables x and y and is an example of a pair of ordinary simultaneous differential equations.

The transverse displacement of a vibrating string is determined by an equation of a totally different kind. If the string is at rest stretched to a tension T between points $x=0$ and $x=a$ of the x -axis, then, if the string is set vibrating, the displacement, y , of a point that originally had a coordinate x will depend not only on x but also on the time t . In other words, y is a function of two independent variables, x and t . Its variation is governed by the fact that the second partial derivative with respect to x is proportional to the second partial derivative with respect to t (see 131), the proportionality constant $c = \sqrt{T/\sigma}$, σ being the mass per unit length of the string. The derivatives in this equation are partial derivatives, and the equation is an example of a partial differential equation. The theory of such equations is markedly different from the theory of ordinary differential equations, and it will be considered later in this article.

Ordinary differential equations

Equations
of the first
order and
first degree

An ordinary differential equation is a relation connecting the function y of an independent variable x and its derivatives y' , y'' , ..., $y^{(n)}$ (see 132). If the derivative of the highest order occurring in the equation is $y^{(n)} = d^n y/dx^n$, the equation is said to be of order n . For example, equation (122) is a first-order equation, and equations (124) and (125) have an order of two. The power to which the highest derivative occurs is called the degree of the equation. Equations (122), (124), and (125) are of the first degree; a second-order differential equation involving $(y'')^2$ and no higher of y' (see 133), however, is of the second degree because the highest derivative occurs to the power 2. If the equation is of a form (see 134) in which the function y and its derivatives occur linearly and in which the coefficients $a_n(x)$, ..., $a_1(x)$, $a_0(x)$ depend only on x and not on y or any of its derivatives, the equation is said to be linear. If $\psi(x) \equiv 0$ (equal for all values of x), the equation is said to be homogeneous; and, if $\psi(x)$ is not equal to zero for all values of x , it is said to be non-homogeneous. Equation (122) is linear and homogeneous, but equation (124) is nonlinear.

$$(132) \quad f(x, y, y', \dots, y^{(n)}) = 0$$

$$(133) \quad (y'')^2 + (y')^3 + y^4 = 0$$

$$(134) \quad a_n(x)y^{(n)} + \dots + a_1(x)y' + a_0(x)y = \psi(x)$$

$$(135) \quad (b^2y - a^3)^{1/2}y' = a$$

$$(136) \quad (1 - x^4)^{1/2}y' + (1 - y^4)^{1/2} = 0$$

HISTORICAL BACKGROUND

The study of differential equations is almost as old as that of the calculus itself. Newton discovered a method of infinite series and the calculus in 1665–66. In 1671 he wrote an account of his theory of “fluxions,” a fluxion being a derivative of a “fluent,” the name Newton gave to his dependent variables. Newton discussed “fluxional equations,” or, as they are now called, differential equations. These he divided into three categories. In modern notation, the first category is that in which dy/dx is a function of x alone or of y alone; the second consists of ordinary differential equations of the first order of the form $dy/dx = f(x, y)$; and the third is made up of partial differential equations of the first order. Newton derived solutions of differential equations by a method using power series with indeterminate coefficients, which he claimed to be universally effective. Though written in 1671 in Latin, his work, entitled *The Method of Fluxions and Infinite Series*, was not published until 1736. As a result it had little or no influence on the development of the theory of differential equations.

Leibniz
and his
followers

A greater impact was made by the work of the German mathematician and philosopher Gottfried Wilhelm Leibniz. Although his investigations were not begun until 1673, Leibniz became known through the publication of his results in 1684 in the *Acta Eruditorum* (“Deeds of Distinguished Men”), a scientific journal that had been established only two years earlier.

Foremost among the devoted followers of Leibniz were the Swiss mathematicians, the brothers Jakob and Johann Bernoulli. With others of their family, they played a notable part in the development of the theory of differential equations and of the use of such equations in the solution of physical problems.

In May 1690 in a paper in the *Acta Eruditorum*, Jakob Bernoulli showed that the problem of determining the isochrone—i.e., the curve in a vertical plane such that a particle will slide from any point to the bottom in exactly the same time, no matter what the starting point—is equivalent to that of solving a first-order nonlinear differential equation (see 135). He then solved the equation by what is now called the method of separation of

variables; the general method was enunciated by Leibniz in the following year. Jakob Bernoulli's paper of 1690 is a milestone in the history of calculus, for in it the term integral occurs in the literature for the first time.

In 1692 Leibniz discovered the method of solving first-order equations of homogeneous type and still later that of solving linear equations of the first order. The problem of finding the general solution of what is now called Bernoulli's equation was proposed by Bernoulli in 1695 and solved by Leibniz and Johann Bernoulli by different methods. Thus, within a few years of the birth of the infinitesimal calculus, most of the known methods of solving first-order ordinary differential equations had been developed.

Numerous applications of the use of differential equations in deriving the solutions of geometric problems were made before 1720. Among these may be mentioned the problem of determining a plane curve the curvature of which is a prescribed function of position and that of finding the orthogonal trajectories of a given family of plane curves. Some of the differential equations formulated in this way were of the second or higher order. Second-order equations of the form $F(y, y', y'') = 0$, in which the independent variable x does not appear explicitly, were discussed as early as 1712 by an Italian mathematician, Count Iacopo Francesco Riccati, although, in fact, Jakob Bernoulli had earlier studied the special case $y' = x^2 + y^2$. Some of the younger members of the Bernoulli family, particularly Daniel, contributed to studies of such equations. Important work on first-order equations of exact type and of first-order equations of degree higher than the first was done in the 1730s by Alexis-Claude Clairaut, a Frenchman who was one of the most precocious mathematicians of all time.

The second period in the history of differential equations was dominated by Leonhard Euler, the Swiss mathematician who made many contributions to the theory, starting in 1728. He introduced several methods of lowering the order of an equation, the concept of an integrating factor, the theory of linear equations of arbitrary order, the development of the use of series solutions, and the discovery that a first-order nonlinear differential equation with square roots of quartics as coefficients (see 136) has an algebraic solution. This last result, which is a special case of Abel's theorem, led to the theory of elliptic functions created in the 1820s by Niels Henrik Abel and Karl Gustav Jacob Jacobi.

Much of the early work on differential equations was concerned with the discussion of basic questions about what is meant by a function or by the solution of a differential equation. Such questions continued to be raised because the answers found satisfactory by one generation of mathematicians were challenged by their successors. The first attempt to establish a rigorous theory of functions was made by Abel and Augustin-Louis Cauchy in the 1820s. Cauchy's work in real analysis gave an entirely new direction to the theory of ordinary differential equations, steering it away from the investigating of techniques of solution into the asking of general questions about the existence and uniqueness of solutions. Cauchy himself proved the first existence theorem and gave methods of deriving solutions through limiting processes. The theory of analytic functions, also due to Cauchy, led to the creation of the theory of differential equations in the complex domain and, in turn, to the study of functions of several complex variables.

Much recent work in ordinary differential equations is of a basic nature, concerned with the conditions that guarantee the existence of a solution of a given equation; the theory is more concerned with establishing that a solution exists than with trying to derive a closed form for it. Such an attitude is essential when many of the practical problems involving differential equations are solved by the use of electronic computers; the validity of numerical processes must be thoroughly investigated. The study of differential equations continues to contribute to the solution of practical problems in control theory, in orbital mechanics, and in many other branches of science and technology, and also to ask challenging questions of

applica-
tions

Recent
work

pure mathematicians working in such apparently abstract subjects as functional analysis and the theory of differentiable manifolds.

TYPES OF PROBLEMS SOLVABLE WITH THIS DISCIPLINE

Some simple examples of how differential equations may arise in the analysis of problems in physics and geometry have already been given. In such problems the unknown quantity has to satisfy not only a differential equation but also some other conditions. For example, the quantity $n(t)$ may have to satisfy the condition that at $t=0$ it takes a prescribed value N . Some other problems that can be solved with the help of differential equations are listed below.

Problems in mechanics. *The catenary.* If a cable of uniformly distributed mass m per unit length is suspended between two points A and B , the curve formed by the cable is called a catenary. If a coordinate system is chosen with an origin vertically below the lowest point of the curve, and with a y -axis that is vertically upward, the shape of the curve is determined by a second-order nonlinear differential equation (see 137), involving a constant a (with the dimensions of length). The constant is expressed in terms of T , the vertical tension acting on the cable at its lowest point, and g , the acceleration caused by gravity, by the formula $a = T/(mg)$. If the distance of the origin below the lowest point of the cable is taken to be a , the required solution must satisfy the conditions $y(0) = a$, $y'(0) = 0$.

Motion in a line under known forces. The motion of a particle of mass m projected vertically upward in a straight line with velocity v is described by a differential equation relating the time derivative of mv to g (see 138)

$$(137) \quad a \frac{d^2y}{dx^2} = \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{1/2}$$

$$(138) \quad \frac{1}{m} \frac{d}{dt}(mv) = -g - R(v)$$

$$(139) \quad \frac{dv}{dt} = -g - R(v)$$

$$(140) \quad \left[1 + \frac{vm'(v)}{m(v)}\right] \frac{dv}{dt} = -g - R(v)$$

$$(141) \quad \frac{d^2r}{dt^2} = -g\left(\frac{R}{r}\right)^2$$

$$(142) \quad r = R, \quad \frac{dr}{dt} = V, \quad \text{when } t = 0$$

$$(143) \quad \frac{d^2x}{dt^2} + g\left(1 + \frac{x}{R}\right)^{-2} = \frac{V_e f}{m_0 - ft}$$

$$(144) \quad \begin{cases} \frac{d^2p}{dt^2} - \rho\left(\frac{d\phi}{dt}\right)^2 = -c\rho^2 \\ \frac{d}{dt}\left(\rho^2 \frac{d\phi}{dt}\right) = 0 \end{cases}$$

$$(145) \quad \begin{cases} L \frac{dx}{dt} + Rx + \frac{q}{C} = E(t) \\ L \frac{d^2q}{dt^2} + R \frac{dq}{dt} + \frac{q}{C} = E(t) \end{cases}$$

$$(146) \quad \begin{cases} L_1 \frac{dx}{dt} + R_1 x + \frac{q}{C} + M \frac{dy}{dt} = E(t) \\ M \frac{dx}{dt} + L_2 \frac{dy}{dt} + R_2 y = 0, \quad \text{with } x = \frac{dq}{dt} \end{cases}$$

and the resistance of the medium $R(v)$, the function R being known. If the mass m is constant, the left side of the equation reduces to the time derivative of the velocity (see 139). If m is a prescribed function of v , the left side can be attacked by the rule for differentiating a product (see 140).

Escape velocity from the Earth. If the acceleration caused by gravity at the Earth's surface is g , then, at time t , the distance r from the Earth's centre of a particle moving vertically upward is determined by a differential equation which states that the second derivative of v is proportional to $(R/r)^2$ (see 141), in which R is the radius of the Earth. If the initial velocity of projection is V , then the initial conditions are the position and velocity at $t=0$ (see 142).

The motion at any point in the upward trajectory is determined by the solution of this initial value problem. If the particle is to escape from the Earth's gravitational field, $(dr/dt)^2$ must exceed zero for all values of r . It turns out that this condition is satisfied only if V^2 is greater than or equal to $2gR$. For this reason $\sqrt{(2gR)}$ is called the escape velocity from the Earth.

Vertical motion of a rocket. A problem of interest is that of a rocket ascending in a straight line under the influence of gravity with a thrust that is constant both in magnitude and direction.

The thrust of the rocket is produced by the ejection of mass at a constant rate f with exhaust velocity V_e , which when measured relative to the rocket is constant. The height x above the Earth's surface at a time t while the rocket is still firing is determined by the nonlinear differential equation (see 143) relating the second derivative of x to an expression of the form $(1 + x/R)^2$ and involving g , the acceleration caused by gravity at the Earth's surface; R , the radius of the Earth; and m_0 , the initial mass of the rocket. The initial conditions in this case are that $x=0$, $dx/dt = V$ when $t=0$.

Motion of a planet under an inverse square law. If a planet is moving in a plane under an inverse square law, then its motion can be described by the plane polar coordinates r, θ , the origin of which is situated at the centre of force.

The inverse square law relates the radial force on the planet to the inverse of the square of the distance from the origin. The motion is described by a pair of second-order differential equations derived from Newton's second law (see 144) involving a constant c .

Problems in other areas of physics. *Electrical circuits.* The electrical current x in a simple circuit containing a resistance R , a self-inductance L , and a capacitance C when a voltage $E(t)$ is applied is determined by a simple differential equation (compare Figure 17A). The drops in voltage across the ends of the resistance and the inductance are, respectively, Rx and $L(dx/dt)$. The drop across the capacitance is q/C , in which q is the charge on the condenser. The current is given by $x = dq/dt$, and the voltage $E(t)$ must equal the sum of the voltage drops. The charge is therefore determined by the differential equation obtained by substituting $x = dq/dt$ (see 145).

Similarly, for the coupled circuits shown in Figure 17B, the currents x and y are determined by a pair of similar linear second-order differential equations (see 146).

Self-oscillatory problems. Certain electrical circuits, such as feedback circuits controlled by thermionic valves, have the property that a source of power increases with the amplitude of the oscillation. To exhibit the main features of the behaviour of such systems, the 20th-century Dutch mathematician Balthasar van der Pol took as his mathematical model a second-order equation (see 147), which is now called van der Pol's equation. This equation is typical of the models describing a series of self-oscillatory problems. For example, the equation for the oscillations of a valve generator with a cubic valve characteristic can be reduced to van der Pol's equation; van der Pol himself used this equation in the theory of the oscillations in a symmetric multivibrator, in which there is an inductance.

Potential theory. In many branches of physics, such as electrostatics, magnetostatics, irrotational motion of perfect fluids, and others, an equation of interest is the partial differential equation named after Pierre-Simon Laplace, the 18th-century French mathematician. This equation

The equations of van der Pol and Laplace

Figure 17: Electrical circuits.

(A) Simple circuit containing a resistance R , a self-inductance L , and a capacitance C . (B) Coupled circuits in which the currents x and y are determined by a set of differential equations.

(see 148) relates second partial derivatives of the potential u . The equation can be expressed in cylindrical coordinates (ρ, ϕ, z) (see 149). If there are solutions of this equation in the form of a product of $\exp(-\xi z)$, $\cos(v\phi)$ and some function of ρ , $R(\rho)$ (see 150), then R must be a solution of a second-order linear ordinary differential equation with variable coefficients so that $R(\rho) = \omega(\xi\rho)$ in which $\omega(t)$ is a solution of a second-order linear equation with variable coefficients (see 151) known as Bessel's equation of order v , so named after Friedrich Wilhelm Bessel, the 19th-century German mathematician and astronomer.

Similarly, Laplace's equation can be expressed in spherical coordinates (see 152). For axisymmetric solutions of the form $u(r, \theta) = r^n \Theta(\theta)$ (i.e., solutions that do not depend on the azimuthal angle ϕ) Θ must be a solution of another linear ordinary differential equation with variable coefficients (see 153). Changing the independent variable in this equation from θ to $\mu = \cos \theta$ gives solutions of the desired form if $\Theta(\theta) = w(\cos \theta)$, in which $w(\mu)$ is any solution of the ordinary differential equation (see 153) called Legendre's equation of order n , named after Adrien-Marie Legendre. (See *Potential theory* below.)

Legendre's equation

Stellar structure. An interesting ordinary differential equation arises in the discussion of the theory of stellar structure. If the gravitational equilibrium of a mass of gas is considered, it is found that its pressure p varies with the distance r from the centre of the mass according to a second-order differential equation involving G , the gravitational constant, and ρ , the density (see 154). The density is related to the pressure through the physical law $\log p = \log k + (1 + 1/\mu) \log \rho$ in which K and μ are constants. If $\log \rho = \log \rho_c + \mu \log \theta$, in which ρ_c is the central density, and a new independent variable $\xi = kr$ is introduced, in which k is defined in terms of ρ_c and constants (see 155), the Lane-Emden equation and initial conditions for it are obtained (see 156). (The equation was named for the astronomers Jonathan Homer Lane of the United States and Robert Emden of Switzerland.) Unless μ is 0 or 1, the equation is nonlinear.

The harmonic oscillator in wave mechanics. One problem in wave mechanics is that of determining the wave function ψ of a particle of mass m moving on the x -axis under the action of a force $-kx$. The wave function ψ for a particle has the physical significance that $|\psi(x, y, z)|^2 dx$ is the probability of finding the particle in a small element of volume dx centred at the point with coordinates (x, y, z) . In this problem the equation describing the particle is a particular case of a more general second-order differential equation named after a 20th-century Austrian physicist, Erwin Schrödinger (see 157), involving E , the total energy of the particle, and h , Planck's constant. The problem here is not so much to solve this ordinary differential equation as to find the possible values of E that ensure $|\psi| \rightarrow 0$ as $|x| \rightarrow \infty$. (For an understanding of convergence to the real number "infinity," see *Real analysis* above.) If the variables are changed to $x = (h^2/4\pi^2 mk)^{1/2} z$, $a = 1/4$, and $\lambda = (4\pi E/h)(m/k)^{1/2}$, an equation relating $d^2\psi/dz^2$ and $(\lambda - z^2)\psi$ (see 158) is obtained. The problem is to find the set of allowed values of λ ensuring the existence of solutions such that $|\psi| \rightarrow 0$ as $|z| \rightarrow \infty$. Such a problem is called a Sturm-Liouville problem (named after the 19th-

century French mathematicians Charles-François Sturm and Joseph Liouville).

Control theory. A different kind of problem involving differential equations arises in optimal control theory. In control theory attention is first of all focused on a process—that is, some action changing with time and usually described by a differential equation or a system of differential equations. In parallel with the concept of process, controls are considered for influencing the particular process being discussed, and the objective is the result achieved by the process through a properly applied control strategy. If, with respect to some criterion of performance, the strategy that is best is sought, the problem is called an optimal control problem.

A simple problem of this kind is that of driving a railroad locomotive from one station to another on the assumption that the same force is available for both starting and stopping—e.g., two rocket motors pointed in opposite directions and each capable of a maximum thrust P . If the locomotive is treated as a particle of mass m and the

Typical control theory problem

$$(147) \quad \frac{d^2x}{dt^2} - \mu(1-x^2)\frac{dx}{dt} + w^2x = 0$$

$$(148) \quad \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0$$

$$(149) \quad \frac{\partial^2 u}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial u}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 u}{\partial \phi^2} + \frac{\partial^2 u}{\partial z^2} = 0$$

$$(150) \quad u(\rho, \phi, z) = e^{-\xi z} \cos(v\phi) R(\rho)$$

$$(151) \quad \begin{cases} \frac{d^2 R}{d\rho^2} + \frac{1}{\rho} \frac{dR}{d\rho} + \left(\xi^2 - \frac{v^2}{\rho^2} \right) R = 0 \\ \frac{d^2 w}{dt^2} + \frac{1}{t} \frac{dw}{dt} + \left(1 - \frac{v^2}{t^2} \right) w = 0 \end{cases}$$

$$(152) \quad \frac{\partial^2 v}{\partial r^2} + \frac{2}{r} \frac{\partial v}{\partial r} + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial v}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 v}{\partial \theta^2} = 0$$

$$(153) \quad \begin{cases} \frac{1}{\sin \theta} \left[\frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} \right] + n(n+1)\Theta = 0 \\ (1-\mu^2) \frac{d^2 w}{d\mu^2} - 2\mu \frac{dw}{d\mu} + n(n+1)w = 0 \end{cases}$$

$$(154) \quad \frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{dp}{dr} \right) + 4\pi G \rho = 0$$

$$(155) \quad k^2 = \frac{4\pi G \rho_c^{1-1/\mu}}{[K(1+\mu)]}$$

$$(156) \quad \begin{cases} \frac{d^2 \theta}{d\xi^2} + \frac{2}{\xi} \frac{d\theta}{d\xi} + \theta^\mu = 0 \\ \theta = 1, \quad \frac{d\theta}{d\xi} = 0, \quad \xi = 0 \end{cases}$$

$$(157) \quad \frac{d^2 \psi}{dx^2} + \frac{8\pi^2 m}{h^2} \left(E - \frac{1}{2} kx^2 \right) \psi = 0$$

$$(158) \quad \frac{d^2 \psi}{dz^2} + (\lambda - z^2) \psi = 0$$

$$(159) \quad m \frac{d^2 x}{dt^2} = f$$

decreases in m caused by loss of fuel and all resistance phenomena are neglected, the product of m and the second derivative of x equals f (see 159), in which x is the distance traveled by the locomotive from its starting point and f is the force applied by the rocket motors. The control is defined by the inequality $|f| \leq P$. As an objective, one of the following conditions could be taken:

1. The journey must be accomplished in the minimum time.

2. To avoid excessive wear on components, the journey must be accomplished with the minimum expenditure of energy.

3. The amount of rocket fuel used should be kept to a minimum.

Once one of these criteria has been decided upon, the optimal control problem consists of designing a scheme for applying f in such a way as to achieve the desired result—i.e., of selecting from the set of solutions of the differential equations corresponding to all permissible forms of f the one that is best.

Chemical kinetics. Simple chemical reactions can be described by first-order ordinary differential equations. A simple first-order reaction such as the decomposition of nitrogen pentoxide may be considered first. If c is the concentration of nitrogen pentoxide at time t , then the derivative of c is equal to the product of a constant k , which is called the rate constant for the reaction, and $-c$ (see 160).

Similarly, in a second-order reaction of the type $A + B \rightarrow A' + B'$ in which a and b are the initial concentrations of A and B , respectively, and x is the change in the concentration of either A or B that has occurred at time t , the derivative of x is proportional to the product of $(a - x)$ and $(b - x)$ (see 161).

Reversible reactions can also be described by differential equations. For example, consider a simple reaction

of the type $A \xrightleftharpoons[k_2]{k_1} B$, such as the interconversion of α -

glucose (A) and β - D -glucose (B) in which a and b are the initial concentrations of A and B and $a - x$ and $b + x$ their values at time t . (If $dx/dt = 0$ the reaction is at equilibrium.) The derivative of x is proportional to the difference of $k_1(a - x)$ and $k_2(b + x)$, in which k_1 and k_2 are constants (see 162).

A catalytic reaction is one in which some substance, known as a catalyst, changes the reaction rate without itself going through any permanent change. In an autocatalytic reaction a substance A is transformed to another substance B , which then acts as a catalyst for the reaction. If x is the concentration of B at time t and N is its final value, then such a process can be described by a differential equation in which dx/dt is proportional to the product of x and $(N - x)$ (see 163).

Growth of populations. To illustrate how ordinary differential equations arise in biology, an equation arising in a simple study of the growth of populations is considered. The expression $p(t)$ denotes the number of inhabitants of a given area at time t , and it is assumed that, in the time interval t to $t + h$, (i) the number of individuals born is Nph , (ii) the number of individuals dying is Mph , (iii) the number of individuals entering the area is Ih , and (iv) the number of individuals leaving the area is Eh , in which N , M , I , and E will, in general, be functions of both p and t . The function $p(t)$ is then determined by the fact that its first derivative is proportional to the obvious combination of these quantities (see 164).

In one population model it is assumed that I and E are constants and that $N = n - vp$, $M = m + \mu p$ in which m , n , μ , and v are constants. If these forms are substituted into the above population equation and $n - m = \epsilon$ and $\mu + v = k$, a nonlinear differential equation known as Verhulst's equation is obtained (see 165), the constant ϵ being called the coefficient of increase and k being called the limiting coefficient.

If the population is isolated (i.e., if there is neither immigration nor emigration), $I = E = 0$, and the equation reduces to a simpler form in which dp/dt equals the product of p and $\epsilon - kp$ (see 166).

Physiology. Regulation of carbon dioxide in the body. An example of the occurrence of a pair of ordinary simultaneous equations in physiology is provided by a simple model of the regulation of carbon dioxide (CO_2) in the human body. In this model it is assumed that the carbon dioxide is distributed between two compartments corresponding to the lungs and the remaining tissue and that respiration is a function of CO_2 only. With further simplifying assumptions it can be shown that during respiration C_A , the alveolar (lung) CO_2 concentration, and C_T , the concentration of CO_2 in the tissue, are determined by the pair of simultaneous equations that relate dC_A/dt and dC_T/dt each to C_A and C_T (see 167), in which V_A and V_T are the respective volumes of the alveolar and tissue compartments; C_i is the concentration of inspired carbon dioxide; a_1 , a_2 , a_3 , b_1 , b_2 are constants; and R is the rate at which carbon dioxide is formed by metabolism.

Distribution of creatinine in the human body. Another example taken from physiology arises in the analysis of a two-compartment model for the distribution of creatinine in the human body. The first compartment is the blood plasma; the second is not clearly identified, but there is evidence that such a compartment exists. If Q_1 , Q_2 denote, respectively, the quantities of creatinine in the first and second compartments, their variation is determined by a pair of linear first-order differential equations relating dQ_1/dt and dQ_2/dt to Q_1 and Q_2 (see 168), with rate constants k_1 , k_2 , and k_3 .

TYPES OF SOLUTIONS

A relation $y = \varphi(x)$ is said to be a solution or integral of the differential equation $f(x, y, y', \dots, y^{(n)}) = 0$ in the range $a \leq x \leq b$ if, when substituted into the equation, it gives a result that is identically zero in that range (see 169). It is frequently difficult or undesirable to express a solution y explicitly as a function of x , but instead to have an implicit relation $F(x, y) = 0$ between the solution y and the independent variable x . Such a relation is a solution if, when solved explicitly for y in terms of x , it yields a

$$(160) \quad \frac{dc}{dt} = -kc$$

$$(161) \quad \frac{dx}{dt} = k(a - x)(b - x)$$

$$(162) \quad \frac{dx}{dt} = k_1(a - x) - k_2(b + x)$$

$$(163) \quad \frac{dx}{dt} = kx(N - x)$$

$$(164) \quad \frac{dp}{dt} = (N - M)p + (I - E)$$

$$(165) \quad \frac{dp}{dt} = \epsilon p - kp^2 + (I - E)$$

$$(166) \quad \frac{dp}{dt} = p(\epsilon - kp)$$

$$(167) \quad \begin{cases} \frac{dC_A}{dt} = \frac{1}{V_A} [a_1 C_T - a_2 C_A - a_3 + (b_1 C_T - b_2)(C_T - C_A)] \\ \frac{dC_T}{dt} = \frac{1}{V_T} [R - a_1 C_T + a_2 C_A + a_3] \end{cases}$$

$$(168) \quad \begin{cases} \frac{dQ_1}{dt} = k_2 Q_2 - (k_1 + k_3) Q_1 \\ \frac{dQ_2}{dt} = k_1 Q_1 - k_2 Q_2 \end{cases}$$

Occurrence
of arbitrary
constants

solution in the way described above. For example, if both sides of a polynomial equation in x and y are differentiated with respect to x , then the function $y(x)$ determined by this implicit relation will be a solution of the differential equation thereby obtained (see 170). The simplest of all ordinary differential equations is $y' = g(x)$, in which g is an elementary function. An example is $g(x) = 2x$. The problem of solving this differential equation is equivalent to finding a function $y(x)$ the derivative of which is $2x$; this leads to the solution $y = x^2 + c$ in which c is an arbitrary constant. The process of integration has led to the occurrence of an arbitrary constant in the solution. It can be seen intuitively (and it can be proved rigorously) that finding the solution of a differential equation of the n th order will somehow be equivalent to performing n integrations and that the final solution $y(x)$ will contain n arbitrary constants of integration.

$$(170) \quad \begin{cases} x^3 + y^3 + 3xy = 1 \\ (x + y^2)y' + x^2 + y = 0 \end{cases}$$

$$(171) \quad (y')^2 + xy' - y = 0$$

$$(172) \quad y = cx + c^2$$

$$(173) \quad y = x + 1$$

$$(174) \quad y(x) = -\frac{1}{4}x^2$$

$$(175) \quad 2(y')^3 = 3y$$

$$(176) \quad 9y^2 = 4(x - c)^3$$

$$(177) \quad \frac{d^2y}{dx^2} + \omega^2 y = 0$$

$$(178) \quad y(x) = c_1 \cos(\omega x) + c_2 \sin(\omega x)$$

$$(179) \quad y(a) = y_0, \quad y'(a) = v_0$$

Any solution of an n th order equation of the form $y = \varphi(x, c_1, c_2, \dots, c_n)$ in which c_1, \dots, c_n are arbitrary constants is called a general solution of the equation. Any solution that may be obtained from the general solution of an equation by assigning particular values to the constants is called a particular solution of that equation. It sometimes happens that a nonlinear differential equation has a solution that cannot be obtained by assigning specific values to the arbitrary constants in the general solution. Such a solution is called a singular solution of the differential equation.

For example, a particular nonlinear differential equation (see 171) has a general solution that is linear in the independent variable (see 172) with an arbitrary constant c . A particular solution may be obtained from (172) by taking $c = 1$ (see 173). On the other hand, a function proportional to x^2 (see 174) also satisfies the differential equation. Because this solution cannot be obtained from the general solution by assigning a particular value to c , it is a singular solution of the differential equation (171). In this instance the graphs of the functions defined by (172) are straight lines, and the graph of the function defined by (174) is a parabola that is the envelope of that family of straight lines (cf. Figure 18).

Similarly, a nonlinear equation with the cube of the derivative proportional to y (see 175) has a general solution with y^2 proportional to $(x - c)^3$ (see 176) and the singular solution $y = 0$. Here the general solution is represented by a family of semicubical parabolas, and the singular solution is the line that passes through the cusp of each member of the family (cf. Figure 19). Such a line is called a cusp locus.

It has been pointed out above that the solution of prob-

Figure 18: Graphs of functions defined by straight lines and a parabola that is the envelope of that family of straight lines (see text).

lems in physics or engineering is equivalent to that of finding solutions of differential equations satisfying certain additional conditions. To illustrate the kind of problem arising in this way, the following equation may be considered: with the product of a constant, ω^2 , and the function y being added to the second derivative of y to give a result of zero (see 177). Its general solution is found to

Boundary
value
problems

Figure 19: A family of semicubical parabolas representing a general solution and a singular solution, which is the line that passes through the cusp of each member of the family (see text).

be the product of a constant, c_1 , and a cosine, added to the product of another constant, c_2 , and a sine (see 178). The solution corresponding to the conditions of y and its derivative at some point a being set equal to y_0 and v_0 , respectively (see 179), in which a , y_0 , v_0 are prescribed real numbers, is obtained by choosing c_1 and c_2 to satisfy the linear algebraic equations obtained by setting the general solution at a equal to y_0 while its derivative is set equal to v_0 (see 180). The solution corresponding to the conditions of y at two different points a and b being set equal to constants y_0 and y_1 , respectively (see 181), is obtained by choosing c_1 and c_2 to satisfy the linear equations obtained by setting the general solution at a and b equal to y_0 and y_1 , respectively (see 182).

Problems of this kind are called boundary value prob-

lems; the problem posed by equations (177) and (179) is called a one-point boundary value problem or an initial value problem, while that posed by equations (177) and (181) is called a two-point boundary value problem.

Another kind of problem can be exemplified by reference to equation (177). It may be stated as a question: Do there exist real values of ω such that the equation (177) has nonzero solutions satisfying the boundary conditions $y(0) = y(a) = 0$? That there are real values of ω follows immediately from the fact that, if n is an integer, then the function $y = \sin(n\pi x/a)$ satisfies these boundary conditions and the differential equation considered above, with $\omega = n\pi/a$ (see 183). Hence, $\pm n\pi/a$, $n = 1, 2, 3, \dots$, are possible values of ω . A problem of this kind is called an eigenvalue problem or a Sturm-Liouville problem.

EXISTENCE AND UNIQUENESS OF SOLUTIONS

From the geometric interpretation of the derivative of a function, it is tempting to assume that the initial value problem consisting of a differential equation and the value y_0 of the function y at some point a (see 184) has a unique solution through each point (a, y_0) of the xy -plane. It is a simple matter, however, to construct differential equations that do not have a solution at all at a specific point and others that have more than one solution—often an infinite number—at a point. For this reason it is necessary to study sufficient conditions for the existence and uniqueness of solutions of the initial value problem (see 184). The proof of the classic theorem in this area depends on the fact that any solution of the initial value problem (184) satisfies the integral equation given by formally integrating both sides of the differential equation, the constant of integration being y_0 (see 185). Conversely, any solution of this integral equation is a solution of the initial value problem (184).

To state the fundamental result, the following concept is required: a function $f(x, y)$ is said to satisfy a Lipschitz condition with respect to y in a region D of the xy -plane if there exists a constant K such that the magnitude of the difference between $f(x, y_1)$ and $f(x, y_2)$ is less than or equal to K times the magnitude of the difference between y_1 and y_2 (see 186), for every pair of points (x, y_1) , (x, y_2) belonging to D . The condition is named after a 19th-century German mathematician, Rudolf Lipschitz.

The basic theorem states that, if $f(x, y)$ is continuous and satisfies a Lipschitz condition with respect to y in some region D of the xy -plane and if (a, y_0) is any point in this region, then the initial value problem (184) has a unique solution.

It turns out that continuity of f is sufficient to guarantee existence and that it is the Lipschitz condition on f that ensures uniqueness.

By generalizing the Lipschitz condition (see 186) to the case in which both f and y are n -vectors and D is a region of the xy -space (of dimension $n + 1$), the theorem can be established for a vector differential equation (see 184). Now any differential equation of order n can be written as a first-order equation for an n -vector. For example, the initial value problem posed by equations (177) and (179) can be written in the form of an initial value problem for a first-order equation (see 187), but in this case z , A , z_0 denote matrices (see 188). The existence theorem for an n th-order equation can therefore be deduced from that for a first-order equation in which the independent variable is an n -vector.

FORMS OF SOLUTIONS

Closed-form solutions. In many cases it is possible to express the solution of a differential equation by a simple formula. For example, if the derivative of n is proportional to $-n$, then the general solution is an arbitrary constant n_0 times a negative exponential (see 189). The pair of equations describing motion in a gravitational field has as the general solution for x a linear function and for y a quadratic (see 190), with arbitrary constants c_1 , c_2 , c_3 , and c_4 . Similarly, the solution of the equation for a catenary satisfying the initial conditions $y = a$, $dy/dx = 0$ at $x = 0$ is a hyperbolic cosine (see 191).

Series solutions. Often when it is not possible to find a

$$(180) \quad \begin{cases} c_1 \cos(\omega a) + c_2 \sin(\omega a) = b \\ -c_1 \sin(\omega a) + c_2 \cos(\omega a) = v_0 \end{cases}$$

$$(181) \quad y(a) = y_0, \quad y(b) = y_1$$

$$(182) \quad \begin{cases} c_1 \cos(\omega a) + c_2 \sin(\omega a) = y_0 \\ c_1 \cos(\omega b) + c_2 \sin(\omega b) = y_1 \end{cases}$$

$$(183) \quad \frac{d^2 y}{dx^2} + \frac{n^2 \pi^2}{a^2} y = 0$$

$$(184) \quad \frac{dy}{dx} = f(x, y), \quad y(a) = y_0$$

$$(185) \quad y(x) = y_0 + \int_a^x f(t, y(t)) dt$$

$$(186) \quad |f(x, y_1) - f(x, y_2)| \leq K |y_1 - y_2|$$

$$(187) \quad \frac{dz}{dx} = Az, \quad z(a) = z_0$$

$$(188) \quad z = \begin{bmatrix} y \\ y' \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix}, \quad z_0 = \begin{bmatrix} y_0 \\ v_0 \end{bmatrix}$$

$$(189) \quad n = n_0 e^{-\lambda t}$$

$$(190) \quad x = c_1 + c_2 t, \quad y = c_3 + c_4 t - \frac{1}{2} g t^2$$

$$(191) \quad y = a \cosh(x/a)$$

$$(192) \quad \sum_{r=0}^{\infty} \frac{(-1)^r \left(\frac{1}{2}x\right)^{2r+v}}{r!(v+1)_r}$$

$$(193) \quad \sum_{r=0}^{\infty} \frac{\left(\frac{1}{2}n + \frac{1}{2}\right)_r \left(\frac{1}{2}n + 1\right)_r}{r! \left(n + \frac{3}{2}\right)_r} x^{-2r-n-1}$$

$$(194) \quad \sum_{r=0}^{\lfloor \frac{1}{2}n \rfloor} \frac{\left(\frac{1}{2} - \frac{1}{2}n\right)_r \left(-\frac{1}{2}n\right)_r}{r! \left(\frac{1}{2} - n\right)_r} x^{n-2r}$$

$$(195) \quad \sum_{r=0}^{\infty} \frac{(-n)_r (n+1)_r \left(\frac{1-x}{2}\right)^r}{r! r!}$$

The
Lipschitz
condition

Power
series

closed-form solution, it is a simple matter to find a solution in the form of an infinite series. This form of solution is particularly appropriate to the solution of second-order linear equations. For example, Bessel's equation has a series solution in powers of $x/2$ (see 192), in which the symbol $(\nu + 1)$, denotes the product $(\nu + 1)(\nu + 2) \cdots (\nu + r)$. Similarly, Legendre's equation has a solution in the form of descending powers of x that is valid only if $|x| > 1$ (see 193). The same equation has a power series solution valid if $|x| < 1$ (see 194), and a series solution in powers of $(1 - x)/2$ that is valid for $-1 < x < 3$ (see 195). It will be noted that in the case in which n is a positive integer,

$$(196) \quad \int_0^a \frac{d\varphi}{\sqrt{(\cos \varphi - \cos a)}} = \frac{2g}{a} t$$

$$(197) \quad \int_1^\infty \frac{e^{-x} dx}{\sqrt{(t^2 - 1)}}$$

$$(198) \quad y_{r+1}(x) = y_0 + \int_a^x f(t, y_r(t)) dt, \quad y_0(x) = y_0$$

$$(199) \quad \frac{dy}{dx} = 1 + x^2 y^2, \quad y(0) = 0$$

$$(200) \quad x, \quad x + \frac{1}{5} x^5, \quad x + \frac{1}{5} x^5 + \frac{2}{45} x^9 + \frac{1}{325} x^{13}, \quad \dots$$

$$(201) \quad y'' = f(x, y, y'), \quad y(a) = y_0, \quad y'(a) = y_1$$

$$(202) \quad y''' = \frac{\partial f}{\partial x} + \frac{\partial f}{\partial y} y' + \frac{\partial f}{\partial y'} y''$$

$$(203) \quad y(a + h) = y_0 + y_1 + \frac{1}{2} y''(a)h + \cdots + \frac{1}{n!} y^{(n)}(a)h^n$$

$$(204) \quad y(a + h) = y(a) + h \sum_{k=0}^p a_k f(a + b_k h, y_0 + c_k h)$$

$$(205) \quad y(a + h) = y(a) + (1 - c)hf(a, y_0) + chf\left(a + \frac{h}{2c}, y_0 + \frac{k_0}{2c}\right)$$

$$(206) \quad y_{r+1} = y_r + (1 - c)k_r + cm_r$$

$$(207) \quad \frac{dy}{dx} = f(x, y)$$

$$(208) \quad \frac{dy}{dx} = f(x)g(y)$$

$$(209) \quad y \frac{dy}{dx} = xy + x$$

$$(210) \quad \int \frac{dy}{g(y)} = \int f(x)dx + c$$

$$(211) \quad \int \frac{ydy}{y+1} = \int xdx + c$$

$$(212) \quad \frac{dy}{dx} = g\left(\frac{y}{x}\right)$$

$$(213) \quad x \frac{dv}{dx} + v = g(v)$$

each of the last two series reduces to a polynomial of degree n in x .

Integral forms. In a similar way, the solution of a differential equation can be expressed in the form of an integral that cannot be expressed in terms of elementary functions. For example, the solution of equation (124) satisfying the initial conditions $\theta = a$, $d\theta/dt = 0$ when $t = 0$ may be expressed by an equation involving an integral of a linear combination of a cosine to the $-1/2$ power (see 196). The integral on the left side of this equation cannot be expressed in terms of elementary functions. Similarly, Bessel's equation of order 0 has the solution as the integral of an expression involving exponentials and square roots (see 197).

Approximations. In many cases it is not possible to derive the solution of a differential equation in any of the above forms, and recourse has to be made to approximate methods.

Iteration method. In dealing with initial value problems, one of the simplest ways of obtaining an approximate solution is to solve the integral equation discussed earlier (see 185) by iteration—i.e., to construct a sequence of approximations $y_1(x)$, $y_2(x)$, \dots , $y_n(x)$ by the scheme of substituting an approximation for y into the integral equation and obtaining as the result a better approximation and repeating the process (see 198). It can be proved that, if the conditions of the existence-uniqueness theorem are satisfied, this sequence will converge to the correct solution. By taking the n th iterate, an approximate solution of the initial value problem is obtained.

For example, for the initial value problem for a certain first-order nonlinear differential equation (see 199), a sequence of approximations that are partial sums of a power series (see 200) is given.

Taylor series method. In theory this method is applicable to an equation of any order. As an example, the initial value problem for a second-order differential equation (see 201) is considered. First $y''(a) = f(a, y_0, y_1)$ is calculated. The given equation is differentiated with respect to x (see 202). This is evaluated at a to yield the value of $y'''(a)$. By successive differentiation $y^{(n)}(a)$ can be found for $n = 3, 4, 5, \dots$, and an approximation to the value of $y(a + h)$ can be found from the truncated Taylor series (see 203). The process is then repeated at the point $x = a + h$, and so on.

The Runge-Kutta methods. To indicate the methods devised by the German mathematicians Carl David Tolmé Runge (1895) and Martin Wilhelm Kutta (1901), the initial value problem (184) is considered. In these methods the Taylor expansion is used indirectly: $y(a + h)$ is calculated (see 204) in terms of $y(a)$, the function $f(x, y)$, and constants $a_0, \dots, a_p, b_0, \dots, b_p, c_0, \dots, c_p$, which are chosen in such a way that, when the expression is expanded for $y(a + h)$ in ascending powers of h , the coefficients agree with those of the Taylor expansion for $y(a + h)$.

For example, if $p = 1$ is taken, a formula involving two values of $f(x, y)$ is obtained (see 205). In this formula $k_0 = hf(a, y_0)$, and c is any nonzero real number. The numerical solution of the initial value problem (184) can be generated by repeated applications of this relationship. If $x_r = a + rh$, $y_r = y(a + rh)$, $k_r = hf(x_r, y_r)$, and $m_r = hf(x_r + h/2c, y_r + k_r/2c)$, ($c \neq 0$), then y_{r+1} can be calculated from y_r , k_r , m_r , and c (see 206). This is known as the Runge-Kutta second-order process. More elaborate schemes can, of course, be derived by taking a higher value of p . (I.N.S.)

methodsRunge-Kutta
second-order
process

FIRST-ORDER EQUATIONS

When first-order equations of the first degree are solved for the derivative, they are of a form in which the derivative y' equals $f(x, y)$, an explicit function of x and y (see 207). There are certain distinguishable types of such equations that may be easily solved and that are now discussed briefly.

Equations with separable variables. If the derivative can be expressed as the product of $f(x)$ and $g(y)$ (see 208), in which $f(x)$ is a function of x alone and $g(y)$ is a function of y alone, it is said to have its variables separable. For example, the nonlinear equation in which the product of

$$(214) \quad \frac{dy}{dx} = \frac{2y^2 + x^2}{xy} = \frac{2\left(\frac{y}{x}\right)^2 + 1}{\frac{y}{x}}$$

$$(215) \quad x \frac{dv}{dx} + v = \frac{2v^2 + 1}{v}$$

$$(216) \quad \int \frac{v dv}{v^2 + 1} = \int \frac{dx}{x} + k$$

$$(217) \quad \log(v^2 + 1) = 2 \log x + \log c$$

$$(218) \quad v^2 + 1 = cx^2$$

$$(219) \quad x^2 + y^2 = cx^4$$

$$(220) \quad \frac{\partial \psi}{\partial x} = P(x, y), \quad \frac{\partial \psi}{\partial y} = Q(x, y)$$

$$(221) \quad P(x, y) + Q(x, y)y' = 0$$

$$(222) \quad \psi(x, y) = c$$

$$(223) \quad \frac{\partial \psi}{\partial x} + \frac{\partial \psi}{\partial y} y' = 0$$

$$(224) \quad \frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}$$

$$(225) \quad 2e^x y y' + y^2 e^x - 1 = 0$$

$$(226) \quad \frac{\partial}{\partial y}(y^2 e^x - 1) = \frac{\partial}{\partial x}(2e^x y)$$

$$(227) \quad y^2 e^x - x = c$$

$$(228) \quad 2xy' + 3y = 0$$

$$(229) \quad 2yy'x^3 + y^2 \cdot 3x^2 = 0$$

$$(230) \quad \frac{\partial}{\partial y}(\mu P) = \frac{\partial}{\partial x}(\mu Q)$$

$$(231) \quad \frac{1}{Q} \left(\frac{\partial P}{\partial y} - \frac{\partial Q}{\partial x} \right) = g(x)$$

$$(232) \quad \frac{\mu'(x)}{\mu(x)} = g(x)$$

$$(233) \quad \mu(x) = \exp \{ \int g(x) dx \}$$

$$(234) \quad y' + a(x)y = b(x)$$

$$(235) \quad \mu(x) = \exp \{ \int a(x) dx \}$$

$$(236) \quad \begin{cases} xy' + (x^2 + 1)y = x \\ a(x) = x + x^{-1} \end{cases}$$

$$(237) \quad \begin{cases} \mu = \exp \{ \int (x + x^{-1}) dx \} \\ = \exp \left[\frac{1}{2} x^2 + \log x \right] = x e^{(1/2)x^2} \end{cases}$$

$$(238) \quad \frac{d}{dx} [x e^{(1/2)x^2} y] = x e^{(1/2)x^2}$$

$$(239) \quad y = x^{-1} + c x^{-1} e^{-(1/2)x^2}$$

y and its derivative equals the sum of xy and x (see 209) has its variables separable. The general solution of such an equation is obtained by moving the expressions involving x to one side of the equation and those involving y to the other, and then integrating both sides (see 210), involving c , as arbitrary constant. For example, the equation just considered (see 209) has general solution in terms of an integral of y divided by $y + 1$ and an integral of x (see 211).

These integrals can be evaluated, giving the result that $y - \log(y + 1) = x^2/2 + c$.

Homogeneous equations. A differential equation in which the derivative dy/dx equals $g(y/x)$, in which g is a function of y/x alone (see 212), is said to be homogeneous. Such an equation is reduced to separable form (see 213) by the substitution $y = xv$. For example, the equation in which dy/dx equals $2y^2 + x^2$ divided by xy (see 214) is homogeneous; the substitution $y = xv$ reduces it to the separable form as a differential equation with v as the dependent variable (see 215). It is possible to obtain the solution of this differential equation by certain integrations (see 216), in which k is an arbitrary constant. Performing the integrations, the general solution is obtained in terms of logarithms (see 217), in which c is an arbitrary constant; ($2k = \log c$)—i.e., the sum of v^2 and 1 equals cx^2 (see 218). Returning to the original variables, the sum of x^2 and y^2 equals cx^4 (see 219), which is the general solution of equation (214).

Exact equations. If there exists a function $\psi(x, y)$ such that the partial derivative of ψ with respect to x equals $P(x, y)$, and the partial derivative of ψ with respect to y equals $Q(x, y)$ (see 220), the differential equation formed by the sum of $P(x, y)$ and the product of $Q(x, y)$ and y' being equal to zero (see 221) is said to be exact. The reason for this is that the function $\psi(x, y)$ defined by $\psi(x, y)$ being equal to an arbitrary constant c (see 222) has a derivative y' that satisfies the equation obtained by differentiating $\psi(x, y)$ with respect to x by the chain rule (see 223).

Hence, because of these relations (see 220), the differential equation (221) follows. It is obvious from equations (220) that a necessary condition for the equation (221) to be exact is that the partial derivative of $P(x, y)$ with respect to y equals the partial derivative $Q(x, y)$ with respect to x (see 224); it can also be shown that this condition is sufficient. For example, a nonlinear differential equation with exponential coefficients (see 225) is exact because the partial derivative with respect to x of the coefficient of y' equals the partial derivative with respect to y of the rest of the equation (see 226). It has the general solution in implicit form with an arbitrary constant (see 227). Instead of saying that the equation (221) is exact, $P(x, y)dx + Q(x, y)dy$ is sometimes termed an exact differential.

Integrating factors. Although a differential equation may not be exact in the form in which it is encountered, it has been proved that it may be made exact by multiplication by a suitable factor. Such a multiplier is called an integrating factor. For example, the equation formed by the sum of $2xy'$ and $3y$ being equal to zero (see 228) is not exact, but multiplying throughout by x^2y gives an equation (see 229) that is exact and has a general solution $y^2x^3 = c$.

If both sides of equation (221) are multiplied by $\mu(x, y)$ and the exactness condition (224) is used, then μ will be an integrating factor of the equation if, and only if, it satisfies the condition that the partial derivative of μP with respect to y equals the partial derivative of μQ with respect to x (see 230). For example, the general first-order differential equation being considered (221) will possess an integrating factor $\mu(x)$ if, and only if, the difference of the partial derivative of P with respect to y and that of Q with respect to x , divided by Q , equals $g(x)$, a function of x alone (see 231), and then μ may be taken to be any solution of the equation given by $g(x)$ being equal to $\mu'(x)$ divided by $\mu(x)$ (see 232); i.e., $\mu(x)$ is an exponential (see 233).

Linear equations. If the above procedure is applied to the linear first-order equation with the coefficient of y being $a(x)$ and the inhomogeneous term being $b(x)$ (see 234), it is found to have an integrating factor $\mu(x)$ equal to an exponential with the integral of $a(x)$ in the exponent (see 235).

$$(240) \quad P_n(x)y^{(n)} + P_{n-1}(x)y^{(n-1)} + \cdots + P_1(x)y' + P_0(x)y = f(x)$$

$$(241) \quad P_n(x)D^n + P_{n-1}(x)D^{n-1} + \cdots + P_1(x)D + P_0(x)$$

$$(242) \quad a_1y_1(x) + a_2y_2(x) + \cdots + a_ny_n(x) = 0$$

$$(243) \quad y(x) = c_1y_1(x) + \cdots + c_ny_n(x) + Y(x)$$

$$(244) \quad W(y_1, \dots, y_n) = \begin{vmatrix} y_1(x) & \cdots & y_n(x) \\ y_1'(x) & \cdots & y_n'(x) \\ \vdots & & \vdots \\ y_1^{(n-1)}(x) & \cdots & y_n^{(n-1)}(x) \end{vmatrix}$$

$$(245) \quad \Pi_n(D)y = f(x)$$

$$(246) \quad \Pi_n(t) = p_nt^n + p_{n-1}t^{n-1} + \cdots + p_1t + p_0, \quad (p_n \neq 0)$$

$$(247) \quad c_1e^{\lambda_1x} + c_2e^{\lambda_2x} + \cdots + c_ne^{\lambda_nx}$$

For example, if the sum of xy' and $(x^2 + 1)y$ equals x (see 236), then $\mu(x)$ is equal to the product of x and an exponential with exponent $x^2/2$ (see 237). The equation can be written as the derivative of the product of $\mu(x)$ and y being equal to $\mu(x)$ (see 238). Integrating and dividing by $x \exp(x^2/2)$ yields the general solution in terms of x^{-1} , an exponential, and an arbitrary constant c (see 239).

LINEAR DIFFERENTIAL EQUATIONS

Equations of n th order. A linear differential equation of order n is an equation involving y and its derivatives linearly, the coefficient of y' being P_n , and the nonhomogeneous term being $f(x)$ (see 240), in which P_n, \dots, P_0, f are given functions of x , and $P_n(x)$ does not vanish identically. The linear differential equation obtained from equation (240) by replacing $f(x)$ by 0 is called the homogeneous equation, corresponding to the nonhomogeneous equation (240). For example, Bessel's equation and Legendre's equation are linear equations of the second order and of homogeneous type.

If the differential operator d/dx is denoted by D and if L is written for the operator formed by the sum of terms of the form $P_j D^j$ (see 241), then equation (240) may be written in the form $Ly = f(x)$ and the corresponding homogeneous equation in the form $Ly = 0$.

Functions $y_1(x), \dots, y_n(x)$ are said to be linearly independent solutions of the homogeneous equation $Ly = 0$ if $Ly_r(x) = 0$, $r = 1, 2, \dots, n$ and if the functions are such that there does not exist a set of constants a_1, a_2, \dots, a_n , not all of which are zero, such that, for all values of x , the sum of the terms $a_j y_j(x)$ is equal to zero (see 242).

The basic result in the theory of linear differential equations is that, if y_1, y_2, \dots, y_n are n linearly independent solutions of $Ly = 0$ and if $Y(x)$ is any solution of equation (240), then the general solution of (240) is $Y(x)$ added to a sum of terms of the form $c_j y_j(x)$ (see 243), in which c_1, \dots, c_n are arbitrary constants.

The general solution of a linear differential equation is therefore the sum of two parts: $c_1 y_1(x) + \cdots + c_n y_n(x)$, which is called the complementary function, and $Y(x)$, which is called a particular integral. To determine whether a set of functions is linearly independent, the following criterion must be used: a necessary and sufficient condition that $y_1(x), \dots, y_n(x)$ are linearly independent is that the Wronskian W , defined by the 19th-century Polish mathematician Hoëné Wronski as the determinant of the matrix formed by the n linearly independent solutions and their first $n - 1$ derivatives (see 244), is not identically zero.

Equations with constant coefficients. There is a simple theory of linear equations of the type (240) in which $P_i(x) = p_i$, a constant, ($i = 0, 1, \dots, n$). Such equations can be written in the form of an expression $\Pi_n(D)y$ set equal to $f(x)$ (see 245), in which $\Pi_n(t)$ denotes the polynomial defined as the sum of terms of the form $p_i t^i$ (see 246).

The form of the complementary function depends on the zeros of the polynomial Π_n . If $\Pi_n(t)$ has n distinct zeros $\lambda_1, \lambda_2, \dots, \lambda_n$, then the complementary function of the equation (245) is in the form of a sum of terms $c_i \exp(\lambda_i x)$ (see 247) in which, as before, c_1, c_2, \dots, c_n denote arbitrary constants. Some of the zeros may, of course, be complex, but if the coefficients p_n, \dots, p_0 are real, then complex zeros when they do occur will occur in complex pairs.

For example, if $\lambda_1 = \mu_1 + i\omega_1$, then there will be another zero, which may be labeled λ_2 , of the form $\lambda_2 = \mu_1 - i\omega_1$; the linearly independent solutions $\exp(\lambda_1 x) \exp(\lambda_2 x)$ may be replaced by $\exp(\mu_1 x) \cos(\omega_1 x) \exp(\mu_1 x) \sin(\omega_1 x)$. Putting this another way, it can be said that, if $\Pi_n(t)$ contains the simple quadratic factor $(t - \mu_1)^2 + \omega_1^2$, then the complementary function contains the corresponding terms that are products of the exponential $\exp(\mu_1 x)$ and a linear combination of the sine and cosine of $\omega_1 x$ (see 248).

On the other hand, if λ_1 is a multiple root, of order m , say—i.e., if $\Pi_n(t)$ has a factor $(t - \lambda_1)^m$ —the complementary function contains the terms $(c_1 x + c_2 x^2 + \cdots + c_m x^{m-1}) \exp(\lambda_1 x)$. Similarly, if $\Pi_n(t)$ has a factor of the form $[(t - \mu_1)^2 + \omega_1^2]^m$, there are $2m$ terms of the analogous form involving $\exp(\mu_1 x) \cos(\omega_1 x)$ and $\exp(\mu_1 x) \sin(\omega_1 x)$ (see 249) in the complementary function.

In many practical cases it is possible to obtain a particular integral $Y(x)$ by inspection. When this cannot be done, the Laplace transform is used. Because for $Y(x)$ any solution (see 245) may be taken, it is only necessary to find the solution $Y(x)$ of that equation satisfying the conditions of $Y(x)$ and its first $n - 1$ derivatives at $x = 0$ being equal to zero (see 250). If a function $\phi(x)$ is defined for all positive real values of x , its Laplace transform is defined as the result of multiplying the function by e^{-px} and integrating from $x = 0$ to infinity (see 251). When $\mathfrak{L}[\phi(p)]$ is the Laplace transform of $\phi(x)$, $\phi(x)$ is said to be the inverse Laplace transform of $\mathfrak{L}[\phi(p)]$ and $\phi(x) = \mathfrak{L}^{-1}[\phi(p); x]$.

