Old Testament history proper ends with the events described in the books of Ezra and Nehemiah. The books of Chronicles give all the preceding history, from Adam to the Babylonian sack of Jerusalem and the exile. The last two verses of the Second Book of the Chronicles are repeated in the first two verses of Ezra: God inspires Cyrus to send the Jews back to Jerusalem to rebuild the Temple. The Persian period of Jewish history ended with the conquest of Alexander the Great in 323 BCE to begin the Hellenistic era, in which some of the biblical (including apocryphal or deuterocanonical) writings were created (for Hellenistic Judaism, see JUDAISM).

Old Testament literature

THE TORAH (LAW, PENTATEUCH, OR FIVE BOOKS OF MOSES)

Composition and authorship. The Torah, or Pentateuch (Five Scrolls), traditionally the most revered portion of the Hebrew canon, comprises a series of narratives, interspersed with law codes, providing an account of events from the beginning of the world to the death of Moses. Modern critical scholarship tends to hold that there were originally four books (Genesis, Exodus, Leviticus, and Numbers) resulting from the division into manageable scrolls—a so-called Tetrateuch—to which later was added a fifth scroll, or book, Deuteronomy. A theory, once widely held, that the Book of Joshua was originally integral with the first five books to form a Hexateuch (Six Scrolls) is now generally regarded as dubious.

The traditional Jewish and Christian view has been that Moses was the author of the five books, that "of Moses" means "by Moses," citing in support passages in the Pentateuch itself that claim Mosaic authorship. Since these claims, however, are written in the third person, the question still arises as to the authorship of the passages; *e.g.*, in Deuteronomy, chapter 31, verse 9: "And Moses wrote this law, and gave it to the priests . . . and to all the elders of Israel." The last eight verses of Deuteronomy (and of the Pentateuch), describing Moses' death, were a problem even to the rabbis of the 2nd century CE, who held that "this law" in the verse quoted refers to the whole Torah preceding it. There are also other passages that seem to be written from the viewpoint of a much later period than the events they narrate.

The documentary hypothesis. Beyond these obvious discrepancies, modern literary analysis and criticism of the texts has pointed up significant differences in style, vocabulary, and content, apparently indicating a variety of original sources for the first four books, as well as an independent origin for Deuteronomy. According to this view, the Tetrateuch is a redaction primarily of three documents: the Yahwist, or J (after the German spelling of Yahweh); the Elohist, or E; and the Priestly code, or P. They refer, respectively, to passages in which the Hebrew personal name for God, YHWH (commonly transcribed "Yahweh"), is predominantly used, those in which the Hebrew generic term for God, Elohim, is predominantly used, and those (also Elohist) in which the priestly style or interest is predominant. According to this hypothesis, these documents—along with Deuteronomy (labelled D)—constituted the original sources of the Pentateuch. On the basis of internal evidence, it has been inferred that J and E are the oldest sources (perhaps going as far back as the 10th century BCE), probably in that order, and D and P the more recent ones (to about the 5th century BCE). Genesis, Exodus, and Numbers are considered compilations of J, E, and P, with Leviticus assigned to P and Deuteronomy to D.

J, E, P, and D documents

The Yahwist, or J, is the master of narrative in biblical literature, who sketches people by means of stories. He takes his materials wherever he finds them, and if some are crude he does not care, as long as they make a good story. The book of Genesis, for example, contains the story of Abraham's passing off his wife as his sister, so if the king took her as a concubine he would honour her supposed brother instead of having her husband killed, a story told by J without any moralistic homily. Not given to subtle theological speculations, J nearly always refers to the Deity as YHWH, by his specifically Israelite personal name (usually rendered "the Lord" in English translations), though he is not hidebound and also employs the term Elohim ("God"), especially when non-Hebrews are speaking or being addressed. He presents God as one who acts and speaks like human persons, a being with whom they have direct intercourse. The Yahwist, however, has one very definite theological (or theo-political) preoccupation: to establish Israel's divinely bestowed right to the land of Canaan.

More reflective and theological in the apologetic sense is the Elohist, or E. No fragment of E on the primeval history (presented in the first 11 chapters of Genesis) has been preserved, and it is probable that none ever existed but that the Elohist began his account with the patriarchs (presented in the remainder of Genesis, in which the J and E strands are combined). The first passage that can be assigned to E with reasonable certainty is chapter 20 of Genesis, which parallels the two J variants of the "She is my sister" story noted above. Unlike these, it tries to mitigate the offensiveness of the subterfuge: though the patriarch did endanger the honour of his wife to save his life, his statement was not untrue but merely (deliberately) misleading. The Elohist is also distinct from the Yahwist in generally avoiding the presentation of God as being like a human person and treating him instead as a more remote, less directly accessible being. Significantly, E avoids using the term YHWH throughout Genesis (with one apparent exception), and it is only after telling how God revealed his proper name to Moses, in chapter 3 of Exodus, that he refers to God as YHWH regularly, though not exclusively. This account (paralleled in the P strand in chapter 6 of Exodus) is apparently based on a historical recollection of Moses' paramount role in establishing the religion of YHWH among the Israelites (the former Hebrew slaves). Also noteworthy is E's choice of the term prophet for Abraham and his characterization of a prophet as one who is an effective intercessor with God on behalf of others. This is in line with his speculations on the unique character of Moses as the great intercessor as compared with other prophets (and also with Joshua as Moses' attendant).

The Elohistic tone and stress

It is inferred from certain internal evidence that E was produced in the northern kingdom (Israel) in the 8th century BCE and was later combined with J. Because it is not always possible or important to separate J from E, the two together are commonly referred to as JE.

The third major document of the Tetrateuch, the Priestly code, or P, is very different from the other two. Its narrative is frequently interrupted by detailed ritual instructions, by bodies of standing laws of a ritual character, and by dry and exhaustive genealogical lists of the generations. According to one theory, the main author of P seems to

have worked in the 7th century and to have been the editor who combined the J and E narratives; for his own part, he is content to add some brief, drab records—with frequent dates—of births, marriages, and migrations. The P material is to be found not merely in Leviticus but throughout the Tetrateuch, including the early chapters of Genesis and one of the creation accounts and ranging from the primeval history (Adam to Noah) to the Mosaic era. Like the Elohist, P uses the term Elohim for God until the self-naming of God to Moses (Exodus, chapter 3, in the P strand) and shows a non-anthropomorphic transcendent stress.