To apply the Laplace transform to the solution of equations of the type (245), a formula is used expressing the Laplace transform of the derivative of a function in terms of the Laplace transform of the function itself. Suppose that the function $Y(x)$ satisfies the conditions (250). Let $\mathfrak{L}[Y(p)]$ denote the Laplace transform of $Y(x)$. For $m = 1, 2, \dots, n$ the Laplace transform of the m th derivative of $Y(x)$ is the product of p^m and $\mathfrak{L}[Y(p)]$ (see 252). Taking the Laplace transform of both sides of equation (245), it is found that $\mathfrak{L}[Y(p)]$ satisfies the simple al-

$$(255) \quad L^* z = (pz)'' - (qz)' + r$$

$$(256) \quad y_2(x) = y_1(x) \int_a^x \frac{dt}{p(t)[y_1(t)]^2}$$

$$(257) \quad \sum_{r=0}^{\infty} a_r x^r + \rho, \quad a_0 \neq 0$$

Homogeneous
and
nonhomogeneous
equations

gebraic equation $\Pi_n(p)\mathcal{L}[Y(p)] = \mathcal{L}[f(p)]$ in which $\mathcal{L}[f(p)]$ denotes the Laplace transform of $f(x)$. For the particular integral, this equation may be solved for $Y(p)$ and the inverse Laplace transform (see 253) may be taken.

Linear equations of the second order. The general theory of linear differential equations will be illustrated by examples of equations of the second order $Ly = f(x)$, in which L denotes the operator $p(x)D^2 + q(x)D + r(x)$. A homogeneous equation $Ly = 0$ is said to be exact if it can be written in the form $DMy = 0$, in which M is a first-order linear differential operator of the form $p(x)D + s(x)$. The equation $Ly = 0$ can be integrated once to give a first-order linear equation in which My is equal to an arbitrary constant c_1 (see 254), which can in turn be integrated by the method described above for the solution of equation (234); this will, of course, involve a second arbitrary constant c_2 . This equation (254) is called a first integral of the original second-order equation. The equation $py'' + qy' + ry = 0$ is exact if, and only if, $p'' - q' + r = 0$ for all values of x , in which case $s(x) = q(x) - p'(x)$.

If the equation $Ly = 0$ is not exact but there exists a function $z(x)$ such that $zLy = 0$ is exact, then z is said to be an integrating factor of $Ly = 0$. From the condition for a second-order equation to be exact, it is easily deduced that z is an integrating factor if it is a solution of the equation $L^*z = 0$, in which the operator L^* is defined in terms of differentiation (see 255) and is called the adjoint of L . If $L^* = L$, the operator L is said to be self-adjoint; the condition for this is that $q(x) = p'(x)$.

The two standard methods of solution

The two standard methods of solving a second-order equation are based on writing the solution in the form $y = uv$, in which u is a prescribed function of x and v is the new dependent variable.

If u is chosen to be any solution of the first-order equation $2pu' + qu = 0$, the resulting equation for v is of the form $v'' + P(x)v = 0$, and the general solution of this equation may be known. This procedure is known as reducing the equation to normal form, or as removing the first derivative.

The second method consists in finding a particular solution of the equation by inspection and taking this solution to be u . The resulting second-order equation for v is, in effect, a first-order linear equation for $w = v'$. This can easily be solved and v obtained by a further integration. This method is particularly useful in the case of a self-adjoint equation $(py')' + ry = 0$; if $y_1(x)$ is any solution of this equation, then the general solution is $c_1y_1(x) + c_2y_2(x)$, in which $y_2(x)$ is defined in terms of $y_1(x)$ and an integral (see 256), the lower limit of integration a being chosen to ensure that the integral exists.

Another method of solving a linear second-order equation is to derive a solution in the form of a power series (see 257) by substituting a series in the equation. If the coefficient of the lowest power of x is equated to zero, a quadratic equation is obtained; either of the roots of this equation gives a possible value of ρ . If the coefficient of x to the power $r + \rho$ is equated to zero, a recurrence relation is obtained for the coefficients a_r of this series.

(I.N.S./Ed.)

BOUNDARY VALUE PROBLEMS

When differential equations occur in the discussion of a physical problem, it usually happens that the solution of interest is not the general solution but the particular solution that satisfies certain additional conditions. For instance, to solve the problem of the catenary does not require the general solution of the second-order differential equation (137) but the particular solution $y(x)$ that satisfies the additional geometric conditions $y(0) = a$, $y'(0) = 0$.

To illustrate the ideas involved, equations of the second order will be discussed; they are easily generalized to equations of the n th order.

Initial value problems. The problem of finding a function $y(x)$ in the interval $a < x < b$ satisfying a second-order differential equation $F(x, y, y', y'') = 0$ and the conditions $y(a) = y_0$, $y'(a) = y_1$, in which y_0, y_1 are prescribed real numbers, is called the initial value problem for the differential equation. The values y_0, y_1 are called the initial values of the required solution. The adjective "initial"

$$(258) \quad y'' + a(x)y' + \beta(x)y = f(x), \quad a < x < b$$

$$(259) \quad y(x) = c_1y_1(x) + c_2y_2(x) + Y(x)$$

$$(260) \quad \begin{cases} c_1y_1(a) + c_2y_2(a) = y_0 - Y(a) \\ c_1y_1'(a) + c_2y_2'(a) = y_1 - Y'(a) \end{cases}$$

$$(261) \quad c_1 = \frac{y_0y_2'(a) - y_1y_2(a)}{W(y_1, y_2; a)}, \quad c_2 = \frac{y_1y_1(a) - y_0y_1'(a)}{W(y_1, y_2; a)}$$

$$(262) \quad \begin{cases} \frac{\partial^2 G}{\partial x^2} + a(x)\frac{\partial G}{\partial x} + \beta(x)G = 0, & G(a, \xi) = 0 \\ \frac{\partial G(a, \xi)}{\partial x} = 0, & G(\xi, \xi) = 0, & \frac{\partial G(\xi, \xi)}{\partial x} = 1 \\ Y(x) = \int_a^x G(x, \xi)f(\xi)d\xi \end{cases}$$

is appropriate because in a dynamical problem (as in the problem of determining the escape velocity from the Earth, discussed above) the conditions of this type specify the initial state and initial rate of change of the system the subsequent history of which is described by the differential equation itself. Initial value problems are also known as one-point boundary value problems.

Linear equations. The linear second-order differential equation with x between a and b —in which $a(x)$, the coefficient of y' , $\beta(x)$, the coefficient of y , and $f(x)$, the inhomogeneous term, are prescribed functions (see 258)—may now be considered with the initial values prescribed as above.

If $y_1(x)$ and $y_2(x)$ are linearly dependent solutions of the homogeneous form of the equation and $Y(x)$ is a particular solution of the nonhomogeneous equation (258), then the solution of the initial value problem for the differential equation is the sum of $Y(x)$ and a linear combination, with constants c_1 and c_2 , of $y_1(x)$ and $y_2(x)$ (see 259).

The constants c_1 and c_2 are chosen to satisfy the simultaneous linear equation arising from setting the solution and its derivative equal to y_0 and y_1 , respectively (see 260). If the particular solution $Y(x)$ is chosen in such a way that $Y(a) = Y'(a) = 0$, the equations for c_1 and c_2 reduce to a simple pair the solution of which can be found by Cramer's rule (see 261), named for the 18th-century Swiss mathematician Gabriel Cramer. This solution involves $W(y_1, y_2; a)$, the Wronskian $y_1(a)y_2'(a) - y_2(a)y_1'(a)$, which is nonzero because the solutions y_1 and y_2 are linearly independent. The solution of the initial value problem is given by equations (259) and (261).

Cramer's rule

Green's function for a linear initial value problem. There is a simple formula for the determination of the particular integral $Y(x)$ of the linear differential equation of second order (see 258) satisfying the initial condition $Y(a) = Y'(a) = 0$. If $G(x, \xi)$ is a function of the two variables x and ξ such that G and its partial derivatives with respect to x satisfy the homogeneous equation, conditions at $x = \xi$ and at $x = a$, then $Y(x)$ can be expressed as an integral of the product $G(x, \xi)f(\xi)$ (see 262). The function $G(x, \xi)$ is called Green's function of the problem (named after George Green, a 19th-century English mathematician). It can be shown that Green's function can be expressed in terms of y_1, y_2 , and the Wronskian $W(y_1, y_2; \xi)$ (see 263) in which $y_1(x)$ and $y_2(x)$ have the same meanings as before.

For example, for the initial value problem in which the sum of the second derivative y'' and $\omega^2 y$ equals $f(x)$ with y and its first derivative equaling y_0 and y_1 , respectively, at $x = 0$ (see 264), the functions $y_1(x) = \cos(\omega x)$ and $y_2(x) = \sin(\omega x)$ may be taken to obtain the formula $G(x, \xi) = \omega^{-1} \sin(\omega(x - \xi))$ from equation (263). Therefore, it is possible to express the solution as the sum of a linear

$$(263) \quad G(x, \xi) = \frac{y_1(\xi)y_2(x) - y_1(x)y_2(\xi)}{W(y_1, y_2; \xi)}$$

$$(264) \quad \begin{cases} \frac{d^2 y}{dx^2} + \omega^2 y = f(x), & x > 0 \\ y(0) = y_0, & y'(0) = y_1 \end{cases}$$

$$(265) \quad y_0(x) = y_0 \cos(\omega x) + \frac{y_1}{\omega} \sin(\omega x) + \frac{1}{\omega} \int_0^x f(\xi) \sin(\omega(x - \xi)) d\xi$$

$$(266) \quad y''' = \frac{\partial g(x, y, y')}{\partial x} + \frac{\partial g(x, y, y')}{\partial y} y' + \frac{\partial g(x, y, y')}{\partial y'} y''$$

$$(267) \quad \begin{cases} y(a) = y_0, & y'(a) = y_1, & y''(a) = g(a, y_0, y_1) \\ y'''(a) = g_x(a, y_0, y_1) + y_1 g_y(a, y_0, y_1) \\ \quad + g_{y'}(a, y_0, y_1) g_{y''}(a, y_0, y_1) \end{cases}$$

$$(268) \quad y(x) = y(a) + \frac{(x-a)}{1!} y'(a) + \frac{(x-a)^2}{2!} y''(a) + \frac{(x-a)^3}{3!} y'''(a) + \dots$$

$$(269) \quad \lambda_1 y(a) + \mu_1 y'(a) = y_0 \lambda_2 y(b) + \mu_2 y'(b) = y_1$$

$$(270) \quad y(x) = y_0 \frac{y_2(x)}{y_2(a)} + y_1 \frac{y_1(x)}{y_1(b)} + \eta(x)$$

$$(271) \quad \eta(x) = y_2(x) \int_a^x \frac{y_1(\xi) f(\xi) d\xi}{W(y_1, y_2; \xi)} + y_1(x) \int_x^b \frac{y_2(\xi) f(\xi) d\xi}{W(y_1, y_2; \xi)}, \quad a < x < b$$

$$(272) \quad G(x, \xi) = \begin{cases} \frac{y_1(\xi)y_2(x)}{W(y_1, y_2; \xi)}, & a < \xi < x \\ \frac{y_1(x)y_2(\xi)}{W(y_1, y_2; \xi)}, & x < \xi < b \end{cases}$$

$$(273) \quad y(x) = \frac{y_0 y_2(x)}{y_2(a)} + \frac{y_1 y_1(x)}{y_1(b)} \int_a^b G(x, \xi) f(\xi) d\xi$$

$$(274) \quad y_1(a) = 0, \quad y_2(b) = 0$$

$$(275) \quad \begin{cases} \dot{x} = a_{11}x + a_{12}y \\ \dot{y} = a_{21}x + a_{22}y \end{cases}$$

$$(276) \quad \begin{cases} (a_{11} - \lambda)A + a_{12}B = 0 \\ a_{21}A + (a_{22} - \lambda)B = 0 \end{cases}$$

$$(277) \quad \begin{vmatrix} a_{11} - \lambda & a_{12} \\ a_{21} & a_{22} - \lambda \end{vmatrix} = 0$$

combination of $\cos(\omega x)$ and $\sin(\omega x)$ and the integral of the product of $f(\xi)$ and Green's function (see 265).

Nonlinear equations. The solution of the initial value problem for a nonlinear equation is a much more difficult problem except in those rare cases in which it is possible to find a general solution of the differential equation. The particular values of the arbitrary constants c_1 and c_2 are then found by fitting the values of $y(a)$ and $y'(a)$.

For equations of the type $y'' = g(x, y, y')$, a solution can be generated in the following manner. Differentiation of both sides of the equation by the chain rule produces an expression for the third derivative y''' (see 266), and it is possible to obtain higher derivatives by repeated differentiation.

Substitution of the initial values, the expressions for $y''(a)$, $y'''(a)$, and higher derivatives at $x = a$ (see 267) in the Taylor expansion about $x = a$ (see 268) leads to a series expansion for the solution of the initial value problem.

Two-point boundary value problems. The problem of finding a function $y(x)$ in the interval $a < x < b$ satisfying a second-order differential equation $F(x, y, y', y'') = 0$ and the conditions $y(a) = y_0$, $y(b) = y_1$ in which y_0, y_1 are prescribed real numbers is called the two-point boundary value problem for the differential equation. This problem can be generalized to cover the boundary conditions expressed by setting linear combinations of y and y' at each point equal to prescribed constants (see 269); only the simple case is treated here.

Linear equations. The two-point boundary value problem for a second-order linear equation (see 258) is considered: $y_1(x)$ and $y_2(x)$ are taken to be linearly independent solutions satisfying the conditions $y_1(a) = 0$, $y_2(b) = 0$, and $\eta(x)$ is taken as the particular solution of the equation (258) satisfying the conditions $\eta(a) = \eta(b) = 0$. The solution of the two-point boundary value problem is then the sum of a linear combination of $y_1(x)$ and $y_2(x)$ and a function $\eta(x)$ (see 270).

Green's function for a linear two-point boundary value problem. It can be shown that the function $\eta(x)$ can be expressed in terms of $y_1(x)$, $y_2(x)$, and integrals involving $f(\xi)$ (see 271), which gives the required particular integral. The function $G(x, \xi)$ defined in terms of the functions and their Wronskian (see 272) is called Green's function of the two-point boundary value problem. In terms of it the solution of the problem may be written as the sum of an integral of $G(x, \xi)f(\xi)$ and a linear combination of $y_1(x)$ and $y_2(x)$ (see 273). In the use of this formula it is necessary to remember that $y_1(x)$, $y_2(x)$ are not completely arbitrary linearly independent solutions of the homogeneous form of (258) but must satisfy the boundary conditions (see 274).

Nonlinear equations. When the general solution of a second-order nonlinear equation is not known, the solution of a two-point boundary value problem is obtained by solving the initial value problem for $y(a) = y_0$, $y'(a) = \gamma$, and (usually by a method of trial and error) finding the value of γ that leads to a solution for which $y(b) = y_1$.

SYSTEMS OF DIFFERENTIAL EQUATIONS

Two simultaneous differential equations in two variables. Two simultaneous equations in two variables will now be considered. They can be solved if they are linear and of first order.

Linear systems. A pair of homogeneous linear equations of the first order with dependent variables x and y and independent variable t can be solved for dx/dt and dy/dt formally written as dotted letters. In other words, the system is reduced to a pair of equations expressing the derivative with respect to t each in terms of a linear combination of x and y (see 275). The functions $x(t) = Ae^{\lambda t}$, $y(t) = Be^{\lambda t}$ satisfy these equations if the linear algebraic equations obtained by substituting these expressions for $x(t)$ and $y(t)$ into the original system are satisfied (see 276).

Regarded as equations for A and B , these equations have a nontrivial solution only if λ is a root of the equation that arises from the requirement that the determinant of the matrix of a system of homogeneous linear algebraic equations be zero (see 277), in which case A and B may be expressed in terms of an arbitrary constant c (see 278).

Two-point boundary value problem

Nontrivial solution of equations

$$(278) \quad A = a_{12}c, \quad B = (\lambda - a_{11})c$$

$$(279) \quad \begin{cases} x(t) = a_{12}c_1 e^{\lambda_1 t} + a_{12}c_2 e^{\lambda_2 t} \\ y(t) = (\lambda_1 - a_{11})c_1 e^{\lambda_1 t} + (\lambda_2 - a_{11})c_2 e^{\lambda_2 t} \end{cases}$$

$$(280) \quad \begin{cases} \dot{x} + 4x + y = 0, & \dot{y} - 6x - y = 0 \\ a_{11} = -4, & a_{12} = -1, & a_{21} = 6 \\ a_{22} = 1, & \lambda_1 = -1, & \lambda_2 = -2 \end{cases}$$

$$(281) \quad x(t) = -c_1 e^{-t} - c_2 e^{-2t}, \quad y(t) = 3c_1 e^{-t} + 2c_2 e^{-2t}$$

$$(282) \quad -c_1 - c_2 = x_0, \quad 3c_1 + 2c_2 = y_0$$

$$(283) \quad \begin{cases} x(t) = (3e^{-2t} - 2e^{-t})x_0 + (e^{-2t} - e^{-t})y_0 \\ y(t) = 6(e^{-t} - e^{-2t})x_0 + (3e^{-t} - 2e^{-2t})y_0 \end{cases}$$

$$(284) \quad \mathfrak{L}[\dot{x}(t); p] = p\bar{x}(p) - x_0, \quad \mathfrak{L}[\dot{y}(t); p] = p\bar{y}(p) - y_0$$

$$(285) \quad \begin{cases} (a_{11} - p)\bar{x}(p) + a_{12}\bar{y}(p) + x_0 = 0 \\ a_{21}\bar{x}(p) + (a_{22} - p)\bar{y}(p) + y_0 = 0 \end{cases}$$

$$(286) \quad (p+4)\bar{x}(p) + \bar{y}(p) = x_0, \quad -6\bar{x}(p) + (p-1)\bar{y}(p) = y_0$$

$$(287) \quad \bar{x}(p) = \frac{(p-1)x_0 - y_0}{(p+1)(p+2)}, \quad \bar{y}(p) = \frac{6x_0 + (p+4)y_0}{(p+1)(p+2)}$$

$$(288) \quad \begin{cases} \bar{x}(p) = \frac{3x_0 + y_0}{p+2} - \frac{2x_0 + y_0}{p+1} \\ \bar{y}(p) = \frac{6x_0 + 3y_0}{p+1} - \frac{6x_0 + 2y_0}{p+2} \end{cases}$$

$$(289) \quad \begin{bmatrix} \dot{x} \\ \dot{y} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}$$

$$(290) \quad \mathbf{z} = \begin{bmatrix} x \\ y \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

$$(291) \quad \dot{\mathbf{z}} = \mathbf{A}\mathbf{z}$$

$$(292) \quad \frac{d^2x}{dt^2} + p(t)\frac{dx}{dt} + q(t)x = f(t)$$

$$(293) \quad \frac{dx}{dt} - y = 0, \quad \frac{dy}{dt} + p(t)y + q(t)x = f(t)$$

$$(294) \quad \mathbf{z} = \begin{bmatrix} x \\ y \end{bmatrix}, \quad \mathbf{A}(t) = \begin{bmatrix} 0 & -1 \\ q(t) & p(t) \end{bmatrix}, \quad \varphi = \begin{bmatrix} 0 \\ f(t) \end{bmatrix}$$

$$(295) \quad \dot{\mathbf{z}} + \mathbf{A}(t)\mathbf{z} = \varphi(t)$$

$$(296) \quad \begin{cases} \dot{x}_1 = a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n \\ \dot{x}_2 = a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n \\ \vdots \\ \dot{x}_n = a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n \end{cases}$$

$$(297) \quad \dot{\mathbf{z}} = \mathbf{A}\mathbf{z}$$

the general solution of the pair of equations (275) may be written as linear combinations of these two solutions involving the a_{ij} and two arbitrary constants, c_1 and c_2 (see 279). For example, if the sum of the derivative of x with respect to t , ax , and y equals zero and the derivative of y with respect to t equals the sum of $6x$ and y , then λ_1 must equal -1 , λ_2 must equal -2 , and the a_{ij} are determined (see 280) so that the general solution is a linear combination of e^{-t} and e^{-2t} involving arbitrary constants c_1 and c_2 (see 281). In order to obtain the solution for which $x(0) = x_0$, $y(0) = y_0$, it is necessary to choose the constants c_1 and c_2 in such a way that the solution satisfies these conditions at $t = 0$ (see 282). These equations are solved for c_1 and c_2 to give the particular solution desired (see 283).

Use of the Laplace transform. To obtain the solution of the pair of first-order linear differential equations (275), the formulas expressing the result of using the Laplace transform (often formally written as a bar over the expression transformed) on a derivative (see 284) are used to obtain simultaneous linear algebraic equations (see 285) for the Laplace transforms $\mathfrak{L}[x(p)]$, $\mathfrak{L}[y(p)]$ of the unknown functions $x(t)$, $y(t)$. For instance, the pair (280) considered above can be attacked in this way (see 286) with the solution giving the Laplace transforms $\mathfrak{L}[x(p)]$ and $\mathfrak{L}[y(p)]$ in terms of p , x_0 , and y_0 (see 287). If these equations are appropriately rewritten (see 288) and the Laplace transforms are inverted, the solution (283) is obtained.

Matrix form of the pair of equations. The pair of equations (275) may be written in matrix form (see 289) if matrices \mathbf{z} , with elements x and y , and \mathbf{A} , with elements a_{11} , a_{12} , a_{21} , and a_{22} (see 290), are introduced. This last equation can be written in a matrix form similar to the form of a single first-order equation (see 291).

Second-order equations. The general second-order linear differential equation (see 292) can be written as a pair of simultaneous equations by defining a new variable y as equal to the first derivative dx/dt (see 293). In terms of matrices (see 294) similar to those in the previous example, this pair can, in turn, be written in matrix form (see 295).

A system of n simultaneous equations in n variables. The system (275) can be generalized to the set of linear differential equations in n variables (see 296), which can be written in matrix form by writing the derivative of \mathbf{z} with respect to t as equal to the matrix product $\mathbf{A}\mathbf{z}$ (see 297), in which \mathbf{z} is an n -component column vector and \mathbf{A} is an $n \times n$ matrix of coefficients (see 298). If \mathbf{z} equals a constant vector \mathbf{c} times an exponential $e^{\lambda t}$ (see 299) and if \mathbf{I} is the unit $n \times n$ matrix, then the matrix product $\mathbf{A}\mathbf{c}$ must equal $\lambda \mathbf{I}\mathbf{c}$ (see 300) for \mathbf{z} to be a solution of the system.

In order for \mathbf{c} to be a non-null vector, it is necessary that $\det(\mathbf{A} - \lambda \mathbf{I}) = 0$; i.e., the vector (299) is a solution of equation (297) only if λ is an eigenvalue (see ALGEBRA: *Linear and multilinear algebra*) of the matrix \mathbf{A} . This is illustrated by equation (277) in the case $n = 2$.

The main result is that the general solution of the system of equations (297) is the product of a constant vector \mathbf{z}_0 and an exponential $e^{\lambda t}$ (see 301), the exponential with matrix exponent being defined by the Maclaurin series expansion of the exponential (see 302) (named after the 17th-century Scottish mathematician Colin Maclaurin).

(I.N.S.)

STABILITY

There are very few differential equations the general solution of which can be derived, and so mathematicians have studied the qualitative properties of solutions of differential equations without solving the equations explicitly. One qualitative phenomenon of great practical interest is the concept of stability of a certain solution of a system of differential equations.

Suppose, for the sake of illustration, that a physical system is represented by a differential equation in which the derivative of an n -vector \mathbf{x} equals a function of \mathbf{x} and t , $f(\mathbf{x}, t)$, which is also an n -vector (see 303), and that $\mathbf{x} = u(t)$ is a special solution of this equation describing a special regime of the system. Any physical system will be subject to small disturbances so that the regime $u(t)$ will not maintain itself, and a disturbed motion $\mathbf{x} = w(t)$ results. As time goes on, either $w(t) \rightarrow u(t)$, in which

If the roots λ_1 , λ_2 of the quadratic equation (277) are distinct, there are two linearly independent solutions, and

$$(298) \quad \mathbf{z} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \dots & a_{nn} \end{bmatrix}$$

$$(299) \quad \mathbf{z} = \mathbf{c}e^{\lambda t}$$

$$(300) \quad (\mathbf{A} - \lambda \mathbf{I})\mathbf{c} = \mathbf{0}$$

$$(301) \quad \mathbf{z}(t) = e^{\lambda t} \mathbf{z}_0$$

$$(302) \quad e^{\lambda t} = 1 + \frac{\lambda t}{1!} + \frac{\lambda^2 t^2}{2!} + \dots + \frac{\lambda^n t^n}{n!} + \dots$$

$$(303) \quad \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t)$$

$$(304) \quad \dot{\mathbf{z}} = \mathbf{g}(\mathbf{z}, t)$$

case stability occurs, or $w(t)$ deviates from $u(t)$ and instability results.

Lyapunov's equation

From $w(t) = u(t) + z(t)$, a 19th–20th-century Soviet mathematician, Aleksandr Lyapunov, obtained an equation in which \mathbf{z} and \mathbf{g} are n -vectors, the derivative of \mathbf{z} with respect to t equals $\mathbf{g}(\mathbf{z}, t)$ (see 304), and $\mathbf{g}(\mathbf{0}, t) = \mathbf{0}$ for $t > 0$. To the regime $u(t)$ of the first equation (see 303) there corresponds the regime $\mathbf{z} = \mathbf{0}$ of the second equation (see 304). The origin $\mathbf{z} = \mathbf{0}$ is now considered as the basic motion and a solution $\mathbf{z}(t)$ of (304) is thought of as a disturbed motion. The terms stability of the undisturbed motion or simply the stability of the origin are used in this case.

The property $\mathbf{g}(\mathbf{0}, t) = \mathbf{0}$ for a suitable range of t characterizes the origin as a critical point of (304). It is assumed that this critical point is isolated and also that \mathbf{g} is continuous and satisfies conditions for the uniqueness of solutions of Lyapunov's equation (304) in a certain region Ω specified by $\|\mathbf{x}\| < A$, $t > 0$, in which $\|\mathbf{x}\|$ denotes the length of the vector \mathbf{x} and A denotes a positive constant. Stability is characterized by Lyapunov as follows: if for any prescribed ε , $0 < \varepsilon < A$, there exists $\delta > 0$ such that every trajectory originating within the sphere $\|\mathbf{x}\| = \delta$ always remains within the sphere $\|\mathbf{x}\| = \varepsilon$, the origin is stable (cf. Figure 20, in which these spheres are denoted by $S(\delta)$ and $S(\varepsilon)$, respectively). If every trajectory originating within $S(\delta)$ tends to 0 the origin is said to be asymptotically stable. If, however, no matter what δ is chosen, some trajectory originating from a point within $S(\delta)$ eventually reaches $S(\varepsilon)$, the origin is unstable.

Lyapunov attacked the stability problem by applying two

Figure 20: Three types of trajectories, stable as represented by Γ_1 , asymptotically stable as represented by Γ_2 , and unstable, drawn in relation to an origin and two spheres denoted by $S(\delta)$ and $S(\varepsilon)$.

distinct methods. The first, applicable only to some analytical systems, consists essentially in finding explicit series solutions convergent near the origin and considering the behaviour of this series as $t \rightarrow \infty$. The second method he used does not require the construction of explicit solutions, and for this reason that method has a greater range of validity than the first; it rests on the construction of a scalar function $V(\mathbf{x}, t)$.

For example, Lyapunov's stability states that if there can be found a positive definite function $V(\mathbf{x}, t)$ the time derivative of which taken along all the trajectories in Ω is negative or zero, then the origin is stable. Of four such theorems of Lyapunov, two refer to stability and two to instability; the latter may be replaced by a more comprehensive theorem of Četaev.

Partial differential equations

In most physical problems any dependent variable is likely to be a function of more than one independent variable. The example of a vibrating string has already been given. Another example is in the study of thermal effects in a solid body in which the temperature u may vary from point to point in the solid as well as from time to time. As a consequence, the function $u(x, y, z, t)$ is written to denote that u depends on (x, y, z) , the coordinates of a typical point, and on the time t .

If for such a function, the difference quotient, the difference between $u(a+h, b, c, \tau)$ and $u(a, b, c, \tau)$, divided by h (see 305), tends to a finite number as h tends to zero, that number is denoted by $u_x(a, b, c, \tau)$, or by $\partial u(a, b, c, \tau)/\partial x$, and is called the partial derivative with respect to x of the function $u(x, y, z, t)$ at the point (a, b, c, τ) . It measures the rate of change at that point of the function u with respect to x , the other variables remaining fixed. As the point (a, b, c, τ) varies, a new function $u_x(x, y, z, t)$ or $\partial u/\partial x$ is generated that expresses the rate of growth with x of the function u . The process can be repeated: the partial derivative of $\partial u/\partial x$ with respect to x is denoted by $\partial^2 u/\partial x^2$. Similarly the consideration of the variation of u with respect to the other variables leads to the definition of the other partial derivatives, the partial derivatives with respect to y, z , and t (see 306); and the partial derivatives with respect to x of these yield in turn the mixed derivatives of the second order in which u is differentiated twice, once with respect to each of two different variables (see 307).

When the laws of physics are applied to a situation involving a function of this kind, a relation involving the function u and its partial derivatives is often obtained. Such a relation is called a partial differential equation. For example, if $u(x, y, z, t)$ were the temperature at time t at the point (x, y, z) in a homogeneous isotropic solid, the variation of u is specified by the heat conduction equation, in which the sum of the second partial derivatives with respect to x, y , and z is proportional to the first partial derivative with respect to t (see 308). The expression on the left side of this equation arises so frequently that it is given a special name and a special symbol; it is called the Laplacian of u and is now denoted by $\Delta_3 u$.

As in the theory of ordinary differential equations, the order of a partial differential equation is defined to be the order of the derivative of highest order occurring in the equation. For example, the heat equation (see 308) is a second-order equation in four variables, an equation stating that the sum of the cube of the partial derivative of u with respect to x and the partial derivative of u with respect to y equals zero (see 309) is a first-order equation in two variables while an equation involving first partial derivatives with respect to x, y , and t with variable coefficients (see 310) is a first-order equation in three variables.

The study of partial differential equations began with the study of continuum mechanics and physics. Although there were some earlier investigations, the first proper studies of these types of equations began in the 18th century with the studies of Leonhard Euler and Jean Le Rond d'Alembert on wave motion, Pierre-Simon Laplace on potential theory, Jean-Baptiste-Joseph Fourier on the conduction of heat, and Carl Friedrich Gauss on potential

theory and electromagnetic theory. The theory of partial differential equations has always gone hand-in-hand with developments in mathematical physics and has drawn much of its strength from the association, as is seen even in the more theoretical works of pure mathematicians of distinction such as Augustin-Louis Cauchy, Bernhard Riemann, and Sofya Kovalevskaya. The growth of abstract analysis has had important repercussions on the theory of partial differential equations, and this influence has in turn suggested fruitful problems to workers in both abstract and numerical analysis.

Probably the simplest partial differential equation involving a function $u(\xi, \eta)$ of two independent variables is the one that may be verbalized as follows: the first partial derivative with respect to one of the variables equals zero (see 311), which may readily be seen to have the general solution of an arbitrary function $f(y)$ of the other variable only (see 312). A comparison with the case of ordinary differential equations in which the equation $u'(x) = 0$ has solution $u(x) = c$ illustrates the point that the role played by arbitrary constants in the theory of ordinary differential equations is taken over by arbitrary functions in the theory of partial differential equations.

Similarly, if the second mixed partial derivative of u with respect to ξ and η equals zero (see 313), then the general solution is the sum of $f(\xi)$ and $g(\eta)$, in which the functions f and g are arbitrary and are each functions of only one variable (see 314).

This statement can be extended to a general partial differential equation of order n for a function of k independent variables. Subject to a variety of restrictions that must be imposed, the general solution of such an equation depends on n arbitrary functions of $k-1$ independent variables.

PARTIAL DIFFERENTIAL EQUATIONS OF SPECIAL INTEREST

Some partial differential equations have arisen so frequently in the study of physics that they have been studied intensively. Collectively, they are known as the equations of mathematical physics, and have throughout the development of the theory of partial differential equations provided the motivation for many studies of theoretical, as well as practical, interest.

Poisson's equation. A simple linear partial differential equation of the second order is named after the 19th-century French physicist Baron Siméon-Denis Poisson. It arises in the mathematical treatment of electrostatics. Gauss's law of electrostatics states that the flux of the electric vector (E_x, E_y, E_z) out of a surface is equal to 4π times the charge contained within that surface; this leads to the relation that the sum of $\partial E_x/\partial x$, $\partial E_y/\partial y$, and $\partial E_z/\partial z$ is proportional to $\sigma(x, y, z)$ (see 315), in which σ , the density of electric charge, is assumed to be known. It is also known physically that the electrostatic field is characterized by the fact that the electric vector can be derived from a potential function u ; i.e., that there exists a function u such that each component of the electric vector equals minus the partial derivative of u with respect to that variable (see 316). The insertion of these expressions into the previous equation leads to the relation that the sum of $\Delta_3 u$ and $4\pi\sigma(x, y, z)$ equals zero (see 317), in which Δ_3 is the Laplacian operator introduced above. Poisson's equation arises also in the theory of the gravitational potential.

Laplace's equation. In the absence of electric charges the function σ of equation (317) reduces to the simpler form in which the Laplacian of u equals zero (see 318). This is called Laplace's equation. It arises also in the analysis of the irrotational motion of a perfect fluid and in the steady-state conduction of heat (see below *The diffusion equation*).

In the cylindrical coordinates (ρ, ϕ, z) Laplace's equation assumes a form that can be derived by the chain rule (see 319) in which it is more suitable for the discussion of problems involving regions bounded by cylinders. In a similar manner, in spherical polar coordinates (r, θ, ϕ) , which are used in the analysis of problems concerning regions that are bounded by spheres or cones, Laplace's equation is transformed to an expression involving partial derivatives with respect to these variables (see 320).

The wave equation. *Sound waves in space.* If, because of the passage of a sound wave, the gas at a point (x, y, z) at time t has velocity (u, v, w) and pressure p and density ρ , then for small oscillations $\rho = \rho_0(1 + s)$, $p = p_0 + c^2\rho_0 s$, in which s is the condensation of the gas and $c^2 = (dp/d\rho)_0$, and ρ_0, p_0 are the equilibrium values of ρ and p . The equations of (small) motions are that the partial derivative of each component of the velocity with respect to time equals the product of c^2 and the appropriate partial derivative of s (see 321); and the equation of continuity is to the same approximation that the sum of $\partial u/\partial x$, $\partial v/\partial y$, $\partial w/\partial z$, and $\partial s/\partial t$ equals zero (see 322). For irrotational motion there exists a function ψ with the property that each component of the velocity equals minus the appropriate partial derivative of ψ (see 323).

The above equations (see 321 and 323) are therefore equivalent to the equation that the partial derivative of $\partial\psi/\partial t - c^2 s$ with respect to each of x, y , and z is zero (see 324). The equation of continuity (322) is equivalent to the restriction that the partial derivative of s with respect to t equals the Laplacian of ψ (see 325) so that the function ψ satisfies the relation that the second partial derivative of ψ with respect to t is proportional to the Laplacian of ψ (see 326). This equation is called the three-dimensional wave equation.

It can also be shown that in the absences of charges or currents the scalar potential and each component of the vector potential of an electromagnetic field satisfy the three-dimensional wave equation with c the velocity of light.

Transverse vibrations of a membrane. If a thin elastic membrane of uniform areal density σ is stretched to a uniform tension T and if, in the equilibrium position, the membrane coincides with the xy -plane, then the small transverse vibration $u(x, y, t)$ of the point (x, y) of the membrane satisfies an equation in which the two-dimensional Laplacian of u (see 327) is proportional to the second partial derivative with respect to t (see 328), and the wave velocity c is defined by the equation $c^2 = T/\sigma$. Equation (328) is called the two-dimensional wave equation.

Transverse vibrations of a string. If a string of uniform linear density σ is stretched to a uniform tension T , and if, in the equilibrium position, the string coincides with

$$(332) \quad \frac{\partial u}{\partial t} = \frac{\partial}{\partial x} \left(\kappa \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(\kappa \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left(\kappa \frac{\partial u}{\partial z} \right)$$

the x -axis, then when the string is disturbed slightly from its equilibrium position, the transverse displacement $u(x, t)$ satisfies an equation in which the second partial derivative of u with respect to x is proportional to the second partial derivative with respect to t (see 329), with constant of proportionality $c^2 = T/\sigma$. This equation is known as the one-dimensional wave equation.

The diffusion equation. Another interesting partial differential equation arises in the analysis of the diffusion process in physical chemistry. This is a process leading to the equalization of concentrations within a single phase, and it is governed by laws relating the rate of flow of the diffusing substance with the concentration gradient causing the flow. If u is the concentration of the diffusing substance, then the diffusion current vector (c_x, c_y, c_z) is

defined by the equations in which each component of the diffusion current vector equals a quantity $-\kappa$ times the appropriate first partial derivative of u (see 330). This is known as Fick's law, named after a 19th-century German physiologist, Adolf Fick, in which κ is the diffusion coefficient for the substance under consideration.

Fick's law

The continuity for the diffusion substance takes a form (see 331) that is similar to the usual continuity equation so that the concentration $u(x, y, z, t)$ satisfies the diffusion equation (see 332) obtained by substituting Fick's law into the equation of continuity. In the most general case, the quantity κ is a function of x, y, z and of the concentration u , but if κ does happen to be a constant, the diffusion equation (332) reduces to the form of the heat conduction equation (308).

The diffusion equation (332) is satisfied also by the temperature u in a solid conducting heat; for that reason this equation is sometimes known as the heat conduction equation. In the steady-state case in which κ is constant, it follows from equation (308) with $\partial u/\partial t = 0$ that u satisfies Laplace's equation (318).

The form (308) of the diffusion equation is also satisfied by the vorticity in a viscous fluid started into motion from rest and by the electric field vector in the propagation of long waves in a good conductor.

If u depends only on one space coordinate x and the time t , the heat conduction equation (308) reduces to a form in which the second partial derivative of u with respect to x is proportional to the first partial derivative of u with respect to t (see 333); this is called the one-dimensional diffusion equation.

The Fokker-Planck equation. An equation very similar to the diffusion equation (333) is the Fokker-Planck equation (named for Adriaan Fokker and Max Planck), linearly relating a quantity P and its first and second derivatives with respect to x with its first derivative with respect to t (see 334), which reduces in the case that the coefficient D of the second derivative is equal to zero to a first-order equation with a variable coefficient of $\partial P/\partial x$ (see 335). The physical interpretation is that P is the probability that a random variable has the value x at time t . For instance, P might be the probability distribution of the deflection x of an electrical noise trace at time t .

Birth-and-death equations. Equations similar to the Fokker-Planck equation arise in the theory of birth and death processes in bacterial populations. If it is assumed that the probability of the birth or death of a bacterium is proportional to the number present, and if $P_n(t)$ is the probability of there being n bacteria in the population at time t , the probability generating function $u(z, t)$ defined by a power series in z with the n th term having coefficient $P_n(t)$ (see 336) satisfies a partial differential equation in which $\partial u/\partial t$ equals a quadratic in z , with constants λ and μ , times $\partial u/\partial z$ (see 337).

Similar equations arise in birth-and-death problems in which different physical assumptions are made and in discussions of the probability distribution of telephone conversations carried on over a certain number of telephone lines.

Schrödinger's equation. In wave mechanics the wave function ψ of a single particle such as an electron has the physical interpretation that $|\psi(x, y, z)|^2 d\tau$ is the probability that the electron will be found in a small element of volume $d\tau$ the centre of which is at the point with coordinates (x, y, z) . In the steady-state case the variation of ψ throughout a field the potential energy of which is $V(x, y, z)$ is described by Schrödinger's equation involving m , the mass of the particle, h , Planck's constant, and E , the total energy of the particle and linearly relating the Laplacian of ψ and the quantity $(E - V)\psi$ (see 338).

Higher-order equations in physics. The above equations are—with the exception of one or two first-order equations—all of the second order. It is therefore important to notice that not all physical problems can be formulated in terms of partial differential equations of the second order.

For instance, a state of plane strain in a two-dimensional solid free from body forces can be specified by three stress components σ_{xx} , σ_{xy} , and σ_{yy} , that satisfy equilibrium conditions that can be stated as first-order linear partial differ-

$$(333) \quad \frac{\partial^2 u}{\partial x^2} = \frac{1}{\kappa} \frac{\partial u}{\partial t}$$

$$(334) \quad \frac{\partial P}{\partial t} = \beta \frac{\partial}{\partial x}(xP) + D \frac{\partial^2 P}{\partial x^2}$$

$$(335) \quad \frac{\partial P}{\partial t} = \beta P + \beta x \frac{\partial P}{\partial x}$$

$$(336) \quad u(z, t) = \sum_{n=0}^{\infty} P_n(t) z^n$$

$$(337) \quad \frac{\partial u}{\partial t} = (z-1)(\lambda z - \mu) \frac{\partial u}{\partial z}$$

$$(338) \quad \Delta_3 \psi + \frac{8\pi^2 m}{h^2} (E - V) \psi = 0$$

$$(339) \quad \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y} = 0, \quad \frac{\partial \sigma_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} = 0$$

$$(340) \quad \sigma_{xx} = \frac{\partial^2 \psi}{\partial y^2}, \quad \sigma_{xy} = -\frac{\partial^2 \psi}{\partial x \partial y}, \quad \sigma_{yy} = \frac{\partial^2 \psi}{\partial x^2}$$

$$(341) \quad \frac{\partial^2}{\partial y^2} \{ \sigma_{xx} - \eta(\sigma_{xx} + \sigma_{yy}) \} \\ + \frac{\partial^2}{\partial x^2} \{ \sigma_{yy} - \eta(\sigma_{xx} + \sigma_{yy}) \} = 2 \frac{\partial^2 \sigma_{xy}}{\partial x \partial y}$$

$$(342) \quad \frac{\partial^4 \psi}{\partial x^4} + 2 \frac{\partial^4 \psi}{\partial x^2 \partial y^2} + \frac{\partial^4 \psi}{\partial y^4} = 0$$

$$(343) \quad \left(\frac{1}{2} \sigma_{xx} - \frac{1}{2} \sigma_{yy} \right)^2 + \sigma_{xy}^2 = k^2$$

$$(344) \quad \left(\frac{\partial^2 \psi}{\partial x^2} - \frac{\partial^2 \psi}{\partial y^2} \right)^2 + 4 \frac{\partial^4 \psi}{\partial x^2 \partial y^2} = 4k^2$$

The Airy
stress
function

ential equations (see 339). If σ_{xx} , σ_{xy} , and σ_{yy} are equal to the appropriate second partial derivatives of any arbitrary function ψ , then they satisfy the equilibrium conditions (see 340) and ψ is called an Airy stress function (after the 19th-century British astronomer George Biddell Airy).

If the body is elastic, the components of stress satisfy compatibility equations involving the second partial derivatives of σ_{xx} , σ_{xy} , and σ_{yy} (see 341), from which it follows that $\psi(x, y)$ satisfies a fourth-order linear equation that can be written $\Delta_2 \Delta_2 \psi = 0$ and is called the two-dimensional biharmonic equation (see 342). (The reason for this is that Laplace's equation is sometimes referred to as the harmonic equation.)

If, instead of being elastic, the body is perfectly plastic, then the stress components satisfy the quadratic condition; this quadratic condition is known as the Hercky-Mises condition (see 343). Hence, the Airy stress function satisfies a fourth-order nonlinear partial differential equation (see 344). (I.N.S./Ed.)

CLASSIFICATION OF PARTIAL DIFFERENTIAL EQUATIONS

In classification, a partial differential equation governing a dependent variable u is said to be linear if u and its partial derivatives occur only to the first power. For example, if second-order equations in two independent variables x and y are considered, then a linear equation involves a sum of u and its first and second derivatives, with coefficients a, b, c, f, g, h , and k that are functions of x and y only (see 345).

The solution of a nonlinear equation is considerably more difficult to obtain than is the solution of a linear

equation; general methods of solution have been devised, however, for two special types of nonlinearity. A nonlinear equation in which the partial derivatives of u occur linearly—but in which u itself does not do so (see 346)—is said to be quasi-linear, whereas, on the other hand, an equation that is linear in only the highest order derivatives (see 347) is said to be semilinear.

First-order equations. There is a particular kind of nonlinear equation of the first order in which the product a and $\partial u / \partial x$ is added to the product of b and $\partial u / \partial y$ to yield c (see 348), in which a, b , and c are functions not only of x and y but of u also. This type of equation has been investigated by the 18th-century French mathematician Joseph-Louis Lagrange.

The general solution of this equation is $F(\xi, \eta) = 0$, in which F is an arbitrary function of two variables and $\xi(x, y, u) = C_1$ and $\eta(x, y, u) = C_2$ form a solution of the simultaneous ordinary differential equations expressed by equating the ratios of dx to a , dy to b , and du to c (see 349). For example, because a system of equations of this form with x^2 for a , y^2 for b , and $(x+y)u$ for c (see 350) has solution $xy/u = c_1$, $(x-y)/u = c_2$, it follows that the general solution of the equation with these terms for a, b , and c (see 351) is $F(xy/u, (x-y)/u) = 0$, in which the function F is arbitrary.

The problem of solving a general nonlinear equation of the first order $f(x, y, u, u_x, u_y) = 0$ in which the function f is not linear in u_x and u_y is more difficult. It turns out that there are three classes of integrals of an equation of this type:

Classes of
integrals in
first-order
equations

1. The first class involves two-parameter systems of surfaces $F(x, y, u, a, b) = 0$; such an integral is called a complete integral.

$$(345) \quad a \frac{\partial^2 u}{\partial x^2} + 2b \frac{\partial^2 u}{\partial x \partial y} + c \frac{\partial^2 u}{\partial y^2} + f \frac{\partial u}{\partial x} + g \frac{\partial u}{\partial y} + hu = k$$

$$(346) \quad a \frac{\partial^2 u}{\partial x^2} + 2b \frac{\partial^2 u}{\partial x \partial y} + c \frac{\partial^2 u}{\partial y^2} + f \frac{\partial u}{\partial x} + g \frac{\partial u}{\partial y} + h(x, y, u)$$

$$(347) \quad a \frac{\partial^2 u}{\partial x^2} + 2b \frac{\partial^2 u}{\partial x \partial y} + c \frac{\partial^2 u}{\partial y^2} = f\left(x, y, u, \frac{\partial u}{\partial x}, \frac{\partial u}{\partial y}\right)$$

$$(348) \quad a \frac{\partial u}{\partial x} + b \frac{\partial u}{\partial y} = c$$

$$(349) \quad \frac{dx}{a} = \frac{dy}{b} = \frac{du}{c}$$

$$(350) \quad \frac{dx}{x^2} = \frac{dy}{y^2} = \frac{du}{(x+y)u}$$

$$(351) \quad x^2 \frac{\partial u}{\partial x} + y^2 \frac{\partial u}{\partial y} = (x+y)u$$

$$(352) \quad u^2(1 + u_x^2 + u_y^2) = 1$$

$$(353) \quad \begin{cases} F(D, D')z = f(x, y) \\ F(D, D') = \sum_r \sum_s c_{rs} D^r D'^s, \quad D = \frac{\partial}{\partial x}, \quad D' = \frac{\partial}{\partial y} \end{cases}$$

$$(354) \quad \sum_{s=1}^n x^{s-1} \phi_s(ax-y) e^{-bx}$$

$$(355) \quad F(D, D') e^{ax+by} = F(a, b) e^{ax+by}$$

$$(356) \quad \sum_{n=0}^{\infty} c_n \cos(nx + \varepsilon_n) e^{-\kappa n^2 t}$$

2. If any one-parameter subsystem $F(x, y, u, a, \varphi(a)) = 0$ is taken and its envelope is formed (by eliminating a from the equations $F = 0, F_a = 0$), a general integral is obtained.
3. If the envelope of the complete integral in (1) (obtained by eliminating a, b from the equations $F = 0, F_a = 0, F_b = 0$) exists, a singular integral of the equation is obtained.

For example, there is the equation in which the sum of 1, u_x^2 , and u_y^2 , which, when multiplied by u^2 (see 352), has the complete integral $(x-a)^2 + (y-b)^2 + u^2 = 1$. If $b = a$ and if the envelope of the resulting subsystem of spheres is written, then the general integral $(x-y)^2 + 2u^2 = 2$ is obtained; moreover, because the envelope of the complete integral consists of the planes $u = \pm 1$, then it follows that $u = 1$ and $u = -1$ are both singular integrals of the equation.

Solutions of nonlinear first-order equations are usually obtained by a method known as Charpit's method, which is too complicated to be described here. The solutions of some special types are, however, easily derived.

If the equation is of the type $f(u_x, u_y) = 0$ —i.e., if it involves only the derivatives u_x, u_y —the complete integral is $u = ax + Q(a)y + b$, in which a and b are arbitrary constants and $q = Q(a)$ is the solution of the algebraic equation $f(a, q) = 0$.

If the equation is of the type $f(u, u_x, u_y) = 0$, u_x and u_y are found by solving the equations $f(u, u_x, u_y) = 0$, $u_x = au_y$ and then determining $u(x, y)$ from the equation $du = u_x dx + u_y dy$.

A separable equation $f(x, u_x) = g(y, u_y)$ is solved by determining u_x and u_y from the equations $f(x, u_x) = a$ and $g(y, u_y) = a$, respectively, and finding u as in the last case.

Clairaut equations

And, finally, there are Clairaut equations, $u = xu_x + yu_y + f(u_x, u_y)$, which have complete integrals $u = ax + by + f(a, b)$.

Linear equations with constant coefficients. Linear partial differentials with constant coefficients can be solved simply. Such an equation can be written in the form of an equality between a linear combination of derivatives $F(D, D')z$ and $f(x, y)$, a function of x and y (see 353). Any solution of the equation is called a particular integral and the most general solution of the corresponding homogeneous equation $F(D, D')z = 0$ is called the complementary function of the equation; if z_1 is a particular integral and u is the complementary function, the general solution is $u + z_1$. It follows from the linearity of the operator F that, if u_1, u_2, \dots, u_n are solutions of $Fz = 0$, then $\sum_{i=1}^n c_i u_i$, in which the c_i 's are arbitrary constants, is also a solution.

The operators $F(D, D')$ are classified into two main types: $F(D, D')$ is reducible if it can be written as the product of linear factors of the form $D + aD' + b$ with a, b constants; if it cannot be written in such a form, then $F(D, D')$ is said to be irreducible.

The form of the complementary function in the reducible case follows from the fact that, if $(D + aD' + b)^n$ is a factor of (D, D') and if the functions $\varphi_1, \varphi_2, \dots, \varphi_n$ are arbitrary, then a sum involving these functions and an exponential (see 354) is a solution of $F(D, D') = 0$. When F is irreducible it is not always possible to find a solution with the full number of arbitrary functions, but it is possible to construct solutions that contain as many arbitrary constants as are required. The method of deriving such solutions depends on the result of differentiating an exponential (see equation 355) so that e^{ax+by} is a solution of $F(D, D') = 0$, provided that a and b are connected through the equation $F(a, b) = 0$. In this manner it is possible to construct a solution of the homogeneous equation that contains as many arbitrary constants as may be required.

For example, the one-dimensional diffusion equation (see 333) has a solution $\exp(ax + bt)$ only if $b = a^2\kappa$, and this relation is satisfied if $a = \pm i\kappa n$ and $b = -\kappa n^2$ are taken. In this way solutions of the diffusion equation can be constructed as the sum of terms each of which is the product of a cosine and an exponential and involving constants c_n and ε_n (see 356).

Semilinear equations of the second order with variable coefficients. Next in order of complexity to an equation with constant coefficients is a semilinear second-order equation (see 347). This equation is reduced to canonical form by changing the independent variables from x, y to ξ, η . The choice of ξ and η is dictated by the nature of the roots $\lambda_1(x, y), \lambda_2(x, y)$ of the quadratic equation $a\lambda^2 + 2b\lambda + c = 0$. There are three cases to be considered, depending on the sign of the discriminant Δ defined by the equation $\Delta = b^2 - ac$:

(i) $\Delta > 0$: If for every (x, y) in a region Ω of the xy -plane, $\Delta > 0$, the roots λ_1, λ_2 are real and distinct. If ξ and η are now chosen to be such that $\xi(x, y) = c_1$ and $\eta(x, y) = c_2$ are, respectively, the integral curves of the ordinary differential equations $y' + \lambda_1(x, y) = 0$ and $y' + \lambda_2(x, y) = 0$, the equation is transformed to the canonical form in which the second mixed partial derivative equals some function of ξ, η, u and the first partial derivatives of u (see 357). In this case the equation is said to be hyperbolic in the region Ω . The curves $\xi(x, y) = c_1, \eta(x, y) = c_2$ are called the characteristic curves of the equation, or, more simply, the characteristics of the equation. An equation that is hyperbolic in a region Ω , therefore, has two families of characteristics in that region.

For example, an equation in which the coefficient of du/dx is $1/x$ and the coefficient of $\partial^2 u/\partial y^2$ is x^2 (see 358) is hyperbolic at all points in the xy -plane, has the two families of characteristics $x^2/2 + y = \text{constant}$ and canonical form with the second mixed partial equal to zero (see 359). On the basis of past equations, it becomes apparent that this equation has the general solution $u = f(\xi) + g(\eta)$, and thus the original equation has the general solution

The three types of semilinear second-order equations

$$(357) \quad \frac{\partial^2 u}{\partial \xi \partial \eta} = h\left(\xi, \eta, u, \frac{\partial u}{\partial \xi}, \frac{\partial u}{\partial \eta}\right)$$

$$(358) \quad \frac{\partial^2 u}{\partial x^2} - \frac{1}{x} \frac{\partial u}{\partial x} = x^2 \frac{\partial^2 u}{\partial y^2}$$

$$(359) \quad \frac{\partial^2 u}{\partial \xi \partial \eta} = 0$$

$$(360) \quad \frac{\partial^2 u}{\partial \eta^2} = h\left(\xi, \eta, u, \frac{\partial u}{\partial \xi}, \frac{\partial u}{\partial \eta}\right)$$

$$(361) \quad \frac{\partial^2 u}{\partial x^2} + 2 \frac{\partial^2 u}{\partial x \partial y} + \frac{\partial^2 u}{\partial y^2} = 0$$

$$(362) \quad \frac{\partial^2 u}{\partial \eta^2} = 0$$

$$(363) \quad u = (x + y)f(x - y) + g(x - y)$$

$$(364) \quad a = \frac{1}{2}(\xi + \eta), \quad \beta = \frac{1}{2}i(\eta - \xi)$$

$$(365) \quad \frac{\partial^2 u}{\partial a^2} + \frac{\partial^2 u}{\partial \beta^2} = k\left(a, \beta, u, \frac{\partial u}{\partial a}, \frac{\partial u}{\partial \beta}\right)$$

$$(366) \quad \frac{\partial^2 u}{\partial x^2} + x^2 \frac{\partial^2 u}{\partial y^2} = 0$$

$$(367) \quad \frac{\partial^2 u}{\partial a^2} + \frac{\partial^2 u}{\partial \beta^2} + \frac{1}{2a} \frac{\partial u}{\partial a} = 0$$

$$(368) \quad u(0, t) = 0, \quad u(a, t) = 0, \quad t > 0$$

$$(369) \quad u(x, 0) = f(x), \quad u_x(x, 0) = g(x), \quad 0 < x < a$$

$$(370) \quad u_{xy} = f(x, y, u, u_x, u_y)$$

$u = f(x^2/2 + y) + g(x^2/2 - y)$, in which the functions f and g are arbitrary.

(ii) $\Delta = 0$: The function ξ is defined in precisely the same way as in case (i), and η is taken to be any function of x and y that is independent of ξ . The canonical form of the equation in this case has the second partial derivative with respect to η equal to a function of ξ , η , u and the first partial derivatives of u (see 360). An equation of this type is said to be parabolic.

For example, an equation in which twice the second mixed partial derivatives is added to the other two second partial derivatives to give a result of zero (see 361) is parabolic. If $\xi = x - y$ and $\eta = x + y$, it is found that it reduces to the canonical form in which the second partial derivative with respect to η equals zero (see 362), with solution $u = \eta f(\xi) + g(\xi)$, in which f and g are arbitrary functions. The solution of the original equation is therefore obtained by substituting the appropriate quantities for η and ξ in this expression (see 363).

(iii) $\Delta < 0$: In this case the roots λ_1 and λ_2 are complex conjugates so that if ξ and η are chosen as in case (i) they will be complex-valued functions of the real variables x and y . In terms of this pair of functions ξ , η another pair α , β are defined as a linear combination of ξ and η involving complex numbers (see 364). When transformed to the new independent variables, the equation takes the canonical form in which the second partial derivative with respect to α , when added to the second partial derivative with respect to β , equals some function of α , β , u , and the first partial derivatives of u (see 365). Such an equation is said to be of elliptic type.

For example, an equation in which the second partial derivative with respect to x , when added to the product of x^2 and the second partial derivative with respect to y , gives zero (see 366) is elliptic throughout the whole xy -plane. If the method in (i) is used, then it is found that $\xi = x^2/2 + iy$ and $\eta = x^2/2 - iy$ may be taken, and hence $\alpha = x^2/2$, $\beta = y$. Transforming to these new variables, the equation has the canonical form with the function being the product of $-1/(2a)$ and the first partial derivative with respect to α (see 367).