The Deuteronomist, or D, has a distinctive hortatory style and vocabulary, calling for Israel's conformity with YHWH's covenant laws and stressing his election of Israel as his special people (for a detailed consideration of D, see below *Deuteronomy*). To the Deuteronomist or the Deuteronomic school is also attributed the authorship of the Former Prophets (Joshua, Judges, Samuel, and Kings), which scholars call the "Deuteronomic history."

Other Pentateuchal theories. This documentary theory of the composition of the Pentateuch has been challenged by eminent 20th-century scholars who have offered alternative or additional methods of analysis and interpretation. Form criticism, for example, has stressed particular literary forms and the historical setting out of which they arose: the sagas, laws, legends, and other forms and the particular tribal or cultic context that gives them meaning. Tradition criticism centres on the pre-literary sources; *i.e.,* on the oral traditions and the circles out of which they originated as accounting for the variety of the materials in the Pentateuch. Archaeological criticism has tended to substantiate the reliability of the typical historical details of even the oldest periods and to discount the theory that the Pentateuchal accounts are merely the reflection of a much later period. The new methods of criticism have served to direct attention to the life, experience, and religion out of which the Pentateuchal writings arose and to take a less static and literal view of the constituent documentary sources; yet most scholars still accept the documentary theory, in its basic lines, as the most adequate and comprehensive ordering of the variegated Pentateuchal materials. The following presentation rests mainly on an analysis and interpretation of the literary sources. (See below *The critical study of biblical literature: exegesis and hermeneutics.*)

In any case, the five books that have come down in various texts and versions have been seen as a unit in the religious communities that preserved them. Their basic content may be divided thus: (1) beginnings of the world and man—the primeval history; (2) patriarchal narratives—from Abraham to Joseph; (3) Egyptian slavery and the Exodus; (4) the revelation and Covenant at Sinai; (5) wanderings and guidance in the wilderness (divisible into two separate sub-blocks, before and after Sinai); (6) various legal materials—the Decalogue, Covenant Code, and passages of cultic and Deuteronomic laws—interspersed in the narrative, which take up the greater portion of the Pentateuch.

Genesis. This book is called *Bereshit* in the Hebrew original, after its first word (and the first word of the Bible), meaning "In the beginning." It tells of the beginnings of the world and man and of those acclaimed as ancestors of the Hebrew people—all under the shaping action and purpose of God. The book falls into two main parts: chapters 1–11, dealing with the primeval history, and chapters 12–50, dealing with the patriarchal narratives; the latter section is again divisible into the story of Abraham, Isaac, and Jacob (chapters 12–36) and the story of Joseph (chapters 37–50), which may be treated as a unit of its own.

The primeval history. The Bible begins with the creation of the universe. It tells the story with images borrowed from Babylonian mythology, transformed to express its own distinctive view of God and man. Out of primary chaos, darkness, void, depths, and waters God creates the heaven and the earth and all that dwell therein—a coherent order of things—by his will and word alone. He says, "Let there be . . ." and there is. Actually, there are two creation accounts: the first (1–2:4), ascribed to P, simply gives a terse day-by-day account including the culminating creation of man, in the divine "image and likeness," followed by the primordial sabbath on the seventh day. The other (2:4–25), ascribed to J, starts with an arid wasteland and the creation of man (Adam), described specifically as being formed by God out of dust and made into a living thing by God blowing the breath of life into him. He and the woman (Eve) created for him out of his rib are put into a paradisal garden (Eden), especially created for them to till and to tend and to sustain life. The two are forbidden only to eat of the tree of the knowledge of good and evil on pain of death (there is also a tree of life in the middle of the garden). The cosmic setting and concern of the P account is thus followed by the human setting and concern of the J account. Creation is followed by temptation, disobedience, and fall and all that follows from that for the history of mankind. At the instigation of the serpent, the shrewdest of the beasts, who holds out the possibility of attaining godlike knowledge, the woman eats of the fruit of the tree of knowledge and gives some to her husband to eat also. Their distinction from beasts and children manifests itself immediately by a sense of modesty about exposing their bodies, and loincloths become the first products of the higher knowledge. The primal human couple are punished by God for their disobedience by being driven out of the idyllic garden into the world of pain, toil, and death.

The eating of the forbidden fruit

The reason given by YHWH to the divine beings is: "Behold, the man has become like one of us, knowing good and evil; and now, lest he put forth his hand and take also of the tree of life, and eat, and live for ever." These words apparently point back to the polytheistic mythology (the existence of divine, magical powers; the gods' jealousy of mankind; the tree of eternal life; etc.) from which the Yahwist drew his images and symbols explaining man's suffering, frustration, and limitation. In the biblical framework and rendering (and subsequent interpretation), the archaic stories and images acquire a different meaning, suitable to the idea of a transcendent deity and an imperfect mankind.

With the exile from the garden, human history and culture begins. In the story of Adam's sons, Cain and Abel, man has already become a herdsman and farmer, and also a murderer: again probably a reflection of older mythical material and, again, one that puts an emphasis on human sin and estrangement from God. In the story of the Flood that follows there are evident borrowings from the Mesopotamian stories of a flood sent by the gods to destroy mankind, but in the biblical account it is emphasized that man's extreme wickedness is the cause and that Noah is saved along with his family by God's deliberate choice because he is a righteous man. (In the flood story in the Babylonian Gilgamesh epic, by contrast, there is no apparent moral reason why the gods resolved to destroy mankind, and the only reason why the hero of the Flood and his kin are saved is that he is favoured by one of the gods, who tricks the others, including the chief god.) After the Flood, God blesses Noah and bestows on man the earth and the things on it for sustenance and makes a covenant with Noah and all creatures that he will never again unleash a world-destroying flood. The permanent order of the world is assured, and God's blessing and covenant make their first explicit appearance in the Bible.

The Flood and the Tower of Babel

In the story of the Tower of Babel, the final story in the primeval history, a primal unity of mankind in which there is only one language is shattered when, in their pride, men decide to build a city and a tower that will reach up to the heavens. YHWH again takes steps to check dangerous collaboration: He says (to the celestial council), "Come, let us go down, and there confuse their language, that they may not understand one another's speech," and scatters them over the earth. Again, the Yahwist has apparently used ancient mythological motifs to explain the diversity of mankind; the story may be regarded as simply a direct borrowing from the older traditions, without any monotheistic adaptation; in its textual setting, however, it may also be taken as another instance of the ruin of primal harmony by human willfulness and pride.

The patriarchal narratives. The universal primal history

The fathers of the Hebrew people

of man in the first 11 chapters of Genesis is followed by an account of the fathers of the Hebrew people; *i.e.,* of the origins of a particular group. From a literary point of view, this portion may be divided into the sagas of Abraham, Isaac, and Jacob and the story of Joseph. Although these narratives are not historical in the ordinary sense, they have an evident historical setting and refer to various particulars that fit in with what is generally known of the time and area. They apparently rest on the traditions of particular families, clans, or tribes and were probably passed down orally before they took written form. Theologically, they are an account of a divine promise and Covenant and of man's faith and unfaith in response, with Abraham as the model man of faith.

The Elohist, as well as J and P, tells the remarkable story of how God singled out Abraham (Abram) to migrate from Mesopotamia and sojourn in Canaan, promised him that he would make him the ancestor of great nations and that his posterity would inherit the land of his sojournings, and singled out as the heirs to the latter promise first Isaac, Abraham's son by his chief wife, Sarah, and then Jacob, the younger of Isaac's two sons; how Jacob acquired the additional name of Israel and how the wives, children, and children's children who, in Jacob-Israel's own lifetime, came to constitute a family of 70 souls, became the nucleus of the Israelite people; and how it came about that this ethnic group, prior to becoming, as promised, the masters of the land of their sojournings, first vacated it to sojourn for a time in Egypt. Apart from the low-keyed P strand, it is mostly splendid narrative, including the Elohist's account of the (aborted) sacrifice of Isaac by his father in response to God's command, a terse story packed with meaning, and the Joseph story about the son of Jacob who is sold into slavery by his brothers, rises to a high post in the Egyptian court, and ultimately helps his family to settle in Egypt. The 12 sons of Jacob-Israel are eponymous ancestors of Israelite tribes (ancestors after whom the tribes are named); the actions and fortunes of the eponymous ancestors, including certain blessings and other pronouncements of Jacob-Israel, account for the future positions and fortunes of the particular tribes. Though there is less history and more legend, much of the atmosphere of an older age is preserved, with the patriarchs represented as seminomadic, essentially peaceful and pastoral tent dwellers—alien residents—among the settled Canaanites and as observing customs otherwise only attested in Mesopotamia. Anachronistic features, however, insinuate themselves from time to time

The God of the patriarchs

The God of the patriarchs is presented as Yahweh—explicitly by the Yahwist and implicitly by E and P—*i.e.,* as the same God who would later speak to Moses. God apparently was originally the personal, tutelary deity of each of the patriarchs, called by a variety of names and later unified into the one God of Abraham, Isaac, and Jacob. There are various cult legends in this portion of Genesis, etiological accounts of the origins of various cult sites and practices; though probably of Canaanite origin, these all indicate the places and customs held holy by the Israelites and perhaps also by their claimed Hebrew ancestors. There are direct appearances of God to some of the main figures in the narratives, intimate personal communication between men and God. God's particular blessing upon and Covenant with Abraham is the paradigmatic high point, to be referred back to continually in later biblical and post-biblical traditions.

Exodus. The title (in the Greek, Latin, and English versions) means "a going out," referring to the seminal event of the liberation of Israel from Egyptian bondage through the wondrous acts and power of God. The book celebrates and memorializes this great saving event in song and story and also the awesome revelation and covenant at Mt. Sinai. The contents of the book may be summarized thus: (1) Israel in Egypt, (2) the Exodus and wanderings, (3) the Covenant at Sinai, (4) the apostasy of the people and renewal of the Covenant, and (5) the instructions on building the Tabernacle and their execution.

The God of the Exodus

Redemption and revelation. Significant in the early chapters is God's special concern for the Hebrew slaves, his reference to them as "my people," and his revelation to Moses, the rebel courtier whom he has picked to be their leader, that he is YHWH, the God of their fathers, an abiding presence that will rescue them from their misery and bring them into Canaan, the land of promise. This assurance is repeated at the critical moments that follow (*e.g.,* "And I will take you for my people, and I will be your God"). In the series of frustrations, obstacles, and redeeming events that are narrated, God's special causal power and presence are represented as being at work. God hardens the Pharaoh's heart, sends plagues that afflict the Egyptians but spare the Hebrews, causes the waters to recede in the Sea of Reeds (or Papyrus Marsh) to permit passage to the fleeing Israelites and then to engulf the pursuing Egyptians ("the horse and his rider he has thrown into the sea"), and gives the people guidance in their wandering in the wilderness. The cryptic "name" that God gives to himself in his revelation to Moses (*'ehye 'asher 'ehye*), often translated "I am that I am" or "I will be what I will be," may also be rendered "I will cause to be that which I will cause to be." In either case, it is a play on, and an implied interpretation of, the name YHWH.

The constancy of God's directive power and concern is displayed notably in the period (40 years) of wilderness wandering (on the eastern and southern borders of Canaan), when Israel is tested and tempered not only by hardship but also by rebellious despair that looks back longingly to Egyptian bondage (see also below *Numbers*). God sends the people bread from heaven (manna) and quail for their sustenance (J and P strands) and, through Moses, brings forth hidden sources of water (JE strand). When the Amalekites (a nomadic desert tribe) attack, Moses, stationed on a nearby hill, controls the tide of battle by holding high the rod of God (a symbol of divine power), and when the enemy is routed he builds an altar called "The Lord is my banner" (E strand). Also inserted here is the account (E) of the visit of Moses' father-in-law, Jethro, a priest of another people (Midianite) who, impressed by YHWH's marvellous deliverance of Israel, blesses, extols, and sacrifices to him—under the name Elohim, but in the context the same God is clearly meant.