INITIAL VALUE AND BOUNDARY VALUE PROBLEMS

In applications of partial differential equations, the concern is not so much with determining the general solution of an equation as with finding the solution that satisfies some other prescribed conditions. Problems involving the solution of a partial differential equation and the fulfillment of additional conditions have been classified into the following types. Only second-order equations in two independent variables will be considered.

Initial value problems. The classic case of an initial value problem arises in the discussion of the transverse oscillations of a stretched string. The transverse displacement $u(x, t)$ satisfies the partial differential equation (329) for $0 < x < a$, $t > 0$, in which a denotes the length of the string. Because the string is assumed to be fixed at its ends, $u(0, t)$ and $u(a, t)$ must both equal zero for all positive values of t (see 368), and if the problem is that of determining the subsequent shape of the string when its initial shape and velocity are prescribed, the function u must satisfy equations in which $u(x, 0)$ and $u_x(x, 0)$ equal prescribed functions $f(x)$ and $g(x)$ (see 369).

These particular equations—that is, (329), (368), and (369)—describe a problem that is analogous to an initial value problem in the theory of differential equations. Arguing from this fact and also from physical intuition, one would expect to realize the existence of a unique solution $u(x, t)$. Because u satisfies the boundary conditions (368) as well as the initial conditions (369), the present problem is said to be a mixed initial and boundary value problem.

A different example is provided by solutions of the heat conduction equation (see 333). Here, on physical grounds, it would be expected that a unique function $u(x, t)$ would be determined by the boundary conditions (see 368) and the single initial condition $u(x) = f(x)$, $0 < x < a$.

Cauchy problems. A generalization of the initial value problems considered above is Cauchy's problem. This is best described for a hyperbolic equation in canonical form

with independent variables x and y (see 370). The Cauchy problem for this equation consists of finding a solution u with the property that prescribed values $u = u(s)$, $u_x = p(s)$, $u_y = q(s)$ are assumed along a given curve with parametric equations $x = x(s)$, $y = y(s)$. Because u , p , q must satisfy the compatibility equation found by the chain rule (see 371), p and q cannot be assigned independently. The values of u and its normal derivative $\partial u / \partial n$ on the curve are in fact sufficient for the specification of u , p , and q . These quantities are referred to as the Cauchy data.

Dirichlet problems. The first boundary value problem, also called the Dirichlet problem, consists of finding a solution $u(x, y)$ of an elliptic equation in a region Ω of the xy -plane that takes on prescribed values on the boundary of Ω .

Neumann problems. The second boundary value problem for an elliptic partial differential equation in a region Ω consists in finding a solution that possesses a prescribed normal derivative $\partial u / \partial n = f$ on the boundary B of Ω .

$$(371) \quad \frac{du}{ds} = p(s) \frac{dx}{ds} + q(s) \frac{dy}{ds}$$

$$(372) \quad \int_B f ds = 0$$

$$(373) \quad \frac{\partial u}{\partial n} + au = f$$

$$(374) \quad \begin{cases} \frac{\partial u}{\partial x} + a_{11} \frac{\partial u}{\partial y} + a_{12} \frac{\partial v}{\partial y} = b_1 \\ \frac{\partial v}{\partial x} + a_{21} \frac{\partial u}{\partial y} + a_{22} \frac{\partial v}{\partial y} = b_2 \end{cases}$$

$$(375) \quad (a_{11} - \lambda)(a_{22} - \lambda) - a_{21}a_{12} = 0$$

$$(376) \quad \begin{cases} D_1 u + (\lambda_1 - a_{11}) D_1 v = b_1 + (\lambda_1 - a_{11}) b_2 \\ D_2 u + (\lambda_2 - a_{11}) D_2 v = b_1 + (\lambda_2 - a_{11}) b_2 \end{cases}$$

$$(377) \quad D_j = \frac{\partial}{\partial x} + \lambda_j \frac{\partial}{\partial y}, \quad j = 1, 2$$

$$(378) \quad \frac{dy}{dx} = \lambda_j(x, y), \quad j = 1, 2$$

$$(379) \quad U = \begin{bmatrix} u \\ v \end{bmatrix}, \quad A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}, \quad B = \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}$$

$$(380) \quad U_x + AU_y = B$$

$$(381) \quad \det(A - \lambda J) = 0$$

$$(382) \quad \sum_{k=1}^m c_{jk} D_j U_k + \sum_{k=1}^m c_{jk} b_k = 0, \quad j = 1, 2, \dots, m$$

$$(383) \quad U_x = AU_y$$

$$(384) \quad u(x, y, \dots, t) = X(x)Y(y) \dots T(t)$$

$$(385) \quad c^2 X''(x)/X(x) = T''(t)/T(t)$$

$$(386) \quad X''(x) + \lambda X(x) = 0, \quad T''(t) + c^2 \lambda T(t) = 0$$

Transverse
oscillations
of a
stretched
string

It is often called a Neumann problem. It turns out the Neumann problem cannot be solved for Laplace's equation $u_{xx} + u_{yy} = 0$ unless the prescribed function f satisfies the condition that the integral of f around the boundary equals zero (see 372).

Robin problems. The third boundary value problem, or Robin problem (Gustave Robin, 1855–97), for an elliptic partial differential equation in a region Ω consists of finding a solution u of the equation satisfying the condition that the sum of au and the normal derivative of u equal f (see 373) at all points of the boundary of Ω , a and f being prescribed.

SYSTEMS OF PARTIAL DIFFERENTIAL EQUATIONS

In many applications it is necessary to consider a pair of first-order equations, each involving one partial derivative with respect to x and two partial derivatives with respect to y (see 374) with coefficients of the partial derivatives with respect to y being a_{11} , a_{12} , a_{21} , a_{22} , which are functions of x and y and b_1 , b_2 are functions of x , y , u . The first stage in solving equations of this type is to transform the system into one in which each equation involves differentiations in one direction only.

If a certain quadratic equation in λ formed from a_{11} , a_{22} , a_{12} , and a_{21} (see 375) has two real distinct roots $\lambda_1(x, y)$, $\lambda_2(x, y)$, the system can be transformed to a pair of equations, each involving only one differentiation operator D_j (see 376), in which D_j is the operator of differentiation consisting of differentiation with respect to x added to the product of λ_j and differentiation with respect to y (see 377) in the direction defined by an ordinary differential equation in which the derivative of y equals λ_j (see 378). It should be emphasized that this reduction is possible if, and only if, the equation (375) has two distinct real roots.

When this is the case, the system is said to be of hyperbolic type. On the other hand, if the roots of (375) are complex, the system is of elliptic type. The two families of curves in the xy -plane defined by the ordinary differential equations (378) are called the characteristics of the system.

If the column vector U , with elements u and v , the column vector B , with elements b_1 and b_2 , and the square matrix A , with elements a_{11} , a_{12} , a_{21} , and a_{22} (see 379), are introduced, the system may be written as a matrix equation relating the partial derivatives U_x and U_y (see 380) and the equation in λ (see 375) as an equation stating that the determinant of $A - \lambda I$ is zero (see 381). It is now an easy matter to generalize the system being considered (see 380) by taking U , B to be column vectors with m components and A is a matrix with m rows and m columns. The determinant equation (381) now has m roots. If these roots are real and distinct the system can be transformed to m equations, each involving only one differentiation operator D_j (see 382). The only change in the interpretation is that the equations defining D_j (377 and 378) now hold for $j = 1, 2, \dots, m$. Again the system (380) is hyperbolic.

A quasi-linear second-order partial differential equation can be replaced by a system of the type in which the partial derivative of U with respect to x equals the matrix product of A and the partial derivative of U with respect to y (see 383), in which U has eight components and A is an 8×8 matrix.

TECHNIQUES OF SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS

Separation of variables. One of the oldest techniques for the solution of a linear partial differential equation for a function u of the independent variables x, y, \dots, t is to assume a solution that is a product of $X(x), Y(y), \dots, T(t)$ of functions of one variable (see 384) and by substituting in the original equation to obtain ordinary differential equations for the functions X, Y, \dots, T .

For example, if u satisfies the one-dimensional wave equation (see 329), the equation has solutions of the type $u(x, t) = X(x)T(t)$ if X and T can be chosen such that the ratio of $X''(x)$ to $X(x)$ is proportional to the ratio of $T''(t)$ to $T(t)$ (see 385). Because the left side of this equation is a function of x alone and the right side is a function of t alone, the two can be equal for all values of x and t

if, and only if, each is equal to a constant $-\lambda c^2$, say; i.e., it is necessary that X and T satisfy second-order linear differential equations with constant coefficients (see 386).

The value of λ is determined by the boundary conditions. For example, if the boundary conditions are that $u(0, t) = u(a, t) = 0$ for all values of $t > 0$, they are satisfied if $X(0) = X(a) = 0$. This is possible only if $\lambda = n^2\pi^2/a^2$, $n = 1, 2, \dots$, when $X(x) = \sin(n\pi x/a)$. If in addition $u(x, 0) = 0$, then $T'(0) = 0$ also; i.e., $T(t) = \cos(n\pi ct/a)$; thus a solution of the equation (329) in the form of a function $u_n(x, t)$ equaling the product of a cosine and a sine, involving t and x respectively (see 387), is obtained. This technique is called separation of variables.

Quite complicated solutions can be constructed by combining this method with the principle of linear superposition. For example, an infinite linear combination of the $u_n(x, t)$, with coefficients c_n (see 388) with u_n given above (see 387), will be a solution of the wave equation (see 329) for $0 \leq x \leq a$, $t \geq 0$, satisfying the boundary conditions $u(0, t) = u(a, t) = 0$ and the initial conditions

Principle
of linear
super-
position

$$(387) \quad u_n(x, t) = \cos\left(\frac{n\pi ct}{a}\right) \sin\left(\frac{n\pi x}{a}\right)$$

$$(388) \quad u(x, t) = \sum_{n=1}^{\infty} c_n u_n(x, t)$$

$$(389) \quad f(x) = \sum_{n=1}^{\infty} c_n \sin\left(\frac{n\pi x}{a}\right)$$

$$(390) \quad u_{xx} + u_{yy} = 0$$

$$(391) \quad u(x, y) = \int_0^{\infty} F(\xi) \frac{\sinh(\xi y)}{\sinh(\xi a)} \sin(\xi x) d\xi$$

$$(392) \quad f(x) = \int_0^{\infty} F(\xi) \sin(\xi x) d\xi$$

$$(393) \quad \begin{cases} \mathfrak{L}[u(x, p)] = \int_0^{\infty} u(x, t) e^{-pt} dt \\ \mathfrak{L}[f(p)] = \int_0^{\infty} f(t) e^{-pt} dt \end{cases}$$

$$(394) \quad I(u) = \int_V F(x, y, z, u, u_x, u_y, u_z) dt$$

$$(395) \quad \frac{\partial F}{\partial u} = \frac{\partial}{\partial x} \left(\frac{\partial F}{\partial u_x} \right) + \frac{\partial}{\partial y} \left(\frac{\partial F}{\partial u_y} \right) + \frac{\partial}{\partial z} \left(\frac{\partial F}{\partial u_z} \right)$$

$$(396) \quad I(u) = \int_V [u_x^2 + u_y^2 + u_z^2] d\tau$$

$$(397) \quad \begin{cases} u_{xx} + u_{yy} + u_{zz} = 0 & \text{within } V \\ u = f, & \text{on } S \end{cases}$$

$$(398) \quad \frac{\partial^2 u}{\partial x^2} - \epsilon \frac{\partial^4 u}{\partial x^4} = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}$$

$$(399) \quad X''(x) - \epsilon X^{(4)}(x) + \lambda X(x) = 0$$

$$(400) \quad \mathbf{L}(\epsilon) = \mathbf{L}(0) + \epsilon \mathbf{L}^{(1)} + \epsilon^2 \mathbf{L}^{(2)} + \dots$$

$$(401) \quad \begin{cases} X_n = X_n^{(0)}(x) + \epsilon X_n^{(1)}(x) + \epsilon^2 X_n^{(2)}(x) + \dots \\ \lambda_n = \lambda_n^{(0)} + \epsilon \lambda_n^{(1)} + \epsilon^2 \lambda_n^{(2)} + \dots \end{cases}$$

Hyperbolic
type and
elliptic
type

$u(x, 0) = f(x)$, $u_x(x, 0) = 0$ if an infinite sequence of constants c_1, c_2, \dots can be found such that $f(x)$ can be written as an infinite series with terms $c_n \sin(n\pi x/a)$ (see 389). This leads to a consideration of the theory of Fourier series (see below *Fourier analysis*). It should also be observed that the values $\lambda_n = n^2\pi^2/a^2$, $n = 1, 2, \dots$, are called the eigenvalues of the stated problem.

Integral transform solutions. Closely related to the method of separation of variables is the method of integral transforms. To illustrate the method, the solution of Laplace's equation in two dimensions (see 390) is considered in the semi-infinite strip $x \geq 0$, $0 \leq y \leq a$, when u satisfies the boundary conditions $u(0, y) = 0$, $u(x, y) \rightarrow 0$ as $x \rightarrow \infty$, $0 \leq y \leq a$ and $u(x, 0) = 0$, $u(x, a) = f(x)$.

The method of separation of variables then gives a solution of the form $\sin(\xi x) \sinh(\xi y)$, in which ξ is any constant. By the superposition principle such a solution, when multiplied by $F(\xi)/\sinh(\xi a)$ and integrated from zero to infinity (see 391), will be the required solution if a function F can be found with the property that for all $x > 0$, $f(x)$ equals the integral from zero to infinity of $F(\xi) \sin(\xi x)$ (see 392). This leads to a consideration of the theory of Fourier integrals. The Fourier sine transform of $f(x)$ is $F(\xi)$.

Probably the best-known example of an integral transform is the Laplace transform, which was considered earlier. To illustrate its use, the solution of the one-dimensional diffusion equation (see 333) is considered in the range $x \geq 0$, $t \geq 0$, and satisfying the conditions $u(x, 0) = 0$, $u(0, t) = f(t)$, $u(x, t) \rightarrow 0$ as $x \rightarrow \infty$. If the Laplace transforms $\mathfrak{L}[u(x, p)]$ of $u(x, t)$ and $\mathfrak{L}[f(p)]$ of $f(t)$ (see 393) are introduced, then it is easily shown that $\mathfrak{L}[u(x, p)] = \mathfrak{L}[f(p)] \exp[-x\sqrt{(p/k)}]$; thus the required solution is the function the Laplace transform of which is $\mathfrak{L}[f(p)] \exp[-x\sqrt{(p/k)}]$. The solution can be found by means of the inversion theorem, which gives a method of finding a function the Laplace transform of which is prescribed.

Variational methods. Approximate solutions of partial differential equations can often be obtained by using the fact that the function u that makes a certain integral an extremum satisfies a partial differential equation.

To illustrate the procedure, the function $u(x, y, z)$ is considered that makes the volume integral $I(u)$ of a function $F(x, y, z, u, u_x, u_y, u_z)$ of the coordinates, u , and its first partial derivatives (see 394), an extremum with respect to twice-differentiable functions that assume prescribed values at all points of the boundary S of V . This must satisfy the Euler-Lagrange equation (see 395). Hence, the solution of the Dirichlet problem for the Euler-Lagrange equation (395) is the function u that takes prescribed values on S and makes $I(u)$ an extremum. The value of this observation lies in the fact that in certain cases direct methods may produce a solution of the extremal problem.

For example, from among the functions that have continuous second derivatives in V and on S and take on the prescribed values f on S , that function which makes the integral of the squares of the first derivatives (see 396) an extremum is the solution of the Dirichlet problem for Laplace's equation (see 397). This is known as Dirichlet's principle.

Perturbation methods. Perturbation theory was created by a British physicist, Lord Rayleigh (John William Strutt), in the 19th century. He gave a formula for computing the natural frequencies and modes of a vibrating system the physical characteristics of which differ slightly from those of a simpler system the behaviour of which is completely known. In terms of the method of separation of variables, a differential equation of the form $[L(\varepsilon) + \lambda]X = 0$ has to be solved, subject to certain boundary conditions, $L(\varepsilon)$ being a differential operator containing a small numerical parameter ε , when the eigenvalues and eigenfunctions of $[L(0) + \lambda]X = 0$ with the same boundary conditions, are known.

For example, the method of separation of variables applied to the one-dimensional wave equation with an additional term of the product of ε and the fourth partial derivative of u with respect to x (see 398) leads to the perturbed form of the first of the separated equations (386), a fourth-order linear ordinary differential equation (see 399).

The perturbation method consists essentially in expanding $L(\varepsilon)$ in powers of ε with coefficients L^1, L^2, \dots , which are differential operators (see 400) and assuming that X_n and λ_n can also be expanded in powers of ε , in which $X_n^{(0)}(x)$ is the eigenfunction corresponding to the eigenvalue $\lambda_n^{(0)}$ of the unperturbed problem (see 401).

Approximate solutions. One of the most frequently used methods of obtaining approximate solutions of partial differential equations is the method of finite differences, which consists essentially in replacing each partial derivative by a difference quotient. To be specific, the case of a function $u(x, t)$ of two independent variables x and t is considered. If the value of u were known at each point (rh, sk) in which r and s are integers and h and k are small positive quantities, an approximation could be made to the partial derivative $\partial u/\partial x$ at the point (rh, sk) by the difference quotient formed by taking the difference between $u_{r+1, s}$ and $u_{r, s}$ and dividing by h (see 402) in which $u_{r, s} \equiv u(rh, sk)$, and the second derivative $\partial^2 u/\partial x^2$ by applying the process again to the difference quotient just obtained (see 403). By applying the same process (see 404), it is possible to find suitable approximations for $\partial u/\partial t$ and $\partial^2 u/\partial t^2$.

One possible finite-difference approximation to the one-dimensional diffusion equation (see 333) is therefore found by replacing the derivatives by the appropriate difference quotients (see 405), and the equation can be solved for $u_{r, s+1}$, with $\rho = k/h^2$. This gives a formula by means of which the unknown $u_{r, s+1}$ might be determined at the $(r, s+1)$ mesh point in terms of the known functions along the s th row. In this way the unknown values of u can be calculated along the first row, $t = k$, in terms of the known boundary values along $t = 0$. The values along

$$(402) \quad \frac{u_{r+1, s} - u_{r, s}}{h}$$

$$(403) \quad \frac{u_{r+1, s} - 2u_{r, s} + u_{r-1, s}}{h^2}$$

$$(404) \quad \begin{cases} \frac{u_{r, s+1} - u_{r, s}}{k} \\ \frac{u_{r, s+1} - 2u_{r, s} + u_{r, s-1}}{k^2} \end{cases}$$

$$(405) \quad \begin{cases} \frac{u_{r, s+1} - u_{r, s}}{k} = \kappa \frac{u_{r+1, s} - 2u_{r, s} + u_{r-1, s}}{h^2} \\ u_{r, s+1} = u_{r, s} + \kappa \rho (u_{r-1, s} - 2u_{r, s} + u_{r+1, s}) \end{cases}$$

$$(406) \quad u_x = A(u)u_y \quad u(0, y) = h(y)$$

$$(407) \quad \int_{\Phi} f(x, y) \frac{\partial^{r+s} \varphi}{\partial x^r \partial y^s} dx dy = (-1)^{r+s} \int_{\Phi} g(x, y) \Phi(x, y) dx dy$$

$$(408) \quad \begin{cases} u_{xx} + u_{yy} = f(x, y) \text{ in } \Omega \\ u = g(x, y) \text{ on } \partial\Omega \end{cases}$$

$$(409) \quad \begin{cases} B(\varphi, u) = - \int_{\Omega} (D_{1,0} \varphi D_{1,0} u + D_{0,1} \varphi D_{0,1} u) dx dy \\ B(\varphi, u) = \int_{\Omega} \varphi f dx dy \end{cases}$$

$$(410) \quad \int_{\Omega} \varphi (u_{xx} + u_{yy}) dx dy = - \int_{\Omega} (\varphi_x u_x + \varphi_y u_y) dx dy$$

Dirichlet's
principle

the second row, $t = 2k$, can be obtained in terms of the calculated values along the first row, and the operation may be repeated as many times as necessary to obtain the values along successive rows in terms of previously calculated values.

If u is the exact solution of the one-dimensional diffusion equation (see 333) and U the exact solution of the difference equation (see 405), then if $U \rightarrow u$ as both h and k tend to zero, the finite difference equations are said to be convergent. At first sight it appears as though the mesh lengths h and k can be chosen arbitrarily, but this is not always so; for example, for the particular case of the difference equation (see 405) convergence occurs only if $\rho \leq 1/2$. In the case of hyperbolic equations, it is possible to combine the use of characteristics with that of finite differences to obtain numerical solutions with a high degree of accuracy.

In order to obtain approximate solutions of boundary value problems for elliptic equations, students of the subject have found that it is sometimes possible to reformulate the problem as an integral equation and then to obtain approximate solutions of it.

EXISTENCE AND UNIQUENESS OF SOLUTIONS TO PARTIAL DIFFERENTIAL EQUATIONS

The basic existence and uniqueness theorem of the theory of partial differential equations is the Cauchy-Kovalevskaya theorem, which in its simplest form relates to a system in two independent variables x, y in which u_x equals the product of $A(u)$ and u_y , $u(0, y)$ being equal to $h(y)$ (see 406), u and h being column vectors with m components, the vector h being prescribed, and A is an $m \times m$ matrix.

To state the result it is necessary to use the fact that a function is said to be analytic at a point if it has a Taylor expansion at that point.

The Cauchy-Kovalevskaya theorem then states that about any point at which the components of the given matrix A and of the given vector h are analytic, a neighbourhood can be found in which there exists a unique vector u , with analytic coefficients, that is a solution of the initial value problem (see 406).

Although it has the appearance of great generality, this theorem has the severe limitation that it is restricted to problems involving only analytic functions. What it does show is that within the class of analytic solutions of equations with analytic coefficients, the number of arbitrary functions required for a general solution is equal to the order of the equation. When k independent variables are involved, a generalization of the theorem shows that each such arbitrary function is a function of $k - 1$ variables.

GENERALIZED THEORY OF PARTIAL DIFFERENTIAL EQUATIONS

The generalized theory of partial differential equations depends on generalizing the concept of a derivative. In order to do this it is necessary to introduce the idea of a test function.

Again the treatment is restricted to two dimensions. The function $\phi(x, y)$ is said to be a test function if it vanishes outside a bounded region Φ of the xy -plane and if it is infinitely differentiable in that region. If f is locally integrable in a region Ω and if there exists a locally integrable function g such that for all test functions ϕ , the integral of $f(x, y)\partial^{r+s}\phi/\partial x^r\partial y^s$ over Φ equals the integral of $(-1)^{r+s}g(x, y)\phi(x, y)$ over Φ (see 407), g is called a generalized derivative of f and $g = D_{r,s}f$ is written.

Now the Dirichlet problem for Laplace's equation in two dimensions may be considered (see 408); in this instance, $\partial\Omega$ denotes the boundary of Ω . A generalized solution of the Dirichlet problem is defined by introducing a bilinear function $B(\phi, u)$, and $B(\phi, u)$ is defined for all test functions ϕ (see 409).

A function u is said to be a generalized solution of the stated Dirichlet problem if, and only if, $u = g$ on $\partial\Omega$ and if for every test function ϕ , $B(\phi, u)$ equals the integral of ϕf over Ω (see 409). On the other hand, a classical solution is a twice-differentiable function that assumes the correct boundary values; therefore, from Green's theorem

(see 410), it follows that, if a classical solution to the stated Dirichlet problem exists, then it is also a generalized solution.

The theory of generalized solutions of partial differential equations forms what is known as the abstract theory of partial differential equations. (I.N.S.)

Dynamical systems on manifolds

NONLINEAR DIFFERENTIAL EQUATIONS AND DYNAMICAL SYSTEMS

The differential equations described so far in this section are mainly linear—that is, the superposition of two solutions is again a solution. However, nonlinear differential equations are also extremely important, but until recently their theory existed only in rudimentary form because their analysis is extremely difficult and requires an entirely new approach. Apart from a few classical tricks of limited interest, nonlinear differential equations can seldom be solved by an explicit formula. Instead, they are studied by approximate methods of numerical analysis, by local analytic methods that apply only in small regions, and by qualitative methods of geometry and topology.

The qualitative theory of differential equations was founded by Henri Poincaré around 1900 and has grown into an extensive and vigorous field. With the rise of interest in nonlinear systems and new phenomena such as “chaos”—the occurrence of random behaviour in deterministic systems—it has become vital to many areas of application and has developed into an extensive subject known as dynamical systems theory.

The natural geometric setting for this theory is that of a manifold, the multidimensional analogue of a curved surface. A dynamical system is a system of first-order ordinary differential equations defined on a manifold. The manifold is called the state space or phase space of the system. It is necessary to use manifolds rather than ordinary Euclidean space because in many applications the natural phase space is “curved.” For example, the state space determining the possible positions of a pendulum is a circle.

Dynamical systems theory is the study, especially from a geometric or topological point of view, of the qualitative properties of solutions of differential equations on manifolds or their discrete-time analogues. Nowadays the term also covers quantitative studies carried out by numerical methods, provided these are based upon a geometric understanding of the nature of the flow. Because the equations for most dynamical systems are nonlinear, the computer plays an important role in the mathematics, both as an experimental tool to suggest rigorous theorems and as an aid to practical applications.

A central concept is that of structural stability, which arose from attempts to describe the “typical” behaviour of a dynamical system—behaviour that persists when the system itself is perturbed. It must be distinguished from the stability of an individual solution—behaviour that persists when the initial conditions of a fixed system are perturbed. Structural stability is a formal way to capture the idea of behaviour that is not destroyed by small changes to the system. It was originally hoped that it would be a generic property—that is, be possessed by almost all dynamical systems. While that hope turned out to be misplaced, the concept remains important.

Another important idea is that of an attractor. An attractor is a region of state space that captures the long-term behaviour of the system. It is now known that structurally stable systems can possess attractors on which the systems behave in an apparently random manner. The equations that define a dynamical system are fully deterministic; that is, given initial conditions lead to uniquely specified behaviour. The sense in which a deterministic model can produce random effects is a major discovery of the last few decades, giving rise to a central branch of dynamical systems theory known as chaotic dynamics. The word chaos—more accurately, deterministic chaos—refers to any instance of such behaviour. The associated attractors are said to be strange or chaotic. Dynamical systems theory provides a major source of understanding for the phenomenon of chaos.

The
Cauchy-
Kovalev-
skaya
theorem

Henri
Poincaré

A dynamical system is a way of describing the passage in time of all points of a given space \mathfrak{S} . \mathfrak{S} can be thought of, for example, as the space of states of some physical system. Then if x is in \mathfrak{S} , one unit in time later x will have moved to a point denoted by x_1 . At time zero x is at x or x_0 . Two units after time zero x will have moved to x_2 . One unit before time zero x was at x_{-1} . If this procedure is extrapolated to fill up the real numbers R , the trajectory x_t is obtained, for all time t , a real number. Thus, for each x , x_t is a curve in \mathfrak{S} and represents the life history of x as t goes from $-\infty$ to ∞ . If x_t is also assumed to be differentiable in (t, x) , then $x \rightarrow x_t$ can be regarded as a transformation, or diffeomorphism, from \mathfrak{S} onto \mathfrak{S} for each t . In this case (\mathfrak{S}, x_t) defines a dynamical system.

Definition
of a state
of a system

In applications of dynamical systems to fields outside of mathematics, the first goal is to explicate the manifold of states \mathfrak{S} . A state of a system is information characterizing the situation at a given moment. The first step in this explication process is to define the state in the most obvious unrestricted way. This will give a space that is possibly too large, and natural constraints on physical laws will cut down the unrestricted states to a subset of attainable or physical states. A physical state is one that has an actual possibility of occurring. These physical states form the final manifold of states. A number of examples in the following section will explain the process given in the previous sentences.

EXAMPLES OF STATE SPACES

Pure
exchange
economy

Example from economics. In the pure exchange economy of theoretical economics, a model is used with n different commodities, each measured in quantity by a positive real number (fixing a unit of measurement). Thus commodity space P will be the set of points of real Cartesian space R^n with each coordinate positive. A point of P represents a bundle of commodities possessed, for example, by a certain consumer in the economy.

It is assumed that there are a finite number of consumers, say m , with the possessions of the i th consumer denoted by x_i in P . An unrestricted state of the economy is a point $x = (x_1, \dots, x_m)$ in which each x_i is in P . The space of all these states is denoted by P^m , the Cartesian product of P with itself m times. Thus, an unrestricted state of the economy simply gives the possessions of the consumers of that economy.

Now, it is supposed that the total resources in this economic model are fixed, say, at a point w in P . Thus, the space of attainable states is a subset W of P^m described by the following condition: (x_1, \dots, x_m) is in W if the sum of the x_i is w .

Examples from classical mechanics. *Particle in Euclidean space E^3 .* Ordinary three-dimensional Euclidean space is denoted by E^3 . A particle in E^3 has its state characterized by its position x , a point in E^3 , and its velocity v , a vector (or point) in E^3 . Thus, v gives the direction in which the particle is moving together with its speed, the length of v . The vector v can be thought of as being based at x . The states of this system are then all pairs (x, v) , x, v each in E^3 . This space is denoted by $E^3 \times E^3$, the Cartesian product of E^3 with E^3 .

Particle on a sphere. D^3 is a unit ball in E^3 , so that D^3 consists of all points whose distance from the origin is less than or equal to one. The 2-sphere S^2 is its boundary, or points of unit distance, from the origin of E^3 . The space of states for the physical system of a particle on S^2 will then be a certain subset of $E^3 \times E^3$ of the first example.

There are two constraints: the first is that x must be in S^2 ; the second is that v must be perpendicular to x . The first constraint follows by definition, and the second constraint follows because, if the velocity were not perpendicular to x , then x would have to leave the 2-sphere. The set of points (x, v) that satisfies these two constraints is the state space \mathfrak{S} for this problem. \mathfrak{S} can also be thought of in the following way. If $T_x(S^2)$ is the tangent space to S^2 at x , so $T_x(S^2)$ is the set of all vectors v in E^3 based at x with v tangent to the surface S^2 (or perpendicular to x), then \mathfrak{S} is the union of all these $T_x(S^2)$ as x varies over S^2 . In other words, \mathfrak{S} is the tangent bundle of S^2 , $T(S^2)$ or the set of all (x, v) in $S^2 \times E^2$ in which v is in $T_x(S^2)$.

Plane rigid body. A point x_0 and a directed line n_0 are fixed in B through x_0 . Then the position of B in the plane E^2 is characterized by the position of x_0 in E^2 and the angle between n_0 and a fixed directed reference line n in E^2 . (For simplicity it is assumed that B has only one possibility for its orientation in E^2 .) Therefore, the space of positions or configurations of B is a three-dimensional space or manifold, the Cartesian product of E^2 and the circle S^1 , $E^2 \times S^1$. In this instance, the fact that there is a correspondence between angles and points on the circle is used. $M = E^2 \times S^1$ is sometimes called the space of generalized coordinates for the configuration of B . If (x, θ) is in $E^2 \times S^1$, then (x, θ) stands for the configuration of B , in which x_0 is located at x and θ is the angle between n_0 and n .

The possible velocities for B at (x, θ) are vectors (v_1, v_2) in $E^2 \times R$ (or E^3), in which v_1 is the ordinary velocity of x in E^2 and v_2 is angular velocity. Therefore, for this mechanical system, the state space \mathfrak{S} is the product $(E^2 \times S^1) \times (E^2 \times R)$ of configuration and velocity space.

A circuit with three electrical components. A series connection between a resistor, an inductance, and a capacitor, wired to form a closed loop, may now be considered. To form the space of states, each of these three components is oriented. A state of the circuit consists of the current through each component and the voltage across each component. If i_p, v_p stand for the current and voltage, respectively, in the resistor, then i_L, v_L stand for current and voltage in the inductance and i_C, v_C for current and voltage in the capacitor. For historical reasons the capacitor is conventionally oriented in the opposite direction from the other two components. The Kirchhoff laws (from the 19th-century physicist Gustav Robert Kirchhoff) imply the following relations on the currents and voltages. The Kirchhoff current law (KCL) asserts that $i_L = i_p = -i_C$, or that the current that flows into a junction between two components is equal to the current that is flowing out. The Kirchhoff voltage law (KVL) asserts that $v_L + v_p = -v_C$, or that the voltages around a loop of components sum to zero.

The
Kirchhoff
laws and
Ohm's
law

The set of states in R^6 satisfying these Kirchhoff laws forms a three-dimensional linear subspace K of R^6 . Any physical state has to lie in K . To obtain the precise set of physical states, another step is needed, in order to bring in the implications of the resistors on (i_p, v_p) .

The most common type of resistor is linear in that it obeys Ohm's law (named for the German physicist Georg Simon Ohm); i.e., $v_p = R_p i_p$, in which R_p is some positive constant. For a physical state, Ohm's law must be satisfied as well as Kirchhoff's laws. This cuts down the space of physical states to a two-dimensional linear subspace \mathfrak{S} for R^6 .

More generally, any resistor, linear or nonlinear, is defined by its characteristic Λ_p , which is a curve in the two-dimensional (i_p, v_p) -plane. Then a generalized version of Ohm's law stipulates that, for a physical state in R^6 , the components (i_p, v_p) lie in Λ_p . It can be proved in the general case that these constraints force the physical states to lie in a two-dimensional manifold Σ of R^6 .

Suppose, for example, that the resistor is current controlled so that the characteristic Λ_p is the graph in R^2 of some smooth real function f . Thus, $v_p = f(i_p)$. In this case it is convenient to take as a representation of Σ the Cartesian (i_L, v_L) -plane R^2 identifying R^2 and Σ under the diffeomorphism $R^2 \rightarrow \Sigma \subset R^6$, which sends (i_L, v_L) into a state in R^6 that is completely determined by i_L and v_L (see 411). Then the space of states for this circuit is equivalent to R^2 or (i_L, v_L) -space.

Simple electrical circuits. This example just given can be generalized to what could be called simple electrical circuits. A simple electrical circuit consists of components and nodes. The components are circuit elements that are either resistors, inductances, or capacitors, each with two terminals. In the circuit, groups of terminals meet at the different nodes. It is assumed that the components have a given orientation so that the current flowing in one direction is given by a positive real number, and the current flowing is given by a negative number if it flows in the opposite direction.

$$(411) \quad (i_\lambda, i_\lambda, -i_\lambda, f(i_\lambda), v_\gamma - f(i_\lambda), v_\gamma) = (i_p, i_\lambda, i_\gamma, v_p, v_\lambda, v_\gamma)$$

$$(412) \quad \left. \frac{d\phi_i(x)}{dt} \right|_{t=0} = X(x)$$

$$(413) \quad \frac{d}{dt} \phi_i(x) = X(x)$$

The unrestricted states of the current have as components the currents through each component and the voltages across each component. So if there are N components, the space of unrestricted states \mathfrak{S} is $2N$ -dimensional Cartesian space \mathfrak{R}^{2N} .

Physical constraints

The laws of physics impose constraints on these states. First of all, Kirchhoff laws assert that a physical state must be in a linear subspace K of \mathfrak{R}^{2N} with dimension K equal N . In formal terms Kirchhoff's current law says that for each node, the sum of the currents entering the node equals the sum of the currents issuing from the node. Kirchhoff's voltage law then requires that the voltages across each component of a closed cycle add to zero. It follows that the set of states in \mathfrak{R}^{2N} satisfying Kirchhoff's current law and Kirchhoff's voltage law forms a linear subspace of dimension N .

The final physical constraint is given by a generalization of Ohm's law. A resistor component p is allowed to have as characteristic any nonsingular curve—i.e., one-dimensional submanifold— Λ_p in the (i_p, v_p) -plane. This means that a physical state in K must have i_p, v_p components satisfying the condition that (i_p, v_p) is in Λ_p . If the p th resistor is linear, then Λ_p is a line through the origin with positive slope. Thus the physical states finally satisfy these further conditions, one for each resistor. The final subspace Σ of \mathfrak{S} defined by these conditions and Kirchhoff conditions will be a submanifold in the general case whose dimension is equal to the number of inductor components plus the number of capacitor components.

MANIFOLDS

In each case of the examples, the state space is a manifold. A manifold can often be thought of as a domain (or open set) in Euclidean space of some dimension. More generally, a manifold is defined by glueing together such open sets; thus, for example, while the 2-sphere is a two-dimensional manifold, it is not equivalent to an open set of the plane. It can be obtained though as the union of two, two-dimensional disks that overlap in a ring. Every k -dimensional manifold can be represented by a k -dimensional surface in Euclidean space of some higher dimension. It is most reasonable to take a manifold—i.e., differentiable manifold—as the basic space of a dynamical system.

If U is an open set in Euclidean space E and x is in U , then a tangent vector of U at x is simply a vector in E , which can be thought of as being based at x . The tangent bundle $T(U)$ is the product $U \times E$, and a point (x, v) in $U \times E$ consists of base point x , vector v .

More generally if x is a point in a manifold M , in which M is represented as a k -dimensional surface in some Euclidean space E , then a tangent vector of M at x is simply a vector in E based at x and tangent to M . The space of all tangent vectors to M at x is the tangent space $T_x(M)$ of M at x . Then $T(M)$, the tangent bundle of M , is the (disjoint) union of all these $T_x(M)$ as x varies over M and is a manifold itself in a natural way.

In all the examples of mechanical systems, the initial step was to take the manifold M of positions or configurations. Then the space of states was the tangent bundle $T(M)$ of M . A state in all of these examples consists of a configuration together with a (generalized) velocity based at that configuration. This persists in much more general examples of mechanical systems.

DYNAMICAL SYSTEMS AS VECTOR FIELDS ON MANIFOLDS

On manifolds (e.g., open sets of Euclidean space) differentiation makes sense, and a differentiable map (i.e., trans-

formation) from a manifold to itself with a differentiable inverse is called a diffeomorphism. In these terms the definition of a dynamical system can be restated as assigning to each time t (a real number), a diffeomorphism $\phi_t: M \rightarrow M$ with ϕ_0 the identity, $\phi_{t+s} = \phi_t \circ \phi_s$, and so that $\phi_t(x)$ is differentiable in (t, x) . Thus for each x in the manifold, the trajectory $\phi_t(x) = x_t$ is a curve through x . The derivative of this curve $t \rightarrow \phi_t(x)$ at $t=0$ can be taken, letting $X(x)$ be the derivative of $\phi_t(x)$ (see 412) to obtain the velocity or the tangent vector of the curve at x . Thus $X(x)$ is in the tangent space $T_x(M)$. The association $x \rightarrow X(x)$ is a vector field on M (or tangent vector field on M). More generally, a vector field on M is any differentiable map $X: M \rightarrow T(M)$ with $X(x)$ in $T_x(M)$. For example, if M is an open set in Euclidean space E , then $T(M) = M \times E$ and a vector field $Y: M \rightarrow M \times E$ must be of the form $Y(x) = (x, X(x))$ for some map $X: M \rightarrow E$. In this case, by a slight abuse of language, X is called a vector field, so that a vector field can be thought of as assigning to each point x , in M , a vector in E based at x .

The notion of vector field on a manifold is of basic importance because among other things a dynamical system is characterized by its associated vector field. A converse to this statement is roughly true, and the converse could be regarded as the fundamental theorem of ordinary differential equations. More precisely, if $x \rightarrow X(x)$ is a vector field on a manifold M , the ordinary differential equation can be considered for $\phi_t(x)$, given by the derivative of $\phi_t(x)$ being equal to $X(x)$ (see 413).

This equation has a solution, at least for all t satisfying $t^-(x) < t < t^+(x)$ in which t^-, t^+ are real functions on M defining some (perhaps maximal) open set Q in $R \times M$ containing $O \times M$. This solution $\phi_t(x)$, defined for (t, x) in Q , then has the properties of a dynamical system except that it may not be defined for all t going to $\pm\infty$. This system of trajectories is still called a dynamical system (or flow), and in this sense vector fields on manifolds are equivalent to dynamical systems.

EXAMPLES OF DYNAMICAL SYSTEMS

Particle in E^3 in a force field. Consider the example of a particle in three-dimensional Euclidean space. It is supposed now that there is a certain vector field, a force field defined on E^3 , say $x \rightarrow F(x)$, $E^3 \rightarrow E^3$. Thus, if the particle is at x in E^3 , the force exerted on it is $F(x)$, and Newton's law reads $ma = F(x)$. Here m is a constant positive real number, the mass of the particle, and $a = x''(t)$ (or the second derivative of x with respect to t) is the acceleration with $t \rightarrow x(t)$ a curve in E^3 that represents the passage of the particle in time. For an actual or physical path, Newton's equation is satisfied, or $mx''(t) = F(x(t))$ for all t .

Newton's equation is seen to be equivalent to the pair of equations (see 414) relating the derivatives of position and velocity to the velocity and the force, respectively. In this last form, the map $(x, v) \rightarrow (v, F(x)/m)$ is a vector field on the state space for this mechanical system $T(E^3)$. This is the form of a vector field on the state space determining the passage in time of the space. The initial conditions are (x, v) , the position and velocity of the particle.

The force field $x \rightarrow F(x)$ is called conservative if it is of the form $F(x) = -\text{grad } V(x)$ in which V is some real function on E^3 . $\text{Grad } V(x)$ is defined as the vector in which the i th component is $\partial v / \partial x_i$, for $i = 1, 2, 3$ (see 415), in terms of Cartesian coordinates. V is called the potential for the system. The classical example of a force field is that of gravitational force. If the source of this force is the point located at the centre of E^3 , then (see 416) the force is inversely proportional to the square of the distance, involving the Euclidean norm on E^3 (see 417) in Cartesian coordinates. In this case, $F(x)$ is a conservative force field because a potential can be chosen (see 418) that is inversely proportional to the distance. This gives what is sometimes called the Kepler problem because the solution curves lead to the elliptical orbits of the Earth about the Sun first announced in the 17th century by the German astronomer Johannes Kepler. Strictly speaking, in the Kepler problem configuration space is $E^3 - 0$, because the vector field describing the dynamics is not defined at 0.

Van der Pol equation. The particular example of an

Diffeomorphisms

Conservative force fields

electrical circuit given earlier is now considered. Physical laws of the inductor and capacitor give the differential equations for motion directly in terms of the representation of the state space found there. More precisely (see 419) the derivative of i_λ is proportional to v_λ and the derivative of v_γ is proportional to i_γ (see 419), in which L , the inductance, and C , the conductance, are constants of proportionality. For simplicity, L and C are taken as constants equal to unity. Here $v_\lambda = v_\gamma - f(i_\lambda)$ and $i_\gamma = -i_\lambda$ by Kirchhoff's laws and the resistor characteristic. The differential equations then become appropriately changed (see 420). The corresponding vector field on \mathfrak{R}^2 at the point (i_λ, v_γ) is $(v_\gamma - f(i_\lambda), -i_\lambda)$.

In the case in which f is linear, of the form $v_p = R_p i_p$, $R_p > 0$, then it can be deduced that all solution curves of this dynamical system tend toward the origin. The origin is a steady state and an attractor. This means that a solution at the origin stays at the origin for all time or that the vector field is zero at the origin (steady state). That the origin is an attractor means that nearby solutions tend to the origin as $t \rightarrow \infty$. Steady-state attractors play a central role in applications of dynamical systems.

On the other hand, if a highly nonlinear characteristic is considered, say the derivative $f'(0) < 0$, then the unique zero $(0, f(0))$ of the vector field can be shown to be a source. This means that orbits tend to $(0, f(0))$ as $t \rightarrow -\infty$. If the characteristic $(i_\lambda, f(i_\lambda))$ stays well inside the first and third quadrants for large $|i_\lambda|$ (a natural assumption even for nonlinear resistors), then as $t \rightarrow \infty$ all orbits tend toward some bounded region in \mathfrak{R}^2 . This follows from a general energy theorem. From these facts, the Poincaré-Bendixon theorem (with I.O. Bendixon) implies the existence of a periodic orbit, and one will be an attractor in the general case. A periodic orbit, period $w > 0$ is an orbit where $\phi_{t+w}(x) = \phi_t(x)$ for all t . This amounts to an oscillatory behaviour of the physical variables. That it is an attractor means that all nearby solutions tend toward it and thus will also oscillate, at least to a high degree of approximation. Periodic attractors are of basic importance in applications of dynamical systems.

The characteristic defined (see 421) by $f(i_\lambda)$ being equal to $\mu(i_\lambda^3 - i_\lambda)$ satisfies the conditions of the previous paragraph. Here there is a unique periodic attractor; the differential equation is called van der Pol's equation.

Volterra-Lotka equations. The equations describing how the populations of rabbits and foxes vary in time are called the Volterra-Lotka equations and are (see 422) a pair of coupled first-order equations with positive constants $\alpha, \beta, \lambda, \mu$. For example, $dr/dt = ar$ governs how the number of rabbits increases eating grass, without taking into account the foxes that eat them. The Volterra-Lotka equation can be interpreted as giving a vector field on the positive quadrant in \mathfrak{E}^2 ; its solution curves are in fact periodic so that the populations are expected to change in cycles under these conditions. (S.Sm./Ed.)

HAMILTONIAN MECHANICS

Hamiltonian mechanics as developed on manifolds has the virtue of including quite general mechanical systems and shows basic principles most simply. To define gradients, the inner product on Euclidean space E was of central importance. Hamiltonians are developed similarly with the bilinear form B , or inner product, replaced by a symplectic bilinear form Ω on E . $B(x, \mathfrak{L}[x])$ is a sum of terms $x_i \mathfrak{L}(x_i)$ (see 423) for Cartesian coordinates $(x_1, \dots, x_n) = x$ on E . E is taken to have even dimension $2n$ and a bilinear form Ω on E is defined (see 424). Not only is it seen that Ω is bilinear, but it is also clearly anti-symmetric, $\Omega(x, \mathfrak{L}[x]) = -\Omega(\mathfrak{L}[x], x)$. It can also be seen that Ω is nondegenerate or that the map $\phi_\Omega = E \rightarrow E^*$ is an isomorphism with $\phi_\Omega(x)(\mathfrak{L}[x]) = \Omega(x, \mathfrak{L}[x])$. In fact, any nondegenerate, antisymmetric bilinear form Ω can be used in the following, and such an Ω is called a symplectic structure on E . Ω can be used to define Hamiltonian dynamical systems.

Open sets of E^{2n} . If U is an open set of E in which E has a symplectic structure (and so has even dimension) and $H:U \rightarrow \mathfrak{R}$ is any differentiable function, called a Hamiltonian in this context, then the derivative $DH:U \rightarrow$

$$(414) \quad \dot{x} = v, \quad \dot{v} = \frac{1}{m} F \quad \text{on} \quad E^3 \times E^3 = T(E^3)$$

$$(415) \quad \left(\frac{\partial V}{\partial x_1}, \frac{\partial V}{\partial x_2}, \frac{\partial V}{\partial x_3} \right)$$

$$(416) \quad F(x) = -\frac{x}{\|x\|^3}$$

$$(417) \quad (\|x\|) = (\sum x_i^2)^{1/2}$$

$$(418) \quad V(x) = -\frac{1}{\|x\|}$$

$$(419) \quad L \frac{di_\lambda}{dt} = v_\lambda, \quad C \frac{dv_\gamma}{dt} = i_\gamma$$

$$(420) \quad \begin{cases} \frac{di_\lambda}{dt} = v_\gamma - f(i_\lambda) \\ \frac{dv_\gamma}{dt} = -i_\lambda \end{cases}$$

$$(421) \quad f(i_\lambda) = \mu(i_\lambda^3 - i_\lambda), \quad \mu > 0$$

$$(422) \quad \frac{dr}{dt} = ar - \lambda rf, \quad \frac{df}{dt} = -\beta f + \mu rf$$

E^* is a 1-form on U , and $X_H = \phi_\Omega^{-1} DH$ is a vector field (or ordinary differential equation) on U . Thus X_H is a map from U to E , and $\Omega(X_H(x), Y)$ equals $DH(x)(Y)$ for all x in U and Y in E . Note that X_H is defined as $\text{grad } H$ except that B has been replaced by Ω .

In terms of the Cartesian coordinates on E in which $\Omega(x, \mathfrak{L}[x])$ has a specific form (see 425), X_H has for its first n coordinates $\partial H / \partial x_{n+i}$ and for its second n coordinates

$$(423) \quad B(x, \mathfrak{L}[x]) = \sum_{i=1}^n x_i \mathfrak{L}(x_i)$$

$$(424) \quad \Omega(x, \mathfrak{L}[x]) = \sum_{i=1}^n x_i \mathfrak{L}(x_{i+n}) - \sum_{i=1}^n x_{i+n} \mathfrak{L}(x_i)$$

$$(425) \quad \begin{cases} \Omega(x, \mathfrak{L}[x]) = \sum_{i=1}^n x_i \mathfrak{L}(x_{i+n}) - \sum_{i=1}^n x_{i+n} \mathfrak{L}(x_i) \\ X_H = \left(\frac{\partial H}{\partial x_{n+1}}, \dots, \frac{\partial H}{\partial x_{2n}}, -\frac{\partial H}{\partial x_1}, \dots, -\frac{\partial H}{\partial x_n} \right) \end{cases}$$

$$(426) \quad \frac{dx_i}{dt} = \frac{\partial H}{\partial y_i}, \quad \frac{dy_i}{dt} = -\frac{\partial H}{\partial x_i}, \quad i = 1, \dots, n$$

$$(427) \quad (y_1, y_2, y_3), y_i = mv_i$$

$$(428) \quad H(x, y) = \frac{1}{2m} \sum y_i^2 + V(x)$$

$$(429) \quad \frac{dx_i}{dt} = v_i, \quad \frac{mdv_i}{dt} = \frac{\partial V}{\partial x_i}$$

$$(430) \quad \frac{1}{2m} \sum y_i^2, \quad \frac{1}{2} m \sum v_i^2$$

$$(431) \quad X_H(x) = \phi_\Omega^{-1} DH(x)$$

$$(432) \quad (DH(x))(X_H(x)) = \Omega_x(X_H(x), X_H(x))$$

The
Poincaré-
Bendixon
theorem

$-\partial H/\partial x_i$ (see 425). If $y_i = x_{n+i}$, $i = 1, \dots, n$ the ordinary differential equations represented by X_H are the classical Hamilton's equations in which the derivative of x_i equals $\partial H/\partial y_i$, and the derivative of y_i equals $-\partial H/\partial x_i$ (see 426).

Particle in E^3 . A special case of the foregoing is the earlier mechanical system of a particle of mass m moving in 3-space under a conservative force field $F(x) = -\text{grad } V(x)$ with $V:E^3 \rightarrow \mathfrak{R}$, (potential) function. Then on the state space $E^3 \times E^3$ coordinates are chosen (x_1, x_2, x_3) for the configuration and y_i is proportional to v_i (see 427) for the second factor (or momentum coordinates). If Ω is taken as above and $H:E^3 \times E^3 \rightarrow \mathfrak{R}$ defined in terms of a sum of the y_i^2 and $V(x)$ (see 428), then Hamilton's equations coincide with Newton's equations (see 429). The term involving the y_i^2 (see 430) is called the kinetic energy, and V is the potential energy of this mechanical system; the sum $K + V$ is the total energy or simply energy.

Manifolds. The concept of symplectic structure can be generalized easily to manifolds. If W is an even-dimensional manifold and x is a point of W , then a symplectic structure Ω at x is simply a nondegenerate, antisymmetric bilinear form on the tangent space $T_x(W)$. A manifold W with such Ω_x given for each x , Ω_x varying differentially with x , is called a symplectic manifold. As before, for each x , $\phi_{\Omega_x}:T_x(W) \rightarrow T_x^*(W)$ is an isomorphism from the tangent space to its dual, the cotangent space at x . Given a Hamiltonian $H:W \rightarrow \mathfrak{R}$, then for each x , the derivative $DH(x)$ is in $T_x^*(W)$, and the above isomorphism converts the 1-form DH to a vector field X_H (see 431). The vector field X_H is then the Hamiltonian vector field (or ordinary differential equation) corresponding to the Hamiltonian H . As a Riemannian manifold is required to define gradient vector fields, a symplectic manifold is required in order to define Hamiltonian vector fields.

Conservation laws. Various physical principles can be derived in this setting. For example, conservation of energy amounts to the function H being constant on trajectories of X_H . This is the same thing as the assertion that for each x , $DH(x)$ evaluated at $X_H(x)$ is zero. But another condition holds (see 432) from the definition of X_H , and the last is zero since Ω_x is antisymmetric.

Liouville's theorem asserts that Hamiltonian systems preserve volume. In this context, that volume on the abstract manifold W is the n -fold wedge product of Ω with itself. Without pursuing the technical definition of wedge product, it can be said that if Ω is defined as above on E in coordinate, then the Liouville volume is just ordinary volume on E . It can be first checked that Ω itself is invariant under a Hamiltonian flow X_H , and then it naturally follows that the wedge product, the Liouville volume is preserved. This can be contrasted with the gradient case. For example, neighbourhoods of a local maximum of a gradient flow are shrunk into smaller subsets by the dynamics. Volume is strictly decreased.

Simple mechanical systems. A simple mechanical system (M, K, V) has a manifold M that is the configuration space of the system. $V:M \rightarrow \mathfrak{R}$ is a function, the potential energy, and kinetic energy K is considered to be given by some Riemannian metric on M . Thus for each x in M there is an inner product K_x on $T_x(M)$ and $K(v) = K_x(v, v)$ for v in $T_x(M)$. This can be compared with the earlier mechanical system of a particle constrained to move on the 2-sphere in E^3 . In this case, K_x on $T_x(S^2)$ is the restriction of inner product on E^3 times half the mass. Together these sum to give the energy $E:T(M) \rightarrow \mathfrak{R}$ as a real function on the tangent bundle of M as defined by $E(v) = K(v) + V(x)$ for v in $T_x(M)$.

To put this into the symplectic perspective, it is convenient to consider the cotangent bundle $T^*(M)$. There is a canonically defined symplectic structure Ω defined on $T^*(M)$, which extends the earlier example of Ω on $E^3 \times E^3$. Furthermore, the energy E can be transferred to $T^*(M)$ by a map called the Legendre transformation $L:T(M) \rightarrow T^*(M)$. More precisely, if $v \in T_x(M)$, then $L(v) = \phi_{K_x}(v)$ in which ϕ_{K_x} is the usual linear map induced by a bilinear form. Then the Hamiltonian $H:T^*(M) \rightarrow \mathfrak{R}$ is defined by $H = E \circ L^{-1}$. The corresponding Hamiltonian vector field X_H on $T^*(M) = W$ gives the dynamics for this mechanical system. The inverse of the Legendre transformation takes

trajectories of X_H back to solutions of the Euler-Lagrange equations on $T(M)$. (S.Sm.)

Potential theory

HISTORICAL SURVEY OF PROBLEMS AND CONCEPTS

Until around 1800, potential theory was actually that part of theoretical physics basically concerned with electrostatics (see the article ELECTRICITY AND MAGNETISM) and Newtonian attraction between masses. The potential of a unit mass concentrated at a point X is

equal at any other point x to the inverse $\frac{1}{|X-x|}$ of the

distance $|X-x|$ to X . It is a harmonic function of x ($x \neq X$); that is, it is equal at x to its mean value on any ball centred at x and not containing X , or, equivalently, it satisfies Laplace's equation (see 433), a second-order partial differential equation. The potential of a general distribution of masses is then defined by multiplication and summation (actually by an operation of integration) and it is harmonic outside of the masses. Thus, physical problems became mathematical ones.

Important results due to the mathematicians Siméon-Denis Poisson and George Green were followed in 1840 by a fundamental work of Carl Friedrich Gauss, amazingly deep and rich, in which he solved for Euclidean space three connected problems that remain essential subject to various adaptations.

The first one is the problem of equilibrium; this is the determination of a distribution of a given mass on a conductor for which the potential is constant on it; this corresponds to minimizing the (potential) energy.

Given masses inside a closed conductor, the second problem asks how they can be distributed on the conductor so as to give the same potential outside. This is solved physically by the phenomenon of influence that creates on the conductor (on which one makes the potential zero) a distribution of masses such that the total potential is zero outside. Similar problems arise by commuting (interchanging) interior and exterior. This operation was later called *balayage* (sweeping-out process) by Poincaré.

The third problem is the determination in a domain of a harmonic function the limiting values of which agree on the boundary with a given function (first supposed to be finite continuous). As noted earlier, this standard boundary value problem was called the Dirichlet problem by Riemann.

For lack of sufficient mathematical tools, the solutions given by Gauss were not rigorous and the results not quite correct or precise; actually they needed some restrictions. Because of these difficulties, the first two problems were put aside for a long time, but the Dirichlet problem, more important, was studied by different methods, which at first were not rigorous either. For example, an important method was based on the minimizing of a so-called Dirichlet integral (Dirichlet principle). This was made rigorous by David Hilbert of Germany only around 1900. If so many great mathematicians gave different solutions, it is perhaps also because the restrictions on the boundary seemed unnecessary; actually they were necessary, as S. Zaremba of Poland and Henri-Léon Lebesgue of France noted after 1900.