The Covenant at Mt. Sinai

God's power and presence manifest themselves impressively in the culminating account of the Covenant at Mt. Sinai (or Horeb). The people, forewarned by God through Moses, agree beforehand to carry out the terms of the Covenant that is to be revealed, because God has liberated them from Egypt and promises to make them his special holy people; they purify themselves for the ensuing Covenant ceremony, according to God's instructions. Yahweh appears in fire and smoke, attended by the blare of a ram's horn at the top of the mountain, where he reveals to Moses the terms of the Covenant, which Moses then passes on to the people below. Here follow in the text the Ten Commandments and the so-called Covenant Code (or Book of the Covenant) of lesser, specific ordinances, moral precepts, and cultic regulations, accompanied by a promise to help the people conquer their enemies if they will serve no other gods. After this comes the Covenant ceremony with burnt offerings and the sacrifice of oxen, with the blood of the animals thrown both on the altar and on the people to sacramentally seal the Covenant, followed by a sacral meal of Moses and the elders at the mountaintop, during which they see God. Many modern scholars hold that this is presented as the initial form of a Covenant renewal ceremony that was repeated either annually or every seven years in ancient Israel.

The stone tablets inscribed by God and Moses

There are certain problems and apparent discrepancies in this account that are explained by critical scholarship as deriving from the combination of different sources, mainly J and E, traditions, or emphases. In the opening portion (chapter 19) the people are gathered at the foot of the mountain so as to hear and meet God, and Moses himself brings down to them God's words. In a later portion (24:12–18, also 32:15–20), after the sacral meal, Moses goes up on the mountain to receive "the tables of stone, with the law and commandments," inscribed by God himself, and returns with two stone tablets written on both sides by the hand of God—which he breaks in anger at the people's worship of the molten calf that has developed in his absence. Later (chapter 34), at God's command, Moses

cuts two new stone tablets, upon which after hearing God's various promises and exhortations, he writes "the words of the covenant, the ten commandments"; finally, he brings the new tablets down to the people and tells them what YHWH has commanded. There seem to be two parallel accounts of the same event, woven together by the skillful redactor into a continuing story. There also seem to be two distinct strands in the account of the sealing of the Covenant in the first 11 verses of chapter 24. According to one, the elders are to worship from afar, and only Moses is to come near YHWH; in the other strand, as noted, the elders eat the sacred meal on the mountaintop in the direct presence of God.

Legislation. The book of Exodus includes not only the narrative and celebration of God's redemptive action in the Exodus and wanderings and his revealing presence at Mt. Sinai but also a corpus of legislation, both civil and religious, that is ascribed to God and this revelation event. The Covenant Code, or Book of the Covenant, presented in chapters 20–23, immediately following the Decalogue (Ten Commandments), opens with a short passage on ritual ordinances, followed by social and civil law applying to specific situations (case law), including the treatment of slaves, capital crimes, compensation for personal injuries and property damage, moneylending and interest, precepts on the administration of justice, and further ritual ordinances. Scholars generally date this code in the later agricultural period of the settlement in Canaan, but some hold that it is analogous to more ancient Near Eastern law codes and may go back to Moses or to his time. In any case, it seems to be a compilation from various sources, inserted into and breaking the flow of the narrative.

Instructions on the Tabernacle. Also interspersed in the story (chapters 25–31) are God's detailed instructions to Moses for building and furnishing the Tabernacle, the clothing and ordination of priests, and other liturgical matters. According to this segment (evidently P in inspiration), an elaborate structure is to be set up in the desert, in the centre of the camp, taken apart, transported, and assembled again, like the simple "Tent of Meeting" outside the camp, where Moses received oracular revelations from God. Indeed, the two concepts seem to have fused and the Tabernacle is also called the Tent of Meeting. Its prime function is to serve as a sanctuary in which sacrifices and incense are offered on altars and bread presented on a table; it is also equipped with various other vessels and furnishings, including a wooden ark, or cabinet, to contain the two tablets of the Covenant—the famous ark of the Covenant. It is, moreover, to be the place of God's occasional dwelling and meeting with the people. Scholars believe that the elaborate details and materials described stem from a later, Canaanite, period but that the essential concept of a tent of meeting goes back to an earlier desert time. An account of the execution of the instructions for the building of the Tabernacle is presented in chapters 35–40 (following the apostasy, tablet breaking, and Covenant-renewal episodes), which duplicates to the letter the instructions in chapters 25–31. After the Tabernacle is completed and consecrated, it is occupied by the "glory," or presence, of YHWH, symbolized by a cloud resting upon it. It is on this note that the book of Exodus ends.

The portable "Tent of Meeting" and elaborate sanctuary

Leviticus. The cultic and priestly laws presented in Exodus are expanded to take up virtually the whole of Leviticus, the Latin Vulgate title for the third of the Five Books of Moses, which may be translated the Book (or Manual) of Priests. With one exception (chapters 8–10), the narrative portions are brief connective or introductory devices to give an ostensibly narrative framework for the detailed lists of precepts that provide the book's content. The source of Leviticus, both for the legal and narrative passages, is definitely identified as P; it is the only book in the so-called Tetrateuch to which a single source is attributed. Apparently the book consists of materials from various periods, some of them going back to the time of Moses, which were put together at a later date, possibly during or after the Babylonian Exile. Recent scholarship tends to emphasize the ancient origin of much of the material, as opposed to the previous tendency to ascribe a late, even post-exilic date. Despite its content and its dry, repetitive style, many interpreters caution against taking Leviticus as merely a dull, spiritless manual of priestly ritual, holding that it is strictly inseparable from the ethical emphasis and spiritual fervour of the religion of ancient Israel. It is in Leviticus that the so-called law of love, "You shall love your neighbour as yourself," first appears. The rituals set forth drily here probably presuppose an inward state in offering to God, as well as humanitarian and compassionate ethics.

The book may be divided thus: chapters 1–7, offerings and sacrifices; chapters 8–10, inauguration of priestly worship; chapters 11–16, purification laws; chapters 17–26, holiness code; chapter 27, commutation of vows and tithes.

Offerings, sacrifices, and priestly worship. The first verse attributes these regulations to YHWH, who speaks to Moses from the Tent of Meeting, beginning with the rules for offerings by the individual layman. These include burnt, cereal, peace, sin, and guilt offerings, all described in precise details. The prescription for priestly offerings is about the same, with some slight differences in the order of actions, and is presented much more briefly. In chapters 8–10 the narrative that was interrupted at the end of Exodus is resumed, and the ordination of Aaron and his sons by Moses, before the people assembled at the door of the Tent of Meeting is described, as are various animal sacrifices by Aaron and his sons under Moses' direction and the subsequent appearance of God's "glory" to the people. Aaron's two older sons are burned to death by fire issuing forth from God because they have offered "unholy fire." This story apparently emphasizes the importance of adherence to the precise cultic details, as does also the account (at the end of the chapter) of Moses' anger at Aaron's two remaining sons for not eating the sin offering. These stories were apparently used by the priestly authors to buttress the authority of the Aaronic priesthood.

The Aaronic priesthood

Purification laws. With chapter 11 begin the regulations on ritual cleanness and uncleanness, starting with animals and other living things fit and unfit to eat—the basis of the famous Jewish dietary laws. Then come the uncleanness and required purification of women after childbirth, skin diseases, healed lepers, infected houses, and genital discharges. Chapter 16, which belongs in the narrative flow immediately after chapter 10, describes the priestly actions on the Day of Atonement, the culmination of ritual cleansing in Israel. It is a chapter rich in details on Israelite ritual and bound up with the salient religious theme of atonement.

The Holiness Code. Next (chapters 17–26) comes what has been designated the "Holiness Code," or "Law of Holiness," which scholars regard as a separate, distinctive unit within the P material (designated H). It calls upon the people to be holy as God is holy by carrying out his laws, both ritual and moral, and by avoiding the polluting practices of neighbouring peoples; and it proceeds to lay down laws, interspersed with exhortations, to attain this special holiness. Although many scholars tend to date its compilation in the exilic period, some see evidence that it was compiled in pre-exilic times; in any case, the consensus is that the laws themselves come from a much earlier time.

These—a most miscellaneous collection—begin with injunctions on the proper (kosher) slaughtering of animals for meat; go on to a list of precepts against outlawed sexual relations (incest, homosexuality) and an injunction against defiling the (holy) land; proceed to a list of ethical injunctions, including the law of love and kindness to resident aliens, all interspersed with agronomic instructions and warnings against witchcraft; and then, after an injunction against sacrificing children, return to the listing of illicit sexual relations and the warning that the land will spew the people out if they do not obey the divine norms and laws. There follow special requirements for preserving the special holiness of priests and assuring that only unblemished animals will be used in sacrifices; instructions on the observance of the holy days—the sabbath, feasts, and festivals; commands on the proper making of oil for the holy lamp in the Tent of Meeting and of the sacred shewbread, to which are appended the penalties for blasphemy and other crimes; and finally, rules for observance

of the sabbatical (seventh) and jubilee (50th) years, in which the land is to lie fallow, followed by rules on the redemption of land and the treatment of poor debtors and Hebrew slaves.

Punishment and atonement for iniquity

This miscellany, presented in chapters 17–25, is followed by a final exhortation, in chapter 26, promising the people that if they follow these laws and precepts, all will go well with them but warning that if they fail to do so all kinds of evil will befall them, including exile and the desolation of the Promised Land. Yet, if they confess their iniquity and atone for it, God will not destroy them utterly but will remember his Covenant with their forebears. Such a passage points to a later time but not necessarily to the exilic period, as some commentators have assumed. The chapter concludes: "These are the statutes and ordinances and laws which the Lord made between him and the people of Israel on Mt. Sinai by Moses," connecting these precepts with the primal revelation in Exodus.

Commutation of vows and tithes. In the final chapter of Leviticus (27), the P material is resumed with a presentation of the rules for the commutation of votive gifts and tithes. It provides for the release from vows (of offerings of persons, animals, or lands to God) through specified money payments. Some commentators understand the vow to offer persons to refer originally to human sacrifice, others as pledging their liturgical employment in the sanctuary. Special provisions are made for the poor to relieve them from the stipulated payments. Only grain and fruit tithes, not animal tithes, are redeemable. This chapter and the book of Leviticus end, like chapter 26, with the verse, "These are the commandments which the Lord commanded Moses for the people of Israel on Mount Sinai."

Numbers. In the Hebrew Bible this book is entitled Bemidbar (In the Wilderness) after one of its opening words, while in English versions it is called Numbers, a translation of the Greek Septuagint title Arithmoi. Each of the titles gives an indication of the content of the book: (1) the narrative of "40 Years" of wanderings in the wilderness, or desert, between Sinai and Canaan; and (2) the census of the people and other numerical and statistical matters, preceding and interspersing that account. It is a composite of various sources (J, E, and predominantly P) and traditions, which as a whole continue the story of God's special care and testing of his people in the events of the archaic period that formed them. Numbers continues the account of what many modern scholars call the "salvation history" of Israel, which apprehends and narrates events (or the image and impact of events) as involving divine action and direction.

The wilderness wanderings and the census of the people

The book may be divided into the following sections: (1) the conclusion of the Sinai sojourn (1:1–10:10), covering 20 days; (2) the wanderings in the desert of Paran (10:11–20:13), covering 38–40 years; and (3) the events in Edom and Moab (20:14–36:13), covering five months.