Some other questions considered in this period include the analytic character of harmonic functions (expansion as power series), other types of boundary value problems (such as the Neumann problem, named for Karl Gottfried Neumann of Germany, for given normal derivatives), the connections of harmonic functions with functions of a complex variable, conformal mapping, Fourier series, similar developments for equations more general

than the Laplace one, polyharmonic functions or more precisely harmonic functions of order p , satisfying to $\Delta^p u = \Delta(\dots \Delta u) = 0$ with $p|\Delta$ -operators.

A second period of the development of potential theory was characterized chiefly by the introduction, in the study of potential theory, of wider notions of measure and integral (those of Lebesgue and Radon), and of capacity, a notion inspired by electrostatics, first clearly defined and discussed by Norbert Wiener of the United States and Charles-Jean de la Vallée Poussin of Belgium, and greatly generalized much later by the French mathematician Gustave Choquet.

The use of integrals allowed a new development of the subject, chiefly by means of a larger definition of the potential of a general distribution of masses—i.e., a measure μ . This potential is defined by the integral of a function N integrated with respect to y and to a measure μ

(see 434) in which $N(x, y)$, called a kernel, is $\frac{1}{|x - y|^{n-2}}$

in the space \mathbb{R}^n with $n \geq 3$ (Newtonian kernel) and is $\log \frac{1}{|x - y|}$ in \mathbb{R}^2 (logarithmic kernel).

A new setting and a generalized solution of the Dirichlet problem appeared (resulting from a remark of Lebesgue and results of Wiener), avoiding any restriction on the boundary; the boundary behaviour of the new solution and its relation with the previous one were made clear later by O.D. Kellogg and Griffith C. Evans of the United States, thanks to the notion of capacity, and a more general problem with discontinuous boundary data was solved by Marcel-Émile Brelot of France.

New important tools, the concepts of subharmonic and superharmonic functions, were introduced by Frigyes Riesz, a Hungarian mathematician. These functions stand in relation to harmonic functions as arcs of convex and concave curves, respectively, do to their chords. They are locally equal modulo harmonic functions to potentials of negative and positive masses, respectively, in the general new sense.

A rigorous and more precise development of the ideas of Gauss was made in the famous thesis of the Swedish mathematician Otto Frostman (1935). A definitive convergence theorem on decreasing potentials of positive masses, given by the French mathematicians Marcel-Émile Brelot and Henri Cartan, was an essential tool for all refinements in potential theory. The sets of (outer) capacity zero emerged as the standard exceptional sets in potential theory and in its application to the functions of a complex variable.

The third period from about 1940 to 1955 was marked by the role of topology in potential theory.

The notion of energy in Euclidean space was used more deeply by Cartan. The measures were considered as points of a space, with the distance to the origin equal to the square root of the energy corresponding to the measure: in such a space the well-known methods of Hilbert space theory (geometry in a space with infinitely many coordinates) were applied, and a striking and powerful theory was developed. Later Jacques Deny continued this theory of finite energy, using, instead of measures, the more general distributions of the French mathematician Laurent Schwartz, but preserving the essential ideas.

Another example of the role of topology is the introduction of the notion of a thin set and equivalently of the fine topology in which all classical potentials become continuous. This notion due to Brelot and Cartan is adapted to the study of discontinuous potentials and nonsmooth boundaries and gives rise to new problems.

The most striking example is the introduction of the Martin boundary. The solution of the Dirichlet problem in a ball had led to the (integral) representation of a positive harmonic function in the ball by means of a positive measure on the boundary. A similar problem for a general Euclidean domain remained unsolved until 1941 when Martin introduced a quite new boundary and its useful minimal part. This work later inspired Choquet's profound study of extreme points of a compact convex set, which is one of the great discoveries in analysis after the mid-20th century.

This period also marks the introduction in potential theory of spaces much more general than Euclidean spaces or certain manifolds and of more general kernels N than the Newtonian or logarithmic ones, N a suitable function of two variables (and even of more general concepts). Around 1940 certain basic properties of the classical theory were introduced as axioms in suitably chosen topological spaces and a discussion began of various generalizations and interactions between different axioms or principles.

Since about 1955 topological refinements and new axiomatizations have been made and the role of probability introduced. Fine topology was extended to the Martin boundary, and it became an essential tool for the study of the boundary behaviour of functions connected with potential theory.

Rather than speaking about the further developments with kernels $N(x, y)$, an axiomatic theory is sketched that is not based on such kernels. Given real-valued continuous functions are used, called harmonic functions, defined on every domain of a suitable topological space and satisfying some well-known properties of the classical theory that are considered as axioms. It was found possible to imitate the classical developments. In this direction, after some attempts, Joseph Leo Doob of the United States constructed a better base of an axiomatic theory but for probabilistic purposes. This inspired a detailed potential theory by Brelot and followers, such as the French mathematician Rose-Marie Hervé. The solutions of partial differential equations of elliptic type more general than that of the Laplace equation satisfy the basic axioms under some restrictions. But the theory is not applicable to equations of a more general type like the classical heat equation. In order to include such equations, Heinz Bauer of West Germany and others extended the previous theory by weakening the axioms. Later the systematic search for all theories satisfying such local axioms was partly solved by Jean-Michel Bony.

On the other hand, the concepts of energy and Dirichlet integral led Deny and the Swedish-born American mathematician Arne Carl-August Beurling to another axiomatic theory of global character, called the theory of Dirichlet spaces (for complex functions). Problems similar to those of equilibrium and balayage were studied.

These axiomatic theories, including interesting cases of the last one, are actually contained in a fundamental probabilistic theory developed by Gilbert Hunt between 1957 and 1958. A function of a point x and of a set e , called a kernel $V(x, e)$, which transforms a nonnegative function f into a nonnegative function Vf , is considered. Under certain conditions, this V may be expressed by means of similar kernels of a certain family $\{P_i\}_{i \geq 0}$ by means of which the so-called excessive functions can be defined. These majorize their P_i -transforms. This $\{P_i\}$ has an essential probabilistic interpretation in terms of "Markov processes," named for the Russian mathematician Andrey Andreyevich Markov, of which the Brownian motion of physics is a particular case.

It was shown by Paul-André Meyer and others that, given any of the above local axiomatic theories, it is possible to find a V for which the excessive functions of the corresponding $\{P_i\}$ are precisely the nonnegative hyperharmonic functions.

Various probabilistic notions like trajectories (of a particle) or martingales led to probabilistic interpretations of concepts and results of the above classical or axiomatic theories. The relations between probability and potential theory, known for a long time as "folklore" in the classical theory, deeply studied by Doob then Hunt and many others, have now produced a new and rich chapter in analysis. The latest researches are also concerned with a converse problem: given a family of functions, under what conditions can one interpret them as potentials or superharmonic functions in the above local axiomatics or excessive functions in a global extension of Hunt theory?

BASIC CONCEPTS AND RESULTS OF CLASSICAL POTENTIAL THEORY

Using more advanced mathematical tools, the most important points of classical theory will now be outlined. A

Sub-
harmonic
and
super-
harmonic
functions

Martin
boundary

Euclidean space \mathbb{R}^n ($n \geq 2$) will be considered first, the case $n = 1$ being rather trivial.

Harmonic functions. A real finite continuous function u on an open set ω is said to be harmonic, if it is equal at each point x to its mean value on any ball (that is, a disc in \mathbb{R}^2) $B_r(x)$ (centre x , radius r), or equivalently (using the corresponding Lebesgue measure), on the boundary $\partial B_r(x)$ ($B_r(x) \subset \omega$). This implies that u is C^∞ (infinitely differentiable) and, further, is equivalent to saying that $\Delta u = 0$ (local condition). Also, $\Delta u = 0$ in the sense of Schwartz is equivalent to saying that u is a function equal almost everywhere to a harmonic function.

The definition implies that a harmonic function that attains its maximum (or minimum) at a point x_0 is constant on a neighbourhood. This maximum or minimum principle is a key tool. A form that will be valid later in more general theories may be stated in the following manner. If at any boundary point (which may be the Aleksandrov point [named for the Soviet mathematician Aleksandr Danilovich Aleksandrov] at infinity) $\liminf u \geq 0$, then $u \geq 0$.

This implies that for a finite boundary function f the Dirichlet problem possesses at most one solution. The question of existence is more difficult. For a ball $B = B_0^R$ and a finite continuous function f , the solution is given by the Poisson integral (see 435) integrated with respect to the measure σ (σ being the normalized measure on ∂B proportional to angle or solid angle). For any f , I_f will denote the upper-integral which is $+\infty$, $-\infty$, or harmonic. Note that by changing $f d\sigma$ into any Radon measure $d\mu$ on ∂B , the corresponding $I_f(y)$ (called a Poisson-Stieltjes integral) is harmonic in B and represents in the general case the difference of two nonnegative harmonic functions.

The Poisson integral I_f implies many properties: a local criterion (by considering in the definition for any x only those $\partial B_r(x)$ with $0 < r < r(x)$ an arbitrary function); analyticity (and various power series); the Harnack inequalities: u harmonic > 0 in B_0^R implies upper and lower bounds for the ratio of u at y to u at zero (see 436), which in turn implies the equicontinuity at any point of any family of positive-bounded harmonic functions.

It should be emphasized that uniform convergence preserves harmonicity and implies local uniform convergence for any derivative, that in a domain (connected open set) an increasing sequence u_n of harmonic functions tends to $+\infty$ or to a harmonic function (uniformly locally in an obvious sense), and that there is an extension to an increasing directed family.

$$(435) \quad I_f^B(y) = \int \frac{R^2 - |y|^2}{|x - y|^n} R^{n-2} f(x) d\sigma(x)$$

$$(436) \quad R^{n-2} \frac{R - |y|}{(R + |y|)^{n-1}} \leq \frac{u(y)}{u(0)} \leq R^{n-2} \frac{R + |y|}{(R - |y|)^{n-1}}$$

$$(437) \quad u(y) = H_1(y) + |y|^2 H_2(y) + \cdots + |y|^{2p-2} H_p(y)$$

$$(438) \quad \bar{B}_x^r(w), \quad u \geq \bar{I}_u^{B_x^r}$$

$$(439) \quad h_x(y) - I_{h_x}^B(y) = G(x, y)$$

$$(440) \quad \int G(x, y) d\mu(x), \quad \mu \geq 0$$

$$(441) \quad \int G(x, y) d\mu(x) + u^*(y)$$

$$(442) \quad G(x, y) = |x - y|^{2-n}$$

$$(443) \quad \int G(x, y) d\mu(x)$$

Polyharmonic functions. Definitions, by iteration of Δ , were previously given. Extensions were made systematically of many properties of harmonic and subharmonic functions. The old development of Almansi is mentioned for a function of ε^{2p} type, harmonic of order p in a domain containing 0, by means of harmonic functions H_i (see 437).

Sub- and superharmonic functions. In an open set ω , u is said to be hyperharmonic if (i) u is lower semicontinuous; (ii) $u > -\infty$; (iii) for each ball contained in an open set, u has a specific lower bound (see 438; equivalently, only at x and for sufficiently small r ; a local definition). In a domain, such a function is either identically $+\infty$ or finite on a dense set and in the first case is called superharmonic ($-u$ is called hypoharmonic and subharmonic, respectively).

The previous minimum-principle is still valid. Any set of superharmonic functions ≥ 0 has a greatest harmonic minorant. The set of the harmonic functions ≥ 0 is a complete lattice for the natural order. The set of the superharmonic functions ≥ 0 is a complete upper semi-lattice for the natural order and also for the specific order defined by setting $u > \omega$ if $u = \omega + a$ nonnegative superharmonic function.

Riesz representation. Any superharmonic function u is locally equal to $\int h(|x-y|) d\mu(x)$ plus a harmonic function, for a suitable measure $\mu \geq 0$.

For a ball B a specific function symmetric in x and y (see 439) is called Green's function. An integral of Green's function integrated with respect to x and μ (see 440), in which nonnegative μ is a Radon measure on B , is superharmonic or $+\infty$. Any superharmonic function u on B with a harmonic minorant is equal to such an integral plus a function u^* (see 441) in which u^* is the greatest harmonic minorant of u on B . (Unique in both local and global representations, μ is called the associated measure.)

In \mathbb{R}^n ($n \geq 3$), the same result is valid in the whole \mathbb{R}^n by taking a specific form of Green's function (see 442).

If u is an e^2 function the result is easy to show; the general case is less easy unless Schwartz distributions are used. It is also possible, for the global form, to use a Choquet theorem on extreme elements.

The fact that $u^* = 0$ means that u is a Green potential (see 443).

Reduced function. On a fixed open set ω , a real function $\varphi \geq 0$ and a set e are considered. The reduced function of φ relative to e (denoted R_e^{φ}) is defined to be the lower envelope of all hyperharmonic nonnegative functions on ω majorizing φ on e . If $\hat{R}_e^{\varphi}(x)$ is the \liminf at x of R_e^{φ} , then \hat{R}_e^{φ} is hyperharmonic.

When φ is superharmonic, \hat{R}_e^{φ} is superharmonic and is called the "swept-out" or "balayaged" function of φ relative to e .

Polar sets and capacity. A set e in an open set ω is called polar in ω if there exists a nonnegative superharmonic function in ω equal to $+\infty$ on e . When there exists a superharmonic $u > 0$ on ω , e is polar if $R_e^u \equiv 0$.

Note that, if a set is locally polar, then it is polar in \mathbb{R}^n ($n \geq 3$) or in any domain where there exists a nonconstant superharmonic function ≥ 0 .

A superharmonic function $u \geq 0$ on $\omega - e$ where e is closed and locally polar has a unique continuation to ω as a superharmonic function. If u is bounded and harmonic, the continuation is harmonic.

A real-valued function ζ (finite or not) defined on the class of all subsets of a Hausdorff space E is called a general capacity if (a) ζ is an increasing function; (b) for any increasing sequence (e_n) of subsets of E , $\zeta(e_n) \rightarrow \zeta(\bigcup e_n)$; and (c) for any decreasing sequence of compact sets K_n , a similar convergent holds expressed in terms of intersection (see 444).

A K -analytic set of E is one that is the continuous image of K_∞ set (countable intersection of K_σ sets; that is, of countable unions of compact sets) contained in a compact space, as, for example, the ordinary-Borel sets (named for the French mathematician Émile Borel) in a space like \mathbb{R}^n . The celebrated Choquet capacitability theorem asserts that any K -analytic set e contained in a K_σ set is " ζ -capacitable" (K compact $\subset e$; see 445).

An example is where E is a ball on \mathbb{R}^n ($n \geq 3$).

Poisson
integral

Choquet
capacitability
theorem

$$(444) \quad \zeta(K_n) \rightarrow \zeta(\cap K_n)$$

$$(445) \quad \zeta(e) = \sup_K \zeta(K)$$

$$(446) \quad C_*(K) = \sup \{C(K) \mid K \subset e, \text{ compact}\}$$

$$(447) \quad C^*(e) = \inf \{C_*(\omega) \mid e \subset \omega, \text{ open}\}$$

$$(448) \quad u(x_0) < \liminf_{x \in e, x \rightarrow x_0} u(x)$$

$$(449) \quad \lim_{r \rightarrow 0} \sigma_r(e \cap \partial B_{x_0}^r) = 0$$

$C(K)$ denotes the supremum of $\{\mu(K), \mu \geq 0, \text{ a measure on } K \text{ whose Green potential is } \leq 1\}$.

It equals the infimum of $\{\nu(E) \mid \nu \geq 0, \text{ a measure on } E \text{ whose Green potential is } \geq 1 \text{ on } K\}$. Letting $C_*(K)$ be an innercapacity (see 446) and $C^*(e)$ be an outercapacity (see 447) then C^* is a general capacity, $C^*(e) = C_*(e)$ for any Borel set e ; and for any relatively compact set e , $C_*(e)$ is the total mass of the measure associated to \hat{R}_1^e in E (which is even a potential). As a consequence of this, in the space E , the sets of outercapacity 0 are thus the polar sets.

Thin sets and fine topology. A set e is thin at $x_0 \notin e$ if $x_0 \notin \bar{e}$ or if there exists a superharmonic function u in the neighbourhood of x_0 such that at x_0 it is strictly less than its inferior limit (see 448). The family of complements of sets thin at x form the family of neighbourhoods of x in the so-called "fine topology" which is the coarsest one, making all superharmonic functions continuous. It is finer than the Euclidean one. In \mathbb{R}^n the definition is extended by saying that e is thin at $x_0 \in e$ if $e - \{x_0\}$ is thin at x_0 .

Thinness of e at x_0 is much stronger than the condition in which σ_r is the surface measure (see 449).

Locally polar sets are characterized as thin at every point, or sets of "fine isolated" points. In \mathbb{R}^2 , for a set thin at x_0 , there exist arbitrarily small circles centred at x_0 and not intersecting the set.

As an example of application: if u is a nonnegative superharmonic function on an open set ω , with a boundary point x_0 such that $C\omega$ is thin at x_0 , then it has a fine limit at x_0 , and this coincides with the Euclidean limit on $\omega \setminus e$ where e is a suitable thin set.

Dirichlet problem. ω is taken to be a bounded open set of \mathbb{R}^n and f is a given extended real-valued function on $\partial\omega$. All hyperharmonic functions v on ω are considered, satisfying $\liminf v \geq f(x)$ and also $< -\infty$, for $y \in \omega$, $y \rightarrow x$ every $x \in \partial\omega$. The lower envelope is a function H_f that, in every component of ω , is $+\infty$, $-\infty$, or harmonic. The similar envelope $H_f = -H_f$ is $\leq H_f$. In case both are equal and finite, the common value is denoted by H_f (solution) and f is said to be resolvable. This happens when f is continuous. Then $H_f(y)$ has, for a fixed y , a linear form $\int f d\rho_y^\omega$ with a measure ρ_y^ω called harmonic measure. For a domain ω , resolvability of any f is equivalent to its ρ_y^ω -integrability (independent of y in ω).

A boundary point x is said to be regular if, for any finite continuous f , $H_f(y)$ tends to $f(x)$ at x . This is equivalent to saying that ω is not thin at x_0 . It will be shown later that the irregular points form a locally polar set, as a consequence of a powerful convergence theorem.

Green's function; Green space. It is possible to define on the space \mathbb{R}^n (compactified from \mathbb{R}^n with an Aleksandrov point \mathbb{U} at infinity) harmonic, hyper-, or superharmonic functions (even in the neighbourhoods of \mathbb{U}) by a suitable mean value property, so as to preserve the minimum principle. The Newtonian and logarithmic kernels may be adapted and the local Riesz representation is preserved with a unique associated measure.

A \mathcal{G} -space is defined to be a Hausdorff space with, for each point x , a homeomorphism of an open neighbourhood V of x onto an open set of \mathbb{R}^n , such that for any two such neighbourhoods say V' and V'' the images of

$V' \cap V''$ under the different homeomorphisms are isometric or also if $n=2$ in conformal (but not necessarily orientation-preserving) correspondence. Examples are \mathbb{R}^n and the classical Riemann surfaces.

This gives, on a \mathcal{G} -space, local notions of harmonic, hyper-, or superharmonic functions. When there exists a nonconstant superharmonic function greater than 0, one says that \mathcal{G} is a Green space. Examples are \mathbb{R}^n ($n \geq 3$) or any bounded domain of \mathbb{R}^n . Then there exists a smallest superharmonic function ≥ 0 whose associated measure contains the unit mass at a point x . It is a generalization $G(x, y)$, still symmetric, of the Green's function of a ball. Green's potential $\int G(x, y) d\mu(y)$ ($\mu \geq 0$ on Ω), when not everywhere $+\infty$, is superharmonic with the greatest harmonic minorant equal to 0. The previous theory may be extended. Here it is only noted that a point at infinity (that is, one whose local image is \mathbb{U}) is nonpolar for $n > 2$ and that it is suitable to define the thinness of $e \in x_0$ at x_0 with the supplementary condition that x_0 is polar. On a Green space, locally polar is equivalent to polar; one says "quasi-everywhere" for "except on a locally polar set."

The general classical convergence theorem. Given on an open set ω (in a \mathcal{G} -space) a family of locally lower-bounded superharmonic functions u_i , $\inf u_i$ (which is at every point the \liminf of $\inf u_i$) is superharmonic and differs from $\inf u_i$ on a locally polar set.

Applications in a Green space Ω : (a) A superharmonic function $u \geq 0$ is considered. Then \hat{R}_u^e is equal to u quasi-everywhere on e , and harmonic outside of \bar{e} . If u is a potential or e is relatively compact, \hat{R}_u^e is a potential. In \mathbb{R}^3 , for example, for a nonpolar compact set e , \hat{R}_1^e is the Newtonian potential of a measure ≥ 0 on e , with value 1, quasi-everywhere on e . This gives a solution of the equilibrium problem of Gauss but with a constant value only quasi-everywhere on e , and it is unique when the potential is bounded.

(b) The set of points where a set e is thin is polar. As an example, the set of irregular points of a Dirichlet problem for a relatively compact open set ω is polar.

(c) In treating a general form of the balayage, if a measure $\mu \geq 0$ with Green's potential V is given, the balayaged potential \hat{R}_μ^e is characterized by the following properties:

- i. This potential is equal to V quasi-everywhere on e ;
- ii. The associated measure b_μ is supported by the "base" B_e of e , which is the set of points where e is not thin ($b_\mu(CB_e) = 0$).

Dirichlet principle. Consider first a bounded open set ω of \mathbb{R}^n and a C^∞ -function f on ω , with a finite Dirichlet norm (see 450) and possessing a finite continuous extension on $\partial\omega$. Then there exists a harmonic function u on ω , unique up to a constant, such that $\|u - f\|$ is minimum; and it is H_f^ω .

This can be generalized by considering a \mathcal{G} -space Ω without any points at infinity, a domain ω relatively compact in Ω and a (BLD) function f on Ω that is a function which is a limit at every point, and also a limit according to the Dirichlet norm, of a Cauchy sequence of C^∞ -functions with finite norms. Let f_ω be the restriction of f_ω to ω . Then the minimizing function u is the projection of f_ω in the Hilbert space of the (BLD) functions on ω defined by the scalar product $\int (\text{grad } u, \text{grad } v) dx$, on the complete subspace of the harmonic (BLD) functions on ω ; u is, in addition, the

$$(450) \quad \|f\| = \sqrt{\int \text{grad}^2 f dx}$$

$$(451) \quad (\mu, \nu) = \int U^\mu d\nu$$

$$(452) \quad \int (U^{\mu_1} - U^{\mu_2})(d\nu_1 - d\nu_2)$$

$$(453) \quad G(x, y), K(x, y) = \frac{G(x, y)}{G(x, y_0)}$$

$$(454) \quad \int K(X, y) d\mu_y(X)$$

$$(455) \quad R_{K(X, y)}^e \neq K(X, y)$$

unique harmonic function the continuation of which by f is (BLD) in Ω .

Energy. First \mathfrak{R}^n ($n \geq 3$) or a ball of \mathfrak{R}^n is considered. Inspired by the kernels $|x - y|^{-n}$, of Marcel Riesz, Cartan introduced with the classical potential U^r the mutual energy of positive measures (see 451), the energy (μ, μ) , and then the same notions for differences of measures of finite energy using for such differences a formal development of an integral (see 452). Then the energy is ≥ 0 and is zero only when $\mu_1 - \mu_2 \equiv 0$ (the principle of energy). The space \mathfrak{G} of these signed measures of finite energy with mutual energy as scalar product is pre-Hilbert, and the subset \mathfrak{G}^+ of the nonnegative measures is complete. As an application, the balayage of a measure μ in \mathfrak{G} relative to a compact K is given by the projection in \mathfrak{G} of μ on the set of measures of \mathfrak{G}^+ supported by K . It is now known that a polar set has μ -measure 0 for (μ, μ) finite; the previous definitions can be directly extended to the case of a Green space and Green's potentials. The principle of energy with its consequences holds. Note that such potentials are BLD functions and also that the energy-norm and the Dirichlet norm are proportional. Other extensions are possible. Deny even developed a similar theory in \mathfrak{R}^n with Schwartz distributions, a fixed one as kernel N , a variable one T , and the convolution as potential.

Martin boundary. In a Green space Ω , Green's function G and its ratio to the functional value obtained by setting the Green's function argument y equal to a fixed point y_0

(see 453) may be considered. Here there exists a compact space $\bar{\Omega}$ (Martin space) unique up to homeomorphism, in which Ω is dense and such that all functions $K(x, y)$ of x have continuous continuations $K(X, y)$ separating the (Martin) boundary $\Delta = \bar{\Omega} - \Omega$. It is identical to the Euclidean closure when Ω is a ball or a sufficiently regular domain, but generally is quite different. A harmonic function $u > 0$ is called minimal if any other similar but smaller function must be proportional to it. The minimal functions are proportional to certain of the functions of y $K(X, y)$ (where X is in Δ) and the corresponding points are called minimal and form a part Δ_1 of Δ .

Any harmonic function $u \geq 0$ has a unique representation as an integral of K integrated with respect to the measure μ_u (see 454) where μ_u is a Radon measure ≥ 0 on Δ supported by Δ_1 . A Dirichlet problem may be studied with this boundary and any finite continuous function is resolutive. A set e is said to be thin at $X \in \Delta_1$ if a condition involving K holds (see 455). The fine topology on Ω may be extended to $\Omega \cup \Delta_1$, in a unique way such that the neighbourhoods of any $X \in \Delta_1$ intersect Ω in sets that are the complements of sets in Ω thin at X .

Among many applications of this new tool, Doob's result is important—that for any superharmonic $u > 0$ and any harmonic $h > 0$, u/h has a fine limit at the points of Δ_1 except on a set of μ_u measure 0. This implies old results, as, for example, the famous result of Pierre Fatou that a harmonic function $u > 0$ in a ball has a nontangential limit almost everywhere on the boundary. (Ed.)

SPECIAL FUNCTIONS

Certain special functions are often used in mathematics and in physics, chemistry, engineering, and other branches of science and technology. It is possible to classify these into elementary functions and higher transcendental functions. The elementary functions include the exponential, logarithmic, trigonometric, and related functions. Frequently the term special functions is only applied to high transcendental functions. Some of the more important ones arising in differential equations will now be described.

The gamma and beta functions. The gamma function arose from attempts to extend the factorial function, $n! \equiv n(n-1)(n-2) \cdots 1$, to nonintegral values of n . This function is defined by $\Gamma(x)$ being equal to the integral from $t=0$ to infinity of $e^{-t} t^{x-1}$ (see 456), for values of x greater than zero. The function has the property that $\Gamma(x+1)$ equals the product of x and $\Gamma(x)$.

It follows that, if n is a positive integer, then $\Gamma(n+1)$ equals $n!$. Furthermore, $\Gamma(1/2)$ equals the square root of π (see 457).

The function was first defined by Euler and is widely used in mathematics, physics, engineering, and especially in probability theory and statistics. It arises in the series solutions of many differential equations.

Some useful related functions are:

(i) The incomplete gamma functions, which are defined by letting the upper or the lower limit of integration be a variable (see 458).

(ii) The beta function $\beta(p, q)$, which is defined as being equal to the integral from zero to one of the products of t^{p-1} and $(1-t)^{q-1}$ (see 459) for positive values of p and q . It is related to the gamma function because $\beta(p, q)$ equals the product of $\Gamma(p)$ and $\Gamma(q)$ divided by $\Gamma(p+q)$ (see 460).

Hypergeometric function. The hypergeometric function is the function $F(a, b; c; x)$ defined by the so-called hypergeometric series (see 461). It gets its name from the fact that it is a generalization of the geometric series $(1+x+x^2+\cdots)$ and reduces to this series when $a=1$ and $b=c$. It satisfies the hypergeometric equation, a second-order linear differential equation with variable coefficients (see 462). Twenty-four solutions of this equation can be expressed in terms of hypergeometric equations.

The hypergeometric equation occurs in problems in fluid flow and other branches of physics and engineering. The hypergeometric function is important in mathematics because many other special functions are related to it.

Legendre polynomials. Legendre polynomials arise as particular solutions of Laplace's equation: $\Delta_3 u = 0$. If R is the distance between a point with Cartesian coordinates (x, y, z) and the point $(0, 0, 1)$, then the reciprocal distance, $1/R$, is a solution of Laplace's equation. If spherical polar coordinates are used for the point (r, θ, ϕ) , this solution is $1 - 2r \cos \theta + r^2$ to the $-1/2$ power. It is axisymmetric because it is independent of ϕ , the azimuthal angle.

If $\cos \theta$ is replaced by μ the solution is $(1 - 2r\mu - r^2)^{-1/2}$, and it can be expanded to give a power series in r with the coefficients being polynomials in μ . Thus it can be written in the form of an infinite series with terms of the form $r^n P_n(\mu)$ for r less than 1 (see 463).

The coefficients P_n are called the Legendre polynomials of degree n .

The polynomials are solutions of Legendre's equation (see 319), a particular case of Laplace's equation expressed in spherical polar coordinates for axisymmetric solutions. They can be produced from the generating function $(1 - 2r\mu - r^2)^{-1/2}$ and are explicitly given by Rodrigues' formula (see 464), which is named after a 19th-century French mathematician, Olinde Rodrigues.

Associated Legendre functions. These are functions satisfying the associated Legendre differential equation, a second-order linear equation with variable coefficients (see 465). This reduces to Legendre's equation when $m=0$. Its solutions are associated Legendre functions (or polynomials). They are denoted by P_n^m and can be expressed in terms of the Legendre polynomials (see 466).

Spherical harmonics. The Legendre polynomials and associated Legendre functions are particular solutions of Laplace's equation. In general, functions satisfying this equation are known as harmonic functions; solutions that are homogeneous in x, y , and z are called spherical solid harmonics. If polar coordinates (r, θ, ϕ) are used, a spherical solid harmonic of degree n , R_n , can be written as the product of r^n and $S_n(\theta, \phi)$ (see 467), a function of θ and ϕ satisfying a second-order linear partial differential equation that is found by substituting R_n into Laplace's equation and separating the variables (see 468). It is called a spherical surface harmonic. If $R_n(x, y, z)$ is a polynomial of degree n (n a positive integer), then S_n is a polynomial in $\cos \theta, \sin \theta, \cos \phi$, and $\sin \phi$.

Zonal, sectoral, and tesseral harmonics. A polynomial spherical harmonic of degree n can be represented uniquely

$$(456) \quad \Gamma(x) = \int_0^\infty e^{-t} t^{x-1} dt$$

$$(457) \quad \begin{cases} \Gamma(x+1) = x\Gamma(x) \\ \Gamma(n+1) = n! \\ \Gamma(\frac{1}{2}) = \sqrt{\pi} \end{cases}$$

$$(458) \quad \begin{cases} \gamma(x, y) = \int_0^z e^{-t} t^{x-1} dt \\ \Gamma(x, z) = \int_z^\infty e^{-t} t^{x-1} dt \end{cases}$$

$$(459) \quad \beta(p, q) = \int_0^1 t^{p-1} (1-t)^{q-1} dt$$

$$(460) \quad \beta(p, q) = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)}$$

$$(461) \quad \begin{cases} 1 + \frac{abx}{c \cdot 1} + \frac{a(a+1)b(b+1)x^2}{c(c+1) \cdot 2!} \\ + \frac{a(a+1)(a+2)b(b+1)(b+2)x^3}{c(c+1)(c+2) \cdot 3!} + \dots \end{cases}$$

$$(462) \quad x(1-x) \frac{d^2y}{dx^2} + [c - (a+b+1)x] \frac{dy}{dx} - aby = 0$$

$$(463) \quad \begin{cases} \frac{1}{\sqrt{1-2r \cos \theta + r^2}} = 1 + r\mu + \frac{1}{2}r^2(3\mu^2 + 1) + \dots \\ = \sum_0^\infty r^n P_n(\mu) \end{cases}$$

$$(464) \quad P_n(\mu) = \frac{1}{2^n n!} \frac{d^n}{d\mu^n} (\mu^2 - 1)^n$$

$$(465) \quad (1 - \mu^2) \frac{d^2\omega}{d\mu^2} - 2\mu \frac{d\omega}{d\mu} + \left\{ (n+1) - \frac{m^2}{1-\mu^2} \right\} \omega = 0$$

$$(466) \quad P_n^m(\mu) = (-1)^m (1 - \mu^2)^{m/2} \frac{d^m}{d\mu^m} P_n(\mu)$$

$$(467) \quad R_n(x, y, z) = r^n S_n(\theta, \varphi)$$

$$(468) \quad \frac{\partial^2 S}{\partial \theta^2} + \cot \theta \frac{\partial S}{\partial \theta} + \csc^3 \theta \frac{\partial^2 S}{\partial \varphi^2} + n(n+1)S = 0$$

$$(469) \quad c_n \frac{r^{2n+1}}{\partial h_1 \partial h_2 \dots \partial h_n} \frac{1}{r}$$

by the product $C_n r^{2n+1}$, in which C_n is a constant, times n differentiations $\partial/\partial h_1, \partial/\partial h_2, \dots, \partial/\partial h_n$ of $1/r$, in which (see 469) h_1, h_2, \dots, h_n are n directions in space, and $\partial/\partial h$ denotes differentiation in a direction h . If the n directions coincide, then, on a unit sphere about the origin, there are n circles of latitude on which the spherical surface (or solid) harmonic vanishes. These divide the sphere into zones, and the spherical harmonic is known as a zonal harmonic. The curves on the unit sphere on which the surface harmonic vanishes are called nodal lines. If the n directions are situated on a plane and are at angles of π/n to each other, the nodal lines are n circles of longitude. These divide the sphere into sectors, the spherical harmonic being known as a sectoral harmonic. If $(n-m)$ directions coincide in one particular direction and the remaining m directions lie in a plane at right angles to this direction and are at angles π/m , then there are m circles of longitude and $(n-m)$ circles of latitude. These divide the

unit sphere into rectangles, the spherical harmonic being a tesseral harmonic.

It can be proved that spherical surface harmonics can be represented by the product $S_n^m(\theta, \varphi)$ of the associated Legendre function $P_n^m(\cos \theta)$ and the complex exponential $\exp[i m \varphi]$ (see 470). Laplace's equation is satisfied by a linear combination of terms $R_n^m(x, y, z)$, which are products of r^n , $\exp[i m \varphi]$, and $P_n^m(\cos \theta)$ (see 471).

$P_n^m(\cos \theta)$ is an associated Legendre polynomial. If $m = n$, the harmonic is a sectoral harmonic. If $1 \leq m \leq n-1$, it is a tesseral harmonic. If $m = 0$, it is a zonal harmonic; the Legendre polynomial $P_n(\cos \theta)$ is a zonal harmonic of degree n .

Spherical harmonics and surface harmonics arise in a variety of physical applications of Laplace's equation. Surface harmonics also arise in connection with Poisson's equation (see 317), the wave equation (see 326), the diffusion equation (see 332), Schrödinger's equation (see 338), and other partial differential equations.

Bessel functions. Just as the Laplace equations expressed in spherical polar coordinates lead to the Legendre equation and Legendre polynomials, its expression in cylindrical polar coordinates leads to the equation known as Bessel's equation. Bessel's equation of order ν is a second-order differential equation with variable coefficients (see 472) and is satisfied by the Bessel function (or Bessel function of the first kind), which can be expressed as a power series in powers of $t/2$ (see 473). $J_\nu(t)$ is the Bessel function of order ν . Such functions were used by the German astronomer Friedrich Wilhelm Bessel in the 19th century

$$(470) \quad S_n^m(\theta, \varphi) = e^{im\varphi} P_n^m(\cos \theta)$$

$$(471) \quad R_n^m(x, y, z) = r^n e^{im\varphi} P_n^m(\cos \theta)$$

$$(472) \quad \frac{d^2\omega}{dt^2} + \frac{1}{t} \frac{d\omega}{dt} + \left(1 - \frac{\nu^2}{t^2}\right) \omega = 0$$

$$(473) \quad J_\nu(t) = \sum_{n=0}^\infty \frac{(-1)^n}{n! \Gamma(\nu + n + 1)} \left(\frac{t}{2}\right)^{\nu+2n}$$

$$(474) \quad Y_\nu = \frac{J_\nu(t) \cos(\nu\pi) - J_{-\nu}(t)}{\sin(\nu\pi)}$$

$$(475) \quad Y_\nu(t) = \lim_{\nu \rightarrow p} \frac{J_\nu(t) \cos(\nu\pi) - J_{-\nu}(t)}{\sin(\nu\pi)}$$

$$(476) \quad \begin{cases} H_1^*(t) = J_\nu(t) + iY_\nu(t) \\ H_2^*(t) = J_\nu(t) - iY_\nu(t) \end{cases}$$

$$(477) \quad \begin{cases} I_\nu(t) = (i)^{-\nu} J_\nu(it) \\ K_\nu(t) = \frac{1}{2} \pi (\sin \nu\pi)^{-1} [I_{-\nu}(t) - I_\nu(t)] \end{cases}$$

$$(478) \quad H_n(x) = (-1)^n e^{x^2} \frac{d^n e^{-x^2}}{dx^n}$$

$$(479) \quad \frac{d^2y}{dx^2} - 2x \frac{dy}{dx} + 2ny = 0$$

$$(480) \quad \int_a^b P_n(x) P_m(x) W(x) dx = 0, \quad m \neq n$$

$$(481) \quad \int_a^b [P_n(x)]^2 W(x) dx = 1$$

$$(482) \quad L_n(x) = e^x \frac{d^n}{dx^n} (x^n e^{-x})$$

$$(483) \quad x \frac{d^2y}{dx^2} + (1-x) \frac{dy}{dx} + nx = 0$$

Nodal
lines

in problems in astronomy; they had been used earlier by Bernoulli and Euler.

A second solution of the equation, if ν is not an integer, is $J_{-\nu}(t)$, leading to the general solution $AJ_{\nu}(t) + BJ_{-\nu}(t)$, A and B being constants.

If ν is an integer, p , the second solution is denoted by $Y_p(t)$, and a general solution is $AJ_p(t) + BY_p(t)$. For nonintegral and zero values of ν , $Y_p(t)$ can be expressed as the difference of $J_p(t)\cos(\nu\pi)$ and $J_{-\nu}(t)$, divided by $\sin(\nu\pi)$ (see 474), and is called a Bessel function of the second kind. It can be shown that if ν tends to an integer p (or to zero) in the limit, the expression gives $Y_p(t)$ (or $Y_0(t)$; see 475). Thus $AJ_p(t) + BY_p(t)$ is a general solution for all values of ν . Bessel functions of the second kind are sometimes called Neumann functions. The functions $H_p^{(1)}(t)$, defined as the sum of $J_p(t)$ and $iY_p(t)$, and $H_p^{(2)}(t)$, defined as their difference (see 476) are called Hankel functions, after the 19th-century German mathematician and historian Hermann Hankel, or Bessel functions of the third kind.

If t is replaced by it (in which $i = \sqrt{-1}$), the differential equation is the modified Bessel equation and its solutions are modified Bessel functions (of the first and second kind) of which $I_p(t)$, the modified Bessel function of the first kind, is the product of $(i)^{-\nu}$ and $J_p(it)$, and $K_p(t)$, the modified Bessel function of the second kind, is defined in terms of $I_p(t)$ and $(\sin \nu\pi)^{-1}$ (see 477). If ν is an integer p , $K_p(t)$ is the limit of the expression.

Bessel functions are widely used in physics, especially in problems in potential theory and diffusion. They frequently arise in problems involving cylindrical boundaries and are sometimes called cylinder functions.

Hermite polynomials. Hermite polynomials are defined in terms of the derivatives of $\exp(-x^2)$ for nonnegative integers n (see 478). They are solutions of Hermite's equation, named after the 19th-century French mathematician Charles Hermite. This is a reduced form of Schrödinger's equations and is used in wave mechanics, especially in the theory of wave functions of the harmonic oscillator. Hermite's equation, also, is a second-order differential

equation, with the coefficient of the first derivative being $-2x$ (see 479).

Orthogonal polynomials. Hermite polynomials are examples of orthogonal polynomials. A system of polynomials P_n is orthogonal on the interval (a, b) with respect to a weight function $w(x)$ if the integral over the interval of the product of two elements of the system, $P_m(x)$ and $P_n(x)$ and the weight $w(x)$, equals zero whenever m and n are not equal (see 480). The system is orthonormal if it is orthogonal and normalized by the integral over the interval of the product of the square of $P_n(x)$ and $w(x)$ being equal to unity (see 481).

Hermite polynomials are orthogonal on the interval $(-\infty, \infty)$ with a weighting function of $\exp(-x^2)$. Other systems of orthogonal polynomials exist. For example, Legendre polynomials are orthogonal in the interval $(-1, 1)$ with a weighting factor of 1. The Laguerre polynomials (named after the 19th-century French mathematician Edmond Laguerre), the n th of which is defined as the product of e^x and the n th derivative of $x^n e^{-x}$ (see 482), are orthogonal over the interval $(0, \infty)$ with a weighting factor of e^{-x} (in some cases more general functions with a weighting factor of $x^a e^{-x}$ are called Laguerre polynomials). These polynomials are solutions of Laguerre's equation (see 483). This, like Hermite's equation, is used in wave mechanics. The associated Laguerre polynomials $L_n^m(x)$ are defined by $L_n^m(x)$ being equal to the m th derivative of the n th Laguerre polynomial (see 484), and they, in turn, satisfy the associated Laguerre equation (see 485). (Ed.)

$$(484) \quad L_n^m(x) = \frac{d^m}{dx^m} L_n(x)$$

$$(485) \quad x \frac{d^2 y}{dx^2} + (m+1-x) \frac{dy}{dx} + (n-m)y = 0$$

FOURIER ANALYSIS

Fourier analysis, one of the most important tools of mathematics and mathematical physics, arose originally from problems involving vibrating cords as studied by Leonhard Euler and Daniel Bernoulli in the 18th century. The subject was named for Jean-Baptiste-Joseph Fourier, whose work on the representation of mathematical functions as sums of trigonometric functions was published in his *Théorie analytique de la chaleur* (*The Analytical Theory of Heat*) in 1822.

FOURIER SERIES

Fourier series are a particular case of the general class of series of functions discussed in the section *Infinite series* above.

An infinite series of the form of a sum composed of a constant term and weighted trigonometric functions with angles $x, 2x$, and so forth (see 486) is called a trigonometric series. The quantities $a_0, a_1, b_1, a_2, b_2, \dots$ are constants and x takes values between $-\infty$ and $+\infty$. If the series converges for all values of x , and $f(x)$ denotes the sum of the series, then $f(x)$ is periodic with a period 2π , because replacing x by $x + 2\pi$ does not change the series. If both sides of $f(x) = \frac{1}{2}a_0 + (a_1 \cos x + b_1 \sin x) + \dots$ are multiplied by $\cos nx$ or $\sin nx$ and the result is integrated over the interval $(0, 2\pi)$, then two integral expressions for the a_n and b_n involving the function f and a trigonometric function are obtained (see 487); this argument is purely formal (it is justified if the series converges uniformly, or

even in some more general case). It suggests, however, an interesting problem. If for any periodic function $f(x)$ with period 2π the numbers a_n, b_n are computed by means of the integral formulas to form a series (see 486), does the series so defined represent the function $f(x)$? The numbers obtained from the formulas (487) are called the Fourier coefficients of $f(x)$ and the series (486) is the Fourier series of $f(x)$. The fact that, subject to suitable conditions on $f(x)$, this problem admits of an affirmative answer is one of the main achievements of the theory.

Although Fourier series originated in mathematical physics, their influence upon the development of analysis has been almost as great. Very often they appear there in a more general form, as orthogonal series (see below), and provide a unifying link in such mathematical theories as differential and integral equations and analytic functions. Especially important are trigonometric (and, in particular, Fourier) series for the theory of analytic functions because for $z = e^{ix}$ the real part of the power series, which is a power series in z with complex coefficients (see 488), is the series already obtained (see 486). Thus trigonometric series are real parts of power series, and so form a bridge between real and complex functions. Aside from the value of trigonometric series as a method of investigation, they have played a great role in the historic development and clarification of various mathematical concepts, some of them quite abstract. A few examples may suffice.

Already in the days of its inception in the 18th century, the theory of Fourier series stirred controversies in connection with the notion of mathematical function. The general attitude at that time was to call $f(x)$ a function if $f(x)$ could be represented by a single analytic expression such as a polynomial, a power series, or a trigonometric series. If the graph of $f(x)$ were arbitrary—e.g., a polygonal line— $f(x)$ would not have been accepted as a

Historical development of Fourier series

Neumann functions

An infinite series of trigonometric functions

$$(486) \quad \frac{1}{2}a_0 + (a_1 \cos x + b_1 \sin x) + (a_2 \cos 2x + b_2 \sin 2x) + \dots$$

$$(487) \quad \begin{cases} a_n = \frac{1}{\pi} \int_0^{2\pi} f(x) \cos nx \, dx \\ b_n = \frac{1}{\pi} \int_0^{2\pi} f(x) \sin nx \, dx \end{cases}$$

$$(488) \quad \frac{1}{2} a_0 + (a_1 - ib_1)z + (a_2 - ib_2)z^2 + \dots$$

$$(489) \quad s_n(x) = \frac{1}{\pi} \int_0^{2\pi} f(x+t) \frac{\sin(n + \frac{1}{2})t}{2 \sin \frac{1}{2}t} \, dt$$

$$(490) \quad \int_0^\pi \frac{|f(x+t) + f(x-t) - 2f(x)|}{t} \, dt$$

function. So it came as a shock to many when the discovery of Fourier series showed that many such arbitrary graphs could be represented by trigonometric series and so should be treated as functions. It took a long time before the matter was clarified, and it was not merely a coincidence that the now universally adopted definition was first formulated in 1837 in a memoir of Dirichlet, devoted to the theory of Fourier series. (Incidentally, this memoir contains the first rigorous proofs of the representation of functions by their Fourier series. The work of Fourier himself and of his predecessors was rather formal.) Another instance of application of trigonometric series to the theory of functions is due to Weierstrass, who in 1861 gave the first example of a continuous function without a derivative at any point. Weierstrass' function was given in the form of a trigonometric series, and it exemplified the general fact that trigonometric series are particularly useful in the construction of functions with various peculiarities. Another much more important example of the influence of Fourier series may be found in the history of the notion of integral. On account of previous formulas (see 487), this notion is a prerequisite to that of Fourier series. It is therefore interesting that the classical definition of integral due to Riemann (usually given in textbooks of calculus) was for the first time expounded in 1854 in his fundamental paper *Über die Darstellbarkeit einer Funktion durch eine trigonometrische Reihe* ("Concerning the Representation of Functions by Trigonometric Series"). The ideas contained in that paper influenced the work of Georg Cantor concerning the uniqueness of the representation of a function by a trigonometric series. Cantor had to consider various sets of points that would not interfere with the uniqueness of representation. Starting from simplest cases he tried to master the structure of such sets—sets of uniqueness (see below *Uniqueness of representation by trigonometric series*). He was not completely successful, but his investigations led him to the general theory of sets, and in particular of point sets, one of the greatest mathematical discoveries of the 19th century. His results have permeated and changed the aspect of many mathematical theories. The theories of measure and of integral developed later by Émile Borel and Henri-Léon Lebesgue, so fundamental in mathematical analysis, are based on Cantor's work on the theory of sets.

Particularly important is the work of Lebesgue, who put Fourier series on a new basis through his theory of integral. Though more general definitions of integral are possible, and though some of them are of interest for Fourier series, Lebesgue's definition is the most appropriate and is almost universally adopted in research. In this connection a French mathematician, Arnaud Denjoy, showed with a definition of integral more general than that of Lebesgue that an everywhere-convergent trigonometric series is always the Fourier series of its sum. Important for Lebesgue's theory is the notion of set of measure zero. A point set S situated, for example, on a straight line is said to be of measure zero if S can be covered by a finite or infinite system of intervals of total length arbitrarily small. In Lebesgue's theory, sets of measure zero are considered

as negligible, and if a certain property holds for all points except those forming a set of measure zero, that property is said to hold almost everywhere.

Convergence and divergence of Fourier series. If $s_n(x)$ denotes the sum of the first $n+1$ terms of the Fourier series (486), using the integral formulas (487), s_n as a function of x is a definite integral from zero to 2π with integrand formed with the function f and certain sine function expressions (see 489), a formula basic for Fourier series. It may be proved that as n increases indefinitely $s_n(x)$ tends to $f(x)$, provided the function $f(x)$ satisfies certain conditions. For example, if the graph of the function $f(x)$ in the interval $0 \leq x \leq 2\pi$ has only a finite number of maxima and minima (Dirichlet's condition), the Fourier series of $f(x)$ converges to $f(x)$ at every point of continuity of the function. At points x at which such a function is discontinuous, the Fourier series also converges, its sum being $[f(x+0) + f(x-0)]/2$ in which $f(x+0)$ represents the limit of the function at the point x from the right, and $f(x-0)$ a similar limit from the left. Another condition ensuring the convergence of the Fourier series to sum $f(x)$ is the convergence of a definite integral from zero to π with integrand formed in terms of the function f and variable x (the Dini condition; see 490). It certainly is satisfied at every point at which the function $f(x)$ is differentiable. These and all other known conditions for convergence are sufficient conditions only. Conditions that would be both necessary and sufficient (and would not be trivial tautologies) are not known. That mere continuity of the function is not sufficient to ensure the convergence of the Fourier series was shown by the German Paul David Gustave du Bois-Reymond in 1873. He constructed a continuous function for which the Fourier series diverges at some points. Whether the Fourier series of a continuous function must converge at least almost everywhere, that is, everywhere except possibly for a set of points of measure zero, was for a long time an unsolved and tantalizing problem. In 1966 it was shown by the Swedish mathematician Lennart Axel Edvard Carleson that it is actually so, a major achievement of mathematical analysis. More generally, Carleson showed that the Fourier series of any integrable (in the Lebesgue sense) function $f(x)$ the square $f^2(x)$ of which is also integrable must necessarily converge almost everywhere. Using his method, the American mathematician Richard Hunt proved in 1967 that the same conclusion holds if $|f(x)|^p$ is integrable for some p strictly greater than 1. That the result fails for $p=1$ was shown in 1926 by the Soviet mathematician Andrey Nikolayevich Kolmogorov, who constructed an integrable function the Fourier series of which diverges at each point. These results basically settle the problem of convergence almost everywhere of Fourier series.

Summability of Fourier series. The fact that Fourier series of continuous functions need not converge everywhere endangered the whole theory of the representation of functions by their Fourier series. The situation was salvaged by the Hungarian mathematician Leopold Fejér in 1900, who showed that the Fourier series of a continuous function $f(x)$ is summable to $f(x)$ by the method of the arithmetic mean. More precisely, if $s_n(x)$ has the same meaning as above, the expression in which σ_n as a function of x is an arithmetic average of terms expressed as $s_n(x)$ (see 491) tends to $f(x)$ at every point of continuity of the function. Following this, Lebesgue proved that for every integrable function $f(x)$ the expression $\sigma_n(x)$ tends to $f(x)$ almost everywhere. This again put the theory on a firm basis, and at the same time showed that summability rather than convergence is important for Fourier series. Using formulas already given (see 489, 491) leads to an expression in which σ_n as a function of x is an integral from zero to 2π with integrand expressed in terms of f and certain sine functions (see 492), but there is one essential difference. The factor $\sin^2 \frac{1}{2}(n+1)t/2(n+1)\sin^2 \frac{1}{2}t$, called Fejér's kernel, is nonnegative, whereas the factor $\sin(n + \frac{1}{2})t/2 \sin \frac{1}{2}t$, Dirichlet's kernel, is of variable sign. This positive character of Fejér's kernel is responsible for many properties of the expressions $\sigma_n(x)$, and in particular for the fact that they represent $f(x)$ better than the $s_n(x)$ do.

Besides the method of the arithmetic mean, many other

$$(497) \quad \frac{1}{\pi} \int_0^{2\pi} f^2(x) dx = \frac{1}{2}a_0^2 + (a_1^2 + b_1^2) + (a_2^2 + b_2^2) + \cdots$$

Abel's
method

methods of summability have been applied to Fourier series. The most important of them is the method of Abel that defines the sum of Fourier series (see 486) as the limit of the expression that is a power series in r with typical coefficient expressed in terms of cosine and sine (see 493), in which r tends to 1 through values less than 1. The last expression may be written as a definite integral from zero to 2π with integrand composed of the function f and a function involving cosine and the variable r (see 494) and is called the Poisson integral of $f(x)$. As r approaches 1, it tends to $f(x)$ at every point of continuity of the function (or almost everywhere, if $f(x)$ is merely integrable).

Conjugate series and functions. For $z = e^{ix}$ the real part of a power series (see 488) is the trigonometric series (see 486). The imaginary part is a trigonometric series, a sum of terms with typical member composed of the sine and the cosine (see 495), called the conjugate of the series (486). Suppose that there is the Fourier series of a function $f(x)$ (see 486); the conjugate series is then almost everywhere summable by the method of the arithmetic mean, or by the method of Abel, the generalized sum being equal to the definite integral from zero to π with integrand constructed of the function f and the tangent (see 496).

This integral is called the function conjugate to $f(x)$ and will be denoted by $f(x)$. The fact that for every integrable function $f(x)$ the integral (see 496) exists almost everywhere is a very remarkable property that is far from obvious even in the case in which $f(x)$ is continuous. Even in this special case, the integral (496) need not exist everywhere; it is a curious fact that continuous functions may have certain metric properties almost everywhere, without having them everywhere. Conjugate series are a link between trigonometric series and power series. They are also of importance for the theory of Fourier series because there seems to be a close relation between the behaviour of the partial sums of Fourier series and the behaviour of certain conjugate functions. As a matter of fact, the proofs of the theorems of Carleson and Hunt (see above) strongly use refined results on conjugate functions. The function conjugate to an integrable function $f(x)$ need not be integrable. Thus the series conjugate to the Fourier series of $f(x)$ need not be a Fourier series.

Parseval's formula. Suppose that one has the Fourier series of $f(x)$ (see 486). If in the formula $f(x) = \frac{1}{2}a_0 + (a_1 \cos x + b_1 \sin x) + \cdots$ both sides are squared and the result is integrated over the interval $0 \leq x \leq 2\pi$, then a definite integral from zero to 2π of the square of the function f is equal to an infinite sum with typical term composed of the square of a_k plus the square of b_k (see 497), called Parseval's formula after Marc Antoine Parseval (1755–1836). The above argument was formal, but rigorous proofs are available to show that the formula is valid for any function $f(x)$ such that $f^2(x)$ is integrable.

Thus the Fourier coefficients a_0, a_1, b_1, \dots of any such function have the property that $\Sigma(a_n^2 + b_n^2)$ is finite. That the converse is true was proved by the mathematicians Frigyes Riesz and Ernst Sigismund Fischer in 1907. The Riesz-Fischer theorem, which is one of the great achievements of the Lebesgue theory of integration, asserts that, given any sequence of numbers $a_0, a_1, b_1, a_2, b_2, \dots$ such that the series $\Sigma(a_n^2 + b_n^2)$ converges, there is always a function $f(x)$ having the numbers a_0, a_1, b_1, \dots as Fourier coefficients and such that $f^2(x)$ is integrable. This function is unique. Thus, the theorems of Parseval and of Riesz-Fischer give a very simple characterization of functions with integrable squares in terms of their Fourier coefficients. There is no other class of function that has a characterization of comparable simplicity and completeness.

Uniqueness of representation by trigonometric series. Can a function be represented by two different and everywhere-convergent trigonometric series? By taking the difference of two such series, the problem may be restated as follows. Can a trigonometric series not identically zero (i.e., a series the coefficients a_n, b_n of which are not all zero) converge everywhere to zero? That this is impossible was proved by Cantor. His result is the simplest theorem on the uniqueness of the representation of a function by a trigonometric series. A point set S situated in the interval $0 \leq x \leq 2\pi$ is called a set of uniqueness (set U , for brevity) if every trigonometric series convergent to zero outside S is identically zero. Otherwise, the set S will be called a set of multiplicity (set M), and there will be trigonometric series convergent to zero outside S , but not identically zero. Generalizing the result just stated, Cantor proved that every set S consisting of a finite number of points, and even certain infinite sets, are sets U . It may be shown that every set U must be of measure zero, but it is remarkable that among sets of measure zero are found sets U as well as sets M . The problem of characterizing sets U and M in structural terms was still unsolved in the mid-1970s. One of its implications is that from the point of view of trigonometric series the notion of set of measure zero is too general, and that special classes of such sets may be of particular importance.

Trigonometric interpolation. A finite sum, a sum from $k=1$ to n of weighted trigonometric terms (see 498), is called a trigonometric polynomial of order n (or less, if both a_n and b_n are zero). A trigonometric polynomial of order n has $2n+1$ coefficients $a_0, a_1, b_1, \dots, a_n, b_n$ and it can be shown that if $2n+1$ distinct points (see 499) are fixed in the interval $0 \leq x < 2\pi$, there is always a trigonometric polynomial of order n or less that takes prescribed values at these points; moreover, this polynomial is unique. Consider now a function $f(x)$ defined on the interval $(0, 2\pi)$ and take the trigonometric polynomial $T(x)$ of order n that coincides with $f(x)$ at certain points (see 499). Such a polynomial is called an interpolating polynomial for $f(x)$. Suppose now that n increases indefinitely; does the polynomial $T(x)$ approach the function $f(x)$ at all points? This must depend on the geometric configuration of the points (see 499) and the answer is not known in full generality. If, however, the points (see 499) are assumed distributed equally to form an arithmetic progression with difference $2\pi/(2n+1)$, and if the function $f(x)$ satisfies some smoothness conditions (e.g., is differentiable), then the answer is affirmative, and the whole problem has points in common with the theory of Fourier series.

Orthogonal series. Fourier series as defined above are a special class of more general series. Suppose that in an interval $a \leq x \leq b$ there is a fixed set of functions $\phi_1(x), \phi_2(x), \dots$ with the integrals involving the product of the functions ϕ_m, ϕ_n being zero if m is not equal to n and being a constant, λ_n , if m equals n (see 500) for all m and n . Such sets of functions are called orthogonal. If a function $f(x)$ has a representation $f(x) = c_1\phi_1(x) + c_2\phi_2(x) + \cdots$, then, multiplying both sides by $\phi_n(x)$, integrating over x in the interval (a, b) , and using orthogonality (see 500) formally leads to the equation in which c_n is a definite integral from a to b involving the function f and the function ϕ_n (see 501) for all n . Conversely, given any function $f(x)$, the latter formulas may be used to construct the series $c_1\phi_1(x) + c_2\phi_2(x) + \cdots$, and it may be asked whether this

series actually represents $f(x)$. This last series is called the Fourier series of $f(x)$ with respect to the orthogonal system $\varphi_1, \varphi_2, \dots$. Trigonometric Fourier series are obtained if for $\varphi_1, \varphi_2, \dots$ the system $1, \cos x, \sin x, \cos 2x, \sin 2x, \dots$ is taken, and for (a, b) the interval $(0, 2\pi)$. Many other orthogonal systems are of considerable importance for mathematics.

In the definition of orthogonality (see 500), it was tacitly assumed that the functions were real-valued. If the functions $\varphi_1, \varphi_2, \dots$ are complex-valued, the definition (500) must be slightly modified, and certain requirements must be met concerning two integrals involving φ_m and φ_n (see 502), in which φ_n is the conjugate (in the sense of complex numbers) to φ_n . The Fourier series is, as before, $c_1 \varphi_1(x) + c_2 \varphi_2(x) + \dots$, but now the Fourier coefficients are c_n as a definite integral from a to b of the function f and a weighted term composed of φ_n (see 503). The most important special case is that of the system e^{inx} ($n = 0, \pm 1, \pm 2, \dots$) that is readily seen to be orthogonal over $(0, 2\pi)$, with all $\lambda_n = 2\pi$. This system is called the complex trigonometric system. The Fourier series of a function $f(x)$ defined in the interval $(0, 2\pi)$ is a sum with integer index ranging from minus infinity to plus infinity with summand of exponential type and coefficient c_n , the coefficient determined by an integral (see 504). The latter series is called the complex Fourier series of $f(x)$ and is meant as a sum including a constant term and terms of exponential type and negative exponential type (see 505). It can be shown that this series is nothing else but the Fourier series (486) with coefficients given by the familiar formula (487). Hence, except for notation, complex Fourier series are the same as ordinary trigonometric Fourier series, but the complex form sometimes simplifies proofs.

Fourier integrals. Fourier series are used for the representation of periodic functions. For the study of a nonperiodic function $f(x)$, the Fourier integral of $f(x)$ is used. It

has the form of an integral from zero to infinity with integrand composed of functions a and b and functions cosine and sine (see 506), in which $a(u)$ and $b(u)$ are defined by the formulas in which a as a function of u is expressed as an integral involving f and the cosine, b as a function of u is expressed as an integral involving f and the sine (see 507). The integral (506) is analogous to the series (486), the only difference being that instead of summation there is integration. The functions $a(u)$ and $b(u)$ are analogues of Fourier coefficients and are called the Fourier transforms of $f(x)$. Under very general conditions, the integral (506) actually represents $f(x)$, the proofs being similar to the corresponding proofs in the case of Fourier series.

Multiple Fourier series. If $\varphi_1(x), \varphi_2(x), \dots$ is an orthogonal system over an interval $a \leq x \leq b$, and if $\psi_1(y), \psi_2(y), \dots$ is another orthogonal system over an interval $c \leq y \leq d$, then it may be shown that the double system $\varphi_m(x)\psi_n(y)$ (in which $m, n = 1, 2, \dots$) is orthogonal over the rectangle $a \leq x \leq b, c \leq y \leq d$ of the plane, and a function $f(x, y)$ defined in this rectangle can be developed into a double Fourier series, a double sum with summand composed of a product of a constant, the function φ_m , and the function ψ_n , two variables x and y being involved (see 508). The most interesting case occurs when both systems φ_m and ψ_n are complex trigonometric systems. The Fourier series is then a double sum with summand composed of a coefficient with double index and exponential with complex argument depending upon x and y (see 509). Similarly, triple Fourier series can be considered, and so on. The problems concerning the behaviour of multiple Fourier series are usually much more difficult than those of ordinary Fourier series.

The integral (506) can also be written in the form of a definite integral from minus infinity to plus infinity with integrand of exponential complex type and coefficient determined by an integral again of exponential type (see 510), which is an analogue of a complex Fourier series. Multiple Fourier integrals are also considered (analogues of multiple Fourier series) and have become a very important tool in various branches of analysis.

$$(518) \quad \hat{f}(x) = (2\pi)^{-1/2} \int_{-\infty}^{\infty} e^{-ixy} f(y) dy$$

$$(519) \quad K(x, y) = (2\pi)^{-1/2} e^{-ixy}$$

$$(520) \quad |e^{-ixy}| = 1$$

HARMONIC ANALYSIS AND INTEGRAL TRANSFORMS

It usually happens in mathematical analysis that certain given functions are to be operated on, and other functions or numbers are thus obtained. Often, the operations used involve integration, and here is found a very general class of operators, the so-called integral transforms. The simplest integral transform is the operation of integrating. If f is a function defined on the interval $[a, b]$, a new function F on $[a, b]$ can be defined (see 511). A somewhat more general example arises if f is multiplied by another function $h(y)$ before integrating: F is expressed as a definite integral from a to b with integrand f multiplied by h , each being functions of the variable of integration (see 512).

The following situation already embraces quite a number of important integral transforms: if the function $f(y)$ is given in the interval $a \leq y \leq b$, and $K(x, y)$ is a function of two variables, defined when $a \leq y \leq b$ and $c \leq x \leq d$, then Φ as a function of x is an integral from a to b with integrand a product of terms including K with two arguments and the function f with a single argument (see 513). This is an integral transform of $f(y)$ by means of the function K , which is called the kernel. [Here K is regarded as fixed, and the integral transform (513) is regarded as an operation that can be performed on any one of a large class of functions f , yielding for each appropriate f a new function Φ .] The operation F as a function of f equal to an indefinite integral of the function f (see 514) is merely a special case of the integral transform (513), in which $K(x, y) = 1$ if $y \leq x$ and $K(x, y) = 0$ if $y > x$. By considering a variety of kernels K , a number of important classical integral transforms are obtained, some of which will be discussed below.

The definitions given above may be generalized in various ways, one of which is to use functions f of several variables (see below). In many important special cases of the integral transform (513), the intervals $[a, b]$ and $[c, d]$ are replaced by the whole real line $(-\infty, \infty)$, or a half-line, such as $[a, \infty)$.

At this stage in the discussion, two technical points should be mentioned. First of all, there may be a restriction to real-valued functions $f(y)$ and $K(x, y)$, or more generally to functions $f(y)$ taking complex values, $f(x) = u(x) + iv(x)$, and likewise for the kernel K . It is preferable to adopt the latter point of view, especially because operations performed on real-valued functions often lead to complex-valued functions anyway. A more delicate point is the notion of integral to be employed. In many cases, especially in practical applications, it is enough to deal with the classical Riemann integral, or with the improper Riemann integral, for example, when functions are integrated over infinite intervals. In most instances, however, coherence and generality are best achieved by introducing the notion of integral due to Lebesgue (see above *Real analysis: Measure and integral calculus*). To help the reader not familiar with Lebesgue's theory, this point will not be stressed, and only in the cases in which the mathematical results depend most strongly on Lebesgue measure or integration will the fact be indicated.

Convolution. Before passing to various special cases, one very important type of integral transform will be indicated. If $f(y)$ is a function defined in $(-\infty, \infty)$, and $k(x)$ is another (fixed) function defined in $(-\infty, \infty)$, then the kernel K as a function of x and y equal to a function of the difference of the arguments (see 515) may be considered. In this case the transform (513) takes the form in which Φ as a function of x is a definite integral over the entire real line of the product of the function k and the function f (see 516). This integral (assuming it converges) is called the convolution of the functions f and k (see 517). The centred asterisk symbol for convolution resembles that of the centred dot for multiplication; and there is actually a close connection between the two notions, as will be indicated below. The convolution is an integral transform occurring often in analysis. Usually, after fixing the kernel k , a class of functions f is considered, and the effect of the transform investigated, in order to determine which properties of functions f are preserved and which properties changed, and in what way. Below are considered a number of important special cases.

The Fourier transform. As a second example of an integral transform, the Fourier transform is now introduced, initially of a function of a single variable. If $f(y)$ is a given function defined in the interval $(-\infty, \infty)$, \hat{f} is a definite integral over the entire real line in which the integrand is composed of a product of a negative complex exponential and the function f (see 518), in which x is a real variable and \hat{f} is called the Fourier transform of f . The Fourier transform is an integral transform of the form already discussed (see 513), with kernel of the form in which K as a function of two variables is of exponential type with negative complex unit multiplied by the product of the variables in the argument (see 519). In view of the fact that the absolute value of the negative complex exponential is unity (see 520), the integral defining $\hat{f}(x)$ converges for all values of x and represents a continuous function of x , provided f is absolutely integrable over $(-\infty, \infty)$. In this case it can also be shown that $\hat{f}(x)$ tends to zero as x tends to $\pm\infty$. The Fourier transform also exists in some cases in which f is not necessarily absolutely integrable on $(-\infty, \infty)$. Thus \hat{f} is an integral transform that makes sense for a large class of functions f ; the study of this transform and its generalizations is called harmonic analysis. It should be added that certain variants of the definition (518) are sometimes useful and frequently occur in the literature. Thus the Fourier transform is sometimes defined by the equation in which \hat{f} is a definite integral extended from minus to plus infinity of the complex negative exponential in which the variables appear as products (see 521), or by omission of the minus sign in the exponent. But adherence here is to the definition (518).

The main questions to be studied are: What are the properties of \hat{f} in terms of those of f , or of f in terms of \hat{f} ; and also, can f be found if \hat{f} is known (the problem of inversion of the Fourier transform)? Typical properties of interest are the size and the smoothness of a function. The former question is considered first.

The simplest way of measuring the size of a function is by giving its bounds, $A \leq f(x) \leq B$. (Upper and lower bounds may be given if f is real-valued; bounds for $|f|$ may also be considered if f is complex-valued.) Other estimates, however, especially in the case of unbounded functions, can also be used. If p is a fixed positive number, $L^p[a, b]$ represents the class of functions f on $[a, b]$ for which the definite integral from a to b of the p th power of

Fourier transforms and inversions

$$(521) \quad \hat{f}(x) = \int_{-\infty}^{+\infty} e^{-2\pi ixy} dy$$

$$(522) \quad \int_a^b |f(x)|^p dx < \infty$$

$$(523) \quad \left(\int_a^b |f(x)|^p dx \right)^{1/p}$$

$$(524) \quad \|f - g\|_p \leq \|f - h\|_p + \|h - g\|_p$$

$$(525) \quad L^p[a, b], \text{ the set of functions such that } \|f\|_p < \infty$$

$$(526) \quad \int_0^1 |f(x)|^p dx \leq \int_0^1 M^p dx = M^p < \infty$$

$$(527) \quad L^2[a, b]: \|f - g\|_2 = \left(\int_a^b |f(x) - g(x)|^2 dx \right)^{1/2}$$

$$(528) \quad X = (x_1, x_2, \dots, x_n) \quad \text{and} \quad Y = (y_1, y_2, \dots, y_n)$$

$$(529) \quad \hat{f}_M(x) = (2\pi)^{-1/2} \int_{-M}^M e^{-ixy} f(y) dy$$

$$(530) \quad \int_{-\infty}^{\infty} |\hat{f}(x)|^2 dx = \int_{-\infty}^{\infty} |f(x)|^2 dx$$

the absolute value of f is finite (see 522). In this case, the p th root of the integral from a to b of the p th power of the absolute value of f (see 523) may serve as a measure of the size of f . It will be called the p th norm, or L^p -norm, of f , denoted by $\|f\|_p$. (For the sake of economy, $[a, b]$ are not displayed in the symbol for the norm of f .) The functions f and g may be considered close to each other if $\|f - g\|_p$ is small. If $\|f - g\|_p$ is regarded as a measure of the distance from f to g , it is natural to expect that the p th norm of the difference between f and g is less than or equal to the sum of two such norms involving a third function h (the triangle inequality; see 524) for any three functions f , g , and h . Indeed, this inequality holds, provided $p \geq 1$. In the vast majority of uses of L^p in analysis, it is customary to consider only the case $p \geq 1$; this will be the assumption below.

It would probably be beneficial to acquaint the reader further with $L^p[a, b]$ (see 525) by means of some simple examples. On a finite interval, say $0 < x < 1$, every bounded function f belongs automatically to L^p , because the integral from 0 to 1 of the p th absolute value of f is less than or equal to a constant, which is less than infinity (see 526), if M is an upper bound for $|f|$. In addition, certain unbounded functions also belong to L^p . If $f_\delta(x) = x^{-\delta}$, with $0 < x < 1$, and $\delta > 0$ fixed, then each f_δ is unbounded; as x tends to zero, $f_\delta(x)$ tends to infinity. If f_{δ_1} is compared with f_{δ_2} , where say $\delta_1 > \delta_2$, however, then it is found that $f_{\delta_1}(x)$ goes to infinity as x tends to zero more rapidly than does $f_{\delta_2}(x)$. Now it may be shown that f_δ belongs to L^p for $p < 1/\delta$, but not for $p \geq 1/\delta$. Thus, an unbounded function may belong to L^p , but, if so, it may not tend to infinity too rapidly. As p increases, more and more functions are ruled out as being too large for L^p , so that fewer functions belong to L^p .

Having considered the L^p -classes in general, an important special case can now be mentioned, namely, $p = 2$. The class L^2 is of fundamental importance in analysis. To understand the special significance of L^2 , it is possible to begin with the formula for the distance between two functions f and g in the L^2 sense for the range a to b , the squared norm identified with the difference of two functions expressed as a square root of the integral of the square of the function (see 527). This equation is very similar to the Pythagoras formula

$$\|X - Y\| = \left(\sum_{j=1}^n |x_j - y_j|^2 \right)^{1/2}$$

for the distance between two points (see 528) in n -dimensional Euclidean space. This similarity suggests a way of understanding $L^2[a, b]$: functions f , g , etc., may be regarded as points that lie in a space $H = L^2[a, b]$, and the geometrical properties of H may be studied almost as if H were merely Euclidean space. Because of the similarity of the distance formulas noted above, virtually all of classical Euclidean and coordinate (analytic) geometry can be carried out in the setting of $L^2[a, b]$. Furthermore, the geometric insights thus gained into the structure of L^2 can be applied to numerous concrete problems throughout analysis. For other L^p -classes ($p \neq 2$), the present state of geometrical understanding is relatively crude, and consequently many simple theorems on L^2 functions become more difficult when generalized to L^p . As a result, it is preferable to use L^2 as much as possible.

In the above, the notion of the Fourier transform was introduced. For which functions f does the definition (518) of f make sense? A great deal of work has been done on this problem, and a few highlights can be mentioned briefly. Suppose f belongs to $L^p(-\infty, \infty)$. If $p = 1$, the integral in the definition of f (see 518) exists as an absolutely convergent integral for each point x . The situation is somewhat different if p is greater than 1. Restriction may be made initially to $p = 2$, which is in many ways the central case of the theory.

To define the Fourier transform of an L^2 function, consider the partial integral in which \hat{f}_M as a function of x is a definite integral from minus to plus M in which the integrand is a product of a negative exponential and the function f (see 529). (This integral is absolutely conver-

gent for all finite M .) It can be shown that \hat{f}_M belongs to $L^2(-\infty, \infty)$ for each fixed M , and that as M tends to infinity, the \hat{f}_M tend to a limit in an appropriate sense. One way to express precisely the convergence of the \hat{f}_M to a limit is as follows: There is one (and only one) function \hat{f} in $L^2(-\infty, \infty)$ for which the distance $\|\hat{f}_M - \hat{f}\|_2$ tends to zero as M tends to infinity; the function \hat{f} is called the Fourier transform of f . Thus, the Fourier transform makes sense for all L^2 functions.

The action of the Fourier transform on $L^2(-\infty, \infty)$ has been exhaustively studied by making use of the geometric properties of $L^2(-\infty, \infty)$ already alluded to above. The main point of the L^2 -theory is Michel Plancherel's celebrated formula, which may be stated thus: a function f in $L^2(-\infty, \infty)$ is considered. By what has been said above, \hat{f} also belongs to L^2 . By means of the Plancherel formula, it is possible to predict exactly the size of \hat{f} in terms of that of f . The formula states that two integrals are identified, each extended over the entire real line and each with integrands of the type absolute value of a function squared, one function being \hat{f} and the other f (see 530). Thus \hat{f} and f have the same L^2 -norms. A closely related theorem asserts that an arbitrary function g in $L^2(-\infty, \infty)$ can be written as the Fourier transform of some function f in L^2 , $\hat{f} = g$, and that there is only one f that serves. It will be explained presently how to calculate f for any given g . These results determine completely the behaviour of the Fourier transform on $L^2(-\infty, \infty)$.

The solution to the problem of inversion of the Fourier transform will now be stated; i.e., an explicit formula will be given for a function f in terms of its Fourier transform \hat{f} . Define the function $\check{g}(x)$ such that \check{g} is definite integral from minus infinity to plus infinity of a product of a complex exponential and the function g (see 531). This operation differs from the Fourier transform only in the negative sign in the exponential and is called the inverse Fourier transform. Just as for the Fourier transform, the integral in the definition of \check{g} (see 531) is absolutely convergent if g is absolutely integrable, while if g belongs to $L^2(-\infty, \infty)$ partial integrals (see 532) may be formed and the limit obtained in the sense described above in connection with \hat{f}_M . Just as was seen above, the inverse Fourier transform sends L^2 functions to L^2 functions and satisfies an equation in which two integrals are equal, each extended over the entire real line, each having as integrand an absolute value of a function squared, one function being g and the other \check{g} (see 533).

The connection between g and the problem of inverting the Fourier transform is as follows: Every function f in $L^2(-\infty, \infty)$ is the inverse Fourier transform of its Fourier transform \hat{f} . In other words, written formally, \hat{f} as a function of x is a definite integral extended over the entire real line of a product in which factors are a complex exponential and the function f (see 534), in which the nonabsolutely convergent integral is defined by the procedure explained above. This formula, which is called the Fourier inversion formula, solves the problem of inverting the Fourier transform and thus completes

Harmonic
oscillations

coverage of the relationship between an L^2 function and its Fourier transform.

For each y , the expression $e^{ixy} = \cos(xy) + i \sin(xy)$ represents a harmonic oscillation in x . Hence, for each y , the integrand in the inverse Fourier transform (see 534) is a harmonic oscillation in x , and so the formula for the inverse (534) gives a decomposition of f into a sum of harmonic oscillations. For this reason the theory of Fourier transforms is often called harmonic analysis.

The notion of Fourier transform that was initially considered for functions of a single variable can be extended to functions of several variables. If x denotes a point in the n -dimensional Euclidean space R^n , then x can be treated as an n -tuple of real numbers (the coordinates of x ; see 535). Correspondingly, $f(x)$ may be written for a function of n real variables $f(x_1, \dots, x_n)$. Similarly, the vector y has n components y_k (see 536) for another point of Euclidean space. It should be noted that in the context of n -dimensional space, x_j, y_k , etc., will represent real numbers, while x, y , etc. (without indices), will denote points of Euclidean space; $x + y$ is defined as the n -tuple in which a vector has n components, each of which is a sum of two terms x_k and y_k (see 537), and ax as the n -tuple

$$(537) \quad (x_1 + y_1, x_2 + y_2, \dots, x_n + y_n)$$

$$(545) \quad \hat{f}(x) = (2\pi)^{-1/2} 2x^{-2} e^{icx} \left[\left(\cos \frac{d}{2} x \right) - 1 \right]$$

$$(546) \quad f(x) = e^{-x^2/2}$$

$$(547) \quad \hat{f}(x) = \exp\left(-\frac{1}{2}x^2\right) = f(x)$$

$$(548) \quad f_\delta(x) = \delta^{-1} \exp\left(-\frac{1}{2} \frac{x^2}{\delta^2}\right)$$

$$(549) \quad \hat{f}_\delta(x) = \exp\left(-\frac{1}{2} \delta^2 x^2\right)$$

$$(550) \quad f(x) = (1 - x)^{a-1/2}$$

$$(551) \quad J_a(x) = c_a x^a \hat{f}(x)$$

$$(552) \quad k(x) = |x|^{a-n}$$

$$(553) \quad |x| = (x_1^2 + \dots + x_n^2)^{1/2}$$

$$(554) \quad \mathfrak{L} f(x) = \int_0^\infty e^{-xy} f(y) dy$$

$$(555) \quad \hat{f}(x) = (2\pi)^{-1/2} \mathfrak{L}(ix)$$

in which a vector has n components, each of which has as a factor a (see 538), which is a real number; $x \cdot y$ will be used for the expression that is a sum of products of components, a typical summand being $x_k y_k$ (see 539), and $|x|$ for the square root of the sum of squares of components equal to the square root of the scalar product of the vector x by itself (see 540). (In geometric terms, $|x|$ is simply the distance from the point x to the origin.) Given a function $f(y)$ defined in R^n , the Fourier transform of f will be called the function in which the transform of f as a function of x is an integral over n -dimensional Euclidean space with complex exponential in the integrand involving a scalar product and with integrand including as a factor $f(y)$ (see 541), with dy representing $dy_1 dy_2 \dots dy_n$. For $n = 1$, this definition coincides with that previously given. Just as in the one-variable case, the integral (541), suitably interpreted, is well defined, and the Fourier transform has all the various properties mentioned above for $n = 1$. In particular, the Plancherel formula holds and the Fourier inversion formula is obtained, in which $f(x)$ is an integral over n -dimensional Euclidean space with the integrand containing as factors the transform of f and the complex exponential involving a scalar product (see 542).

A key equation shows that the transform of the partial derivative of f with respect to one of the variables is equal to a product of i times the variable times the transform of f (see 543), which will later be applied to partial differential equations.

Examples of Fourier transforms. A few examples of Fourier transforms will be given, largely restricted to the one-variable case. (1) If $f(x) = 1$ for x belonging to a finite interval $[a, b]$ and $f(x) = 0$ for x outside this interval, then the transform of f is proportional to a difference of exponentials times the reciprocal of i times x (see 544). (2) The function $f(x)$ is called a triangular function if $f = 0$ outside an interval $[a, b]$, $f = 1$ at the centre point $c = \frac{1}{2}(a + b)$, and is linear in the intervals $[a, c]$ and $[c, b]$. Then the transform of f is proportional to a product of three functions of x , one being algebraic, one being exponential, and one being trigonometric (see 545), in which $d = b - a$ is the length of $[a, b]$. (3) The expression in which f as a function of x is a negative exponential with the square of x over 2 appearing in the argument (see 546) is a function basic in the calculus of probability (see PROBABILITY THEORY). Then the transform of f is the same as f , namely, the negative exponential with the square of x over 2 in the argument (see 547), and so f is its own Fourier transform. Slightly more generally, by setting f_δ as a function of x proportional to a negative exponential in which the reciprocal of the square of δ appears in the argument and in which the reciprocal of δ is the proportionality factor (see 548), then the transform of f_δ is a negative exponential in which the square of δ is a factor with the square of x in the argument (see 549); here can be seen an instance of an important general principle: As f becomes more concentrated, \hat{f} spreads out. In the present example, the graph of f_δ is a bell-shaped curve of width δ , while the graph of \hat{f}_δ has width $1/\delta$. (4) By selecting suitable f , a large number of functions important in analysis are obtained as \hat{f} . Consider only one example. Set f as a function of x equal to the difference of 1 and x raised to the $a - 1/2$ power (see 550) if $-1 < x < 1$, and $f(x) = 0$ otherwise. Then J_a as a function of x includes the transform of f as a factor and x raised to the a power as a factor (see 551), which is called the Bessel function of order a . (Here c_a is a constant the value of which is of no present concern.) This function occurs often in mathematical physics and elsewhere. (5) Finally, one example in higher dimensions will be given. If $k(x)$ is defined on R^n by an equation such that $k(x)$ is the absolute value of x raised to the $a - n$ power (see 552), in which $0 < a < n$, and the length of x equals the square root of the sum of squares of the components (see 553), then $\hat{k}(x) = c_a |x|^{-a}$, in which c_a is a certain positive constant. Use will be made of the example later.

Variants of the Fourier transform. In addition to the Fourier transform, harmonic analysis deals with other closely related integral transforms. It is sufficient here to list only a few. (1) The Laplace transform: If $f(y)$ is a

The
Laplace
transform

function defined on the interval $(0, \infty)$, the Laplace transform of f , denoted by $\mathcal{L}f$, is given by an equation such that the Laplace transform of f as a function of x is a definite integral from zero to infinity in which the negative exponential appears as a factor in the integrand and the product of x and y constitutes the argument in the exponential, f being the remaining factor in the integrand (see 554), for all real or complex values of x for which the defining integral converges. It may be observed that extension of the domain of f to the whole real line by setting $f(x) = 0$ for $x < 0$ gives formally the equation in which the transform of f is proportional to the Laplace transform of i times x (see 555), for all real values of x . Thus, the Laplace transform is a natural extension of the Fourier transform, and for this reason the former is sometimes called the Fourier-Laplace transform. This integral transform is rather useful in studying ordinary differential equations and also in the theory of analytic functions (see above *Differential equations: Linear differential equations*; and below *Functional analysis*). (2) The Hankel transform of a function f defined in the interval $(0, \infty)$ is given by $H_\alpha f(x) = \int_0^\infty J_\alpha(xy) \cdot (xy)^{1/2} f(y) dy$, in which J denotes the Bessel function defined in the last section. This transform occurs in the study of those functions and equations in Euclidean space that depend only on the distance from the origin. (3) The Mellin transform of a function on $(0, \infty)$ is defined as $Mf(x) = \int_0^\infty x^{-it} f(t) dt$ for all real values of x . As seen below, the Mellin transform, first expressed by Robert Hjalmar Mellin (1854–1933), arises from the multiplicative structure of the real line just as the Fourier transform comes from the additive structure.

Convolution and the Fourier transform. The notion of convolution is now extended to functions of n real variables. If $x = (x_1, x_2, \dots, x_n)$ is an n -tuple of real numbers and $f(x)$, $g(x)$ are functions of x , then $f * g$ as a function of x is an integral over the n -dimensional Euclidean space of a product of f and g , arguments $x - y$ and y appearing in the functions of the integrand (see 556), in which $dy = dy_1, dy_2, \dots, dy_n$; such an expression is called the convolution of f and g . When $n = 1$ this reduces to the previous definition. By making a change of variable $z = x - y$, $dz = dy$, this integral may be written in the form of an integral over n -dimensional Euclidean space of the product of f and g , the variables z and $x - z$ serving as arguments, respectively (see 557), so that $f * g = g * f$.

It is easily shown that a linear combination of functions f_1 and f_2 convoluted with g equals a linear combination of convolutions (see 558). The connection between convolutions and Fourier transforms lies deeper. If f and g both have Fourier transforms \hat{f} and \hat{g} , respectively, then a simple formal argument shows that a transform of the convolution is the product of the transforms (see 559), so that in terms of the Fourier transform, convolution corresponds to multiplication. In view of the analogy between Fourier transform and inverse Fourier transform, the result could also be interpreted as follows: to multiplication of functions corresponds the convolution of their Fourier transforms. And so, convolution actually is a kind of multiplication. Clearly, the properties of $f * g$ depend on those of both f and g . The theory of convolutions shows that the “good” properties of both f and g (integrability over R^n , boundedness, continuity, differentiability, etc.) are inherited by their convolution. For instance, the formula in which a general differential operator composed of powers of partial derivatives operating upon a convolution is equal to a convolution in which one function remains unmodified and the other is modified with the equivalent differential operation (see 560) holds for differentiation. Now if f belongs to L^p , in which $p > 1$, and g belongs to L^q , then it can be shown that $h = f * g$ belongs to L^r in which r is defined by a relationship in terms of equality between reciprocals r , p , and q (see 561; provided r is positive), and hence r is greater than q , and the inequality in which the r th norm of h is less than or equal to the product of the p th norm of f and the q th norm of g (see 562) holds.

Convolutions are useful in giving approximations to general functions by good functions. This approximation is based on the following idea: For any kernel

$$(556) \quad (f * g)(x) = \int_{R^n} f(x - y)g(y)dy$$

$$(557) \quad \int_{R^n} f(z)g(x - z)dz$$

$$(558) \quad (\alpha f_1 + \beta f_2) * g = \alpha(f_1 * g) + \beta(f_2 * g)$$

$$(559) \quad \widehat{f * g} = \hat{f} \cdot \hat{g}$$

$$(560) \quad \left(\frac{\partial}{\partial x_1}\right)^{a_1} \left(\frac{\partial}{\partial x_2}\right)^{a_2} \cdots \left(\frac{\partial}{\partial x_n}\right)^{a_n} (f * g) \\ = \left[\left(\frac{\partial}{\partial x_1}\right)^{a_1} \left(\frac{\partial}{\partial x_2}\right)^{a_2} \cdots \left(\frac{\partial}{\partial x_n}\right)^{a_n} f\right] * g \\ = f * \left[\left(\frac{\partial}{\partial x_1}\right)^{a_1} \left(\frac{\partial}{\partial x_2}\right)^{a_2} \cdots \left(\frac{\partial}{\partial x_n}\right)^{a_n} g\right]$$

$$(561) \quad \frac{1}{r} = \frac{1}{p} + \frac{1}{q} - 1$$

$$(562) \quad \|h\|_r \leq \|f\|_p \|g\|_q$$

$$(563) \quad \int_{R^n} k(x)dx = 1$$

$$(564) \quad k_\varepsilon(x) = \varepsilon^{-n} k\left(\frac{x}{\varepsilon}\right) = \varepsilon^{-n} k\left(\frac{x_1}{\varepsilon}, \frac{x_2}{\varepsilon}, \dots, \frac{x_n}{\varepsilon}\right)$$

$$(565) \quad \int_{R^n} k_\varepsilon(x)dx = \int_{R^n} k(x)dx = 1$$

$$(566) \quad \frac{\partial^2 u}{\partial x_1^2} + \frac{\partial^2 u}{\partial x_2^2} + \cdots + \frac{\partial^2 u}{\partial x_n^2} = -f$$

$k(x) = k(x_1, x_2, \dots, x_n)$ of, say, a total integral over n -dimensional Euclidean space of k equal to 1 (see 563), and given any positive number ε , a new kernel $k_\varepsilon(x)$ can be formed by the equation in which k_ε as a function of x is a product of the negative n th power of ε and k as a function of n arguments, the typical one being x_k divided by ε (see 564). For any f , the convolution of f with k_ε can also be defined. The graph of $k_\varepsilon(x)$ is that of $k(x)$, contracted horizontally by the ratio ε , and expanded vertically by the ratio ε^{-n} , so that the integral over n -dimensional Euclidean space of k_ε is 1 (see 565) for all ε . It is assumed for the moment that $k(x) = 0$ outside the sphere of radius 1 centred at the origin. Then $k_\varepsilon(x) = 0$ outside the sphere of radius ε centred at the origin. On the other hand, if f happens to be continuous at the point x_0 , then $f(x)$ is practically constant on a ball of radius ε centred at x_0 , and so it is not difficult to see that $f_\varepsilon(x)$ tends to $f(x_0)$ as ε tends to zero. For this reason, $f_\varepsilon = k_\varepsilon * f$ is called an approximate identity. The functions f_ε provide good approximations to f under very general circumstances. For example, if k is absolutely integrable and f is in L^p , then likewise f_ε is in L^p , and $\|f - f_\varepsilon\|_p$ tends to zero as ε tends to zero; if f is uniformly continuous, then f_ε tends uniformly to f as ε tends to zero. It may be noted that if k is a good function—say a times differentiable—then k_ε is likewise good, and so f_ε is good. Thus the convolution $k_\varepsilon * f$ gives an approximation to f by good functions.

Applications to partial differential equations. The applications of convolutions and Fourier transforms will now be illustrated with an example from partial differential equations and potential theory. If a distribution of electrical charges throughout Euclidean space R^n ($n \geq 3$) has a density of charge at the point x given by a function $f(x)$,

“Good”
functions

it can be shown that the electrical potential $u(x)$ arising from the charge distribution f satisfies an expression in which the sum of second-order partial derivatives of u taken with respect to each of the n arguments is equal to the negative value of f (see 566).

Traditionally, the left-hand side (see 566) is called the Laplacian of u and denoted by Δu or $\nabla^2 u$. The equation $\Delta u = 0$ is called Laplace's equation and its solutions are called harmonic functions. The inhomogeneous Laplace equation (566) is sometimes called Poisson's equation. Now given any f (subject to some technical conditions that are not specified) the equation (566) can be solved by using the Fourier transform. To do so, the effect of the Fourier transform on Δu must be examined. From two consecutive applications of an earlier formula (543), it can be seen that the transform of the second-order partial derivative of u with respect to one variable all considered as a function of x is a product of the negative square of the variable times the transform of f (see 567), and therefore the transform of Δu as a function of x is the negative of the squared absolute value of x times the transform of u (see 568). Consequently, the Fourier transform changes (566) to the equation in which the absolute square of x times the transform of u as a function of x is equal to the transform of f as a function of x (see 569), which has the solution that the transform of u as a function of x is equal to the square of the reciprocal of the absolute value of x multiplied by the transform of f considered as a function of x (see 570). In principle, this formula (570) solves the problem completely. For, given any well-behaved function f , the function \hat{u} may be computed from its definition (see 541), \hat{u} found from the above formula (570), and then passage from \hat{u} back to u made by means of the Fourier inversion formula. This procedure, however, is cumbersome in practice, and in order to solve the problem (566) more explicitly, the solution (570) will be combined with a formula involving convolution. If k as a function of x is equal to a constant times the $2-n$ power of the absolute value of x (see 571), in which c is a constant the exact value of which is not of concern here, $k(x)$ is called the Newtonian potential. Some calculations show that the transform of k as a function of x is the -2 power of the absolute value of x (see 572; see above *Examples of Fourier transforms*). It can be seen that the transform of the convolution of k and f is by calculation the transform of u (see 573) by virtue of the formula (570) for \hat{u} . Consequently, $u = k * f$; that is, u as a function of x is proportional to an integral over n -dimensional Euclidean space in which the integrand includes as a factor f and as a factor the reciprocal of the absolute difference between x and y raised to the $n-2$ power (see 574).

Thus an explicit solution has just been found to the inhomogeneous Laplace equation.

Certain formulas (see 570 and 574) form the starting point for many further investigations in harmonic analysis. Some formulas (see 570, 574) may be generalized to define an interesting family of integral transforms, the fractional integrals. If a is any positive number, the transform of $I^a f$ as a function of x is a product, one term of which is the negative a power of the absolute value of x , one term of which is the transform of f , considered as a function of x (see 575), or, what is in fact the same thing, the product $I^a f$ considered as a function of x is equal to a constant times an integral over n -dimensional Euclidean space in which the integrand contains as a factor f and as a factor the reciprocal of the $n-a$ power of the absolute

difference between x and y (see 576). It follows that $(I^a f)$ tends to zero at infinity more rapidly than f . Because rapid decrease of a Fourier transform \hat{g} corresponds (more or less) to smoothness of the function g , it can be seen that I^a transforms rough functions f to smooth functions $I^a f$. It may be said that a function g on R^n belongs to the class $L_p^a(R^n)$ if g arises by applying I^a to an L^p function f : $I^a f = g$. The classes $L_p^a(R^n)$, called Sobolev spaces (after Sergey L'vovich Sobolev), are a powerful tool to measure the smoothness of functions, occurring often in harmonic analysis and partial differential equations. In the special case in which $n = 1$, $1 < p < \infty$ and $a = \text{integer } k$, a func-

$$(567) \quad \widehat{\frac{\partial^2 u}{\partial x_j^2}}(x) = -x_j^2 \hat{f}(x) \quad \text{for } j = 1, 2, \dots, n$$

$$(568) \quad \widehat{\Delta u}(x) = -(x_1^2 + x_2^2 + \dots + x_n^2) \hat{u}(x) = -|x|^2 \hat{u}(x)$$

$$(569) \quad |x|^2 \hat{u}(x) = \hat{f}(x)$$

$$(570) \quad \hat{u}(x) = |x|^{-2} \hat{f}(x)$$

$$(571) \quad k(x) = c|x|^{2-n}$$

$$(572) \quad \hat{k}(x) = |x|^{-2}$$

$$(573) \quad \widehat{k * f}(x) = |x|^{-2} \hat{f}(x) = \hat{u}(x)$$

$$(574) \quad u(x) = c \int_{R^n} \frac{f(y)}{|x-y|^{n-2}} dy$$

$$(575) \quad \widehat{I^a f}(x) = |x|^{-a} \hat{f}(x) \quad \text{for all } x \text{ in } R^n$$

$$(576) \quad I^a f(x) = c_a \int_{R^n} \frac{f(y)}{|x-y|^{n-a}} dy \quad \text{for all } x$$

tion f belongs to L_p^a if, and only if, its k th derivative $f^{(k)}$ is in L^p . When a is not an integer, the Sobolev spaces give meaning to such statements as "the function f is $3^{1/2}$ times differentiable."

In addition to the inhomogeneous Laplace equation, there are a number of other partial differential equations arising from mathematical analysis and physics that can be solved by methods that are similar to those outlined above.

Generalizations of the Fourier transform. Much of the highly developed theory of Fourier integrals, which has just been sketched in the setting of Euclidean space, can actually be carried out in a wider context. The theory of various generalizations of the Fourier transform is known as abstract harmonic analysis. In addition to providing new mathematical results, abstract harmonic analysis sharpens an understanding of classical Fourier analysis by elucidating the essential unity that exists among the many classical integral transforms: Fourier integrals, Fourier series, Mellin transforms, and expansions in spherical harmonics, to cite a few examples. The present exposition of abstract harmonic analysis will concentrate on the part of the subject that is easiest to understand, namely the study of Fourier transforms on Abelian groups (see below), and attention will now be turned to this topic. It is best to begin by viewing the classical theory from a proper perspective.

From its very definition (see 541) it can be seen that the

Abstract
harmonic
analysis

$$(577) \quad \chi_x(y) = e^{ix \cdot y}$$

$$(578) \quad \hat{f}(x) = (2\pi)^{-n/2} \int_{R^n} \chi_x(y) f(y) dy$$

$$(579) \quad \chi_x(y_1 + y_2) = \chi_x(y_1) \cdot \chi_x(y_2)$$

$$(580) \quad (x + y) + z = x + (y + z)$$

for any three elements x , y , and z in G

$$(581) \quad \chi(y_1 + y_2) = \chi(y_1) \cdot \chi(y_2)$$

$$(582) \quad (x_1, x_2, \dots, x_n) + (y_1, y_2, \dots, y_n) \\ = (x_1 + y_1, x_2 + y_2, \dots, x_n + y_n)$$

The
inhomo-
geneous
Laplace
equation

Sobolev
spaces

Fourier transform on R^n is built up from the functions of such a form as χ as a function of y equal to a complex exponential containing a vector product of x and y in the product (see 577). (Here x is thought of as a fixed point in R^n and $\chi_x(y)$ regarded as a function of y .) Indeed, the Fourier transform (541) may be rewritten in a form such that the transform of f as a function of x is an integral over n -dimensional Euclidean space of a product of χ_x and f (see 578). The essential property of χ_x that is used in harmonic analysis is the multiplicative law of the exponential: χ_x operating upon the sum of y_1 and y_2 is a product of terms, χ operating upon y_1 and y_2 , respectively (see 579). Now if G is any set on which there is defined some notion of the sum $y_1 + y_2$ of two elements y_1 and y_2 of G , and also some notion of integral, then the key formulas (578) and (579) are valid for complex-valued functions χ_x and f defined on G , and thus harmonic analysis can be carried out on G . More precisely, the following definitions can be made:

Abelian groups

An Abelian group is a set G , together with an operation $+$, that combines any two elements x and y of G into a third element $x + y$ of G , and that satisfies axioms 1–4:

1. $(x + y) + z = x + (y + z)$ for any three elements x , y , and z in G (the associative law; see 580).

2. $x + y = y + x$ for any two elements x and y in G (the commutative law).

3. There is an element called 0 in G , with the property that $x + 0 = x$ for every element x of G (existence of an identity element).

4. Corresponding to any given element x in G , there is an element called $(-x)$ in G , which satisfies the equation $x + (-x) = 0$ (existence of an inverse element).

A locally compact Abelian group is an Abelian group in which, very roughly, statements such as “ x is close to y ” or “ f is a continuous function,” or various similar remarks involving the limit concept can be made. (The precise definition is omitted, because it is technical and requires some background in general topology. All the Abelian groups considered in this article, however, will be locally compact.) If G is a locally compact Abelian group, a character χ of G is a continuous complex-valued function defined on G , which has the properties: (a) $\chi(y)$ has modulus one for every element y of G ; (b) χ operating upon $y_1 + y_2$ is equal to the product of χ operating upon y_1 and χ operating upon y_2 (see 581) for every two elements y_1 and y_2 of G .

A significant portion of harmonic analysis can be carried out in the setting of locally compact Abelian groups. Three classical examples that will be used later are now considered. (1) $G = R^n$ is an Abelian group under the sum between two n component vectors that is a vector of n components, a typical one being $x_k + y_k$ (see 582), with identity element $(0, 0, \dots, 0)$; the inverse of the vector composed of n components is the vector composed of n negatives of the same components (see 583). The characters of R^n are seen to be precisely the functions $\chi_x(y) = \exp(ix \cdot y)$. Thus, characters play a basic role in harmonic analysis on R^n . (2) $G = R^+$, the set of all positive real numbers is not an Abelian group under ordinary addition. (For instance, axiom 3 is violated, for the only number a with the property that $x + a = x$ for all x in R^+ is zero, and zero does not belong to R^+ .) If the symbol $+$ is allowed to stand for multiplication of real numbers, however, then R^+ becomes a locally compact Abelian group. (For instance, the identity element demanded by axiom 3 is one, and the inverse of a given element x of R^+ is $1/x$.) The characters of R^+ are functions $\chi_t(x) = x^t$, in which t is any fixed real number. It should be possible to do harmonic analysis on R^+ in terms of the functions $\chi_t(x)$, and as will be seen below, this is the case. (3) The circle, denoted by S^1 , may be made into a group by regarding it as the set of all complex numbers z of modulus $|z| = 1$, with the operation $+$ as ordinary multiplication of complex numbers. Then S^1 becomes a locally compact Abelian group. Via the correspondence $z = e^{i\theta}$, the circle S^1 may also be thought of as consisting of all angles θ in the interval $[0, 2\pi]$. The characters on S^1 are precisely the functions in which χ_n as a function of θ is a complex exponential with the product $n\theta$ in the argument, n being

any integer (see 584). According to the classical theory of Fourier series (see above *Fourier series*), any integrable function $f(\theta)$ defined on $[0, 2\pi]$ may be expanded in an infinite series of a form such that f as a function of θ is an infinite sum with indices extending from minus infinity to plus infinity and summands having factors a_n and either a factor of exponential form or of the form χ_n , arguments being θ (see 585), in which a_n being a transform of n is an integral from zero to 2π of the product of f with either a negative exponential or the complex conjugate of χ (see 586). Here again, characters appear as the fundamentals of harmonic analysis on the group $G = S^1$.

Returning to the general theory of Abelian groups: If χ_1 and χ_2 are two characters of a locally compact Abelian group G , a new character, denoted $\chi_1 + \chi_2$, may be defined by the formula $(\chi_1 + \chi_2)(y) = \chi_1(y) \cdot \chi_2(y)$ for every element y in G . Under this “addition” operation, the set \hat{G} of all the characters of G becomes a locally compact Abelian group, called the dual group or character group of G with $\chi_0(x)$ identically equal to 1 as the identity element, and $(-\chi)(y) = 1/\chi(y)$ as the inverse to a given character χ . For the three classical examples above, the dual groups G are as follows: R^n is its own dual group, R^1 is the dual group of R^+ , and the set Z of integers $0, +1, +2, \dots$ with the operation of addition is the dual group of S^1 . In each case, the Fourier transform \hat{f} of a function f on G is a function on the dual group G .

In order to define the Fourier transform and study harmonic analysis on a generally locally compact Abelian group G , it is desirable to have a notion of the integral of a real- or complex-valued function defined on G . Initially only continuous functions f that are equal to zero outside of some bounded—i.e., compact—subset of G will be considered. The class of all such functions is denoted by $C_c(G)$. In the known case, $G = R^n$, $I(f)$ equal to an integral over n -dimensional Euclidean space of f (see 587), defined for functions in $C_c(G)$, has the following key properties: (a) I as a function of a linear combination of f and g is a linear combination of I as a function of f and I as a

$$(584) \quad \chi_n(\theta) = e^{in\theta}, \quad \text{in which } n = 0, \pm 1, \pm 2, \dots$$

$$(585) \quad f(\theta) \sim \sum_{n=-\infty}^{\infty} a_n e^{in\theta} = \sum_{n=-\infty}^{\infty} a_n \chi_n(\theta)$$

$$(586) \quad a_n = \hat{f}(n) = (2\pi)^{-1} \int_0^{2\pi} e^{-in\theta} f(\theta) d(\theta) \\ = (2\pi)^{-1} \int_0^{2\pi} \overline{\chi_n(\theta)} f(\theta) d(\theta)$$

$$(587) \quad I(f) = \int_{R^n} f(x) dx$$

$$(588) \quad I(af + bg) = aI(f) + bI(g)$$

$$(589) \quad f_{x_0}(x) = f(x + x_0)$$

$$(590) \quad I(f) = k \int_{R^n} f(x) dx$$

$$(591) \quad I(f) = \int_{R^n} f(x) dx$$

$$(592) \quad I(f) = \int_0^{2\pi} f(\theta) d\theta$$

$$(593) \quad I(f) = \int_0^{\infty} f(t) \frac{dt}{t}$$

$$(594) \quad \hat{f}(\chi) = c \int_G \chi(y) f(y) \quad \text{for all } \chi \text{ in } G$$

function of g (see 588) for any functions f and g in $C_c(R^n)$ and any two numbers a and b . (b) If $f(x) \geq 0$ for all x , then $I(f) \geq 0$; in fact, $I(f) > 0$ unless $f(x)$ is identically zero. (c) For a given function f and an element x_0 of G , the translate f_{x_0} of f by x_0 is defined by the equation in which f_{x_0} as a function of x is equal to f as a function of the sum x and x_0 (see 589) (thus on R^n , the graph of f_{x_0} is obtained from that of f simply by sliding horizontally)—then for arbitrary f and x_0 , the equation is $I(f_{x_0}) = I(f)$ (translation-invariance of the integral).

Moreover, it is not hard to prove that the only way of associating a number $I(f)$ to each f in $C_c(R^n)$ in such a way that (a), (b), and (c) are satisfied is to set $I(f)$ equal to a constant times an integral over n -dimensional Euclidean space of f (see 590) for some positive constant k . Thus, except for an insignificant constant factor, properties (a), (b), and (c) uniquely characterize the Riemann integral on R^n . In the general case of a locally compact Abelian group G , a method of associating a number $I(f)$ to each function f in $C_c(G)$ is an integral if properties (a), (b), and (c) hold. It can be shown that on any locally compact Abelian group G , there is one and (essentially) only one integral on G ; it is called the Haar integral on G , and $I(f)$ is written $\int_G f$, by analogy with the case $G = R^n$. Once the Haar integral is defined for functions in $C_c(G)$, it may be extended to a large class of (possibly discontinuous) functions on G . (See *Real analysis: Measure and integral calculus*.) Thus, in particular, L^p classes are definable on any locally compact Abelian group.

Haar measure can be illustrated by considering the same three classical examples. On $G = R^n$, the Haar integral is just $I(f)$ equal to an integral over n -dimensional Euclidean space of the function f (see 591), as was seen above. On $G = S^1 = [0, 2\pi]$, the Haar integral is given by $I(f)$ as an integral from zero to 2π of f (see 592). Finally, on $G = R^+$, the Haar integral is I as a function of f equal to an integral over the positive real line of f divided by its argument (see 593).

The basic notions of the character group and Haar integral having been defined, the basic results of harmonic analysis on a locally compact Abelian group G can be stated. For any absolutely integrable function f on G , the Fourier transform \hat{f} of f is defined to be the following function on the character group \hat{G} : the transform of f as a function of χ is a constant times the integral over G of the product of χ and f (see 594). If f is a square-integrable function on G , then the integral (594) need not converge absolutely, but can be interpreted by a procedure analogous to that used above to define (541) in the case $G = R^n$. Moreover, several of the major results of harmonic analysis on R^n are also valid on G . For example, there is the Plancherel formula: two integrals are equal, one extended over G , one over \hat{G} , the integrand of the first being the absolute squared of f , the integrand of the second being the absolute squared of \hat{f} (see 595), and there is the Fourier inversion formula: f as a function of x is a constant times

the integral over \hat{G} of a product of terms, one being the complex conjugate of χ , the other being \hat{f} (see 596); both hold for suitable functions f on G . (Integration over \hat{G} in formulas [595] and [596] makes sense, because \hat{G} is a locally compact Abelian group, and thus has its own Haar integral. The bar over $\chi(x)$ [see 596] denotes complex conjugation.) Convolutions and approximate identities can be defined on G , and their relationship to the Fourier transform is much the same as in the Euclidean case $G = R^n$. On a general locally compact Abelian group, however, there is no notion of differentiation, so that the rich interplay between harmonic analysis and partial differential equations in the Euclidean case is lost.

The meaning of the Fourier transform (594) and inverse Fourier transform (596) may be illustrated by the three classical examples $G = R^n$, $G = R^+$, and $G = [0, 2\pi]$. On R^n , the Fourier transform and inverse Fourier transform are precisely the usual expressions (see 541 and 542). The Fourier transform (594) on R^+ is given by an expression in which f is an integral extended over the positive real axis with integrand composed of three terms, one of which is x to a complex exponent, one of which is f , one of which

$$(595) \quad \int_G |f(x)|^2 = \int_{\hat{G}} |\hat{f}(\chi)|^2$$

$$(596) \quad f(x) = c \int_{\hat{G}} \overline{\chi(x)} \hat{f}(\chi)$$

$$(597) \quad \hat{f}(t) = \int_0^\infty x^{it} f(x) \frac{dx}{x}$$

$$(598) \quad \text{for } R^+, \quad f(x) = c \int_{-\infty}^\infty x^{it} \hat{f}(t) dt$$

$$(599) \quad \hat{f}(n) = (2\pi)^{-1} \int_0^{2\pi} e^{inx} f(x) dx$$

$$(600) \quad f(x) = \sum_{n=-\infty}^\infty \hat{f}(n) e^{-inx}$$

$$(601) \quad (2\pi)^{-1} \int_0^{2\pi} |f(x)|^2 dx = \sum_{n=-\infty}^\infty |\hat{f}(n)|^2$$

is the reciprocal of x (see 597), and thus is none other than the Mellin transform defined earlier. The inversion formula (596) becomes an expression in which f as a function of x is a constant times an integral extended over the entire real line, one factor in the integrand being x raised to a complex exponent, the other factor being \hat{f} (see 598; the Mellin inversion formula). Finally, on $G = [0, 2\pi]$, the Fourier transform becomes an expression in which f as a function of n is proportional to the integral from zero to 2π of the product of an exponential times f , nx being the argument in the exponential (see 599). In other words, the Fourier transform on G simply associates to every function f on $[0, 2\pi]$ its sequence of Fourier coefficients. The inversion formula (596) asserts that f as a function of x is a sum extending over integers from minus infinity to plus infinity with summand composed of the product f times an exponential, nx appearing in the exponential (see 600), and the Plancherel formula (see 595) specializes to Parseval's relation, the expression in which an integral and a sum are equal, the integral extending from zero to 2π and applying to the integrand absolute square of f , the sum extending over integers from minus infinity to plus infinity with summand being the absolute square of \hat{f} (see 601). Thus the basic elementary results in the classical theories of Fourier series and integrals are part of the larger whole of harmonic analysis on locally compact Abelian groups.

Finally, it is noted that highly significant results are known about Fourier analysis on non-Abelian groups—i.e., roughly, mathematical structures satisfying axioms 1, 3, and 4 above but not axiom 2.

REPRESENTATIONS OF GROUPS AND ALGEBRAS

Since their formal introduction in the early 19th century, groups have been one of the principal objects of mathematical attention (see ALGEBRA: Groups). Their widespread and profound applications to such physical subjects as crystallography, quantum mechanics, and hydrodynamics and to such other mathematical regimes as number theory, harmonic analysis, and geometry have demonstrated their importance.

The main general technique for studying groups is the method of group representation. Technically, a representation of a group is a homomorphism of it into another group, most commonly into the group of invertible linear transformations (or matrices) on some linear space. Less technically, this method amounts to comparing the given group with better known examples of groups. Representation theory plays a significant part in all branches of mathematics in various ways; it also is important in theoretical physics, particularly in quantum theory.

Historical development. The general representation theory for finite groups was developed by the mathematicians Ferdinand Georg Frobenius, Issai Schur, and William

Burnside at the end of the 19th and the beginning of the 20th century. Nothing of the deeper theory of finite groups developed by such later workers as Emil Artin and Richard Brauer has been discussed here. The extension of the finite group theory to compact groups is due in part to Schur, who developed the representation theory of the rotation group in those terms. The general extension to compact groups of the completeness and orthogonality of the finite-dimensional irreducible unitary representations is known as the Peter-Weyl theorem (published in 1927). Lie groups are named after Sophus Lie, a Norwegian mathematician who discovered their fundamental properties in the last decades of the 19th century. A deeper analysis of their properties and, in particular, the classification of the semisimple groups were carried out by Élie-Joseph Cartan in the early part of the 20th century. The general finite-dimensional representation theory for semisimple Lie groups was developed principally by Weyl in the mid-1920s, as were the connections between group theory and quantum mechanics. The general representation theory for topological groups started with the discovery by Alfred Haar in the early 1930s of an invariant measure on locally compact groups. The existence of a separating family of irreducible unitary representations for locally compact groups was established by the Soviet mathematicians Izrail M. Gel'fand and Dmitry A. Raikov in the early 1940s. The decomposition of unitary representations of locally compact groups into irreducible and factor unitary representations was carried out by Friederich I. Mautner at the end of the 1940s. This decomposition was based on the powerful theory of operator algebras developed by John von Neumann in collaboration with Francis Joseph Murray in the 1930s and early 1940s. In particular, the theory of factors is their creation. A general duality and function transform theory based on the Murray-von Neumann operator algebras was developed by Irving E. Segal in the early 1950s. George W. Mackey created a forceful technique for the analysis of representations of groups with type I representations by generalizing the Frobenius theory of induced representations. The detailed analysis of the infinite-dimensional representations of the semisimple Lie groups is the work of Gel'fand, Mark Aronovich Naimark, and Harish-Chandra. The fact that these groups have type I representations is a consequence of Harish-Chandra's results. Jacques Dixmier established this same fact for the so-called nilpotent Lie groups. Examples of Lie groups with representations not of type I are known.

Groups. To sketch briefly, a group is a set on which a multiplication satisfying certain specific properties is defined. Corresponding to each pair of elements a, b (in a given order) is another element (written ab), and this law of combination has the properties: (1) $a(bc) = (ab)c$; (2) there is an element e , called the group identity element, such that $ae = ea = a$; and (3) for each a there is an element a^{-1} , called the inverse of a such that $aa^{-1} = a^{-1}a = e$. If in addition $ab = ba$ for each a and b , the group is said to be Abelian (also commutative). A homomorphism is a mapping (function, correspondence) f of one group G into another group H such that $f(ab) = f(a)f(b)$ for each a and b in G ; that is, f preserves multiplication. The positive and negative integers with their usual addition provide an example of an infinite Abelian group (here, addition plays the role of group multiplication, 0 is the group identity and, for example, -5 is the group inverse to 5). The two integers 0 and 1 with the usual addition as group multiplication (except that 1 is to combine with 1 to give 0) provide an example of a finite Abelian group, as does the set of two integers $+1$ and -1 with the usual multiplication of integers. The mapping of an integer into 0 if it is even and into 1 if it is odd provides an example of a homomorphism of the group of integers onto the first two-element group. The function which assigns 0 to $+1$ and 1 to -1 is an example of an isomorphism (i.e., one-to-one homomorphism) of the second two-element group onto the first. Structurally, as far as group theoretical properties are concerned, the existence of this isomorphism indicates that both two-element groups are the same—they are different (isomorphic) representations of the same abstract group, so to speak.