The conclusion of the Sinai sojourn. The book opens with a command from God to Moses, early in the second year after the Exodus, to take a census of the arms-bearing men over 20 in each of the clans of Israel. Moses and Aaron, aided by the clan chiefs, take the count, clan by clan, and reach a total of 603,550 men—according to critical scholars, an unbelievably large total for the time and conditions. The Levites, to whom is entrusted the care of the Tabernacle and its equipment, are exempted from this secular census and are counted in a later census, of males one month and over, along with a census of firstborn males from other tribes. The Lord had required that the latter be consecrated to him when he slew all the firstborn of the Egyptians but spared those of the Israelites; now the bulk of them were released by the Levites being taken in their stead to minister to the priests, while for the excess of firstborn over Levites "redemption" payments were collected. A further census of men 30–50 years old is taken among the Levite clans, so as to assign them their various duties, which are here stipulated. Also specified are the positions of the tribes (separated into four divisions of three tribes each) in the camp and on the march, with an assignment of specific portions of the Tabernacle and its equipment to be carried by the Levite clans. YHWH is to give the signal to break camp by lifting the cloud by day or the fire by night from above the Tabernacle and then to advance it in the direction the people are to march. YHWH's signal is to be followed by a blast by the priests (Aaron's sons) on two specially made silver trumpets.

YHWH's signal: a cloud by day and a fire by night

The above directions are set forth in chapters 1–4 and 9–10 (through verse 10). There are intervening chapters containing various materials: expelling leprous or other unclean persons from the camp, the ordeal for a woman suspected of adultery, regulations for Nazirites (those who take special ascetic vows), the offerings brought at the dedication of the Tabernacle, and the purification of the Levites preparatory to taking up their special sacred functions. The priestly emphasis of the materials in chapters 1–10 is evident, and it is also clear that there are various strands of priestly interpretation involved.

Wanderings in the desert of Paran. This section apparently combines various traditions of how the Israelites came into Palestine, and J, E (or JE), and P sources have been discerned in these chapters. The traditional "40 years" in the wilderness (38 or 39, according to critical calculations) were spent mostly in the wilderness of Paran, with a short stay in the oasis of Kadesh, according to P; while, according to J, they spent most of their time in Kadesh; and chapter 13, verse 26, puts Kadesh in the wilderness of Paran, thus encapsulating both traditions. The discrepancy may stem from two separate traditions of how the tribes entered Canaan: from the south or from the north through Transjordan.

The P narrative begins (chapter 10, verse 11) with the lifting of the cloud from the Tabernacle and the setting out of the Israelites for the Promised Land, with their holy Tabernacle and ark, in the order prescribed in chapter 2. According to the P account (verses 11–28), the cloud settles down over the wilderness of Paran, the signal to make camp; whereas in the JE account (verses 29–36) it is the ark of the Covenant that goes ahead to seek out a stopping place, and where it stops the Israelites rest, the cloud simply accompanying them overhead (perhaps to shield them from the blazing desert sun). Chapters 11–12 (JE) deal with the complaints of the people about their hardships and the rebellion of Miriam and Aaron against their brother Moses. When the people express their longing for the good food they had in Egypt and their disgust with the unvarying manna, God sends them a storm of quail, which remain uneaten because he also sends them a plague. This is a somewhat different account from that in Exodus, but the point is the same: the mighty, infinite power of God (chapter 11, verse 23). (Also inserted here is the story of God visiting his spirit on 70 selected elders so that they may share Moses' burdens.) When Miriam and Aaron question God's speaking only through Moses, God proclaims his unique relation with Moses, who alone receives direct revelations from God, not indirectly through dreams and visions, like the prophets.

Chapters 13–14 tell of the despatch of spies from Paran to reconnoiter Canaan and of the despair, rebellion, and unsuccessful foray of the people in response to the spies' reports. Scholars discern two separate accounts of the spying incident artfully woven together. According to the JE account, the spies go only as far as Hebron in the south and return with a glowing report of a fertile land, which is, however, they warn, too strongly defended to be taken from that quarter: only one spy, Caleb, advocates attacking it. In the P account the spies reconnoiter the whole country and give a pessimistic report of it as a land that "devours its inhabitants," who are, moreover, giants compared to the Israelites. The people cry out in despair at this report and want to go back to Egypt, while Caleb and Joshua (added by P) plead with them to trust in God and go forward to take the land. God, disgusted with the people, condemns them to wander in the wilderness for 40 years and decrees that only their children, along with Caleb and Joshua, shall enter into the land of promise. Ruefully, the people now decide to attack and go forth, against Moses' warning, to a resounding defeat.

The spies' report and the people's rebellion

Chapter 15 is a P document or addition, setting forth various ritual regulations. Chapters 16–18 deal with the comparative rights and duties of priests and Levites. Chapter 16 is a composite document dealing with revolts

against Moses and Aaron by certain Levites who question their special authority in a community where all are holy, as also by certain Reubenites who resent Moses' leadership. The dispute is settled when 250 revolting Levites attempt to offer incense (a priestly Aaronic function) and are consumed by fire sent by God, while the leaders of the revolt are swallowed up in the earth. Yet the stubborn people continue their complaint against Moses and Aaron, bringing forth the Lord's anger and a plague, from which they are saved by Aaron's (proper and effective) offering of incense. This latter incident occurs in chapter 17 in the Hebrew text and Jewish translations but concludes chapter 16 in some Christian versions. Chapter 17 in both arrangements, with its story of Aaron's rod, associates Levitical with Aaronic authority; Aaron's name is inscribed on the staff of Levi, which alone among the staffs of the chiefs of the tribes of Israel blossoms and bears fruit, thus authenticating Aaron's, and thereby the Levites', special claims. The relative functions and payments (tithes) of priests and Levites are prescribed in chapter 18. Chapter 19, inserted here, has to do with purification from uncleanness incurred through touching the dead, accomplished through washing in water mixed with the ashes of a red heifer.