Iso-
morphism

Group representations. The process of group representation may be likened to measuring some physical object with a ruler. By comparing the object to be studied with the known object (the ruler), special information is obtained. Spreading the object out completely along the ruler might be thought of as an isomorphic representation, but such a procedure may not be possible. For example, a polyhedron would have to be studied by applying a series of partial measurements and combining them (corresponding to combining information from homomorphic representations). It would be hoped that sufficiently many measurements could be made to give detailed information—corresponding to the case of sufficiently many (a separating family of) representations so that each pair of distinct elements is carried into a pair of distinct elements by at least one of the representations. An instance of combining information is afforded by the simple fact that a group with a separating family of representations in Abelian groups is itself Abelian (ab and ba are identified by all such representations). It would help little to make measurements with an unmarked straightedge; in the same way, the representations would be expected to take place in groups with some discernible structure. On the other hand, if the ruler is too specialized, for example, circular, it is available for only a limited type of measurement; by analogy, the class of groups in which the representations take place should remain broad enough to have general application. The so-called linear groups, groups of invertible linear transformations on a linear vector space, are well suited to this task. Representations in such groups often are referred to as linear representations, or simply as representations if confusion is unlikely. In particular, representations by unitary operators on Hilbert spaces, called unitary representations, and representations by operators on finite-dimensional linear spaces, called finite-dimensional representations, have proved very useful.

In applying the technique of representations to the study of groups, the allied method of associating an algebra, the so-called group algebra, with the group has a key function. (An algebra is a linear space with a multiplication satisfying certain specific conditions.) For finite groups and the complex group algebra, this amounts to associating with the group sums of formal complex multiples of the group elements and multiplying two such sums by distributing products in the usual way, commuting numbers past group elements, and multiplying group elements by means of the group multiplication.

Group
algebra

A linear representation of the group can be extended to the group algebra by assigning to each sum of multiples of group elements the same sum of multiples of the operators (matrices) corresponding to those group elements under the given representation. This extension is a representation of the group algebra, a mapping into the algebra of operators on the representation space that preserves both products and sums. The analysis of the algebra representation is somewhat simpler than that of the group representation and yields much information about the group representation. The process of extension can be reversed, for the group elements are found in a natural way among those of the group algebra; a representation of the group algebra gives rise to a representation of the group.

There are several ways of constructing new representations from one or more given representations. The first, restriction of a representation, starts with a representation f of a group G (or algebra) and a subspace V of the representation space that is mapped into itself by each of the representing operators, a so-called reducing or invariant subspace. The restricted representation assigns to each g in G the operator $f_g|_V$ on V that is $f(g)$ restricted (in its action) to V . If V is not 0 or the full space, the representation f is said to be reducible. If no such proper invariant subspace exists, the representation is said to be irreducible. (In the case of representations on Hilbert spaces, subspace is understood to mean closed subspace.) Representations of finite groups enjoy the important property of complete reducibility. If V is a reducing subspace, there is a complementary space V' that is also invariant; V and V' have only 0 in common and each vector in the representation space is the sum of one from V and one from V' .

The representation f is said to be the direct sum of f_V and $f_{V'}$. This description of direct sum from an internal viewpoint has an external counterpart. If f and f' are representations of G on spaces V and V' , respectively, a representation $f \oplus f'$, called the direct sum of f and f' , on the direct sum $V \oplus V'$ of V and V' (i.e., the linear space of pairs of elements, one from V and one from V') is defined by assigning to each group element g the operator on $V \oplus V'$ that transforms a pair (v, v') into the pair $([f(g)](v), [f'(g)](v'))$. In the case of reducing complementary spaces V and V' for a representation f , it is an easy matter to see that $f_V \oplus f_{V'}$ is f when the full space is viewed as $V \oplus V'$. In a similar manner, direct sums of more than two representations can be defined. For finite groups, the process of decomposition of a representation may be continued on each of the restricted representations until a full reduction into irreducible representations is effected; the representation is a direct sum of irreducible representations and such a decomposition is unique.

The tensor product

A more complicated procedure for constructing representations from families of representations, the tensor product, stems from the tensor product of linear spaces (the space of sums of multiples of formal products of basis elements one from each space in a given order—the dimension is the product of the dimensions of the individual spaces as contrasted with that of the direct sum which is the sum of the dimensions). If f and f' are representations of G on spaces V and V' , respectively, then $f \otimes f'$, their tensor product, assigns to each g in G the operator $f(g) \otimes f'(g)$ that transforms one of the generating elements $v \otimes v'$ of the tensor product $V \otimes V'$ of V and V' into $[f(g)](v) \otimes [f'(g)](v')$. In particular, the square of a representation consists of tensoring it with itself (similarly for higher powers).

Irreducible representations. A problem of some importance and difficulty is that of describing the irreducible representations that appear in the decomposition of the higher powers of irreducible representations of specific groups, because these are the basic representations not only of the general theory but also of the fundamental physical situation to which the theory applies. Concerning the possible occurrence of a representation that is reducible in the description of a general scheme for quantum mechanics, Claus Hugo Hermann Weyl, who was one of the founders of modern representation theory, wrote, "Nature could hardly be expected to indulge in such a superfluous luxury."

In dealing with representations of a given group, there is clearly no additional information to be obtained by passing from one representation to a second the space of which can be identified with that of the first in such a way that the operators corresponding to each group element under both representations act in the same way on the spaces (relative to the identification). In this case, the representations are said to be equivalent. (Technically, if f and f' are the equivalent representations of G on spaces V and V' , there is a linear isomorphism P of V onto V' such that $Pf(g)P^{-1} = f'(g)$ for each g in G .) When a representation f of a group is expressed as the direct sum of irreducible representations and precisely n of these are equivalent to a given irreducible representation f' , then f' is said to occur in f with multiplicity n . If the group G has m elements the set of complex-valued functions on G is a linear space of dimension m (addition and scalar multiplication performed pointwise). A natural representation of G on this space is available—to the function a is assigned the function a_g the value of which at g' is $a(g^{-1}g')$, and $f(g)$ is taken to be the transformation of the function space so defined. Then f is a representation of G , called the left regular representation of G . In a similar manner, there is the reflected situation of the right regular representation of G . The crucial property of the regular representations is that each contains every irreducible representation of G in its direct sum decomposition (with multiplicity equal to the dimension of the representation space—as a consequence of the reflection situation of the right and left regular representations). The regular representation is an isomorphic one, from which it is concluded that the group G has a separating family of irreducible representations.

If f is a representation of the finite group G as operators on a Hilbert space, then the function that assigns to a pair of vectors x, y in the space the number $\sum_g (f(g)x, f(g)y)$ is again an inner product equivalent to the original one and relative to which each $f(g)$ is a unitary operator (orthogonal transformation, in the real case), so that each such representation of G is equivalent to a unitary representation of G . If f and f' are a pair of inequivalent (irreducible) unitary representations of G , then the sum over g of a product of inner products is zero, one of the inner products being composed of f', x' , and y' (see 602), in which x, y , and x', y' are orthonormal pairs of vectors in their respective spaces (the same holds when $f' = f$ and x', y', x, y is an orthonormal set such that not both $x = x'$ and $y = y'$); while $\sum_g |(f(g)x, y)|^2$ is the number of elements in G , called the order of G , divided by the dimension of the representation. These are the so-called orthogonality relations. The sum of the diagonal entries of the matrix corresponding to an operator on a basis for some finite-dimensional space is called the trace of the operator. It is independent of the basis chosen. If f is a representation of the finite group G on a finite-dimensional space, the function that assigns to each element of G the trace of its representing operator is called the character of f . A critical result of the theory states that two such representations are equivalent if, and only if, their characters are identical; the study of such representations is reduced to the study of the characters of G . The character of a direct sum of representations is the sum of their characters and that of a tensor product is their product. The character of the n -dimensional identity representation, which assigns the identity operator on n -dimensional space to each group element, has the constant function n as its character, and that of the regular representation is 0 at each group element except the identity in which it takes the value equal to the order of the group; this equality value is easily checked on the basis consisting of functions that are 1 at some group element and 0 at all others. The characters of the irreducible representations are precisely those characters k such that $\sum_g |k(g)|^2$ is the order of G .

Schur's lemma

Schur's lemma, which states that the only operators commuting with a unitary irreducible representation are the scalar multiples of the identity operator, is a key result in the development of representation theory. (Because each representation of a finite group is equivalent to a unitary representation, Schur's lemma covers all such representations.) Applying this fact to Abelian groups, it follows that each irreducible unitary representation of such a group is one-dimensional; each group element is mapped into a complex multiple (having absolute value 1) of the identity operator. The function on the group that assigns to each element its corresponding complex number is the character of the representation. There is, of course, no need to distinguish between the representation and its character in this situation. The complex conjugate of such a character is again a character as is the product of two such characters. With this multiplication, the characters form a group—the character or dual group (to the original group). If G is an Abelian group and G' its dual, then each g in G gives rise to a character of G' that assigns to an element of G' its value at g . The duality theorem for Abelian groups states that the mapping of G just described is an isomorphism of G onto the character group of G' ; roughly speaking, G is the dual group of its dual group. A function a on G may be viewed as the element $\sum_g a(g)g$ in the group algebra of G , and each character g' of G has the extension to this group algebra that assigns to $\sum a(g)g$ the number $\sum a(g)g'(g)$. Denoting this number by $a'(g')$, the transformation that maps a onto a' is an isomorphism of the group algebra of G onto the function algebra of G' , the linear space of functions on G' with pointwise multiplication. For finite Abelian groups, this function mapping is the counterpart of the Fourier transform, which is so important in mathematical analysis (see above *Harmonic analysis and integral transforms*).

$$(602) \quad \sum_g (f(g)x, y)(f'(g^{-1})x', y') = 0$$

Topological groups and Lie groups. The applications of the theory of group representations to mathematical analysis and to physics entail, for the most part, the description of the representations of infinite groups that have a topological structure related to their group structure—the so-called topological groups. (The topological structure is a mathematical formulation of the concepts of nearness. The topological groups are those in which nearness is so defined that the product of an element and the inverse of another element is near to the group identity, provided both elements are themselves near the identity.)

The most important and the most intensively studied of these groups are the Lie groups. These are the topological groups in which the topology near each point is like that of n -dimensional Euclidean space for some fixed n . A more general class of topological groups, the locally compact groups, have received some attention. These include the discrete groups (those in which no group element is infinitely near the others—every group can be given such a topology), the Lie groups, and those that can be constructed from these two classes by certain group-theoretic processes. The various Euclidean spaces with vector addition as group multiplication and the complex numbers of modulus 1 (the circle group) with the usual multiplication of complex numbers each with its usual notion of nearness are examples of Abelian Lie groups. The invertible operators on n -dimensional Euclidean space form a non-Abelian Lie group, the general linear group of dimension n . Here group multiplication is the multiplication of operators, and two operators are near each other if the images of a specific vector under those operators are near each other.

Haar
measure
of locally
compact
groups

The crucial property of locally compact groups is the existence of a measure on them, Haar measure (a notion of volume for subsets), which assigns the same number (measure) to a subset of the group and to the subset obtained from it by left multiplying each element of the subset by a fixed group element (each left translate of the set). Those groups with finite total measure constitute an especially important subclass, the compact groups. The circle group and the subgroup of the general linear group consisting of those operators that preserve the lengths of vectors, the orthogonal group (unitary group in the complex case), are examples of compact Lie groups. The finite groups are compact (discrete) groups.

The most satisfactory aspects of this general theory are to be found in its application to the classes of compact groups and of Abelian (locally compact) groups. The theory of representations developed for finite groups is valid for continuous representations of compact groups on Hilbert spaces, once summation over the finite group (divided by the group order) is replaced by integration with respect to Haar measure (normalized so that the group has measure 1). The equivalence of such representations with unitary ones, the character theory, direct sum decomposition into irreducible representations, the orthogonality relations, and the existence of a separating family of (finite-dimensional) irreducible unitary representations are valid for compact groups. The critical new fact that must be established in the general case is the finite dimensionality of each irreducible representation. The duality theory for finite Abelian groups carries over intact to the general case. The dual (character) group of a compact Abelian group is discrete (and that of a discrete group is compact). In particular, the character group of the circle is the additive group of integers—the correspondence between (L_2) functions on the circle and those on the integers (described for finite Abelian groups) is the Fourier series expansion of periodic functions. The additive group of real numbers is its own dual, and the function mapping, in this case, is the important Fourier transform.

The representations of the three-dimensional rotation group, R_3 , supply an excellent and physically significant illustration of the theory for compact groups. The group R_3 consists of linear transformations of (real) three-dimensional space that preserve the lengths of vectors and have determinant 1. The rotations preserve area on the unit sphere about the origin (best described in terms of three-dimensional polar coordinates), so that each such rotation

induces a unitary transformation on the Hilbert space of square integrable functions over the sphere. The resulting unitary representation decomposes into a direct sum of irreducible, finite-dimensional unitary representations. From a direct analytical study this representation can be shown to decompose into a direct sum of spaces of odd dimension, one for each odd number. This decomposition is effected by means of the spherical harmonic functions on 3-space and their associated surface harmonics on the sphere. The orthogonality relations for the surface harmonics establish the fact that this decomposition yields all the irreducible representations of R_3 .

For general locally compact groups it is still possible to establish the existence of a separating family of strongly continuous irreducible unitary representations, and it is still possible to decompose reducible representations into a direct integral of irreducible representations; but much of the value of this fact is lost in the observation that the decomposition can often be performed in many totally distinct ways, so that no irreducible component of one decomposition is equivalent to any component of the others. These developments have given rise to the opinion that the appropriate process is not decomposition into irreducible representations but rather into factor representations. (A unitary representation is said to be a factor representation when the weak closure of the sums of multiples of the representing unitary operators has only multiples of the identity operator in its centre. Such an algebra of operators is said to be a factor.) The factors have been broadly classified into types depending on the nature of a dimension function on the projections in the factor (its discreteness or nondiscreteness, its finiteness or infiniteness). The so-called factors of type I are the most manageable type from the point of view of group representations. These are the factors isomorphic with the algebra of all bounded operators on some Hilbert space. The (direct integral) decomposition of a group representation into factor representations is essentially unique. When the resulting factors are of type I the decomposition of the representation into irreducible components is also essentially unique. The problem of the types of factor representations a specific group has (the so-called type problem) is central to the general theory. In particular, establishing that specific classes of groups have only type I representations is of vital importance to the general theory.

The detailed investigation of a Lie group and its representations proceeds via the study of its associated Lie algebra. If the Lie group with its associated topology is thought of as a surface in three-dimensional space (or, more generally, a manifold in n -dimensional space), each vector in the tangent plane (space) at the group identity determines a unique vector at each group element by means of (left) translation by that group element. Relative to (*i.e.*, in the direction of) the invariant vector field so obtained, (differentiable) functions can be differentiated to give another function on the group. If two such vector fields are involved, differentiation is performed with respect to each successively in both orders, and the result of one is subtracted from that of the other; the mapping on functions obtained by this process is the same as that due to differentiation with respect to some third invariant vector field. This third vector field is said to be the Lie product or bracket of the other two. These vector fields, or—what amounts to the same thing because each is determined by a tangent vector at the group identity e —the tangent space at e , with the Lie product is the Lie algebra of the group (it is a nonassociative algebra). Because differentiation is a local process, depending only on the points near a point at which it takes place, the Lie algebra of a group is in reality a construct associated only with that portion of the group near the identity—the so-called local Lie group. Several Lie groups that are distinct globally may have the same local structure and hence the same Lie algebra; for example, the circle group and the group of real numbers both have the real line with the Lie product of each pair of elements 0 as their Lie algebra.

The distinction between Lie groups that have the same Lie algebra is a (global) topological one. Loosely speaking, they differ in the number and relation of the holes in

Lie algebra
of a group

them. A particular one of them covers the other; that is, maps homomorphically onto the other by a mapping that is an isomorphism near the identity. For example, the circle has a hole, the real line does not, and the real line may be wrapped homomorphically around the circle. In the family of Lie groups with a given Lie algebra, there is one that covers all the others—the so-called universal covering group of the others (also called simply connected covering group—the one that has no holes). The group of reals is the universal covering group of the circle. The rotation groups in dimensions 3 and higher are not themselves simply connected but have a twofold universal covering group; each point in the rotation group is the image of precisely two points in this covering group. These are the spinor groups ($\text{Spin}(n)$ for the n -dimensional rotation group R_n).

The Lie algebra of a Lie group may be thought of as a linear approximation to the local Lie group in the same sense that a tangent plane to a surface is the best planar approximation in the neighbourhood of the point of

tangency. The multiplicative nature of the local group is made linear (additive) by the transition to the Lie algebra in much the same way that the logarithm converts multiplicative numerical problems into additive ones. In fact, there is a generalized logarithmic mapping (which preserves differentiability) carrying the local Lie group onto a neighbourhood of the origin in the Lie algebra—or, technically more manageable, an exponential mapping of the entire Lie algebra into the group. By means of this mapping, (local) questions about the group can be transferred to questions about the Lie algebra, which are more easily handled because of the added linearity.

The deeper analysis of the representation theory for Lie groups, the finite-dimensional representations of which are completely reducible (the semisimple Lie groups), involves the undertaking of a profound analysis of the semisimple Lie algebras and the so-called theory of weights that is associated with their representations. It has been established for such groups that their unitary representations on Hilbert spaces are of type I. (A.Zy./C.L.F./Ed.)

CALCULUS OF VARIATIONS

The calculus of variations is an old subject; some of its problems were considered and partially solved by the ancient Greeks. Leonhard Euler in the mid-18th century deduced the first general rules for dealing with the subject, while much of the terminology was introduced soon after by Joseph-Louis Lagrange.

When two points, A and B , are given in a plane, as shown in Figure 21, there is an infinity of arcs joining them. A simple problem of the calculus of variations is that of finding in this group of arcs (such as E and E') one that has the shortest length, the solution of the problem being a straight line segment. It may also be desired, however, to find in the group of arcs joining A with B one down which a particle, started with a given initial velocity, will fall from A to B in the shortest time; or which one of these arcs, when rotated about the x -axis, will generate a surface of revolution of minimal area.

Figure 21: Simple problem of arc length (see text).

These examples are typical problems of the calculus of variations of the so-called simplest type.

These problems illustrate the usual situation in the calculus of variations, in which mathematicians seek to find that arc from some given class for which some quantity, whose value depends on the entire arc (its length, etc.), is a minimum or a maximum. The calculus of variations also deals with problems involving surfaces or functions of several variables. For example, if a circular wire is bent in any way, dipped in a soap solution, and then withdrawn, the soap film spanning the wire will assume the shape of the surface of least area bounded by the wire.

The calculus of variations has been useful as a unifying principle in mechanics and as a guide for the determination of new laws of physics.

Albert Einstein's theory of general relativity, for example, utilizes the calculus of variations extensively. One of the most widely applicable variational statements of classical mechanics is known as Hamilton's principle (after the 19th-century Irish mathematician William Rowan Hamilton); it states that the trajectories of many dynamical systems are the solutions of some variational problem involving an energy integral.

The introduction of the calculus gave great impetus to

the study and to the solution of variational problems. After a number of special problems had been solved, Euler in 1744 deduced the first general rule, now known as Euler's differential equation, for the characterization of the maximizing or minimizing arcs.

MATHEMATICAL FORMULATION OF VARIATIONAL PROBLEMS

All the problems mentioned in the first paragraph of this section reduce to the determination of that differentiable arc $y = y(x)$ joining the two points (x_1, y_1) and (x_2, y_2) that minimizes an integral extended over a segment of the x -axis and having its argument a function of x , of y , and of the derivative of y (see 603). The length of the arc and the area of the surface of revolution obtained by revolving it around the x -axis are found from elementary calculus to be given respectively by the integrals of the general type described above in which the function in the integrand involves the square root of one plus the square of the derivative of y (see 604). In the case of the curve of steepest descent, the time required for a bead to descend along a wire in the shape of an arc from the point (x_1, y_1) to the point (x_2, y_2) under the action of gravity is given by the integral of the above type with a special form in the integrand that accounts for the special type of problem involved (see 605) if friction is neglected; here the term a in the integrand is of the form v_1^2 divided by twice g (see 606), in which v_1 is the initial velocity of the bead and g is the acceleration of gravity.

It is the case in the preceding examples that the function $f(x, y, p)$ occurring in the minimizing integral (see 603) has one of several forms, each involving the square root of one plus p^2 (see 607). The integrals arising from Hamilton's principle are of the type in formula (603), in which x is replaced by the time t (this usually does not appear in the function f in such applications) and the single variables y and p are replaced by several variables y_1, \dots, y_n and p_1, \dots, p_n , the p_i standing for the derivatives dy_i/dt .

EULER'S EQUATION

Euler's differential equation for the determination of a minimizing arc is derived as follows: Suppose that $y = y(x)$ is a minimizing arc that passes through the two points, and assume that the second derivative y'' and the second partial derivatives of f are all continuous. If $\eta(x)$ is any differentiable function which vanishes at the end points x_1 and x_2 (see 608), then for any λ the arc obtained by adding to the function y the function λ times η (see 609) is another arc joining the two given points. Forming an integral for this new arc gives a function $I(\lambda)$ in the form of a definite integral in which λ appears as a parameter (see 610) which is differentiable and must have a minimum for $\lambda = 0$.

From elementary calculus, it follows that the integral in-

Determina-
tion of a
minimizing
arc

Hamilton's
principle

$$(603) \quad \int_{x_1}^{x_2} f[x, y(x), y'(x)] dx, \quad y' = \frac{dy}{dx}$$

$$(604) \quad \begin{cases} \int_{x_1}^{x_2} \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx, & \text{length of arc} \\ \int_{x_1}^{x_2} 2\pi y(x) \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx, & \text{area of surface} \end{cases}$$

$$(605) \quad \int_{x_1}^{x_2} (a - y)^{-1/2} \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx$$

$$(606) \quad a = y_1 + \frac{y_1^2}{2g}$$

$$(607) \quad \sqrt{1 + p^2}, \quad 2\pi y \sqrt{1 + p^2}, \quad \sqrt{1 + p^2}/\sqrt{a - y}$$

$$(608) \quad \eta(x_1) = \eta(x_2) = 0$$

$$(609) \quad y = y(x) + \lambda \eta(x)$$

$$(610) \quad I(\lambda) = \int_{x_1}^{x_2} f[x, y(x) + \lambda \eta(x), y'(x) + \lambda \eta'(x)] dx$$

$$(611) \quad I'(0) = \int_{x_1}^{x_2} \left\{ \eta(x) f_y[x, y(x), y'(x)] + \eta'(x) f_p[x, y(x), y'(x)] \right\} dx = 0$$

$$(612) \quad \int_{x_1}^{x_2} \eta(x) \left\{ f_y - \frac{d}{dx} f_p \right\} dx = 0$$

$$(613) \quad \frac{d}{dx} f_p = f_y$$

$$(614) \quad f_{pp} \frac{d^2 y}{dx^2} + f_{py} \frac{dy}{dx} + f_{px} = f_y$$

volving λ can be differentiated with respect to the parameter λ . A necessary condition for a minimum is that this derivative should be equal to 0 (see 611). The integral that results is called the first variation of the original integral (see 603); this corresponds roughly to the total differential of a function of several variables, the function $\eta(x)$ corresponding to the set of differentials of the variables. Now, using the differentiability assumptions, the term involving $\eta'(x)$ in the first variation (see 611) may be eliminated by integrating by parts to obtain an integral of which the integrand includes η as a factor, the total integral being equal to 0 (see 612).

Because the last integral expression (see 612) holds for every function $\eta(x)$ allowed above, it follows from a well-known theorem in analysis that the first derivative of f_p is restricted to equal f_y (see 613), which is Euler's differential equation; it is understood in the derivation that the values x , $y(x)$ and $y'(x)$ are to be inserted in the expressions for f_p and f_y .

If Euler's equation (see 613) is written out in more detail, the rules of differentiation yield an equation in which the second derivative of y appears (see 614), which shows that Euler's equation is of the second order. Euler's equation becomes singular, however, if $f_{pp} = 0$. Therefore, regular variational problems are those for which f_{pp} never vanishes; in that case, it is assumed that $f_{pp} > 0$, which makes minimum problems more natural than maximum problems.

SOME QUESTIONS INVOLVING ARCS

The analysis leading to Euler's equation applies just as well to a maximizing arc as to a minimizing one. The first

attempt to find a condition that would single out a minimizing arc was to consider the second variation, which is obtained, for any given $\eta(x)$, by finding $I''(0)$, $I(\lambda)$ being defined by (610).

Clearly $I''(0) \geq 0$ for every $\eta(x)$ if $y(x)$ is a minimizing arc, but the condition that $I''(0) \geq 0$ for every $\eta(x)$ is not sufficient to ensure that $y(x)$ is minimizing. The attempt to find conditions that would ensure a given arc being a relative minimum led to a variety of rather interesting discoveries and also raised a number of new questions.

After Weierstrass' famous example of a continuous function that does not possess a derivative at any point (thereby showing that a function with a continuous first derivative does not necessarily have to have a continuous second derivative), the question then was raised as to why a minimizing arc, or, more generally, why any arc for which the first variation is zero for every η , should possess a continuous second derivative, as is required in the derivation of Euler's equation. By the end of the 19th century, the problem of the existence of a minimizing arc had been raised, and the existence had been proved by Hilbert under certain hypotheses. Leonida Tonelli developed the so-called direct methods of the calculus of variations in order to simplify and amplify the results of Hilbert concerning the existence of minimizing arcs.

Tonelli's methods

These results were applied to general situations by the metric geometry methods of Karl Menger and Herbert Busemann. Most of the remaining problems involving arcs were solved between 1910 and 1940 by such mathematicians as Oskar Bolza, Gilbert Ames Bliss, and Edward James McShane.

The fact that not every minimum problem has a solution is seen by studying a definite integral extending from 0 to 1 symbolized by I in which the integrand includes the derivative of y (see 615). In this case $0 < I < 1$ for every $y(x)$. Setting $y(x) = x^n$, $n = 1, 2, \dots$ shows that I may be made arbitrarily close to 1. By taking $y(x)$ to be equal to x plus a sinusoidal function (see 616), it is seen that I may be made arbitrarily close to zero. There is, however, no $y(x)$ for which I is equal to zero or one.

MULTIPLE-INTEGRAL PROBLEMS

Meanwhile interest had developed in problems involving functions of two or more variables, and the derivation of Euler's equation had been extended to integrals of a more complicated form (see 617). Replacing z by $z + \lambda \zeta$, in which ζ has a role similar to that of η in the preceding problem, $\zeta = 0$ on the boundary of the region G , and proceeding as in the derivation of Euler's equation (see 610–612) results in the equation known as Euler's equation (see 618) for the multiple integral (see 617).

Early in the 19th century Carl Friedrich Gauss and William Thomson, Lord Kelvin, had observed that Laplace's equation was the Euler equation for a particular integral (see 619), as is seen by setting $f(x, y, z, p, q) = (p^2 + q^2)/2$ in the derivation of Euler's equation for the multiple integral (see 617, 618).

This fact is the formal basis for what is now known as Dirichlet's principle, which states that (subject to certain hypotheses) there is a unique function z that minimizes the integral of the sum of squares of z_x and z_y (see 619) among all differentiable functions having given boundary values and that that unique function is the solution of Laplace's equation with those boundary values.

This principle has proved to be of great importance not only in potential theory and in the theory of partial differential equations, but also in the theory of functions of a complex variable and in conformal mapping. The applications to these fields was begun by Bernhard Riemann around 1850 and important advances have been made in them since 1935 by such mathematicians as Richard Courant, Lars V. Ahlfors, Donald Clayton Spencer, Menahem Max Schiffer, Paul Roesel Garabedian and others. Riemann simply assumed the principle but, of course, the objections that were raised concerning problems involving arcs applied to the Dirichlet principle with even greater force; the first proof of the principle was given by Hilbert in 1900.

Bernard Riemann

The almost simultaneous solutions by Jesse Douglas and

$$(615) \quad \begin{cases} I = \int_0^1 \{1 + [y'(x)]^2\}^{-1} dx \\ y(0) = 0, \quad y(1) = 1 \end{cases}$$

$$(616) \quad y(x) = x + n \sin n\pi x, \quad n = 1, 2, \dots$$

$$(617) \quad \begin{cases} I = \iint_G f[x, y, z(x, y), z_x(x, y), z_y(x, y)] dx dy \\ z_x = \frac{\partial z}{\partial x}, \quad z_y = \frac{\partial z}{\partial y} \end{cases}$$

$$(618) \quad \frac{\partial}{\partial x}(f_p) + \frac{\partial}{\partial y}(f_q) = f_z, \quad p = z_x, \quad q = z_y$$

$$(619) \quad \frac{1}{2} \iint_G (z_x^2 + z_y^2) dx dy$$

$$(620) \quad f(x_1 + \eta_1, \dots, x_n + \eta_n) - f(x_1, \dots, x_n) \\ = \frac{1}{2} \sum_{i,j=1}^n a_{ij} \eta_i \eta_j + R$$

$$(621) \quad a_{ij} = \frac{\partial^2 f}{\partial x_i \partial x_j}$$

$$(622) \quad -\xi_1^2 - \dots - \xi_r^2 + \xi_{r+1}^2 + \dots + \xi_s^2$$

The
Plateau
problem

Tibor Radó in 1930 of the problem of the Belgian physicist Joseph Antoine Ferdinand Plateau, *i.e.*, the proof of the existence of a minimal surface (surface of least area) bounded by a simple closed curve in space, aroused a renewed interest in variational problems for surfaces. The Plateau problem was solved for surfaces bounded by several curves and for more complicated surfaces by Douglas, Courant, and others. More general variational problems for surfaces were solved by Tonelli, McShane, Charles B. Morrey, Jr., Lamberto Cesari, A.G. Sigalov, and others between 1930 and 1957 by extending the direct methods of Tonelli; these involve considering the surfaces as points in a space in which limits are defined and using the general theorem in functional analysis that a function that is lower-semicontinuous on a compact set attains its minimum on that set. In order to apply this theorem it was found expedient to enlarge the classes of arcs or surfaces, etc., within which the minimum is sought. Unfortunately,

the enlarged classes usually contain surfaces that do not possess the properties of differentiability required in the derivation of Euler's equation.

In the case of the Plateau problem the differentiability of the solutions follows from the Dirichlet principle. The differentiability of the generalized solutions of certain other problems for surfaces was proved by Morrey, and some of his results were extended in 1957 to problems in higher-dimensional spaces by Ennio De Giorgi and John Nash, Jr.

An interesting attack on problems for surfaces has been made by L.C. Young, Wendell Helms Fleming, and others through their introduction of generalized surfaces.

MORSE'S THEORY OF CRITICAL POINTS

If a function $f(P)$ is defined on an n -dimensional manifold, its behaviour near a particular point may be studied by introducing coordinates, in which case f becomes just a function of n coordinates x_1, \dots, x_n . A point (*i.e.*, set of numbers x_1, \dots, x_n) is a critical point of f if all its partial derivatives are zero there. If x_1, \dots, x_n is such a point, then a formal finite difference constructed with the function f equals the summation of terms plus a final term symbolized by R (see 620), in which R consists of the higher order terms; here the coefficients in the summation of terms are obtained from the second-order partial derivatives (see 621) evaluated at the point. It is known that linear combinations ξ_1, \dots, ξ_n of the η_i can be chosen so that the double sum becomes expressed in terms of the squares of the ξ_i , the indices ranging from one through r to s (in which r is zero if there are no negative terms, etc.; see 622). Moreover, the numbers r and s are independent of the coordinate system and the way the ξ_i are chosen as long as the given quadratic form (see 622) is obtained. If $s = n$, the critical point is said to be nondegenerate, in which case r is called the index.

Harold Marston Morse, a 20th-century American topologist, first proved certain inequalities between the number of critical points of a given index of a (nondegenerate) function on a manifold and the so-called Betti numbers (after the 19th-century Italian mathematician Enrico Betti) of the manifold. His greatest contribution was to generalize the notion of a nondegenerate critical point and his inequality results to situations in which the functions and spaces were too general for differentiability to be defined. Morse applied his theory to spaces the elements of which were arcs or closed curves on a manifold or surfaces in space. He was able to prove the existence of unstable minimal surfaces (*i.e.*, surfaces furnishing some critical value other than a minimum to the area) and to prove such theorems as that there exist at least three closed shortest paths on a sphere. His theory has been applied to variational problems for arcs with great success. Stephen Smale and others have found a way to apply the Morse theory to multiple integral problems. (C.B.My.)

FUNCTIONAL ANALYSIS

A broad view of functional analysis

EARLY DEVELOPMENT

The development of analysis in the 19th century led eventually to the realization that limit processes originally developed for sequences of values of a single function could usefully be applied to whole sequences of functions and, further, that individual functions of interest could be studied to advantage using an indirect technique that established the properties of such a function by considering appropriate sequences of other, and generally simpler, functions that converged to it. This approach was pioneered by Jean-Baptiste-Joseph Fourier, a French mathematician who died in 1830, and it was developed subsequently by many other mathematicians, who improved and generalized the theory of Fourier series, which Fourier's work initiated. Studies of functions using this same method of approximation also played a central role in the theory of functions of a complex variable, the systematic work of Karl Weierstrass in the 19th century being especially

Fourier's
contribution

notable in this connection. Out of repeated applications of the technique of functional approximation there grew the gradual realization that individual functions ought to be looked at as members of broader collections or spaces of functions. By focusing attention not on a single function f in isolation but rather on an appropriate collection of functions containing f , and on the special position or defining property of f within this collection, important properties of a particular function f could in many cases be established in a more ready and transparent fashion than was otherwise possible; old proofs could be simplified, and new proofs could be attained. In such studies it was often useful to make use of expressions assigning a value to each member of a space of functions; such expressions were dubbed functionals, this term being coined in analogy with the word function, which designates a rule assigning a value to each member of a collection of numbers. The body of mathematical work growing out of the viewpoint outlined above, in which functions are studied collectively, and in which the older methods of analysis

are applied to whole collections of functions, consequently became known as functional analysis.

At the turn of the 20th century, the work of Vito Volterra and Erik Ivar Fredholm began to underscore the utility of the functional approach and to make use of this approach in an explicit way. At about the same time, studies undertaken by David Hilbert, Erhard Schmidt, Frigyes Riesz, and others served to make plain the analogies between analytic and classical algebraic principles that emerged when collections of functions were regarded as abstract global totalities, and the value of regarding a function as a point in a space of functions became plain. This was recognized clearly by Schmidt, for example, in a 1908 study of systems containing infinitely many equations; Schmidt introduced various geometric notations and terms, which are still in use, for describing spaces of functions. At approximately the same time the foundations of modern point-set topology, originally the study of geometric properties that remain unchanged under continuous maps, were being laid by Maurice-René Fréchet, Felix Hausdorff, and Riesz. These topological studies gave an abstract and extremely general form to the basic notions of continuity and differentiability that played a central role in the older analysis, thus allowing these notions to be carried over to spaces of functions. General definitions of the type of space of functions in which the new functional methods could be applied were offered a few years later by Norbert Wiener and Stefan Banach. In 1932 Banach's *Théorie des opérations linéaires* summarized much of the most interesting work in functional analysis up to that time and inspired much of the work in functional analysis through succeeding decades. The important general class of Banach spaces take their name from him. At about the same time John von Neumann began a brilliant series of investigations into the functional analysis of Hilbert space (see below *Hilbert space; spectral analysis*), which is that particular space of functions bearing the closest geometric analogy with ordinary Euclidean space. This work, which gave an abstract, transparent, and greatly generalized form to older analyses of integral equations by Hilbert and Schmidt, soon made contact with other broad areas of algebra and classical analysis, and has led to rich subsequent developments. Von Neumann's work had also a particularly close relation to, and influence on, the mathematical apparatus of quantum physics.

LINEAR FUNCTIONAL ANALYSIS; THEORY OF DISTRIBUTIONS

Linear
properties

Many important spaces of functions are linear. A collection of functions possesses this property if the sum of any two functions belongs to the same collection and if an arbitrary constant multiple of a function in the collection still belongs to the collection. For example, the sum of two continuous functions is continuous, the sum of two bounded functions is bounded, the sum of two smooth functions is smooth, etc., so that continuous functions constitute a linear space of functions, smooth functions another, bounded functions a third, etc. When a space of functions is linear, useful analogies exist between its elements and the vectors of ordinary two- and three-dimensional space. These analogies suggest many useful geometric lines of investigation, and the availability of addition and multiplication operations makes it possible to adapt many of the powerful algebraic procedures of conventional vector algebra or linear algebra to the study of function spaces. To emphasize this analogy, one often speaks of a collection of functions having the property of linearity as a linear space of functions, and of its elements as points or vectors.

Many significant methods of functional analysis grow out of this analogy. Using terminology adapted from vector algebra, a function f which is the sum of terms of the type $a_k f_k$ (see equation 623), in which a_1, \dots, a_n are numbers

$$(623) \quad f = a_1 f_1 + \dots + a_n f_n$$

$$(624) \quad F(a_1 f_1 + a_2 f_2) = a_1 F(f_1) + a_2 F(f_2)$$

and f_1, \dots, f_n are functions belonging to the same space as f , is spoken of as a linear combination of f_1, \dots, f_n ; the expression $a_1 f_1 + \dots + a_n f_n$ may be called the expansion of f in terms of f_1, \dots, f_n . The same terms are also used in connection with infinite sums of the form $a_1 f_1 + a_2 f_2 + \dots$, provided that these sums are convergent (i.e., approach a limit) in an appropriate sense. In studying a problem set within some particular function space, it is often useful to find some particularly simple collection of functions f_1, f_2, \dots in terms of which every function may be expanded. The observation that such expansions could be useful for analysis goes back to Daniel Bernoulli and Leonhard Euler in the 18th century, who, in studying the motions of a vibrating string, found it useful to expand certain functions in terms of simpler ones. The British engineer Oliver Heaviside and many other 19th-century mathematicians showed that other similar series expansions were useful for treating a wide range of specific problems. Modern functional analysis affords a comprehensive generalization of all these earlier investigations and makes plain the relatively simple algebraic-geometric basis on which they rest.

Expansion
of
functions

Many techniques related to the linear combination of functions are used within functional analysis. Certain important function-associated operations have the property that when applied to the sum of two functions they give a value that is the sum of the values obtained by applying the same operation to the two functions individually. Designating such an operation by the symbol F , this general property may be represented by an algebraic formula (see 624). An operation or functional having this property is said to be linear. Many of the central operations of classical analysis—as, for example, differentiation and integration—are linear: the integral of the sum of two functions is the sum of their integrals, etc. Taking an abstract and general view, functional analysis sees in the collection of all operations satisfying the condition (624) another space of objects, related in a natural way to an initial collection X of functions f . If the operations F in (624) are restricted to have numerical values, one speaks of F as a linear functional on the collection X ; if the operations F have values that are themselves functions, one calls F a linear operator on X ; if the values of F lie in X , F is called a linear operator in X . The collection of all linear functionals on X , the collection of all linear operators on X , and the collection of all linear operators in X , all form spaces associated with the space X in a natural way. The collection of all linear functionals on X is often called the conjugate space or dual space of X , and it is conventionally designated by the symbol X^* . The conjugate space X^* is important in functional analysis for a variety of reasons. Many operations that are defined for the elements of X carry over in a natural way to the elements of X^* . The study of X^* , and of various detailed relationships between X and X^* , can yield important information concerning X . Moreover, consideration of the dual space X^* of an artfully chosen collection X may provide the key to the solution of a problem in which X itself plays only a subsidiary role.

The theory of distributions, introduced in the late 1940s by Laurent Schwartz, gives a famous example of the systematic use of this last observation. Schwartz begins by considering the space of all extremely smooth functions f of a real variable y that are zero for sufficiently large values of the variable y . This collection X_0 of functions is one of the smallest (i.e., most restricted) yet still quite general classes of functions that can be defined. Analytically important operations, such as differentiation and integration, are easily defined for the elements of X_0 ; the relationship between X_0 and X_0^* allows these operations to be carried over to the very much larger space X_0^* . The elements of X_0^* are called distributions by Schwartz. Because X_0 can be regarded as a subspace of X_0^* , the elements of X_0^* have a natural interpretation as generalized functions. Schwartz's construction makes differentiation, etc., available over a wide range of nonconventional mathematical objects, and in a manner preserving all the formal properties of these operations that are central to traditional analysis. There results a considerable broadening of the differential and integral calculus, including and generalizing many of the

Schwartz's
theory of
distribu-
tion

formal extensions of calculus developed on *ad hoc* lines for specific application, notably by Heaviside and the British physicist P.A.M. Dirac. Until Schwartz's development of the theory of distributions, most of these schemes of formal calculation lacked rigorous justification and were regarded as slightly illegitimate curiosities. Distribution theory has brought these and even more powerful tools for calculation into general mathematical currency (see below *Generalized functions, or theory of distributions*).

GEOMETRIC PRINCIPLES; ANALYSIS OF LINEAR OPERATORS

As already noted, linear functional analysis aims to exploit the formal similarity that exists between addition of functions and addition of vectors in two, three, and more dimensions and, accordingly, tends to consider any collection of functions having the necessary property of linearity as an infinite-dimensional analogue of the familiar Euclidean spaces. In accordance with this fundamental point of view, a systematic attempt is made to carry as many useful geometric notions as possible over from two- and three-dimensional Euclidean space to arbitrary linear collections of functions. One notion of this kind, which has been quite successfully exploited in functional analysis, is that of convexity. A body B in two- or three-dimensional Euclidean space is convex if, and only if, the entire straight-line segment S between any two of its points belongs to the body; if B is closed, this will be the case if, and only if, the midpoint of each such segment S belongs to the body. Phrased in terms of vector algebra, this last condition amounts merely to the demand that the midpoint $(f+g)/2$ of S belongs to B whenever the endpoints f and g of S are both points of B ; in this formulation, the notion of convexity generalizes immediately to any linear space of functions. This last observation suggests that many of the properties of convex bodies in two and three dimensions can be carried over to convex collections of functions within a linear space of functions; and such is indeed the case. Thus, for example, if one is given a convex body B in three-dimensional space and a point p not belonging to the body, one can always draw a plane with the point on one side of the plane and the body on the other side. If the equation of the plane is written $F(x) = c$, it follows that $F(p)$ is smaller than c , but that $F(x)$ is larger than c for each point x of the body B . This simple but basic geometric fact generalizes at once to convex collections B in linear spaces of functions, giving the so-called Hahn-Banach theorem, a theorem possessing many applications. This case will serve to illustrate the more general remark that functional analysis contains generalizations of much of the rich geometric theory of convex bodies, in which corners, shortest paths, inscribed and circumscribed bodies, cones, and so forth, are all studied to advantage. Many of the most useful inequalities belonging to the older analysis of single functions turn out to have simple geometric interpretations when they are reformulated in functional-analytic terms.

As has already been noted, an operation F on functions with values $F(f)$ that are themselves functions satisfying the algebraic condition (see 624) is called a linear operator. Such a linear operator may be regarded as the natural generalization, to linear spaces of functions, of the rectangular matrices of conventional finite-dimensional vector algebra. If F is a linear mapping in a space X —i.e., if the values $F(f)$ of F belong to the same space X as do the functions f for which F is defined—then F is analogous not merely to a rectangular but to a square matrix; i.e., to a matrix having equally many rows and columns. Matrices of this type may freely be added and multiplied; the study of their particularly interesting algebraic relationships, which in the finite dimensional case was initiated in the 19th century by Arthur Cayley of Great Britain, generalizes at once to linear operators. Given that F is a linear operator in a linear space X , the “square” of F , for example, may be defined as the transformation G specified by the formula $G(f) = F(F(f))$, and higher powers of F may be defined in analogous fashion. The elementary infinite series that expresses the nonnegative reciprocal of $1-x$ as a sum of all integer powers of x (see 625) then generalizes in a straightforward way to linear operators,

$$(625) \quad \frac{1}{1-x} = 1 + x + x^2 + x^3 + \dots$$

$$(626) \quad e^x = 1 + x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \dots$$

$$(627) \quad e^F = I + F + \frac{1}{2}F^2 + \frac{1}{6}F^3 + \dots$$

$$(628) \quad a^{t_1} a^{t_2} = a^{t_1+t_2}$$

$$(629) \quad e(t_1)e(t_2) = e(t_1+t_2)$$

its generalization proving to be the key to many of those results of the early-20th-century theory of linear integral equations from which the historic development of modern functional analysis began. Other power series can also be used to define functions of a linear operator F , provided always that F acts in a single linear space X of functions; i.e., that F is defined for each f in X and that each value $F(f)$ of F belongs to X . For example, the exponential function e^x has the power series expansion, with coefficients formed of reciprocals of factorials (see 626), which suggests the possibility of defining an operator exponential by writing a formal power series for the linear operator f with coefficients as before (see 627); here I denotes the unit, or identity, linear operator specified by the equation $I(f) = f$. This definition of an exponential function for linear operators is in fact quite useful and provides the key to several important calculations and theorems. Further extension of this same technique yields a systematic calculus of functions of linear operators.

Other analogies between collections of operators and ordinary algebra have been quite fruitful for functional analysis. To give a further example, the exponential function a^t has the property that the product of two function values evaluated at distinct points is equal to the function value evaluated at the sum of the two corresponding points (see 628). Moreover, any continuous numerical function $e(t)$ having this multiplicative property—i.e., any function satisfying the condition that the product of two function values for distinct points is equivalent to the function value for the sum of the distinct points (see 629)—is necessarily expressible as an exponential function; i.e., $e(t) = a^t$. This fact suggests the study of families $E(t)$ of linear operators depending on a real parameter t and satisfying the algebraic condition that is defined by the formula given as (630), namely: $E(t_1)E(t_2) = E(t_1+t_2)$. Operator families satisfying this condition are called semigroups of linear operators; they arise in a variety of physical, mathematical, and probabilistic settings. Naturally enough, their study centres upon techniques for defining fractional powers A^t of a linear operator A and around attempts to find conditions guaranteeing that a particular semigroup $E(t)$ of linear operators must have the exponential form $E(t) = A^t$.

HILBERT SPACE; SPECTRAL ANALYSIS

In the preceding paragraphs it was stressed that many of the most fruitful ideas of functional analysis arise in analogy with algebraic and geometric notions belonging to the vector analysis and the geometry of two- and three-dimensional Euclidean space. These analogies become most compelling if there is imposed upon the spaces of functions a condition that plays a fundamental role in

$$(630) \quad E(t_1)E(t_2) = E(t_1+t_2)$$

$$(631) \quad |f+g|^2 = |f|^2 + |g|^2 - 2|f||g|\cos\theta$$

$$(632) \quad [F(f), g] = [f, F(g)]$$

$$(633) \quad g(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} f(y)e^{ixy} dy$$

Relation of
Pythagoras'
theorem
to Hilbert
space

Euclidean geometry: namely, the relation contained in Pythagoras' theorem. For easy generalization it is useful to state Pythagoras' relationship in the following slightly unconventional way: the sum of the squares of the lengths of the diagonals of a parallelogram is equal to twice the sum of the squares of the length of its sides. A linear space of functions in which every parallelogram has this property is called a Hilbert space, in honour of Hilbert, whose penetrating investigations of integral equations in certain particular spaces of this kind influenced the subsequent development of formal functional analysis in a particularly profound way. For such spaces it may be shown that the Pythagoras principle allows many other familiar geometric facts to be derived. For example, one can define a notion of the angle between two vectors in such a way as to preserve all the ordinary geometric properties of angles. This is done by analogy with the law of cosines of Euclidean trigonometry, according to which the square of the length of the vector sum of two functions is equal to the sum of the squares of the lengths of the two vectors taken separately minus a term equal to twice the product of the lengths of the vectors multiplied by the cosine of the angle θ between them (see 631). The geometrically significant expression $|f| |g| \cos \theta$, which has particularly simple algebraic properties, and which plays a fundamental role in geometric investigations of Hilbert space, is then called the inner product of the vectors f and g and is often designated by the symbol (f, g) .

In analogy with ordinary geometry, a linear transformation R in a Hilbert space is called a rotation if it preserves lengths; i.e., if the length of the vector $R(f)$ is in every case the same as the length of the vector f . In Hilbert space, rotations and other related basic geometric transformations continue to have many of the familiar properties possessed by similar transformations in ordinary Euclidean two- and three-dimensional space. Orthogonal (mutually perpendicular) sequences f_1, f_2, f_3, \dots of functions in Hilbert space—that is, sequences of functions for which the inner product (f_i, f_j) is equal to zero whenever the indices i and j are different—appear as the geometric analogue of sets of mutually perpendicular axes in ordinary Euclidean space. The process of expanding a function as a linear combination of such vectors is then seen to be closely analogous to the geometric decomposition of a vector into components directed along several mutually orthogonal axes; this gives a transparent geometric meaning to the expansion into sines and cosines introduced by Fourier.

In Hilbert space it is possible to distinguish a class of linear operators, the study of which constitutes one of the most successful branches of the whole of functional analysis. A linear operator F in Hilbert space is said to be self-adjoint if it satisfies the simple algebraic condition that identifies two inner products, one with the left-hand element being the effect of the linear operator x operating upon a vector and one being an inner product in which a right-hand number is the effect of the linear operator f operating upon a second vector (see 632).

Given a bounded function $m(x)$, the mapping, which sends each function $f(x)$ into the product function $m(x)f(x)$, is linear; a mapping M of this particularly simple kind is called a multiplication operator. Multiplication operators are the simplest general type of linear operator, self-adjoint (see 632). The fundamental spectral theorem of Hilbert and von Neumann asserts that, given any self-adjoint linear operator in Hilbert space, one can always find a rotation R of the Hilbert space and a multiplication operator M such that $R(Ff) = M(Rf)$ for each vector f of the Hilbert space; this means that in the rotated axes defined by the rotation, R , F is expressed, in the simplest possible way, as an operation of multiplication. Many other useful properties of self-adjoint linear operators in Hilbert space follow from this basic theorem, and, generally speaking, the spectral theorem tends to reduce the study of a particular self-adjoint operator F to the problem of finding the rotation R that allows F to be expressed as a multiplication. Many of the most interesting linear transformations of classical analysis turn out to be rotations of this type. This observation covers not only Fourier's initial sine-cosine series expansion and all

the Sturm-Liouville generalizations of this expansion, but also many related integral expansions, of which the most famous is the Fourier integral, which expresses a rotated version $g = R(f)$ of an initially given function f by the formula that expresses g as a definite integral extended over the entire real line, the integrand being the product of f and an exponential function, multiplied by an appropriate normalizing factor (see 633).

Linear operators satisfying the self-adjointness condition (see 632) are of common occurrence in classical mathematical physics, wherein the self-adjointness condition is often a consequence of some underlying law of energy conservation. They also are of fundamental importance in quantum theory, in which the self-adjointness condition appears as an assumption basic to the physical interpretation of the theory.

The spectacular conceptual and computational simplifications afforded in the study of self-adjoint operators by the spectral theorem has led to a long series of efforts to generalize this theorem to linear operators F not satisfying the basic condition of self-adjointness (see 632). Unfortunately, these efforts, in which the works of Nelson Dunford and Ciprian Foiaş have featured prominently, have been successful only in part. The fact is that general linear operators are more complex than self-adjoint operators, even if attention is restricted to operators acting in Hilbert space. Moreover, phenomena appear in the study of general operators in Hilbert space that have no analogue in the more elementary algebraic theory of finite square matrices acting in spaces of vectors. In spite of this, it has been possible to find classes of non-self-adjoint operators having many properties in common with multiplication operators and with other special classes of linear operators of simple structure for which calculation is easy.

LINEARIZATION AS A METHOD; ERGODIC THEORY, CLASSICAL AND GENERALIZED HARMONIC ANALYSIS

As has been noted, linear functional analysis makes systematic use of the possibility of expressing one function as a linear combination of others, thereby attaining great simplifications in the problems that it studies. Problems for which this is not possible—i.e., cases in which it is necessary to deal with sets of points or of functions within which an operation of addition is not available in any useful way—are normally much more complicated. When problems of this kind are attacked, it is generally necessary to have recourse to the elaborate tools of global (or algebraic) topology, and, even so, the attack may be unsuccessful. Global topological methods began to be used extensively in functional analysis around 1960, though work in the 1930s by the mathematicians Juliusz Schauder and Jean Leray and by the topologist Marston Morse introduced some basic techniques.

The use of global topological methods in combination with more conventional techniques of functional analysis defines what has come to be called nonlinear functional analysis (see below). The relative simplicity of linear spaces suggests, however, that whenever it is possible to relate a linear space to an object to be studied, even if this object is initially nonlinear, analysis of the linear space may allow interesting properties of the original object to be established. This technique, which may be called linearization, has been applied successfully in a great variety of rather important investigations. Ergodic theory, which grew originally out of statistical mechanics (that is, out of the statistical analysis of physical systems containing a large number of particles of interest), constitutes an important instance of this general remark.

If at a given instant one records the momentary position and velocity of each particle in a system of particles, one obtains a multidimensional vector v ; v is called the momentary state of the system, and the collection of all relevant vectors v is called the system's phase space. It follows from the laws of Newtonian mechanics that after t seconds have elapsed a system initially in a state v will find itself in a state $\phi_t(v)$, in which the mapping ϕ_t is determined by the details of the forces that each particle exerts on all the others. The Newtonian law of energy conservation implies that even if the time parameter t is allowed to vary, all the

Self-
adjoint
linear
operators

Ergodic
theory

states $\varphi_i(v)$ will lie on some single energy surface. Given this fact, detailed investigation of the overall motion of a system will naturally focus on one single such surface and on the transformations $\varphi_i(v)$, all of which map each point of such a surface to some other point of the same surface. These energy surfaces are, however, described by complicated equations and are in consequence highly curved, nonlinear objects. This characteristic makes direct study of the transformations φ_i difficult. Using the technique of linearization described above, some of these difficulties may be alleviated, as follows.

An appropriate linear space of functions $f(v)$, defined for all the points v of an energy space, is set up, and the nonlinear maps φ_i are used to define linear maps F_i in this space of functions; F_i is defined simply by specifying that $F_i(f)$ is to be the function g given by the formula in which the value of g at v is equal to the function f evaluated at a nonlinear map of the argument v (see 634). A suitable choice of functions f will yield a Hilbert space within which the maps F_i turn out to have properties that allow them to be studied using the Hilbert space spectral theorem mentioned in the preceding section. This makes it possible to establish a number of interesting facts concerning the nonlinear maps φ_i . The method sketched above has been used in a series of investigations stretching from the 1930s to the present day, in which the names von Neumann, Birkhoff, Hopf, Kolmogorov, Sinai, Arnold, and Ohrenstein feature prominently. These investigations have elucidated many properties of nonlinear mappings significant for mechanics, probability theory, and geometry.

A closely related method has played a central role in the elucidation of important algebraic problems. In abstract algebra, a group is a collection of elements x, y , etc., any two of which may be multiplied to give a product xy , any one of which has an inverse x^{-1} satisfying $x^{-1}(xy) = y$ and $(yx)x^{-1} = y$. If a group is given, the linear space of all functions f on the group may be considered, and for each group element x a linear mapping F_x can be defined by requiring that $F_x(f)$ be the function g specified by the simple formula identifying the function value of g with the function value of f , the argument of the former being y , the argument of the latter being the group product yx (see 635). If appropriate conditions are imposed upon the functions f , a Hilbert space of functions will result; each of the mappings F_x will then be a linear transformation to which the spectral theorem can be seen to apply. This theorem then implies that one can find functions called group characters and irreducible representation coefficients, related to the mappings F_x in particularly simple ways. The line of reasoning just described was initiated by Ferdinand Georg Frobenius and Issai Schur, who analyzed the properties of finite groups using this method. The gradual development of functional analytic technique subsequently made it possible to extend Schur's techniques to important groups containing infinitely many elements, including the groups of three-dimensional and of higher-dimensional rotations, and of the Lorentz group, which is important in all relativistic physical theories. In this connection the work of Claus Hugo Hermann Weyl, I.M. Gel'fand, M.A. Naimark, and Harish-Chandra has been particularly important.

Because of the close correspondence (see 635) between

$$(634) \quad g(v) = f[\varphi_i(v)]$$

$$(635) \quad g(y) = f(yx)$$

$$(636) \quad S(f) = F(f) + G(f)$$

$$(637) \quad P(f) = F[G(f)]$$

$$(638) \quad \begin{cases} (F + G) + H = F + (G + H) \\ F(GH) = (FG)H \\ F(G + H) = FG + FH \end{cases}$$

the mappings F_i and the fundamental group multiplication operation yx , group characters and irreducible representation coefficients are most useful for analyzing the algebraic structure of a group. They inevitably play a central role in the understanding of any system of functions having a given group of symmetries. Such function systems occur in crystallography, in the study of sound and electromagnetic waves, and in the quantum theory of nuclear, atomic, and molecular energy levels and scattering processes.

FUNCTIONAL ALGEBRA

If a linear space of functions is given, and if F and G are both linear operators acting in this space, then F and G can be added and can be multiplied together. The sum of F and G is the linear operator S defined by the formula $S(f) = F(f) + G(f)$ (636). The product of F and G is the linear operator P defined by the formula $P(f) = F[G(f)]$ (637). The sum of F and G is customarily designated by $F + G$, and the product of F and G by FG .

The algebraic combinations of linear operators (see 636, 637) have many of the formal properties that are familiar from ordinary algebra; for example, the identities known as the laws of associativity for addition and multiplication as well as the distributive law (see 638) all hold. This observation suggests that the methods of algebra can fruitfully be applied to the study of collections of linear operators. This is indeed the case; the subject area that arises when algebraic techniques are combined with the methods of functional analysis is called functional algebra.

Functional algebra began to develop rapidly after 1941, in which year a famous paper of Gel'fand demonstrated that important earlier work of Wiener on Fourier series could be conceptually simplified by reformulating it in algebraic terms, and that some of the methods of functional analysis could be fruitfully combined with abstract algebraic arguments and with reasonings adapted from the classical theory of functions of a complex variable. The theory initiated by Gel'fand subsequently achieved many points of contact with profound questions in classical analysis.

Gel'fand's
contribution

A brilliant series of papers by von Neumann and F.J. Murray led at about the same time to the development of yet another major branch of functional algebra. Von Neumann and Murray considered algebras of operators in Hilbert space; that is, sets V of linear operators having the property that $F + G$, FG , and cF all belong to V whenever F and G belong to V (c is an arbitrary numerical constant). A linear operator F in Hilbert space can always be written as $F = H_1 + iH_2$, in which H_1 and H_2 are self-adjoint and i is the square root of -1 ; the operator F^* , which is called the adjoint of F , is then related to F in much the same way that the complex conjugate \bar{z} of a complex number z is related to z .

It had been known for some time that *-closed algebras V of finite square matrices—that is, algebras having the property that F^* is a member of V whenever F is a member of V —had a particularly simple structure, and von Neumann and Murray set out to generalize this structural fact to *-closed algebras of operators in Hilbert space. The class of algebras that these two studied are currently known either as W^* -algebras or as von Neumann algebras.

In the von Neumann-Murray theory, a far-reaching generalization of the Hilbert space spectral theorem may be established, according to which a general W^* -algebra is decomposable into a family of simpler W^* -algebras, which were called factors by von Neumann and Murray. The simplest factors are finite or infinite matrix algebras. More complex factors also exist, and these are related in various interesting ways to algebraic structures such as infinite discrete groups, the decomposition of a general W^* -algebra into factors providing a quite useful tool for the treatment of a number of the main properties of group characters and irreducible representation coefficients.

NONLINEAR FUNCTIONAL ANALYSIS

As has been noted above, nonlinear functional analysis attempts to combine the global methods of topology with the approximation techniques used in linear functional analysis, thereby making it possible to study systems of

functions in which the simplifications afforded by linearity are not available. This part of functional analysis was initiated in the late 1920s by Schauder, who showed that the Brouwer fixed-point theorem of topology could be generalized to linear functional spaces. Subsequent work extended other basic theorems of topology to linear functional spaces and applied these principles to the study of various interesting classes of partial differential equations, including the equations of fluid flow. This work revealed the topological basis underlying several subtle existence theorems of classical analysis.

At about the same time Morse established some important results concerning the behaviour of smooth functions on curved surfaces, showing that the number of critical points of such a function (*i.e.*, the number of points at which the rate of change of the function in every direction is zero) is closely related to certain topological properties of the surface. Morse himself extended his results from finite-dimensional surfaces to spaces of curves; the suggestion, implicit in this pioneering work, that the topology of curved functional spaces ought to be studied, lay dormant for 20 years, probably because adequate study tools were not available. In the late 1950s, however, the leads left by Morse began to be pursued. Subsequently, the area of contact between global topology and functional analysis has broadened significantly, topology having contributed to the solution of nonlinear analytic problems, and the study of certain linear and nonlinear functional spaces having provided keys to questions in pure topology. (J.T.Sc.)

Generalized functions, or theory of distributions

In the second half of the 19th century mathematical analysts had raised their sights beyond the relatively orderly world of analytic functions—that is, functions with convergent Taylor expansions (after the English mathematician Brook Taylor)—and had begun to study and handle nonanalytic and even nondifferentiable functions. This led to the discovery of various kinds of pathological behaviour, or behaviour that was unfamiliar to the classically trained intuition. The complexity of the picture, in the theory of functions of real variables, was further compounded with the appearance of the integration theory formulated by Henri-Léon Lebesgue, one of the great events in the history of mathematics. Standard ingredients of Lebesgue's theory are measurable and integrable functions and sets, which can exhibit irregularities of a degree and of a nature unknown until then. The Lebesgue theory had a strong influence on the investigation of integral equations. The space \mathcal{L}^2 —the space of (Lebesgue) square integrable functions—was recognized by Hilbert to be the right framework for the study of many problems in the calculus of variations. What is now called its Hilbert space structure was described and exploited, notably by Hilbert and by Riesz, to unify and reinterpret earlier results on integral equations, among them the pioneering work of Fredholm, in which ideas from finite-dimensional linear algebra had been transposed with unexpected success.

In 1894, quite off the mainstream of research in pure mathematics, Heaviside introduced his symbolic calculus to help solve the ordinary differential equations that arise in the theory of electrical circuits. His suggestion was simple and daring: replace the differentiation operator d/dx by the variable p , which amounts to replacing the differential equation under study, namely, an n th order linear inhomogeneous equation (see 639), by a multiplicative equation (see 640). Solve the latter for $\hat{y}(p)$ by division and revert, possibly with the help of appropriate tables of correspondences, from the symbolic solution $\hat{y}(p)$ to the actual solution $y(x)$. Although highly successful from the pragmatic viewpoint, Heaviside's calculus remained unexplained for several decades. Among other features it entailed the differentiation of nondifferentiable functions, such as the so-called Heaviside function $Y(x)$ with a unit step at the origin (see 641).

The need to extend the operation of differentiation beyond its classical limitations is also strongly felt in pure mathematics, particularly in the theory of partial differen-

$$(639) \quad y^{(n)} + a_1 y^{(n-1)} + \cdots + a_n y = f(x)$$

$$(640) \quad (p^n + a_1 p^{n-1} + \cdots + a_n) \hat{y}(p) = \hat{f}(p)$$

$$(641) \quad Y(x) = 1 \text{ for } x > 0, \quad Y(x) = 0 \text{ for } x \leq 0$$

$$(642) \quad \int_{-\infty}^{+\infty} f'(x) \phi(x) dx = - \int_{-\infty}^{+\infty} f(x) \phi'(x) dx$$

$$(643) \quad \int_{-\infty}^{+\infty} \phi(x) \delta(x) dx = \int_{-\infty}^{+\infty} \phi(0) \delta(x) dx = \phi(0)$$

$$(644) \quad \phi(0) = \int_{-\infty}^{+\infty} \phi(x) \delta(x) dx = \int_{-\infty}^{+\infty} Y'(x) \phi(x) dx$$

$$(645) \quad \int \delta'(x) \phi(x) dx = - \int \delta(x) \phi'(x) dx = -\phi'(0)$$

$$(646) \quad \delta = \lim_{y \rightarrow +0} \frac{1}{2\pi i} \left\{ \frac{1}{x - iy} - \frac{1}{x + iy} \right\}$$

tial equations. One of the fundamental concepts of functional analysis, that of duality and of linear functionals, led, around 1930, to the introduction of weak derivatives. Two functions f and ϕ are considered with real or complex values, defined and continuously differentiable on the real line \mathbb{R} . Furthermore, it is assumed that ϕ vanishes identically outside some finite interval. The classical formula of integration by parts leads to an equality in integrals involving the functions f and ϕ and their derivatives (see 642). It is clear that the right-hand side of this equality makes sense even when f is not differentiable, for instance when f is the Heaviside function (see 641). When $f = Y$ the value of the right-hand side is $\phi(0)$, whereas the left-hand side makes no sense at all: if the derivative of Y is to have a reasonable meaning, it must vanish for all $x \neq 0$. But then integration over the set consisting of a single point, $x = 0$, if understood in Lebesgue's sense, can only yield zero, not $\phi(0)$. In order to resolve this apparent paradox and to extend the concept of derivative, the expressions that continue to make sense when applied to nondifferentiable functions (in the classical sense), such as the right-hand side in the integration by parts (see 642), are retained. The latter is viewed as a linear functional in ϕ , which varies in the class C_c^1 of once continuously differentiable functions on the real line, vanishing outside a finite interval. It is precisely this functional that is called the weak derivative of f . Now, if f happens to be continuously differentiable (in the classical sense), its weak derivative will coincide with the integration of $\phi f'$, in other words, with the integration of ϕ with respect to the density $f'(x)dx$, a functional of ϕ that, from now on, shall be identified to the concept of f' itself, the classical derivative of f . As for integration by parts (see 642), it becomes a special identity, valid when f' is continuous or, more generally, locally integrable.

It is not possible here to give an account of all the currents and crosscurrents that eventually culminated in the present-day formulation of the theory of generalized functions, from the work of Jacques Hadamard on the Cauchy problem (see above), which goes back to World War I, to that of Torsten Carleman, Arne Beurling, and especially of Salomon Bochner, just before and after World War II. A contribution particularly relevant to the present discussion, however, is that of the physicists, foremost among them Dirac, in their efforts to create the mathematical tools required by the development of quantum field theory. Dirac introduced in 1925, and systematically used thereafter, the mathematical object that was soon to be called Dirac's function and to be defined as a function $\delta(x)$ equal to 0 for all points $x \neq 0$ and to $+\infty$ at $x = 0$, the integral of which, moreover, is equal to $+1$. Though such a definition is unacceptable, that of the associated functional, which to every continuous function ϕ assigns

Weak
derivatives

Dirac's
function

Lebesgue's
integration
theory

the number $\phi(0)$ (see 643), is unobjectionable. As a matter of fact, δ turns out to be an object that rigorous mathematicians had been using for quite a while, for instance in the theory of summation of Fourier series, as the limit of sequences of true functions, the limit of which was never explicitly written down. Dirac's δ also entered into Heaviside's symbolic calculus: it is the function having a symbolic transform equal to the constant one. And returning to the earlier consideration of the weak derivative of Heaviside's function, and momentarily adopting the physicist's notation (see 644), it is seen that $Y' = \delta$: the weak derivative of Heaviside's function is Dirac's function or, rather, as it is now called, Dirac's distribution.

There is no reason not to repeat the procedure of weak differentiation and apply it to δ itself. Again in physicists' notation, an integral identity can be obtained (see 645). In mathematical language this simply means that δ' is the functional that, to every continuously differentiable function ϕ , assigns the number $-\phi'(0)$. If one wishes to iterate this procedure and define the m th derivative of δ for any $m = 1, 2, \dots$, one must evaluate the relevant functionals on functions ϕ , the degree of differentiability of which accordingly increases. Finally, it is convenient to use, as test-functions, the infinitely differentiable (or C^∞) functions. Thus, $\delta^{(m)}$ will be the functional that to every $\phi \in C^\infty$ assigns the value $(-1)^m \phi^{(m)}(0)$.

Laurent Schwartz's idea (in 1947) was to give a unified interpretation of all the generalized functions that had infiltrated analysis as (continuous) linear functionals on the space C_c^∞ of infinitely differentiable functions vanishing outside compact sets. He provided a systematic and rigorous description, entirely based on abstract functional analysis and on duality. It is noteworthy that such an approach had a precedent, in the presentation by André Weil of the integration of locally compact groups: there, Radon measures on the group G are introduced and handled as continuous linear functionals on the space $C_c^0(G)$ of the continuous functions in G that vanish outside some compact subset. Because of the demands of differentiability in distribution theory, the spaces of test-functions and their duals are somewhat more complicated. This has led to extensive studies of topological vector spaces beyond the familiar categories of Hilbert and Banach spaces, studies that, in turn, have provided useful new insights in some areas of analysis proper, such as partial differential equations or functions of several complex variables. Schwartz's ideas can be applied to many other spaces of test-functions beside C_c^∞ , as he himself and others have shown; numerous examples can be found.

The Schwartz procedure is rather unsatisfactory if the analytic functions (on real space) are to be taken as test-functions, an action desirable in order to increase the pool of generalized functions: because analytic functions are fewer than C^∞ functions, the linear functionals on the space of the former are more numerous than those on C_c^∞ . Such an increase of the pool is permitted when the functions intervening in the problem under consideration, for example the coefficients of a partial differential equation, are analytic. It was noted some time ago (in particular, by theoretical physicists) that many important distributions could be regarded as jumps across the real line of holomorphic functions of nonreal z . The simplest example is Dirac's δ expressed in terms of a limit (see 646), which means that the integration of the function under the limit sign, with respect to $\phi(x)dx$ with arbitrary $\phi \in C_c^\infty$, converges to $\phi(0)$. Observations such as these were developed and systematized by Mikio Sato and others, resulting in the theory of hyperfunctions, which is based not on functional analysis but on cohomology of sheaves and which appears to be the right framework for the treatment of differential problems within the (real) analytic category. The term sheaf involves the notion of functions or distributions defined only locally, while cohomology involves patching local distributions together to create a genuine distribution of the type described above. (F.Tr.)

TAYLOR, *General Theory of Functions and Integration* (1965, reprinted 1985); and EDGAR ASPLUND and LUTZ BUNGART, *A First Course in Integration* (1966). These all require a good foundation in calculus. Additional references include A.N. KOLMOGOROV and S.V. FOMIN, *Introductory Real Analysis*, rev. ed. (1970; originally published in Russian, 2 vol., 1954–60); M.E. MUNROE, *Calculus* (1970), and *Introductory Real Analysis* (1965); H.L. ROYDEN, *Real Analysis*, 3rd ed. (1988); WALTER RUDIN, *Principles of Mathematical Analysis*, 3rd ed. (1976); G.H. HARDY, *A Course of Pure Mathematics*, 10th ed. (1952, reprinted 1975); and ANGUS E. TAYLOR and W. ROBERT MANN, *Advanced Calculus*, 3rd ed. (1983).

General references to the elements of the theory of convergent series may be found in any book of calculus. More advanced texts include TOMLINSON FORT, *Infinite Series* (1930); THOMAS J. I.A. BROMWICH, *An Introduction to the Theory of Infinite Series*, 2nd ed. rev. (1926, reprinted 1965); KONRAD KNOPP, *Theory and Application of Infinite Series*, 2nd ed. (1951, reissued 1971; originally published in German, 2nd enlarged ed., 1924), containing a wealth of material; and I.I. HIRSCHMAN, *Infinite Series* (1962, reprinted 1978). Also useful are GODFREY H. HARDY, *Divergent Series* (1949, reprinted 1973); H.R. PITT, *Tauberian Theorems* (1958); and, for summability of integrals and related topics, K. CHANDRASEKHARAN and S. MINAKSHISUNDARAM, *Typical Means* (1952).

The following works concern vector and tensor analysis. Textbooks on the algebra of vectors include, in approximate order from elementary to advanced, DANIEL ZELINSKY, *A First Course in Linear Algebra*, 2nd ed. (1973); DANIEL T. FINKBEINER II, *Introduction to Matrices and Linear Transformations*, 3rd ed. (1978); KENNETH HOFFMAN and RAY KUNZE, *Linear Algebra*, 2nd ed. (1971); PAUL R. HALMOS, *Finite-Dimensional Vector Spaces*, 2nd ed. (1958, reprinted 1974); and NATHAN JACOBSON, *Lectures in Abstract Algebra*, vol. 2, *Linear Algebra* (1953, reprinted 1975). Vector analysis is examined by LOUIS BRAND, *Vector and Tensor Analysis* (1947); HARRY LASS, *Vector and Tensor Analysis* (1950); I.S. SOKOLNIKOFF and R.M. REDHEFFER, *Mathematics of Physics and Modern Engineering*, 2nd ed. (1966); and S. SIMONS, *Vector Analysis for Mathematicians, Scientists, and Engineers*, 2nd ed. (1970). CLAUDE CHEVALLEY, *The Construction and Study of Certain Important Algebras* (1955); and A.I. BORISENKO and I.E. TARAPOV, *Vector and Tensor Analysis with Applications*, rev. ed. (1968, reissued 1979; originally published in Russian, 3rd ed., 1966), are works that may be consulted by the reader interested in tensor algebra. References on tensor analysis and its applications include HENRY D. BLOCK, *Introduction to Tensor Analysis* (1962); D.F. LAWREN, *An Introduction to Tensor Calculus, Relativity, and Cosmology*, 3rd ed. (1982); I.S. SOKOLNIKOFF, *Tensor Analysis: Theory and Applications to Geometry and Mechanics of Continua*, 2nd ed. (1964); and LÉON BRILLOUIN, *Tensors in Mechanics and Elasticity* (1964; originally published in French, 1938). See also JERROLD E. MARSDEN and ANTHONY J. TROMBA, *Vector Calculus*, 3rd ed. (1988). (Hy.K./A.Zy./C.L.F./D.T.F./Ed.)

Complex analysis: The reader interested in the foundations of the subject and the Cauchy theory may consult LARS V. AHLFORS, *Complex Analysis*, 3rd ed. (1979); E.T. COPSON, *An Introduction to the Theory of Functions of a Complex Variable* (1935, reprinted 1972); EINAR HILLE, *Analytic Function Theory*, 2 vol. (1959–62, reprinted 1977–82); KONRAD KNOPP, *Theory of Functions*, 2 vol. (1945–47; originally published in German, vol. 1, 5th ed., 1937, and vol. 2, 4th ed., 1931); ZEEV NEHARI, *Conformal Mapping* (1952, reissued 1975); E.C. TITCHMARSH, *The Theory of Functions*, 2nd ed. (1939, reissued 1975); and E.T. WHITTAKER and G.N. WATSON, *A Course of Modern Analysis*, 4th ed. (1927, reissued 1979).

Elliptic functions and related topics are discussed in FRANK BOWMAN, *Introduction to Elliptic Functions, with Applications* (1953, reissued 1961); PAUL F. BYRD and MORRIS D. FRIEDMAN, *Handbook of Elliptic Integrals for Engineers and Scientists*, 2nd ed., rev. (1971); and A. FLETCHER et al., *An Index of Mathematical Tables*, 2nd ed. (1962).

Classic works dealing with the theory of functions of several complex variables and related subjects include ROBERT C. GUNNING and HUGO ROSSI, *Analytic Functions of Several Complex*

Variables (1965), containing an extensive bibliography; LARS HÖRMANDER, *An Introduction to Complex Analysis in Several Variables*, 2nd ed. (1979); RAGHAVAN NARASIMHAN, *Introduction to the Theory of Analytic Spaces* (1966); and KIYOSHI OKA, *Collected Papers*, rev. ed. edited by R. REMMERT (1984; originally published in French, 1961). (K.Iw./R.Na./Ed.)

Differential equations: A good elementary introduction to the theory of ordinary differential equations is WALTER LEIGHTON, *A First Course in Ordinary Differential Equations*, 5th ed. (1981). The best accounts of the classical theory are contained in EARL A. CODDINGTON and NORMAN LEVINSON, *Theory of Ordinary Differential Equations* (1955, reprinted 1984); PHILIP HARTMAN, *Ordinary Differential Equations* (1964, reprinted 1982); and EINAR HILLE, *Lectures on Ordinary Differential Equations* (1968). The qualitative theory is discussed in V.V. NEMYTSKII and V.V. STEPANOV, *Qualitative Theory of Differential Equations* (1960, reprinted 1989; originally published in Russian, 1949). The theory of differential equations in Banach spaces is treated in HENRI CARTAN, *Differential Calculus* (1971; originally published in French, 1967). See also ROGER C. MCCANN, *Introduction to Ordinary Differential Equations* (1982).

Elementary accounts of partial differential equations, especially of the equations of mathematical physics, and of techniques of solving them may be found in ARNOLD SOMMERFELD, *Partial Differential Equations in Physics* (1949, reissued 1967; originally published in German, 2nd ed., 1947); and IAN N. SNEDDON, *Elements of Partial Differential Equations* (1957). The classical theory is treated fully in I.G. PETROVSKY, *Lectures on Partial Differential Equations* (1954, reissued 1966; originally published in Russian, 1950); BERNARD EPSTEIN, *Partial Differential Equations: An Introduction* (1962, reprinted 1975); and PAUL R. GARABEDIAN, *Partial Differential Equations*, 2nd ed. (1986). Finite-difference methods of obtaining approximate solutions are contained in GEORGE E. FORSYTHE and WOLFGANG R. WASOW, *Finite-Difference Methods for Partial Differential Equations* (1960). DOROTHY L. BERNSTEIN, *Existence Theorems in Partial Differential Equations* (1950, reissued 1965), gives a complete account of existence and uniqueness theorems. For an introduction to the abstract theory, see AVNER FRIEDMAN, *Partial Differential Equations* (1969, reprinted 1976); and ROBERT W. CARROLL, *Abstract Methods in Partial Differential Equations* (1969).

The reader interested in dynamical systems on manifolds can obtain additional background on manifolds from SHLOMO STERNBERG, *Lectures on Differential Geometry*, 2nd ed. (1983); SERGE LANG, *Differential Manifolds* (1972, reissued 1985), a very basic book; and MICHAEL SPIVAK, *Calculus on Manifolds: A Modern Approach to Classical Theorems of Advanced Calculus* (1965), an especially readable elementary work. Works on the mathematics of chaos include JAMES GLEICK, *Chaos: Making a New Science* (1987); and IAN STEWART, *Does God Play Dice?* (1989). For more information on ordinary differential equations, in addition to the works mentioned above, see WITOLD HUREWICZ, *Lectures on Ordinary Differential Equations* (1958, reissued 1970), a highly recommended and less-imposing book than most on this subject; and SOLOMON LEFSHETZ, *Differential Equations: Geometric Theory*, 2nd ed. (1963, reprinted 1977), which discusses structural stability and the van der Pol equation. For the mathematics of electrical circuits, see CHARLES A. DESOER and ERNEST S. KUH, *Basic Circuit Theory* (1969). GERARD DEBREU, *Theory of Value* (1959, reissued 1979), gives a good background in mathematical economics. An excellent standard text with a traditional view is HERBERT GOLDSTEIN, *Classical Mechanics*, 2nd ed. (1980). Other approaches are found in LYNN H. LOOMIS and SHLOMO STERNBERG, *Advanced Calculus*, rev. ed. (1990); RALPH ABRAHAM and JERROLD E. MARSDEN, *Foundations of Mechanics*, 2nd ed. rev. and enlarged (1978, reprinted 1987); and V.I. ARNOLD and A. AVEZ, *Ergodic Problems of Classical Mechanics* (1968, reprinted 1988; originally published in French, 1967).

Classical potential theory is examined in a number of works. WOLFGANG J. STERNBERG and TURNER L. SMITH, *The Theory of Potential and Spherical Harmonics*, 2nd ed. (1946), is an elementary work. OLIVER DIMON KELLOGG, *Foundations of Potential Theory* (1929, reprinted 1970), is more advanced. GRIFFITH CONRAD EVANS, *The Logarithmic Potential, Discontinuous Dirichlet and Neumann Problems* (1927); and L.L. HELMS, *Introduction to Potential Theory* (1969, reprinted 1975), use modern integration theory. MASATSUGU TSUJI, *Potential Theory in Modern Function Theory*, 2nd ed. (1975), deals with applications. For modern developments in potential theory, see MARCEL BRELOT, *Lectures on Potential Theory*, expanded ed. (1967), and *On Topologies and Boundaries in Potential Theory* (1971); PAUL A. MEYER, *Probability and Potentials* (1966; originally published in French, 1966); R.M. BLUMENTHAL and R.K. GETTOOR, *Markov Processes and Potential Theory* (1968); and JOHN WERMER, *Potential Theory*, 2nd ed. (1981).

(I.N.S./S.Sm./Ed.)

Special functions: In addition to the many works on various aspects of analysis that contain discussions of special functions, there are also works devoted entirely to special functions. MILTON ABRAMOWITZ and IRENE A. STEGUN (eds.), *Handbook of Mathematical Functions, with Formulas, Graphs, and Mathematical Tables* (1964, reissued 1972), is a large handbook covering many special functions, statements of mathematical properties, bibliographies, and other information. A very extensive treatise is BATEMAN MANUSCRIPT PROJECT, *Higher Transcendental Functions*, ed. by ARTHUR ERDÉLYI, 3 vol. (1953–55, reprinted 1981). IAN N. SNEDDON, *Special Functions of Mathematical Physics and Chemistry*, 3rd ed. (1980), contains a good treatment of special functions. For spherical harmonic functions, see T.M. MACROBERT, *Spherical Harmonics*, 3rd ed. rev. (1967). There are also many works entirely devoted to one or another particular special function. (Ed.)

Fourier analysis: Fourier series and related topics are discussed in G.H. HARDY and W.W. ROGOSINSKI, *Fourier Series*, 3rd ed. (1956, reissued 1965); ANTONI ZYGMUND, *Trigonometric Series*, 2nd ed., 2 vol. (1959, reissued 1988); SALOMON BOCHNER, *Harmonic Analysis and the Theory of Probability* (1955); E.C. TITCHMARSH, *Introduction to the Theory of Fourier Integrals*, 3rd ed. (1986); NORBERT WIENER, *The Fourier Integral and Certain of Its Applications* (1933, reissued 1988); GABOR SZEGÖ, *Orthogonal Polynomials*, 4th ed. (1975); M.J. LIGHTHILL, *Introduction to Fourier Analysis and Generalised Functions* (1958, reissued 1970); RICHARD R. GOLDBERG, *Fourier Transforms* (1961); R.E. EDWARDS, *Fourier Series*, 2 vol. (1967); and YITZHAK KATZNELSON, *An Introduction to Harmonic Analysis*, 2nd corrected ed. (1976). H.S. CARSLAW, *Introduction to the Theory of Fourier's Series and Integrals*, 3rd ed. rev. and enlarged (1930, reissued 1950); and DUNHAM JACKSON, *Fourier Series and Orthogonal Polynomials* (1941, reissued 1961), contain elementary theory based on Riemann integration.

In addition to the references on Fourier series, the reader interested in harmonic analysis and integral transforms may wish to consult MICHAEL B. MARCUS and GILLES PISIER, *Random Fourier Series with Applications to Harmonic Analysis* (1981); N.K. BARY (BARI), *A Treatise on Trigonometric Series*, 2 vol. (1964; originally published in Russian, 1961), which deals with the classical theory of Fourier series and integrals; ELIAS M. STEIN and GUIDO WEISS, *Introduction to Fourier Analysis on Euclidean Spaces* (1971), which treats the n -dimensional theory extensively and systematically and also has a systematic treatment of convolutions; and I.I. HIRSCHMAN and D.V. WIDDER, *The Convolution Transform* (1955), another good reference on convolutions. For variants of the Fourier transform (such as Hankel or Mellin transforms), see GEORGE N. WATSON, *A Treatise on the Theory of Bessel Functions*, 2nd ed. (1944, reprinted 1966); D.V. WIDDER, *The Laplace Transform* (1941); and BATEMAN MANUSCRIPT PROJECT, *Tables of Integral Transforms*, ed. by ARTHUR ERDÉLYI, 2 vol. (1954). The topic of singular integrals is treated in ELIAS M. STEIN, *Singular Integrals and Differentiability Properties of Functions* (1970, reissued 1986). An exposition of abstract harmonic analysis may be found in WALTER RUDIN, *Fourier Analysis on Groups* (1962). LYNN H. LOOMIS, *An Introduction to Abstract Harmonic Analysis* (1953); and HERMANN WEYL, *The Classical Groups: Their Invariants and Representations*, 2nd ed. (1946, reissued 1966), deal with both abstract harmonic analysis and representations of groups and algebras. Some additional references on representations of groups and algebras are CLAUDE CHEVALLEY, *Theory of Lie Groups* (1946); FRANCIS D. MURNAGHAN, *The Theory of Group Representations* (1938, reprinted 1963); L.S. PONTRYAGIN, *Topological Groups*, 3rd ed. (1986; originally published in Russian, 1938); HERMANN WEYL, *The Theory of Groups and Quantum Mechanics* (1931, reissued 1949); and G. DE B. ROBINSON, *Representation Theory of the Symmetric Group* (1961).

(A.Zy./C.L.F./Ed.)

Calculus of variations: There are many works available on the calculus of variations. For an introduction to the theory for problems involving arcs only, see GILBERT A. BLISS, *Calculus of Variations* (1925, reprinted 1962), and *Lectures on the Calculus of Variations* (1946, reprinted 1980). For problems involving multiple integrals, see CHARLES B. MORREY, *Multiple Integrals in the Calculus of Variations* (1966). For expositions of Morse's theory of critical points, see MARSTON MORSE, *The Calculus of Variations in the Large* (1934). (C.B.My.)

Functional analysis: A comprehensive account of a large part of linear functional analysis is found in NELSON DUNFORD and JACOB T. SCHWARTZ, *Linear Operators*, 3 vol. (1958–71). The first volume covers the general theory of linear operators and the second the theory of self-adjoint operators in Hilbert space. This work includes a bibliography of several thousand items and gives historical accounts of many of the topics that it discusses. A systematic study of semigroups of linear operators, together with more general background material on functional analysis, is contained in EINAR HILLE and RALPH S. PHILLIPS, *Functional*

Analysis and Semi-groups, rev. ed. (1957). For an account of the application of Hilbert space spectral theory to the analysis of differential equations, see M.A. NAIMARK, *Linear Differential Operators* (1967; originally published in Russian, 1954); and ch. 13 in vol. 2 of the work by Dunford and Schwartz cited above. For further developments in the application of functional analysis to differential equations, see TOSIO KATO, *Perturbation Theory for Linear Operators*, 2nd ed. (1976, reprinted 1984); and PETER D. LAX and RALPH S. PHILLIPS, *Scattering Theory*, rev. ed. (1989). The spectral analysis of non-self-adjoint operators is reviewed in vol. 3 of Dunford and Schwartz cited above. ION COLOJOARA and CIPRIAN FOIAȘ, *Theory of Generalized Spectral Operators* (1968), contains additional material concerning this developing area. PATRICK BILLINGSLEY, *Ergodic Theory and Information* (1965, reprinted 1978), gives an elegant short account of many of the main theorems of ergodic theory; see also WILLIAM PARRY, *Entropy and Generators in Ergodic Theory* (1969). Harmonic analysis is treated in many works; in particular, see EDWIN HEWITT and KENNETH A. ROSS, *Abstract Harmonic Analysis*, vol. 1, *Structure of Topological Groups, Integration Theory, Group Representations*, 2nd ed. (1979), which gives a useful picture of this area. GERALD M. LEIBOWITZ, *Lectures on Complex Function Algebras* (1970), gives an account of some of the deeper issues in classical harmonic analysis. The generalized Fourier integral theory central to harmonic analysis is closely related to some of the principal theorems of group representation theory and of functional algebra. MARTIN BURROW, *Representation Theory of Finite Groups* (1965), contains an account of the representation theory of finite groups. The final chapter of SIGURDUR HELGASON, *Differential Geometry*

and *Symmetric Spaces* (1962), contains the representation theory of noncompact continuous groups. M.A. NAIMARK, *Normed Rings*, rev. ed. (1970; originally published in Russian, 1956), covers many results of functional algebra. A more specialized discussion, devoted to the theory of von Neumann or W^* -algebras, can be found in J.T. SCHWARTZ, *W^* -Algebras* (1967). For a general account of the use of global topological methods in functional analysis, see Schwartz's *Nonlinear Functional Analysis* (1965). The reader interested in the present state of this rapidly developing field should consult the current journal literature.

The most used text on generalized functions is I.M. GEL'FAND *et al.*, *Generalized Functions*, 5 vol., trans. from Russian (1964–68), a very clearly written work, with numerous applications to partial differential equations, mathematical physics, and harmonic analysis. See also D.S. JONES, *The Theory of Generalized Functions*, 2nd ed. (1982).

For a discussion on the general theory of locally convex spaces, see ALEX P. ROBERTSON and WENDY ROBERTSON, *Topological Vector Spaces*, 2nd ed. (1973), which is very clear and very short. FRANÇOIS TRÈVES, *Topological Vector Spaces, Distributions, and Kernels* (1967), is another reference on distributions. HANS BREMERMAN, *Distributions, Complex Variables, and Fourier Transforms* (1965), is a short and well-written book, with a slant toward applications to physics and to electrical circuits, emphasizing the boundary values of analytic functions. KÔSAKU YOSIDA (YOSHIDA), *Functional Analysis*, 6th ed. (1980), is a wide-ranging presentation of functional analysis, from the theory of linear operators in Hilbert spaces to Banach algebras, ergodic theorems, and diffusion equations. (J.T.Sc./F.Tr.)

Physical and Chemical Analysis and Measurement

Any of the innumerable forms of matter can be subjected to various processes for the purpose of establishing its identity, separating it into its components, purifying it, or determining some physical or chemical property. Similarly, electromagnetic radiations from cosmic rays to radio waves can be characterized by measurements of their wavelength, intensity, variability with time, and so on.

The sections of this article differ from one another in a qualitative way: some of them deal with broad categories of techniques, supplementing broad treatments of general principles with brief descriptions of specific methods or fields of application, while others deal with narrowly defined topics, presenting considerable detail concerning the design of instruments or apparatus.

This article is divided into the following sections:

Chemical analysis	523
General considerations	
Principal stages in chemical analysis	
Principles of analytical methods	
Chemical separations and purifications	530
Basic concepts of separations	530
Principles of specific methods	533
Chromatography	535
History	
Methods	
Theoretical considerations	
Applications	
Spectroscopy	540
Introductory survey of optical spectroscopy	540
General principles	
Practical considerations	
Foundations of atomic spectra	546

Radio-frequency spectra	559
Spectral analyses	560
Analyses of photographic data	
Analyses with scanned spectra	
Astronomical spectroscopy	561
The nature of astronomical spectra	
The development of astronomical spectroscopy	
Principles of design for spectroscopic instruments	
Programs in spectroscopy	
Mass spectroscopy	573
History of mass spectroscopy	
Ion production and detection	
The analysis of ions	
Principal applications	
Radiation measurement	578
The structure of matter and its interactions with radiation	
Detection processes and detection mediums	
Applications in science, industry, and technology	
Astronomical photometry	
Materials testing	590
Mechanical testing	
Measurement of thermal properties	
Measurement of electrical properties	
Testing for corrosion, radiation, and biological deterioration	
Nondestructive testing	
Bibliography	594

CHEMICAL ANALYSIS

Chemical analysis is that branch of chemistry concerned primarily with the techniques of chemical characterization and measurement; its function is to establish the chemical composition of matter, regardless of its solid, liquid, or gaseous form. Chemical analysis answers the following questions: (1) what elements or compounds are present? (qualitative analysis); (2) how much is present or how pure is it? (quantitative analysis); (3) which chemical fragments can be identified and measured as to quantity? (functional group analysis); (4) how are the elemental parts and functional groups arranged? (structural and stereochemical analysis).

The forms of matter to be investigated range from simple (pure) elements or compounds to complex mixtures; they may be of organic or inorganic origin; they may be of low molecular weight or have molecular weights as high as tens of millions. An analysis may involve the use of a few grams of sample (macro scale) or less than 1/10,000,000 of a gram (submicroscale), and methods exist for even smaller amounts. Analyses are based on mathematical expressions of biological, chemical, or physical principles; they may involve cheap and simple glassware or expensive and complex instrumentation.

At the end of the 19th century the German chemist Wilhelm Ostwald emphasized the application of science to the art involved in the identification of different substances and the determination of their composition. Fifty years later the development of a rigorous methodology gave the foundation of reliable analytical procedures. Analytical

chemistry is currently defined as a branch of chemical research directed toward the development and improvement of practical analytical procedures.

The most important details of any problem in analytical chemistry are (1) the validity of the sample to be analyzed, (2) the method used to analyze it, (3) the accuracy of the result, and (4) the cost of the analysis in money and time. A standardized analytical procedure can be carried out by relatively unskilled personnel, an important economic factor that has led to the modern distinction between "chemical analysis" and "analytical chemistry." In essence, the performance of an analysis according to detailed instructions is an art demanding care, patience, practice, and technical expertise; usually it is entrusted to an analyst who may not have a thorough understanding of the chemistry or scientific basis of the principle involved but who carries out the instructions of the analytical chemist who is responsible for devising the method in use and for supervising the training of the lesser skilled, lower paid operators, coordinating their activities, and evaluating their results.

Chemical analysis today largely employs methods developed since 1945; this article gives prominence to the principles on which these methods are based, and places important classical techniques in proper perspective.

GENERAL CONSIDERATIONS

Historical background. The chemical balance is of such early origin that it was ascribed to the gods in the earliest

Performance of chemical analysis

documents available. The use of standard weights, made of stone, and the first "institute of standards," supervised by priests, are traced to Babylonian times (2600 BC). Two nonmetals, sulfur and carbon, and seven metals (copper, gold, iron, lead, mercury, silver, tin) and their alloys were used in ancient times; the value of silver and gold probably gave the major incentive for the acquisition of analytical knowledge. In the 4th century BC, the purity of gold samples was estimated from the yellow marks they made on a touchstone.

Pliny the Elder (AD 23–79) appears to have described the first wet test: an extract of gallnuts turns black if iron sulfate is an adulterant in copper sulfate.

The English natural philosopher Robert Boyle is credited with the introduction of the term analysis in the chemical sense. He distinguished between mixtures and compounds, used acid–base indicators, used hydrogen sulfide as a reagent, and defined elements in the modern sense in his book *The Sceptical Chymist* (1661).

Early gravi-
metric
analysis

Gravimetric analysis probably originated toward the end of the 17th century with a German physician-chemist, Friedrich Hoffmann (of Halle, the Younger), who precipitated chlorides with silver nitrate and sulfates with lime. The innovations, inventions, and discoveries in techniques are legion and often difficult to credit, but a list of major contributions in the 18th century would include chemical microscopy, flame tests for the alkali metals, the blowpipe and bead tests for qualitative analysis, and titrimetric analysis. Although many chemists became involved from this time onward, the most important names associated with the development of titrimetry in the 19th century are Joseph-Louis Gay-Lussac in France, Robert Bunsen in Germany, and Karl Friedrich Mohr, also in Germany, who introduced oxalic acid as a titrant and devised the modern form of the burette (1853). The only major advance in titrimetry in the 20th century has been the introduction of complexometric techniques.

Antoine-Laurent Lavoisier, the French chemist, who died in the French Revolution, is accepted as the founder of quantitative analysis through his extensive use of the balance. Others among main contributors in the 19th century were Justus von Liebig of Germany and Jean-Baptiste-André Dumas of France. Although organic elemental analysis was revolutionized before 1900, a successful method for determining oxygen was not developed until 1939. Micromethods and sub-micromethods are 20th-century developments.

Inorganic aspects of analysis were developed before 1800, with introduction of the term stoichiometry. Jöns Jacob Berzelius of Sweden in the early 19th century was the dominant influence.

Gas analysis was pioneered by Bunsen in Germany and Marcellin Berthelot in France. This field has been revolutionized since 1952 by chromatography.

Electro-
chemical
methods

Electrochemical methods were first devised by the German chemist Clemens Winkler in the 19th century; the first potentiometric titrations were reported at the end of that century. As physicists progressed with studies of electricity, chemists were quick to exploit the development of several electrochemical-instrumental methods of analysis. The polarograph was an outstanding invention in 1922.

The development of the spectroscope by the German chemists Gustav Robert Kirchhoff and Bunsen in 1859 led to the discoveries of new elements. Although flame photometry was suggested in the 19th century, it was first effectively applied in 1928. Advances in physics at the start of this century led to the utilization of X-rays and ultraviolet and infrared radiation in chemical analysis, and they became the basis of powerful instrumental methods, as has the mass spectrograph (1920). Radiochemical methods proliferated in the period 1945–60 as a result of the developments in nuclear technology.

Since 1950, important techniques based on resonance phenomena, on atomic absorption and fluorescence, and on laser, ion, and electron probes have been developed. All these and the trend toward increased automation and computerization depend on the recent advances in electronics technology.

Perhaps the greatest impact on all branches of chemi-

cal analysis since 1940, however, has been made by the application of chromatographic principles, first described in 1903, aspects of which were developed in 1941 (partition chromatography), 1944 (paper chromatography), and 1952 (gas chromatography). Molecular-sieve chromatography (gel filtration, gel permeation chromatography) and thin-layer chromatography were introduced about 1956 (see below).

General approach to chemical analysis. Chemical analysis has to answer every conceivable question arising from the identity and composition of matter; *i.e.*, of everything in existence. Chemical analysis is primarily a service function with the object of trying to give the information requested as efficiently as possible.

In addition to purely qualitative and quantitative analyses relating to the composition of the material, analysis of its properties may be required; *e.g.*, molecular structure, biological activity, or physical properties such as the molecular weight, boiling point, freezing point, osmotic pressure, and surface tension.

Although there are some analytical measurements for which only one method is valid in particular circumstances (*e.g.*, a nondestructive method may be imperative if the object is of value), the steadily increasing intensity of scientific effort over the past 100 years has produced a wide range of methods for most common analyses. The choice of method may lie between a classical wet method or a modern instrumental one; the methods vary in sensitivity, selectivity, speed, and accuracy, and their applicability may depend on the absence of some other specific component. Sometimes there is no choice available; *e.g.*, if less than a critical amount of sample is supplied or if an official or referee method is specified. The latter is essential in any legal dispute or when goods are being tested for conformity to specification. It is rare for two different chemical methods to give identical results or for a physical method to give precise agreement with a chemical method.

PRINCIPAL STAGES IN CHEMICAL ANALYSIS

The main steps in a complete analysis are (1) collecting the sample, (2) deciding what analytical data are required, (3) making a preliminary examination of the sample, (4) selecting the most appropriate analytical method, (5) converting the sample or component in question into the state to which the analytical method can be applied, (6) performing the actual determination, and (7) calculating the results in a form that answers the questions asked.

Sampling. Every stage in the above scheme is important, but everything depends on the fact that the sample is truly representative of the whole that it represents.

Sampling is the process of obtaining a small portion possessing all the essential physical and chemical characteristics of the entire batch from which it was extracted. Some materials are relatively easy to sample: a small bag of household sugar, a bottle of brandy, or a tank of hospital oxygen. More difficulty is encountered in obtaining a representative 25-gram (about one-ounce) sample from a 25-ton shipment of coal or wheat. The accepted ways of achieving representative sampling are based on statistical procedures.

There are no general sampling methods applicable to all types of material. Specialized methods depend on whether a gas, liquid, or solid is involved. In the sampling of solids, particle size is an important variable, and the problem can be much more difficult than for liquids or gases, in which a uniform, homogeneous condition usually—but not necessarily—exists. Mechanical devices are available for sampling large volumes of material; in many industrial processes, continuous sampling or monitoring may be possible; *e.g.*, of the cyanide or mercury level in a waste effluent or of radioactive substances in a nuclear reactor coolant.

Preparation of samples for analysis. Inadvertent chemical or physical modification of the sample must be avoided during its preparation for analysis. Biological substances are particularly susceptible to such changes, and it may be difficult to establish that the component under test has not suffered some transformation during the preparation stages. The analyst can only try to achieve extraction or

Representative
samples

preparation under the mildest conditions possible. A useful check is to put the product isolated through a second, identical extraction cycle; if the reextracted product is identical to that first extracted, there can be some confidence in its acceptability for analysis. Extraction without modification is difficult for some materials, and some irreversible change in solubility, molecular size and shape, or other property may have to be tolerated if progress is to be made at all; if the nature and extent of the change is understood, allowance can be made in the interpretation of the results.

As examples of the pitfalls that analysts must avoid, samples to be analyzed for heavy metals should not be pulverized in an iron mortar; solutions to be analyzed for alkali metals should not be stored in glass vessels; solutions containing silver should not be exposed to light; carbohydrates or proteins should not be extracted with hot anhydrous solvents.

Errors and evaluation of results. An understanding of the different types of error and how they arise is extremely important. Analysts must be conversant with the terms absolute and relative error, accuracy, precision, average, range, standard deviation, coefficient of variation, and confidence limits for the mean.

Errors may be indeterminate or determinate. The former are accidental, random errors of chance that account for a proficient analyst's finding values such as 21.6, 21.7, 21.5, and 21.6 in four attempts at a simple analysis. Determinate errors may be operative, personal, instrumental, or methodic. The last named (also known as chemical errors) are inherent in all chemical systems of measurement; reactions may not go to completion or may involve equilibria; precipitates in gravimetric procedures usually have small but finite solubility; chemicals are rarely 100 percent pure, and the trace impurities can cause disproportionately high errors. Instrumental errors arise from internal or external effects on measurements made with any instrument—*e.g.*, with a maladjusted balance, or inaccurate weights, or a recorder with a drifting base line; such faults should of course be rectified, and instrumental error is more correctly reserved for errors that arise from design characteristics of instruments. Personal errors result from failure of the analyst to overcome personal perceptual and cognitive inabilities; *e.g.*, lack of sensitivity in judging certain colours. Operative errors occur when necessary attention to analytical practice or experimental detail is not given; *e.g.*, precipitates not dried at the recommended temperature. In these the analyst is culpable.

At the outset of any analytical procedure, it is essential for the analyst to contemplate the various steps he will carry out, assign reasonable magnitudes to the experimental values likely to become involved (volumes of solutions, weights of samples and of products), and so proceed to estimate the maximum possible error likely to occur. This technique pinpoints the critical stage of the procedure; *i.e.*, that expected to give the largest individual contribution to the error. Particular care can then be directed to that stage or perhaps an alternative approach devised; in particular, time need not be wasted by excessive care over stages contributing little toward the error.

How does the analyst know that the procedure yields reasonable results? He carries out replicates (reproducible duplicates, preferably on widely differing amounts of sample); carries out the procedure without the sample in order to allow for the impurities present in the reagents; makes comparative tests with other methods; and carries out determinations on pure chemicals, synthetic test mixtures, or analytical standards; *i.e.*, substances carefully selected and tested for homogeneity and for which an agreed value has been established from the independent results of many laboratories. There is also the standard-addition method, in which a known weight of a pure specimen of the substance under test is added to the sample to be analyzed. If the recovery of the material added (*i.e.*, the difference between the values for the analysis of the sample before and after the addition of the standard) is correct, there can be some confidence that the answer for the sample itself is also satisfactory.

Separation methods. Although any physical or chemical

property can be made the basis for a qualitative or a quantitative method of analysis, very few tests are specific (valid for one substance or element only, even in the presence of others), and thus analysis is not generally possible without prior separation of the desired component from others that respond to the procedure used. Quite a few analytical tests are selective (valid for a small number of substances or elements, which therefore are not differentiated, in the presence of all others). The availability of a specific or a selective reagent may obviate a gross separation.

There are two main approaches in separation methods: (1) physical segregation of the required component from all others, or at least from those that will interfere in the analytical procedure selected, and (2) chemical modification of the potential sources of interference so that their chemical activity is effectively suppressed.

Several separation methods depend on transfer of matter from one phase to another. Some of these are sufficiently selective and efficient to allow the desired transfer to be effected by a single application (*e.g.*, volatilization, electrodeposition, precipitation). Other methods are effective only as multistage processes (*e.g.*, fractional distillations, ion exchange, and chromatographic processes).

Precipitation. Precipitation is the process of depressing the solubility of a dissolved substance to the extent that it separates from the solution. It may be brought about by changing the substance to a less soluble one by a chemical reaction or by decreasing the dissolving power of the solvent. Precipitation by chemical reaction constitutes the basis for the classical group-separation system of qualitative inorganic analysis. A simple example is the separation of silver, mercury, and lead as a group from other common metals; the addition of dilute hydrochloric acid forms the chlorides of all metals present, but the chlorides only of silver, mercury, and lead are insoluble in excess dilute hydrochloric acid.

Phase distribution. Under this classification there are important modern methods; *e.g.*, ion exchange, solvent extraction, countercurrent distribution, and chromatographic methods. The most common ion exchangers are polymeric cross-linked resins (usually made in the form of tiny beads to increase permeability to solvents) that have cationic (positively charged) or anionic (negatively charged) sites. Resins with both kinds of sites or mixtures of resins can also be used. A column of a cation-exchange resin is first activated by washing with acid, then with water, to remove excess acid. If a solution containing, for example, sodium or potassium ions is then passed through the column, these cations displace an equivalent amount of hydrogen ions from the anionic sites in the resin; the displaced hydrogen ions appear in the solution emerging from the column, and a quantitative result can be obtained by titration of the hydrogen ions. Solvent extraction takes advantage of the different solubilities of substances in two liquids that are not soluble in one another. If two materials, *A* and *B*, are both soluble in water, but only *A* is soluble in ether, *A* may be separated from *B* by stirring or shaking the water solution with ether, allowing the layers to settle, and removing the ether layer. The effectiveness of this process is expressed by the distribution coefficients of the two substances in the chosen solvents. For each substance, the distribution coefficient is the ratio of its solubilities in the two solvents; two substances having widely different distribution coefficients can be separated readily by solvent extraction. Countercurrent distribution is essentially a method of repetitive solvent extraction, in which a stream of the extracting solvent, flowing in one direction, is continually mixed with and separated from a stream, flowing in the opposite direction, of a solution of the mixture of substances to be separated. Substances having distribution coefficients that differ only slightly can be separated by this procedure.

Chromatography—covered in detail in a later section of this article—is a technique for separating the components of mixtures by taking advantage of their different distribution coefficients between a continuously moving liquid or gaseous “mobile phase” and a “stationary phase,” which may be a solid, a liquid supported on a solid, or a gel. The separation process usually involves placing a suitable

Types of
errors

Ion-
exchange
resins

Tests of
accuracy

amount of the mixture at the top of the chromatographic device (a paper strip or a column containing the stationary phase), then allowing a suitable solvent mixture or other mobile phase to flow through it. The separated components emerge in the mobile phase.

Paper
chroma-
tography

In paper chromatography a sheet or strip of porous paper is the support for the stationary phase. The sample is applied as a small spot on the paper, and the mobile phase can either descend or ascend through the paper, causing different components of the sample to separate, because they migrate at different rates. The choice of solvent system is rather empirical, although effective mobile phases for most separations that have to be effected in analysis are now well known. Paper chromatography is sometimes carried out in two dimensions: after treatment with one mobile phase, the paper is dried, turned through 90°, then treated with a different mobile phase. Paper chromatography is widely used for separating all types of organic and inorganic compounds.

In thin-layer chromatography, the stationary phase (often alumina) is applied as a slurry to glass plates, to which it adheres on drying. The sample is applied as a spot or streak and separated as in paper chromatography. Very sharp separations can be obtained in short times with simple apparatus, and the recovery of separated components from the alumina is easily achieved.

For column chromatography, a long, narrow, tubular column is packed with the stationary phase (cellulose powder, charcoal, alumina, ion-exchange resin, etc.). The separation of some classes of materials—e.g., polysaccharides—is difficult to detect, but a possible solution is to convert the substances to coloured forms by treatment with reactive dyestuffs prior to chromatographic separation.

Molecular-
sieve
chroma-
tography

Molecular-sieve chromatography is a technique by which substances can be separated on the basis of differences in their molecular size and shape. The column is packed with a porous gel, glass, or silica preparation; these substances have pores of closely controlled size that act as sieves. The larger molecules cannot pass through the pores and travel down the column by the shortest route possible, emerging quickly. The smaller molecules can pass through the pores and gain access to internal volumes; they therefore percolate down through the column by a longer path length and emerge more slowly. The technique is widely used for proteins, polysaccharides, and synthetic polymers.

Of all the chromatographic techniques, gas chromatography has probably made the greatest impact. Test mixtures are added as suitable solutions to prepared columns (which may be of glass, copper, or stainless steel) positioned in a thermostatically controlled oven. An inert carrier gas sweeps the vaporized test mixture through the column, which is usually packed with a porous inert support coated with an involatile liquid (silicone oils, polyesters, polyglycols). The gas emerging from the column passes through a sensitive, high-speed detector that registers the presence of the separated components of the sample. For well-characterized systems, the identity of a component can be correlated with the time required for it to appear under standardized operating conditions. Positive identification, however, requires more rigorous evidence, such as that obtainable by subjecting the fractions to infrared spectrophotometry or mass spectroscopy.

Complex formation and masking. In its simplest terms, an interfering substance is excluded from chemical activity in solution by the addition of an ion with which it preferentially forms a complex ion; e.g., iron (III) can be masked by the addition of either fluoride or cyanide, which give the complex anions $(\text{FeF}_6)^{3-}$ or $[\text{Fe}(\text{CN})_6]^{3-}$, respectively, so that there is no longer free iron available to interfere with the analysis of some other component.

Other methods. Differences in particle size, mass, and density give rise to separations by simple filtration, sieving, differential sedimentation, flotation, centrifugation (the ultracentrifuge is important in the study of natural and synthetic polymers), dialysis, and molecular-sieve chromatography. Magnetic, thermal, and electrical methods have limited applicability. Simple illustrations are the separation of magnetic from nonmagnetic metals and the analysis of copper in its alloys by electrodeposition on a

preweighed platinum cathode. Biological materials often can be separated by taking advantage of the different rates at which they migrate under the influence of an electric field.

PRINCIPLES OF ANALYTICAL METHODS

Analytical methods can be classified most conveniently according to whether they are (1) qualitative or quantitative, (2) applicable to organic or inorganic substances, (3) based on chemical, physicochemical, or physical principles, (4) classical or instrumental, (5) carried out on samples that can be classified as macro (10^{-1} g), semimicro (10^{-1} – 10^{-3} g), micro (10^{-3} – 10^{-6} g), submicro (10^{-6} – 10^{-8} g), nanogram (10^{-9} g), or picogram (10^{-12} g), or (6) deal with major (greater than 1 percent), minor (0.01–1 percent), or trace (less than 0.01 percent) components of the sample. Authorities differ in the specific figures they quote for these scales of analysis. Other clarifications should also be made. Some tests can form the basis for both qualitative and quantitative procedures; classical (e.g., volumetric or gravimetric) methods are also instrumental in the sense that at least a balance is usually required. By “instrumental analysis” is understood the use of a modern, sophisticated instrument, such as a spectrophotometer or a mass spectrometer.

Classical (or “wet”) methods. *Inorganic qualitative analysis.* There are separate systematic schemes for dealing with the identification of cations (e.g., Fe^{3+} , Ca^{2+} , K^{+}) and of anions (e.g., SO_4^{2-} , Cl^{-}). Because the schemes depend on chemical processes occurring in solutions, insoluble substances require pretreatment of some kind, such as fusion with oxidizing or nonoxidizing alkaline or acidic fluxes, to render them soluble before the schemes can be applied. There are many preliminary tests of great value: analysts can deduce much from what happens when a sample is heated alone or in the presence of simple reagents; from a visual or a microscopic study of the solid sample; and from flame tests, observed either with the naked eye or with the aid of a simple hand spectroscope. After these preliminary tests, the sample must be prepared for series of chemical treatments by dissolution in the least acidic solvent possible. There is the possibility of chemical modification of the sample at this early stage; indeed, it is impossible to avoid on occasion. Sometimes chemical modification is used deliberately to achieve solubility or effect a separation.

The tests for anions are more difficult and less systematic than those for cations, yet successful analysis for cations is dependent on correct identification of the anions. The classical analysis for the common cations is based on their separation into the following groups: Group I—chlorides of lead, silver, mercury; Group II—sulfides of copper, lead, mercury, bismuth, cadmium, arsenic, antimony, tin; Group III—hydroxides of iron, chromium, aluminum; Group IV—sulfides of cobalt, manganese, nickel, zinc; Group V—carbonates of calcium, barium, strontium. Subseparations within these groups are then possible, and discrete tests are applied finally for sodium, potassium, lithium, magnesium, and ammonium cations.

Inorganic quantitative analysis. This covers the determination of the percentage composition of inorganic materials; i.e., those based on any of the elements with the exclusion of carbon. It is therefore a vast part of chemical analysis and virtually impossible to summarize briefly.

The main chemical methods of quantitative analysis involve gravimetry and titrimetry (volumetric analysis). Gravimetric methods have declined steadily in use since World War II; although accurate, they are slow. Basically, the constituent to be determined is precipitated from solution as an insoluble derivative that can be isolated, dried, and weighed. This insoluble derivative is preferably a compound of definite composition, coloured, crystalline, very insoluble, and stable at an appropriate drying temperature.

Titrimetric methods are based on finding (by burette) the volume of a reagent of known concentration (a standard solution) required to react quantitatively with a known amount of the substance being analyzed. A method of detecting the end point (equivalence point) of a volumetric reaction is required. Some systems are self-indicating; that is, some intrinsic change in colour occurs at the end point,

Indicators

as in titrations with potassium permanganate, when the first drop of titrant in excess imparts a permanent pale pink colour to the solution. More frequently, however, a chemical indicator is required, such as phenolphthalein or methyl red for acid-base titrations or diphenylamine or phenanthroline for redox (oxidation-reduction) systems. The function of an indicator is to give a sharp change in colour immediately after the true equivalence point has been reached. There are many special types of titration, but it is always essential that a quantitative relationship should exist between the titrant and the substance being determined and that the reaction be rapid.