Events in Edom and Moab. Chapter 20, verse 14, resumes the narrative of Israel's onward march, starting with their arrival in the wilderness of Zin and stay at Kadesh, marked by Miriam's death and God's exclusion of Moses and Aaron from entering the Promised Land because of their ascribed lack of confidence in God when Moses drew forth water from a rock in response to still more Israelite complaints, but did so in anger and impatience, striking the rock twice with his rod, instead of telling it to give forth water, as the Lord had instructed (the incident of the waters of Meribah). Refused permission by the King of Edom to pass through that land, over the much-used King's Highway, they proceed from Kadesh to Mt. Hor, where Aaron dies and is succeeded by his son Eleazar, and from which they proceed (chapter 21) to bypass Edom in an attempt to approach Canaan from the east. Arrived at the border of what was geographically part of Moab but politically the Amorite kingdom of Sihon, they are refused passage and proceed to defeat the Amorites and take possession of their land. This is from the JE strand of the composite narrative; the P strand does not recognize the existence of settled and politically organized populations between Kadesh and the plains of Moab.

Balaam, the pagan prophet of YHWH

At this point, in chapters 22–24, apparently a very mixed composite of various J and E strands, is presented the fascinating story (or collection of stories) of the non-Israelite seer, or prophet, Balaam, from the region of the Middle Euphrates. Alarmed at the Israelite host encamped at his border, the King of Moab commissions the seer Balaam to put a curse on them, but Balaam refuses, at the order of YHWH, who is also the God of Balaam. On three occasions at the King's request Balaam seeks an oracle from God against Israel, but each time, to the King's rage, he is told by the Lord that Israel is graced with the divine blessing and cannot be cursed. The seer, who is ordered back to his own country, without payment by the disgruntled King, offers a final, unsolicited oracle prophesying the destruction of Moab and other nations by Israel's might: "I will let you know what this people will do to your people in the latter days."

Chapter 25 (combining JE and P strands) provides a lurid interlude in which the Israelites go whoring after Moabite women and offer sacrifices and worship to their god, Baal of Peor. Phinehas, the son of Eleazar, is so incensed at the sight of an Israelite consorting with a Midianite woman that he kills them both, thus ending a plague that has broken out and earning God's special favour: a covenant of perpetual priesthood with him and his descendants (a forward reference to the Zadokite priesthood of post-exilic times). This account is connected by the last two verses with God's call for Israel to harass and smite the Midianites (see below). After the plague ends, in the account (P) in chapter 26, a second census of arms-bearing men and of the Levites is taken, and again a fantastically large total, 601,730, is given, perhaps referring to a much later time. It is noted at the end that all of the previous 603,730 had died in the wilderness, as prophesied, except for Caleb and Joshua, who have been especially picked out by God. This census, coming at the end of the 40-year period of wilderness wanderings, is for the purpose of allotting lands to the various tribes and families. Hence the logical positioning of the passage (P) in the first 11 verses of chapter 27 assuring that a family may inherit through a daughter when there is no son and through a brother when there are no children and through the closest relative when there are neither.

At this point (chapter 27, verse 12) comes the impressive and poignant passage (also P) in which Moses ascends the heights, at God's bidding, to look over the Promised Land, which he is not to enter, and calls on God to appoint a leader to succeed him. At God's command, Moses selects Joshua, and before the priest Eleazar and the whole community he lays his hands on him and commissions him to lead Israel. It is noteworthy that Joshua is invested only with some of Moses' authority and is to learn God's will through Eleazar and the sacred lot (Urim), not directly, as did Moses.

Sacrificial rules for holy days

Again, the narrative is interrupted by three chapters (P) dealing with various religious regulations. Chapters 28–29 stipulate the sacrifices to be made by the whole community daily, on the sabbath, at the new moon, and on these holidays: the Feast of Unleavened Bread (Passover), the Feast of Weeks (Shavuot), The Feast of Trumpets, *i.e.*, New Year (Rosh Hashana), the Day of Atonement (Yom Kippur), and the Feast of Tabernacles (Sukkot). The last two verses of chapter 29 specify that these public offerings are in addition to individual offerings, such as those specified in chapter 15. Critical scholars hold that these elaborate regulations stem from a much later (post-exilic) period, though they may go back to very ancient practices. Some see them as a liturgical commentary on chapter 23 of Leviticus, which presents the cycle of feasts and festivals (see above *Leviticus*). Chapter 30 gives women special exemption from keeping vows (presumably of offerings or abstinence) when countermanded by a father or husband; only widows or divorcees are bound, like men, unconditionally to keep their vows.

Chapter 31, likewise from P, deals with the annihilation of the Midianites following God's command at the end of chapter 25. The Israelites, a thousand from each tribe, go forth to battle led by the priest Eleazar, who carries the sacred vessels and the trumpets. They kill every man and seize all the movable property but spare the women and children. Moses, however, orders every male child and all nonvirgin women killed. There follow instructions for purification for the stain caused by killing a person or touching a dead body and for the distribution of the booty, which includes sheep, cattle, asses, and 32,000 virgins. The rules are that half of the spoils go to the fighting men, half to the rest of the people; in addition, the Lord's share is allotted thus: one five-hundredth of the fighting men's portion goes to the priest, and one-fiftieth of the people's portion goes to the Levites. Scholars are inclined to treat this chapter as a piece of fiction intended really to set forth the rules for purification and dividing the spoils through an invented story. The seer-diviner Balaam is here (verse 16) blamed for the whoring and apostasy incidents in chapter 25; but texts providing his connection with these events are lacking.

Special settlement of Reuben and Gad east of the Jordan

Chapter 32, dealing with the settlement east of the Jordan, concludes the narrative portion of Numbers and thus of the Tetrateuch (a story that is continued in chapter 34 of Deuteronomy and in the Book of Joshua). This very composite account (JEP) tells how the tribes of Reuben and Gad, after an initial angry remonstrance from Moses, are granted permission to settle in the rich pasturelands east of the Jordan on the assurance that after they erect sheepfolds and fortified towns for their flocks and families, they will provide the shock troops spearheading the advance of the Israelites into Canaan, and will not return to their homes until their brethren hold the land. Thereupon Moses allots the various conquered kingdoms and towns east of Jordan to the Gadites and Reubenites. The various Gadite, Reubenite, and Manassite towns are listed.