Analysis for the rarer elements. Major technological changes in recent years have resulted in increased utilization of many of what were known earlier as rare elements. Some examples are the use of titanium, zirconium, hafnium, niobium, tantalum, vanadium, tungsten, and molybdenum in metallurgical developments of special alloys for aeronautics and space exploration; boron, rare earth, and transuranic elements have been studied extensively in atomic-energy programs and silicon, germanium, gallium, and indium in modern electronics. Other rarer elements (*e.g.*, beryllium) have been studied in connection with rocket-propellant research or research into aspects of pollution. The recent lunar-exploration programs have further stimulated analytical research.

Although there are classical separation schemes for the analysis of rarer elements, more rapid and sensitive methods are now in demand: chromatography, ion exchange, solvent extraction, atomic absorption and other spectroscopic techniques, complexometry, polarography, and other electrochemical procedures are all used frequently in this field of analysis.

Organic qualitative analysis. Organic chemistry is the study of the numerous compounds of carbon (excluding carbonates). Carbon combines very commonly with hydrogen, oxygen, and nitrogen; frequently with sulfur, phosphorus, and the halogens; and relatively infrequently with other elements.

Organic compounds are distinguished from inorganic by their behaviour on heating in air. The experienced analyst can tell much from the ease of initiation of combustion, smokiness of flame, formation of acidic reaction gases, and deposition of any residue.

The presence of carbon and hydrogen is most simply shown by heating a small amount of the substance being tested with an excess of dry, powdered copper(II) oxide in a large, dry test tube. Carbon dioxide and hydrogen are the primary products. The carbon dioxide is detectable by the formation of insoluble calcium carbonate with limewater; the hydrogen reacts with the copper oxide to form water, which condenses on the upper, cold, dry surface of the tube. Lassaigne's test, used to detect the presence of nitrogen, halogens, and sulfur, involves fusion with metallic sodium; sodium cyanide (nitrogen), sodium halide (halogens), or sodium sulfide (sulfur) is formed if any of these elements is present. Standard inorganic tests for cyanide, halides, and sulfide are then applied. Phosphorus is detected by fusing the organic substance with a mixture of sodium peroxide and carbonate. The phosphorus is converted to phosphate, which is then detected by the standard colorimetric reaction with ammonium molybdate in nitric acid. The presence of metals in organic compounds is determined by standard inorganic tests.

Organic quantitative analysis. This falls into two distinct sections—elemental analysis and functional-group analysis.

The elemental analyses most often required are for carbon, hydrogen, nitrogen, sulfur, phosphorus, and the halogens. The determination of metals is made by a quantitative ashing technique. Carbon and hydrogen are analyzed by modifications of Liebig's method (1831): combustion in excess of oxygen effects quantitative conversion to carbon dioxide and water, which can be determined by absorption in weighing tubes containing chemical absorbents. Nitrogen is commonly determined by the Dumas method (combustion and conversion to elemental nitrogen, the volume of which is measured) or by the Kjeldahl method (conversion to ammonium sulfate, from which ammonia

is steam distilled and determined titrimetrically). Sulfur, halogens, and phosphorus are now commonly determined by the Schöniger oxygen-flask technique (combustion in a flask filled with oxygen); after combustion, the reaction products are dissolved by adding distilled water to the flask, in which the final titrimetric or colorimetric procedure is carried out.

The most common functional group analyses involve the determination of alkoxy (*e.g.*, methoxy, ethoxy), hydroxyl, acetyl, epoxy, amino, carboxyl, peroxy, nitro, cyano, and active hydrogen groups. These demand more analytical skill but give a more rigorous assessment of the percentage purity of a compound than can be obtained from elemental analysis. As an indication of a typical functional-group analysis, Zeisel's method for alkoxy groups involves reaction of the compound with hydriodic acid; the methoxy groups are converted quantitatively to methyl iodide, which can be absorbed and determined titrimetrically.

Instrumental methods. Optical methods. There are about 20 distinct analytical techniques based on optical phenomena: some are of such great importance in general chemical analysis that no modern laboratory could function without them; others are restricted in application to particular compound classes. Taken together, however, the optical methods of analysis form the most widely used group of instrumental physicochemical methods.

Given a good pair of eyes and natural daylight, anyone should be able to distinguish between a solution of copper(II) sulfate pentahydrate (blue) and sodium chloride (colourless); and anyone should be able to tell which of two copper(II) sulfate pentahydrate solutions is the more concentrated; *i.e.*, the more intensely coloured of the two. These are applications of colorimetry; *i.e.*, of optical phenomena involving changes that are manifest in the visible part of the spectrum. The basic requirements for this approach to analysis are a source of light (the sun in this case) and a detector (the human eye). Sunlight (white light) is composite—*i.e.*, it contains light of many wavelengths (colours); these wavelengths can be separated from each other by dispersion devices (prisms, gratings). In many optical methods of analysis, chemicals are studied with the aid of monochromatic radiation; *e.g.*, the light from a sodium or mercury lamp, or from a laser.

Why do solutions of copper(II) sulfate pentahydrate and sodium chloride have different colours when examined in sunlight? The sodium salt does not absorb any of the wavelengths in sunlight at all; the copper salt absorbs radiation of all wavelengths except the blue, so that only the blue component can be reflected or transmitted to the detector. This difference in absorption characteristics results from the different electronic structures of sodium and copper atoms. By replacing the human eye with an electronic device such as a photocell or the even more sensitive combination of a photomultiplier and an amplifier, the sensitivity of measurement can be greatly increased.

The range of colours to which the human eye is sensitive, from red to violet, is only a very narrow segment of the electromagnetic spectrum of radiation. Of progressively decreasing wavelength (*i.e.*, increasing frequency and, hence, more energy) are the ultraviolet, X-ray, γ -ray, and cosmic-ray regions of the electromagnetic spectrum. Of progressively increasing wavelength are the infrared and microwave regions. All these regions are used in chemical analysis: whether a molecule absorbs in the ultraviolet or microwave part of the spectrum depends on the structural features of the molecule; that is, on which elements are involved and on the structural arrangements of the atoms in the molecule.

Spectrochemical methods. Spectrochemical methods, which are important modern instrumental techniques, may involve examination of the emission of radiation by molecules that have been suitably excited by heat or some other form of energy; or the absorption of radiation of particular wavelengths by molecules; or, less commonly, the reflection of radiation. Radiant energy can be absorbed by certain molecules and subsequently reemitted in a modified form; as a result, fluorescence, phosphorescence, and Raman spectra (extra spectrum lines produced when light is scattered by passing through transparent substances)

Colorimetry

Nitrogen, halogens, and sulfur in organic compounds

occur. These techniques are also useful analytically. (See also the section *Spectroscopy* below.)

Nephelometry and turbidimetry

The other optical phenomena of analytical use involve optical rotation (polarimetry), optical rotatory dispersion (ORD), and refraction. Light-scattering measurements can be made on suspensions or colloidal solutions by nephelometry, in which the measurement is made at right angles to the incident beam, or by turbidimetry, in which the transmitted light is measured. By measuring the intensity of the scattered light at different angles to the incident beam, the molecular weights of polymers can be obtained. All these methods are important in certain fields of analysis, but they are not general, and space does not permit their further discussion.

When some elements are heated strongly, light having a unique distribution of wavelengths is radiated. This behaviour forms the basis of emission spectroscopy, an extremely sensitive, accurate, and rapid automatic method for the qualitative and quantitative analysis of mixtures of many nonmetallic and metallic elements.

A cheaper and more convenient form of emission spectroscopy is flame photometry, applicable to substances that emit visible or ultraviolet light when their solutions are sprayed as a fine mist into a flame. The method is particularly suitable for the alkali and alkaline-earth metals, but a good-quality flame photometer can be used to determine more than 30 of the elements, with detection limits frequently lower than one part per million. Colorimetry involves measurement of the intensity of absorption of visible light. It is therefore restricted to the analysis of coloured substances or substances that can be converted conveniently into coloured derivatives. Standard solutions are prepared to find the concentration of solution that gives exactly the same colour intensity as the test substance under carefully standardized conditions. More accurate and sensitive results are obtained with simple instruments, such as the Dubosq colorimeter, which requires only one standard solution to be made up: colour match is achieved by a system of plungers that effectively change the depths of solution viewed in the comparison cells. The Lambert-Beer law relates the intensity of absorption of a solution to the concentration and effective depth of solution in an absorption cell. Absorption of microwaves (radiation having wavelengths between one centimetre and 100 centimetres) is characteristic of some gaseous molecules. It gives valuable structural information but is not of general analytical importance. Certain specific wavelengths that depend on the structure of the compound under test are absorbed when a beam containing all wavelengths of infrared radiation is passed through a suitably prepared specimen of almost any organic or inorganic compound (the main exceptions are diatomic gases such as oxygen, nitrogen, and hydrogen, and the alkali halides). The most useful range of wavelengths is that between 2.5 and 16 micrometres, also called microns (one micrometre = 10^{-6} metre). (These wavelengths often are expressed by the wave number, the number of waves in one centimetre: radiation having a wavelength of 10 micrometres has 1,000 waves per centimetre, or a wave number of $1,000\text{ cm}^{-1}$.) Solids, liquids, and gases can be examined, and mixtures can be analyzed. Both carbon dioxide and water vapour absorb strongly in the infrared region and must be excluded from the apparatus. Sensitive quantitative analyses can be carried out, but perhaps the greatest use of this technique has been in the qualitative identification of organic compounds. Structural information concerning the presence and, more importantly, absence of certain functional groups is obtained; for example, hydroxyl groups absorb in the $3,300\text{--}3,600\text{ cm}^{-1}$ region, cyano groups in the $2,200\text{--}2,250\text{ cm}^{-1}$ region, and carbonyl groups in the $1,650\text{--}1,800\text{ cm}^{-1}$ region. From $650\text{--}1,500\text{ cm}^{-1}$ the absorption spectrum of a compound is a unique "fingerprint" that differs from that of any other compound. The interpretation of spectra is a specialized skill that requires much experience.

Electrons in the molecules that have structures involving unsaturated bonds can absorb quanta of energy corresponding to electromagnetic radiation in the region of the spectrum from 180 to 400 nanometres (the ultraviolet

region). The major application of ultraviolet spectrometry is in the analysis of aromatic compounds, vitamins, and other biochemical molecules, although the technique is useful for many inorganic molecules. As in the case of modern infrared instrumentation, ultraviolet spectrometers scan the entire spectrum range automatically and produce a graph of the intensity of absorption in relation to the wavelength.

Atomic-absorption spectroscopy was introduced in 1955, and applications of the technique have grown steadily since then. By 1971 it was possible to make very sensitive and specific analyses of about 60 elements by this method. A solution of the compound under analysis is sprayed into a flame, in which a reservoir of atoms in various energized states is formed. A beam of radiation is passed through the atom reservoir: if copper is being determined, a copper-containing source must be used to give a beam of radiation of exactly the same wavelengths as those emitted by the energized atoms. Absorption of energy therefore occurs; the amount of energy absorbed can be detected electronically and is directly proportional to the number of atoms present.

Atomic-fluorescence spectroscopy has become very important since 1955 and gives very sensitive analyses of metals such as zinc, mercury, cadmium, magnesium, and silver.

Raman spectroscopy is another technique, in which the radiation scattered in a direction perpendicular to that of the incident beam is measured. The spectra are complementary to infrared spectra, and the technique has experienced a revival and extension in recent years as a result of the development of laser sources of radiation.

X-ray and electron diffraction are specialized methods of great value in determining molecular structures. Electrons have a much more restricted penetration than X-rays and can be used only to examine gases, very thin films, and surface layers. The introduction of computer techniques has allowed the X-ray method to be applied to very complex protein and polysaccharide molecules.

X-ray fluorescence (XRF) is a nondestructive method of elemental analysis widely used for metallurgical and geological specimens. Qualitative and quantitative analyses are possible for elements with atomic number greater than 12, although several lighter elements can be analyzed if ancillary equipment is available. When an element is irradiated with X-rays of appropriate wavelength, X-rays of a different wavelength, characteristic of the element, are emitted. Complex mixtures can usually be analyzed without prior separation of the components, as in the determination of additives or contaminants in motor oils. Samples are best examined in solution, but very finely powdered samples can be used. There is, unfortunately, a lack of sensitivity for some elements, as compared with other methods.

Mass spectrometry. The principles of mass spectrometry are described in detail in a later section. To summarize, molecular ions are produced from the sample by a beam of electrons produced by a hot filament. The ions are accelerated electrically to form a beam that is deflected magnetically into separate beams according to the mass-to-charge ratio of the ions involved. These beams can be made to pass through series of slits to reach the ion-collector electrode separately. The "time of flight" spectrometer operates on a different principle: the charged particles are separated by their different velocity of escape from the accelerator stage.

Mass spectroscopy is an important analytical technique of great sensitivity and accuracy. It gives quantitative results for major and minor components of mixtures, gives determinations of molecular weights and of isotopic abundances, and is widely used in the analysis of complex organic molecules. It is one of the few techniques with the sensitivity required to analyze the very small fractions often obtained from chromatographic processes. The mass spectrum ("cracking pattern") of a compound, like the infrared spectrum, is unique and gives unequivocal proof of the identity of a substance. Solid, liquid, and gaseous samples can be analyzed, and its rapidity makes it useful for monitoring process gas streams that alter rapidly.

Ultraviolet spectrometry

Infrared spectrometry

Nuclear
magnetic
resonance

Magnetic-resonance spectrometry. This technique has revolutionized, since about 1955, the structural analysis of organic compounds and certain classes of inorganic materials. The sample must be soluble in one of a range of solvents containing deuterium atoms in place of hydrogen in order to eliminate interference with the signals from hydrogen atoms in the sample under test.

The nuclei of certain atoms (*e.g.*, the common isotopes of hydrogen, nitrogen, fluorine, and phosphorus but not of carbon or oxygen) act as tiny bar magnets. These nuclei can therefore be influenced by strong external magnetic fields; quantum considerations dictate that they must become aligned either toward or against the applied field. If radiation of the appropriate frequency for absorption is passed through the specimen, the energy absorbed causes transitions from the one alignment to the other; the nuclei are then said to be in resonance. Measurements of the frequency and extent of the absorption by the nuclei form the basis of analysis. The field strength of the magnet must be constant and uniform to within one part in 10^8 . Field strengths of 14,000 gauss (the electromagnetic unit of magnetic induction) or 23,500 gauss commonly are used; the corresponding irradiation frequencies required to produce resonances are approximately 60 megahertz (one hertz is one cycle per second) and 100 megahertz.

In a fixed external magnetic field, the exact radio frequency at which a nucleus absorbs depends upon its stereochemical location in the molecule concerned, because the electrons in that molecule produce local fields that cause shielding effects, which vary from position to position within the molecule. In essence, the different hydrogen nuclei, for example, in a complex molecule can be distinguished and the nature of their immediate environment identified in terms of a value termed the chemical shift. For hydrogen atoms, distinction can be made among aliphatic, olefinic, acetylenic, aromatic, aldehydic, amino, amido, hydroxylic, phenolic, and carboxylic environments.

Electron spin resonance (ESR) spectroscopy is a resonance technique (also known as electron paramagnetic resonance) applicable to species having unpaired ("odd") electrons, and it is useful for the analysis of free radicals, molecules in triplet states (having two unpaired electrons), and certain transition metal ions and complexes.

Thermometric methods. When substances are heated, physical changes and chemical reactions or decompositions take place; the nature of these and the temperatures at which they occur are characteristic of the substances under test.

Differential
thermal
analysis

Differential thermal analysis is based on the change of temperature of a sample when heat is supplied at a constant rate. Complex changes in the solid sample, which may either liberate heat (exothermic reaction) or abstract heat (endothermic reaction), can occur; the responses of many substances in this procedure are therefore fairly complex, characteristic patterns. This technique has the advantage that the data can be obtained automatically over long periods by continuously recording instruments, and it is used frequently in the analysis of metallurgical, mineralogical, and polymeric samples.

Thermogravimetry is based on the thermobalance, which records continuously the change in weight of a sample as it is heated. The temperature at which loss in weight occurs and the extent of that loss can give useful analytical data for polymers and other classes of material.

Pyrolysis has been used increasingly in recent years to characterize polymeric materials. The sample is heated to the temperature at which decomposition to simple gaseous compounds takes place; these products are analyzed by gas chromatography or mass spectrometry.

Calorimetry, cryoscopy, and ebulliometry are examples of other thermal methods available for analytical purposes, but they are not used extensively.

Radiochemical methods. The analytical aspects of radioactivity are covered in the section *Radiation measurement*.

Following the impetus given to nuclear energy programs and radiochemistry in the 1940s, analytical methods based on radioactivity have become widely used, because of their

unparalleled combinations of selectivity and sensitivity. It is not unusual for analysis to be performed on as little as 10^{-15} gram of material. Although the cost of radiochemicals and of the irradiation of chemicals in nuclear reactors is high, the cost of laboratory counting equipment is comparatively low. Safety precautions additional to those in any chemical laboratory are always required; for many substances these precautions are easily met, but for the more dangerous isotopes very special remote-handling equipment and biological shielding are required.

Radiometric analysis is used to analyze substances on the basis of their small natural content of some radioactive isotope; *e.g.*, natural samples of potassium contain a very small proportion of the isotope potassium-40, which is a β emitter of long half-life (1.28×10^9 years). Another modification of this method is to analyze a nonradioactive substance by converting it to a radioactive form; *e.g.*, chloride ions can be determined with great sensitivity by the addition of radioactive silver nitrate, which leads to the deposition of radioactive silver chloride. The analysis can be based on the radioactivity of the latter or on the decrease in radioactivity of the silver nitrate added.

Activation analysis takes advantage of the fact that many elements become radioactive when irradiated with neutrons in a nuclear reactor. The active isotopes formed vary widely in terms of their half-lives, and a decay curve is obtained by plotting the intensity of radioactivity against time. From this and supplementary data (such as identifying the different γ radiations present) the composition of the original mixture of elements can be found. The sensitivity obtainable depends on the neutron-capture cross section of the element involved, the intensity of the neutron source, and the half-life of the isotope produced.

Neutron
activation
analysis

The method of isotope dilution can be employed to determine the amount of some element, *E*, in a mixture. A small, known amount of a radioactive isotope of *E* is incorporated into the mixture; the element *E*, including the added radioactive isotope, is then separated from the mixture, and its radioactivity is determined. It is then a simple calculation to establish the concentration of *E* in the original mixture, on the assumption that there is no difference in the percentage recoveries of *E* and its isotope from the mixture.

Electrochemical methods. In potentiometric analysis, the concentration of a solution is determined in terms of the measurable electrical potential; the electronic circuitry used is designed so that the measurement is made under conditions in which no current flows. The instrumental measurement of pH (the negative logarithm of the hydrogen ion, H^+ , concentration; *i.e.*, a measure of the acidity or alkalinity of a solution) is based on potentiometry. Ion-selective electrodes, sensitive to the activity of a particular ion in solution, are available for hydrogen ions, fluorides, the alkali metals, calcium, silver, etc., and these have greatly extended the analytical utility of potentiometry. Potentiometric titration is frequently used to locate end points in terms of the change in electromotive force of a suitable galvanic cell caused by the addition of known volumes of titrant. By means of simple electronic circuitry, this principle can be extended so that titrations can be done automatically.

The conductivity (reciprocal of resistance) of a solution depends on the identity of the ions present and their concentration. Analytical applications include the titration of mixtures of weak and strong acids, determination of rates of reaction, solubilities of slightly soluble salts, and the end points for titrations in which precipitates or slightly ionized compounds are formed.

Oscillometry (high-frequency titrimetry) determines changes in composition by measuring changes in dielectric constant or conductivity; these can be detected by applying high-frequency alternating signals to electrodes, which can be external to the cell containing the solution under test.

In voltammetry, a small, inert electrode (usually of gold or platinum) is used in conjunction with a larger electrode, at which the corresponding current density is very small, so that the current flowing depends on the rate of transfer of electroactive material (ions or molecules that can be oxidized or reduced at the electrode) from the bulk

of the solution to the smaller electrode. If a large excess of an inert electrolyte (*e.g.*, potassium chloride) is present, the rate of transfer becomes almost completely diffusion controlled (limited only by the rate at which the particles move through the solution, rather than by the rate at which the electrochemical reaction occurs). Voltammetry is useful for the analysis of both organic and inorganic compounds, and it can be carried out (1) with variable voltage, (2) with variable current, or (3) at constant current (a special case known as chronopotentiometry). For each of these methods, a graph of the relationship between current and voltage is an S-shaped curve from which the identity and the concentration of the electroactive substance may be determined.

Polarography

Polarography is an important technique that can be regarded as a special case of voltammetry. A large, non-polarizable reference electrode is used in conjunction with a small, polarizable electrode of special design—a capillary tube—from which small drops of mercury emerge at regular, short intervals into the solution. The voltage across these two electrodes is swept; the “halfwave potential” at which the required chemical reaction begins and the magnitude of the resulting “diffusion current” give a basis for qualitative and quantitative analysis. Although either electro-oxidizable or electroreducible substances can be examined, the dropping mercury electrode usually is connected to form the cathode (the negatively charged electrode, at which electrons are available to reduce oxidized substances); in the electrolysis of metal ions, the ions are reduced to the metal itself, which amalgamates with (*i.e.*, dissolves in) the drops of mercury. This method is nondestructive and sensitive and applicable to inorganic and organic molecules. Only very small volumes of dilute solutions are required, and the method is applicable to mixtures. Several instrumental variations of the basic principle have been developed.

Amperometry utilizes the principles of polarography and conductometry and is useful for detecting end points in slow or incomplete reactions involving precipitations and complexometric reactions. In an amperometric titration (sometimes called a polarometric titration because a simple polarographic dropping mercury electrode and reference electrode form the essential circuitry required), the change in the diffusion current at a convenient applied voltage is measured in relation to the volume of titrant. The diffusion current decreases linearly to a minimum at the equivalence point then increases as excess of titrant is added.

Coulometry involves the direct application of Faraday's laws of electrolysis: when a single electrode reaction occurs at 100 percent current efficiency, the number of equivalents of the substance involved is directly proportional to the number of faradays (one faraday is equal to about 96,500 coulombs) of electricity consumed. In direct (primary)

coulometry, the substance under test reacts directly at an electrode at a constant applied voltage. As the reaction proceeds, the current decreases. It is frequently preferable to work at constant current. Indirect (secondary) coulometry is more widely used. The quantity of electricity required to generate a low concentration of a titrant is found, this titrant reacting stoichiometrically (*i.e.*, quantitatively), as it is formed, with the substance being analyzed.

Electrodeposition (electrogravimetry) is a simple technique frequently used for copper, transition metals, and noble metals. The test solution is electrolyzed exhaustively at constant voltage or (more commonly) at constant current; the increase in weight of the working electrode (usually a mesh of platinum carefully prepared so that the metal will be electrodeposited in a firm layer) is determined. Efficient stirring is required to prevent concentration polarization. Metals can be separated if their standard electrode potentials differ by about 0.25 volt and if the electrolysis is carried out at a voltage midway between those electrode potentials.

Physical methods. The determination of vapour density, vapour pressure, depression of freezing point, and elevation of boiling point, which lead to the determination of molecular weight, are important techniques, but they are not now used very frequently. The determination of viscosity and osmotic pressure also lead to the determination of molecular weight and are especially useful in the study of colloidal systems such as natural polymers (starch, cellulose, pectin, proteins) or synthetic polymers (polyethylene, nylon) of high molecular weight. Surface tension, sedimentation rates, and particle size distribution are also frequently determined for materials of these classes.

Electrical properties are also widely used; the dielectric constant and dipole moment are useful analytical properties for organic molecules. The refractive index can be measured very accurately and is a very useful way of testing the purity of compounds or measuring the concentration of solutions.

Optically active molecules have the ability to rotate the plane of polarized light. The magnitude and direction of the rotation can be measured with great accuracy by a polarimeter, and this form of analysis is widely used for sugars and polysaccharides.

Other important physical methods of analysis include the determination of calorific values, heats of combustion, activation energy, and reaction rates. Mixtures of similar components, which are difficult to separate conveniently, frequently, can be analyzed in terms of the different rates of reaction of the components. The rates of chemical reactions can be increased by small amounts of catalysts, and a useful method of finding the concentration of some substances is to find a reaction for which the substance acts as a catalyst, then measure its concentration in terms of the increased rates of reaction. (D.M.W.A.)

CHEMICAL SEPARATIONS AND PURIFICATIONS

Since ancient times, man has used methods of separating and purifying chemical substances for improving the quality of his life. The extraction of metals from ores and of medicines from plants is older than recorded history. In the Middle Ages the alchemists' search for the philosophers' stone (a means of changing base metals into gold) and the elixir of life (a substance that would perpetuate youth) depended upon separations. In the industrial and technological revolutions, separations and purifications have assumed major importance. During World War II, for example, one of the main problems of the Manhattan Project, which led to the atomic bomb, was the separation of uranium-235 from uranium-238. Many industries now find separations indispensable: the petroleum industry separates crude oil into products used as fuels, lubricants, and chemical raw materials; the pharmaceutical industry separates and purifies natural and synthetic drugs to meet health needs; the mining industry is based on separation and purification of metals.

Separations and purifications also find their places in

medicine and the sciences. In the life sciences (biology, pharmacology, etc.) many advances can be directly traced to the development of each new separation method. The first step in understanding the chemical reactions of life is to learn what substances are present in samples obtained from biological sources. The complexity of these mixtures is shown by the fact that more than 300 compounds have been identified in urine. Identification first requires isolation by separation. Modern medicine depends upon purifications, such as that performed by the artificial kidney, and separations, such as those involved in clinical analysis of biological fluids.

Basic concepts of separations

This section is concerned with separations of the smallest subdivisions of matter, such as atoms, molecules, and small particles (sand, minerals, bacteria, etc.). Such processes start with a sample in a mixed state (composed of more than one substance) and transform it into new sam-

Industrial and military importance

Basic
factors

ples, each of which—in the ideal case—consists of a single substance. Separation methods, then, can be defined as processes that change the relative amounts of substances in a mixture. In chemical methods, one may start with a completely homogeneous mixture (a solution) or a heterogeneous sample (*e.g.*, solid plus liquid); in the act of separation, some particles are either partially or totally removed from the sample.

Reasons for making separations. There are two general reasons why separations are performed. First, the mixture may contain some substance that it is desirable to isolate from the rest of the mixture: this process of removing substances considered to be contaminants is called purification. For example, in the manufacture of synthetic drugs, mixtures containing variable proportions of several compounds usually arise. The removal of the desired drug from the rest of the mixture is important if the product is to have uniform potency and is to be free of other components that may be dangerous to the body.

The second reason for performing separations is to alter the composition of a sample so that one or more of the components can be analyzed. For example, the analysis of air pollutants to assess the quality of the air is of great interest, yet many of the pollutants are at a concentration too low for direct analysis, even with the most sensitive devices. Pollutants can be collected by passing samples of air through a tube containing an adsorbent material. By this process the pollutants are concentrated to a level such that straightforward analysis and monitoring can take place. In a second example, several impurities in a sample may interfere with the analysis of the substance of primary interest. Thus, in the analysis of trace concentrations of metals in rivers, organic substances can cause erroneous results. These interferences must be removed prior to the analysis.

Classification of separations. There are a variety of criteria by which one can classify separations. One is based on the quantity of material to be processed. Some methods of separation (*e.g.*, chromatography) work best with very small samples, while others (*e.g.*, distillation) are more suited to large-scale operations.

One may also classify separations on the basis of the physical or chemical phenomena utilized. These phenomena can be divided into two broad categories: equilibrium and rate (kinetic) processes. Table 1 lists a number of chemi-

two phases are mixed. Because the dye is soluble in the benzene as well as in the water, the dye is extracted into the benzene at the start of the mixing. But just as the dye tends to move into the benzene phase, so it also tends to be dissolved in the aqueous phase. Thus dye molecules move back and forth across the liquid-liquid interface. Eventually, a condition is reached such that the tendencies of the dye to pass from benzene to water and from water to benzene are equal, and the concentration of the dye (as measured by the intensity of its colour) is constant in the two phases. This is the condition of equilibrium. Note that this is not a static condition, but rather a dynamic one, for many molecules continue to pass through the liquid-liquid interface (although of equal number in both directions).

The condition of equilibrium in this example can be described in terms of the distribution coefficient, K , by the equation

$$K = \frac{\text{concentration of dye in the benzene phase}}{\text{concentration of dye in the water phase}},$$

in which the concentrations in the equilibrium state are considered. For $K = 1$, there are equal concentrations of the dye in the two phases. If K were larger, more dye would be found in the benzene phase at equilibrium. At $K = 100$, 99.01 percent is in the benzene, and only 0.99 percent is in the water (assuming equal volumes of the two liquids). For certain purposes, this condition might be considered to represent essentially complete removal of the dye from water, but more often $K = 1,000$ is selected (*i.e.*, 99.9 percent removal).

Separation results when the distribution coefficient values for two substances (*e.g.*, two dyes) differ from one another. Consider $K = 100$ for one substance and $K = 0.01$ for a second substance: then, upon reaching equilibrium, 99 percent of the former substance will be found in the benzene phase, and 99 percent of the latter substance will be found in the aqueous phase. It is clear that this sample is rather easily separated by liquid-liquid distribution. The ease of the separation thus depends on the ratio of the two distribution coefficients, α (sometimes called the separation factor):

$$\alpha = \frac{K_2}{K_1},$$

in which K_1 and K_2 are the respective distribution coefficients of components 1 and 2. In the above example, $\alpha = 10,000$. In many other cases, α can be very small, close to unity (α is defined such that it is always unity or greater): then separation is difficult, requiring very efficient methods. Part of the art of separations is finding conditions that produce large separation factors of pairs of substances.

In Table 1 most of the important chemical equilibrium separation methods are subdivided in terms of the two insoluble phases (gas, liquid, or solid). The example previously cited involved extraction (liquid-liquid). Each of the other methods is described in the course of this article.

Separations based on rates. Rate separation processes are based on differences in the kinetic properties of the components of a mixture, such as the velocity of migration in a medium or of diffusion through semipermeable barriers.

The separation of mixtures of proteins often is difficult because of the similarity of the properties of such molecules. When proteins are dissolved in water, they ionize (form electrically charged particles). Both positive and negative electrical charges can occur on various parts of the complex molecule, and, depending on the acidity or alkalinity of the solution, a protein molecule as a whole will be either positively or negatively charged. For a given set of solution conditions, the net charges on different proteins usually are unequal.

Electrophoresis takes advantage of these charge differences to effect a separation. In this method, two electrodes are positioned at opposite ends of a paper, starch gel, or other appropriate supporting medium. A salt solution is

cal separation methods based on equilibria, and Table 2 indicates those methods based on rate phenomena.

Separations based on equilibria. All equilibrium methods considered in this section involve the distribution of substances between two phases that are insoluble in one another. As an example, consider two insoluble liquids (*e.g.*, benzene and water). If a coloured compound is placed in the water and the two phases are mixed, colour

Table 2: Separations Based on Rate Phenomena

barrier separations	field separations	other
membrane filtration dialysis ultrafiltration electrodialysis reverse osmosis	electrophoresis ultracentrifugation electrolysis	enzyme degradation molecular distillation

appears in the benzene phase, and the intensity of the colour in the water phase decreases. These colour changes continue to occur for a certain time, beyond which no changes take place, no matter how long or vigorously the

used to moisten the medium and to connect the electrodes electrically. The mixture to be separated is placed in the centre of the supporting medium, and an electrical potential is applied. The positively charged proteins move toward the negatively charged electrode (cathode), while the negatively charged proteins migrate toward the positively charged electrode (anode). The migration velocity in each direction depends not only on the charge on the proteins but also on their size: thus proteins with the same charge can be separated.

This example demonstrates the separation of charged species on the basis of differences in migration velocity in an electric field. The extent of such a separation (based on the rate of a process) is time-dependent, a feature that distinguishes all such separations from those based upon equilibria.

The velocity can be either positive or negative: it depends not only on the size and electrical charge of the molecule but also on the conditions of the experiment (*e.g.*, voltage between the two electrodes). In analogy to equilibrium methods, the separation factor can be defined as the ratio of migration velocities for two proteins,

$$\alpha = \frac{v_2}{v_1}$$

The extent of separation (*i.e.*, how far one protein is removed from another) depends on the different distances traversed by the two proteins:

$$\text{extent} = v_2 t - v_1 t,$$

in which t is the time allowed for migration. Thus the extent of separation is directly proportional to the time of migration in the electric field.

Another major category of rate separation methods is based on the diffusion of molecules through semipermeable barriers. Besides different charges, proteins also have different sizes, and this latter property can be used as the basis of separation. If a vessel is divided in half by a porous membrane, and a solution of different proteins is placed in one section and plain water in the other, some of the proteins will be able to diffuse freely through the membrane, while others will be too large to fit through the holes. Still others will be able to just squeeze through the holes and so will diffuse more slowly through the membrane. In reality there is distribution of hole sizes, so that most protein molecules can diffuse through the membrane if given sufficient time. In any event, the extent of separation will be dependent on the time allowed for diffusion to take place.

Table 2 lists the various barrier separation methods discussed in this article. The differences in the methods involve the type of substances diffusing through the semipermeable barrier and whether an external field or pressure is applied across the membrane.

Particle separations. Up to this point, only separations at the molecular level have been mentioned. Separations of particles are also important in both industry and research. Particle separations are performed for one of two purposes: (1) to remove particles from gases or liquids or (2) to separate particles of different sizes. The first reason underlies many important applications. The electronics industry requires dust-free "clean rooms" for assembly of very small components; the household vacuum cleaner uses a stream of air to pick up particles of dust and dirt, which are separated from the air prior to its release in the room. The second purpose deals with the classification of particles from samples containing particles of many different sizes. Many technical processes using finely divided materials require that the particle size be as uniform as possible. The more important particle separation methods are filtration, sedimentation, elutriation, centrifugation, particle electrophoresis, electrostatic precipitation, flotation, and screening, which are described in a later section.

Single-stage versus multistage processes. As shown earlier, ease of separation in equilibrium methods is based on the value of the separation factor, α . When this value is large, separation is easy, requiring little input of work. Thus, if α lies between 100 and 1,000, a single equilibra-

tion in liquid-liquid extraction is sufficient to separate at the level of 90 percent or higher. This type of process is called a single-stage process.

If the separation factor is smaller, separation is more difficult: more work must be done on the system to achieve the desired separation. This result can be accomplished by repeating the equilibration process many times, such a method being called a multistage process.

To better envision this, consider a liquid-liquid extraction experiment in which the volumes of the two liquid phases (A and B) are equal and in which equal amounts of two components, 1 and 2, are present in one of the phases (say A). If $K_1 = 0.5$ and $K_2 = 2.5$, then $\alpha = 5$, according to the previous definition. After equilibration, 66.7 percent of component 1 and 28.5 percent of component 2 remain in the original liquid phase (A), because $K_1 = 0.5 = 33.3/66.7$ and $K_2 = 2.5 = 71.5/28.5$; so that the concentration ratio in this phase has gone from unity to 66.7/28.5, or 2.3. If the extracting liquid phase (B) is removed and replaced with an equal portion of fresh liquid (B) containing none of components 1 and 2, and a second extraction is performed, 44.4 percent of component 1 and 8.1 percent of component 2 are left in the original phase (A). The concentration ratio has increased from 2.3 to 5.5; however, note that there is less of components 1 and 2 in the original phase. If the equilibration is carried out again with fresh solvent (B), the original phase contains 29.6 percent of component 1 and only 2.3 percent of component 2, a concentration ratio of approximately 13. Thus the purity of component 1 is increased by repeating the process of equilibration.

Before examining multistage separations in more detail, consider an alternate procedure, by which component 2 (with $K = 2.5$) could be removed from the original liquid phase. Three consecutive extractions with fresh solvent result in the removal of $100 - 2.3 = 97.7$ percent of the component. Instead of three separate equilibrations, what would happen if one extraction were performed, using the same volume of liquid B used in the three consecutive extractions? It can be calculated that only 88 percent of component 2 would be extracted in this case. Thus, repeated equilibrations with a small amount of solvent remove more material than a single extraction with a large amount. This fact has important practical application.

Returning to the separation of two components, the experiments described are quite wasteful of material. While the concentration ratio is 13, only 30 percent of the concentrated component remains in the original phase. It seems clear that the extracted phase should not be discarded. The separation can be performed without loss of either component by employing a sequence of extractions: each vessel in a series is half filled with the denser, or lower, liquid phase (without components 1 and 2). The mixture is added to the lower phase (A in the above example) of the first vessel, and fresh upper phase (B) is added in the correct amount; after shaking to achieve equilibration, the upper phase is transferred to the second vessel, and fresh upper phase is added to vessel 1. Vessels 1 and 2 are both equilibrated, and the upper phases are moved along the train, one vessel at a time.

In this experiment, component 2 (with $K = 2.5$) will move more quickly down the train of vessels than component 1. After a large number of transfers, the different migration velocities of the two components result in complete separation. The number of transfers required to achieve complete separation is dependent on the value of the separation factor (α) of the two components; the smaller the value is, the larger must be the number of tubes.

This discontinuous, multistage, liquid-liquid extraction scheme has been highly refined: an especially designed apparatus is used to permit automatic operation. This method has played an important role in biochemistry for preparation of purified materials. In advanced models of this machine, the lower phase is transferred to the left after each equilibration, and the upper phase is transferred to the right; the sample is initially placed in the central vessel of the train. Because flow of the two solvents occurs in both directions, this mode of operation is called countercurrent.

The multi-stage process

Diffusion through membranes

Principles of specific methods

Equilibrium separations. *Distillation.* Distillation is a method of separation based on differences in the boiling points of substances. It has been known for centuries. The essential operation in distillation is the boiling of a liquid; converting it into a vapour, which is then condensed to a liquid that is collected separately rather than allowed to flow back into the original liquid.

Above the surface of any pure liquid (or solid) substance, a definite amount of its vapour is present. The concentration of the vapour and, therefore, the pressure it exerts increase as the temperature is raised. When the pressure of the vapour equals the pressure of the surroundings (one atmosphere in an open vessel at sea level), the substance boils: bubbles of vapour form within the liquid and rise to the surface. Above the surface of a mixture, the vapour contains all the substances present in the mixture, each making a contribution to the total pressure exerted by the vapour. The boiling point of the mixture is the temperature at which the total vapour pressure equals the pressure of the surroundings. In general, the composition of the vapour above a liquid mixture differs from that of the liquid: the vapour contains a larger proportion of the substance having the lower boiling point. This difference in composition of the two phases is the basis of separations effected by distillation. If the boiling points are widely different, only the component of lowest boiling point makes an appreciable contribution to the vapour, and condensation of the vapour provides practically pure material.

Separation by distillation, thus, is based on gas-liquid equilibrium, differing from the previously cited example of liquid-liquid extraction in that the phases are constituted from the components themselves. The ease of separation is obviously based on the differences in the boiling points of the substances; because boiling point is related, to a first approximation, to the molecular weight of the substance, distillation separates on the basis of weight (or size) of molecules. If the boiling points are close together, it is not possible to make a complete separation of two components in a single stage process, as the component of higher boiling point enters the vapour phase before the lower boiling component is completely removed. Such a case necessitates a multistage operation, which can most conveniently be achieved by placing a column above the boiling liquid solution. This glass column contains some loosely packed material (e.g., glass beads), and the hot vapours from the boiling solution partially condense on the surfaces. The condensed liquid flows back toward the solution until it meets rising hot vapours, whereupon the more volatile portion of the returning liquid revaporizes, and the less volatile part of the rising vapour condenses. Thus in the column there occurs a multistage operation, the eventual outcome of which is that the component of lower boiling point concentrates at the upper part of the column and that of higher boiling point in the lower part. Condensation of the vapour at the top of the column provides material much richer in the component having the lowest boiling point.

Distillation finds its greatest application in the large-scale separation of liquid mixtures, as in petroleum-refining plants, where crude oil is distilled into fractions having various boiling points, such as gasoline, kerosene, and lubricating oils. The large towers in refineries are efficient distillation columns that effect sharp separation of the fractions. Distillation is a procedure essential to the chemist, who uses it to purify synthetic products. In general, however, because of its inability to handle small quantities of material or to separate closely similar compounds, the current use of distillation for difficult separations is limited.

Chromatography. Chromatography is a separation process involving two phases, one stationary and the other mobile. Its principle is closely related to that of multistage liquid-liquid extraction, covered earlier in this article. Typically, the stationary phase is a porous solid (e.g., glass, silica, alumina) that is packed into a glass or metal tube. The mobile phase flows through the packed bed or column. The sample to be separated is injected at the beginning of the column and is transported through the

system by the mobile phase. In their travel through the column, the different substances distribute themselves according to their relative affinity for the two phases. The rate of travel is dependent on the values of the distribution coefficient, the components more soluble in the stationary phase requiring larger time periods for elution (complete removal from the column). Thus, separation is based on differences in distribution behaviour reflected in different migration times through the column. As in repetitive extraction, the larger that the separation factor is for a pair of components, the shorter will be the column necessary to resolve them. Chromatography is analogous to multistage extraction, except that in chromatography there are no discontinuous steps but rather a continuous flow.

By the mid-20th century, gas chromatography probably had become the principal separation technique in the laboratory, as the result of its speed, resolving power, and especially its sensitivity. Since both gas-liquid and gas-solid chromatography (GLC and GSC) depend on vaporization, they are best suited to compounds that can be vaporized without suffering decomposition.

As already noted, GLC involves vapour-liquid equilibrium but is unlike distillation in that the phases consist of components other than those to be separated. The gas phase is considered to be a carrier, transporting the components of the sample along the column in a manner analogous to the moving phase in liquid-liquid extraction. Either helium or hydrogen usually is used as the carrier gas, although nitrogen is sometimes used. The stationary liquid phase is coated on a solid support that is packed into the column. Most frequently the solid support is a diatomaceous earth. (For further coverage of this topic, see the section *Chromatography* below.)

Special adsorbents called molecular sieves are used in certain separations. These materials contain pores of approximately the same dimensions as small molecules. Advantage can be taken of this property in the separation of molecules having linear structures from molecules having bulky structures. The former can readily get into the pores, but the latter are unable to penetrate. This is an example of an exclusion mechanism of separation (based on shape differences). Molecular sieves also play an important role in the drying of gases: water, a very polar substance (i.e., its positive and negative electrical charges are unevenly distributed within the molecule), is readily adsorbed on the particles, but less polar gases are not retained.

Sublimation, another method of gas-solid distribution, is not used very often. In sublimation a solid evaporates without passing through the liquid state; thus it is somewhat analogous to distillation, in that both methods involve evaporation. In the case of a solution made up of two solids, it is possible to separate the two components if the vapour pressures of the solids are different. Since not all substances sublime, the applicability of the method is limited.

Crystallization and precipitation. Crystallization is a technique that has long been used in the purification of substances. Often, when a solid substance (single compound) is placed in a liquid, it dissolves. Upon adding more of the solid, a point eventually is reached beyond which no further solid dissolves, and the solution is said to be saturated with the solid compound. The concentration (that is, the amount of the solid dissolved in a given volume of the solvent) of the saturated solution depends upon the temperature, in most cases a higher temperature resulting in a higher concentration.

These phenomena can be employed as a means of effecting separation and purification. Thus, if a solution saturated at some temperature is cooled, the dissolved component begins to separate from the solution and continues to do so until the solution again becomes saturated at the lower temperature. Because the solubilities of two solid compounds in a particular solvent generally differ, it often is possible to find conditions such that the solution is saturated with only one of the components of a mixture. Upon cooling such a solution, part of the less soluble substance crystallizes alone, while the more soluble components remain dissolved.

Crystallization, the process of solidifying from solution,

Gas
chroma-
tography

Liquid-
vapour
equilib-
rium

is highly complex. Seed particles, or nuclei, form in the solution, and other molecules then deposit on these solid surfaces. The particles eventually become large enough to fall to the bottom of the container. In order to achieve a high purity in the crystallized solid, it is necessary that this precipitation take place slowly. If solidification is rapid, impurities can be entrapped in the solid matrix. Entrapment of foreign material can be minimized if the individual crystals are kept small. Best results are obtained by cooling the solution slowly while stirring the liquid. Stirring promotes the formation of many nuclei, so that many small crystals form, rather than a few large ones. It is sometimes necessary to add a seed crystal to the solution in order to begin the crystallization process: the seed crystal provides a solid surface on which further crystallization can take place. (Additional coverage of this topic appears in the article *MATTER*.)

Chemical
precipitation

The term precipitation sometimes is differentiated from crystallization by restricting it to processes in which an insoluble compound is formed in the solution by a chemical reaction. It often happens that several substances are precipitated by a given reaction. To achieve separation in such cases, it is necessary to control the concentration of the precipitating agent, so that the solubility of only one substance is exceeded. Alternatively, a second agent can be added to the solution to form stable, soluble products with one or more components in order to suppress their participation in the precipitation reaction. Such compounds, often used in the separation of metal ions, are called masking agents.

Precipitation was used for many years as a standard method for separation and analysis of metals. By the mid-20th century, however, it had been replaced by selective and sensitive instrumental methods that directly analyze many metals in aqueous solutions.

Zone melting. Another separation procedure based on liquid-solid equilibria is zone melting, which has found its greatest use in the purification of metals. Purities as high as 99.999 percent often are obtained by application of this technique. Samples are usually in a state of moderate purity before zone melting is performed.

The zone-melting process is easy to visualize. Typically, the sample is made into the form of a thin rod, from 61 centimetres to three metres (two to 10 feet) or more in length. The rod, confined within a tube, is suspended either horizontally or vertically, and a narrow ring that can be heated is positioned around it. The temperature of this ring is held several degrees above the melting point of the solid, and the ring is caused to travel very slowly (a few centimetres per hour) along the rod. Thus, in effect, a melted zone travels through the rod: liquid forms on the front side of this zone, and solid crystallizes on the rear side. Because the freezing point of a substance is depressed by the presence of impurities, the last portion of a liquefied sample to freeze is enriched in the impurities. As the molten zone moves along, therefore, it becomes more and more concentrated with impurities. At the end of the operation, the impurities are found solidified at the end of the rod, and the impure section can be removed by simply cutting it off. High purities can be achieved through multistage operation, either by recycling the ring several times or by using several rings in succession.

Liquid-solid adsorption and ion exchange. Liquid-solid adsorption is similar to gas-solid adsorption in that the equilibrium involves a distribution between a three-dimensional phase (gas or liquid) and a two-dimensional phase (solid surface). Thus, many of the types of separations are similar for the two methods. Separations are based on the properties of classes of compounds; e.g., amines (alkaline) from alcohols (neutral), esters (neutral) from acids, etc. Because in liquid-solid adsorption there is no step (such as vaporization) strongly affected by molecular weight, separations within a given class of compounds are poor.

Liquid-solid chromatography is the oldest of the chromatographic methods. Until the mid-20th century, the experimental procedure had not changed much from its original form. A vertical tube one to two metres long and one centimetre wide was filled with adsorbent particles

roughly 100–200 micrometres in diameter. The sample was introduced at the top of the column, and the mobile liquid phase was allowed to flow down the column. The solution emerging from the bottom of the tube was collected in fractions for analysis or subsequent use. In general, this method was characterized by poor efficiency, slow separations, and poor reproducibility. By means of later developments, including the use of smaller tubes, smaller adsorbent particles, and high liquid velocities, speeds and efficiencies comparable to those of gas chromatography have been achieved.

Liquid-solid adsorption chromatography also can be performed on thin, flat plates (thin-layer chromatography, or TLC). TLC is inexpensive and rapid but not as sensitive or efficient as column chromatography. In practice, the adsorbent is spread on a glass plate and dried. The sample is applied as a spot near one end of the plate, which is placed (vertically) in a shallow reservoir containing the mobile phase. As the mobile phase travels up the plate by capillary action, the sample dissolves in the liquid, and its components are transported up the plate to new positions at varying distances from the starting point.

Ion-exchange chromatography is a subdivision of liquid-solid chromatography, but its importance is such that it deserves special mention. As the name implies, the process separates ions; the basis of the separation is the varying attraction of different ions in a solution to oppositely charged sites on a finely divided, insoluble substance (the ion exchanger, usually a synthetic resin). In a cation-exchange resin all the sites are negatively charged, so that only positive ions (cations) can be separated; an anion-exchange resin has positively charged sites.

An important application of ion exchange is the removal of dissolved iron, calcium, and magnesium ions from hard water. The negative sites on a cation exchanger are first neutralized with sodium ions by exposure to a strong solution of common salt (sodium chloride); when the hard water is passed through the resin, the undesirable ions in the water are replaced by sodium ions.

Exclusion and clathration. Differences in the sizes of molecules can be the basis for separations. An example of these techniques is the use of molecular sieves in gas-solid chromatography. Exclusion chromatography (or gel-permeation chromatography) has proved effective for the separation and analysis of mixtures of polymers (large molecules formed by combining many smaller molecules). In this method the largest molecules emerge from the chromatographic column first because they are unable to penetrate the porous matrix of the support. Smaller molecules appear later because they can traverse the whole porous matrix. A column can be calibrated with polymer samples of known molecular weight so that the time required for emergence of the unknown mixture can be used to deduce the molecular weights of the components of the sample as well as their proportions; such molecular weight distributions are very important characteristics of polymers. Exclusion chromatography also finds use in the separation of mixtures of proteins, which are natural polymers.

In clathration, separation also is based on fitting molecules into sites of specific dimensions. Upon crystallizing from solution, certain compounds form cages (on the molecular scale) of definite size. If other substances are present in the liquid solution and they are small enough, then they will be entrapped in the cage; larger components will be excluded. This method has been used in large-scale processes for separating chemicals made from petroleum.

Rate separations. *Field separations.* Electrophoresis, described in an earlier section of this article, finds its most important application in the separation of proteins for analysis. It is also possible to use it in a preparative mode. In this case, the sample is continuously fed (with a salt solution) at the top centre of a vertically mounted sheet of paper. As the sample flows down the paper, it is subjected to an electrical potential at right angles to the flow. The various species disperse across the paper depending on their charge and mobility and drop from the coarsely serrated bottom edge of the paper into receivers.

Ultracentrifugation involves separation on the basis of the centrifugal force created by very rapid rotation (50,-

Thin-layer
chroma-
tography

000 revolutions per minute or more). Different species, depending on their masses, will settle at different speeds under these conditions. Ultracentrifugation finds its greatest use in the separation of polymeric materials, such as proteins and nucleic acids.

Electrolytic refining Electrolytic separations and purifications are effected by taking advantage of the different voltages required to convert ions to neutral substances. A particularly important example of this method is the refining of copper. Copper ores typically contain minor amounts of other metals that are not removed by the initial processes that reduce the ores to the metal. A slab of the impure copper and a sheet of pure copper are placed in a vessel containing a solution of sulfuric acid in water, and the two pieces of copper are connected to a source of direct electric current, so that the pure copper becomes the cathode (negatively charged electrode) and the impure copper becomes the anode (positively charged). The anode dissolves, the metal atoms becoming positive ions that migrate through the solution to the cathode. The voltage between the electrodes is regulated so that, as the metal ions arrive at the cathode, only the copper ions are reduced to metal atoms, which deposit on the cathode. Some of the original impurities, such as zinc and nickel, remain as their ions in the solution, because their conversion back to neutral metal atoms requires a higher voltage than that of the system; other impurities, such as silver and gold, never dissolve at all, but, as the atoms around them dissolve, they fall to the bottom of the vessel as a slime from which they can be recovered by other processes.

Barrier separations. Several separation methods depend upon penetration of molecules through semipermeable membranes. Membrane filtration involves simple migration resulting from a concentration difference on the two sides of the membrane. In ultrafiltration, this diffusion through the membrane is accelerated by means of a pressure difference. In electrodialysis, an electrical field accelerates the migration.

Unrestricted migration of the individual components of a solution results in equalization of the concentration of each component throughout the solution. All the components take part in this process: there is just as much tendency for the solvent to diffuse from regions where its concentration is high (and the solution is therefore dilute) to regions where its concentration is low (and the solution is concentrated) as there is for the dissolved substance to diffuse from regions where it is concentrated to those where it is dilute. In many separations, attention is focussed on the tendency of the dissolved particles to migrate, while the corresponding tendency of the solvent particles to migrate is largely ignored. Osmosis, however, is a phenomenon in which only the solvent is free to migrate through a membrane that separates two regions of different composition. The solvent, driven by its tendency to move from the region where its concentration is higher, passes from the dilute solution into the concentrated one and would continue to do so indefinitely if the liquid levels on the two sides of the membrane remained the same. But, as the solvent passes through the membrane, the amounts of the two solutions become unequal, and the resulting difference in pressure eventually brings the migration to a stop. This pressure difference is called the osmotic pressure of the solution.

In a separation technique called reverse osmosis, a pressure is applied opposite to and in excess of the osmotic pressure to force the solvent through a membrane against its concentration gradient. This method is an effective means of concentrating impurities, recovering contaminated solvents, cleaning up polluted streams, and desalinating seawater. Dialysis, a technique frequently used in biochemistry, is a membrane-separation method used for removing dissolved salts (small particles) from solutions of proteins or other large molecules.

Enzyme-catalyzed reactions. Enzymes are highly specific biological catalysts capable of discriminating between molecules having similar structures. One compound may be chemically changed in the presence of an enzyme, while another, otherwise inseparable from the first, is not affected. This selectivity has been used as a basis of sep-

aration; the method is not frequently used but may be invoked when two very closely related molecules cannot be separated by other means.

Particle separations. Sedimentation. Particles such as viruses, colloids, bacteria, and small fragments of silica and alumina may be separated into different fractions of various sizes and densities. Suspensions of relatively massive particles settle under the influence of gravity, and the different rates can be exploited to effect separations. To separate viruses and the like, it is necessary to employ much more powerful force fields, such as those produced in an ultracentrifuge (500,000 times gravity).

Filtration and screening. In filtration, a porous material is used to separate particles of different sizes. If the pore sizes are highly uniform, separation can be fairly sensitive to the size of the particles, but the method is most commonly used to effect gross separations, as of liquids from suspended crystals or other solids. To accelerate filtration, pressure usually is applied. A series of sieves is stacked, with the screen of largest hole size at the top. The mixture of particles is placed at the top, and the assembly is agitated to facilitate the passage of the particles through successive screens. At the end of the operation, the particles are distributed among the sieves in accordance with their particle diameters.

Elutriation. Elutriation is a method of separation of particles. The particles are placed in a vertical tube in which water (or other fluid) is flowing slowly upward. The particles fall through the water at speeds that vary with their sizes and densities. If the flow rate of the water is slowly increased, the most slowly sinking particles will be swept upward with the fluid flow and removed from the tube. Intermediate particles will remain stationary, and the largest or densest particles will continue to migrate downward. The flow can again be increased to remove the next size of particles. Thus, by careful control of flow through the tube, particles can be separated according to sizes.

Particle electrophoresis and electrostatic precipitation. As the name implies, particle electrophoresis involves the separation of charged particles under the influence of an electric field; this method is used especially for the separation of viruses and bacteria. Electrostatic precipitation is a method for the precipitation of fogs (suspensions of particles in the atmosphere or in other gases): a high voltage is applied across the gas phase to produce electrical charges on the particles. These charges cause the particles to be attracted to the oppositely charged walls of the separator, where they give up their charges and fall into collectors.

Flotation. There are a few methods that use foams to achieve separations. In these, the principle of separation is adsorption on gas bubbles or at the gas-liquid interface. Two of these methods are foam fractionation, for the separation of molecular species, and flotation, for the separation of particles. When dissolved in water, a soap or detergent forms a foam, if gas is bubbled through the solution. Collection of the foam is a means of concentrating the soap. Because proteins produce foams, foam fractionation has also been used to concentrate these substances. The value of the method lies in its speed and in the fact that no heat is applied during the process (proteins usually are damaged by heat). The method is not very selective, however.

Flotation is a process in which particles are carried out of a suspension by a foam. In this case, a soap or other chemical agent first adsorbs on the surface of the particle to increase its ability to adhere to small air bubbles. The clinging bubbles make the particle light enough to float to the surface, where it can be removed. By proper selection of the chemical, particles having similar densities but different compositions can be separated. This method is extremely important in concentrating the valuable constituents of minerals before chemical processing to recover the metals present. (B.L.K.)

Chromatography

As explained previously, chromatography is a technique for separating chemical substances on the basis of rela-

Use of
foams

Advantages as a separation method

tive rates of adsorption from a moving liquid or gaseous stream. It is widely used in biochemical research for the separation and identification of chemical compounds of biological origin. In the chemical industry the technique is employed to separate and analyze complex mixtures, such as petroleum. Because certain forms of chromatography are capable of detecting extremely small amounts of materials, they are used to identify trace contaminants, such as chlorinated insecticides, in biological materials.