The rest of the book of Numbers (P in its final form)

consists of an itemized summary of the route from Egypt to the plains of Moab outside Canaan (chapter 33) and various additional materials (chapters 34–36). Verses 50–56 of chapter 33 present the divine command to dispossess the people of Canaan, destroy their idols and cultic places, and apportion the land to each clan by lot. In chapter 34 the Lord specifies the boundaries of the whole land of Canaan that is to be Israel's inheritance and names the tribal leaders who, along with Eleazar and Joshua, are to oversee the division of the land by lot. In chapter 35, the Lord orders 48 towns with extensive pasturelands to be set aside for the Levites; six of these are to be cities of refuge for manslayers whose guilt of intentional murder has not yet been determined and who are provided sanctuary from the traditional blood vengeance. Although these settlements do not constitute an independent tribal territory but are scattered through the territories of the other tribes, the contradiction with chapter 18, verse 24, of Leviticus, commanding that the Levites are to have no share of the land but are to subsist solely on tithes, is obvious and raises critical questions. Finally, chapter 36 concludes the book of Numbers with a supplement to the law of inheritance through daughters laid down in chapter 27, enjoining daughters from marrying outside the tribe, so that the tribe will hold its portion of the land, which was given from God, in perpetuity. As before, the general injunction is laid down in a story dealing with a particular case (the daughter of Zelophehad).

Deuteronomy. *Special nature and problems.* The English title of this work, meaning "second law," is derived from a faulty Greek translation of chapter 17, verse 18, referring to "a copy of this law": the implication being that the book is a second law or an expanded version of the original law for the new generation of Israelites about to enter Canaan. Hebrew texts take the opening words of the book as title, Ele ha-Devarim (These Are The Words), or simply Devarim (Words). As noted in *Composition and authorship,* above, the book is in a class by itself in the Pentateuch, so much so that modern scholars tend to consider it apart from the other four books, and some see it in style, content, and concerns more closely related to the succeeding books of Joshua, Judges, Samuel, and Kings, constituting a "Deuteronomic history." In spite of its homogeneous style and tone—it is assigned for the most part to a single source, D—the content indicates to critical scholars very composite traditions, ages, and situations behind the finished form. This book has elicited a library of scholarship going back to the early 19th century, not only because of the complicated critical and historical problems calling for solution but also because of its spiritual and theological message, which gives it a special place among Old Testament writings.

In form, the book is ostensibly a discourse by Moses "to all Israel" in the final month in Moab before they go over the Jordan into Canaan. Actually it comprises three separate discourses, a set of laws, two poems, and various other matters, all ascribed to Moses directly—here it is Moses who sets forth the laws, not God through him. These materials are centred on the presentation of the rules of life and worship for the coming stay in the Promised Land, along with exhortations and explanations pointing to YHWH, the marvellous liberator from Egypt and guide in the wilderness, as the divine source and reason for the commands. The traditional view was that, with the possible exception of the account of Moses' death, the whole book was written by Moses, based on the phrase "And Moses wrote this song" in chapter 31, verse 22.

Deuteronomy identified with Josiah's "book of the law"

Some early Church Fathers identified the book with "the book of the law" (II Kings, chapter 22, verse 8), found in the 18th year of King Josiah's reign (*c.* 621 BCE), and made the basis of his great religious reform the following year. Wilhelm M.L. de Wette, a German biblical scholar, in 1805 established the predominant modern view that Deuteronomy (or its nucleus, or main portion) was found in Josiah's time and was a distinctive book, separate from the Tetrateuch. He also held that it was composed shortly before its discovery; other, more recent, scholars would put it as much as a century earlier and connect it with earlier reforms, while some associate it with the writings and teachings of the 8th-century-BCE prophet Hosea and with the E source. Furthermore, the references to localities near Shechem as cultic places, taken with certain passages in Joshua, indicate a northern provenance for the book and not the southern source connected with a cultic centre at Jerusalem, as had been previously supposed from the associated material in II Kings. Some scholars see the form and occasion of Deuteronomy as a Covenant renewal ceremony in which the whole law is read, as in Joshua, chapter 8, verses 30–35, and thus view it as a liturgical document, as well as a lawbook. In any case, the tendency is to see various layers of materials and lines of transmission, perhaps going back to quite early preliterary sources, before its final formation in the 8th or 7th century BCE.

The book may be divided as follows: (1) introductory discourse to the whole book (chapter 1 to chapter 4, verse 43); (2) introductory discourse to the lawbook (chapter 4, verse 44, through chapter 11); (3) the lawbook (chapters 12–28); (4) concluding exhortation and traditions about the last days and death of Moses (chapters 29–34).

First introductory discourse of Moses. The first introductory discourse, spoken by Moses, traces the journey of the Israelites from Mt. Horeb to Moab, with some noticeable differences in detail from the account in Exodus and Numbers and an emphasis on Moses being banned from entrance into the Promised Land because the Lord was angry at the Israelites. To this historical retrospect is appended an exhortation to the people to obey God's laws and norms, recalling the imageless God of the revelation and Covenant at Horeb as a warning against making images and serving man-made gods. The uniqueness and soleness of the God of the Exodus and Covenant, his power and presence in his marvellous acts of redemption and revelation, and his gracious selection of Israel are proclaimed in rhetorical questions; moreover, it is emphasized that the God of Israel ("YHWH your God") "is God in heaven above and on the earth beneath; there is no other." The injunctions against idolatry appear to come from later experience and religious crisis in Canaan. The fact that other nations have their own gods and objects of worship is recognized elsewhere in Deuteronomy.

The Shema: "Hear, O Israel"

Second introductory discourse. The second discourse, also ascribed to Moses, again refers to the Covenant at Horeb and sets forth the Ten Commandments, which the people are admonished to obey rigorously, emphasizing the mediating function of Moses at Horeb between the awesome divine presence and the awestruck people. Israel is further admonished to obey the law through wholehearted love of God, expressed in what became the central liturgical expression of Israel's faith, beginning, "Hear, O Israel: The Lord is our God, the Lord Alone. You must love the Lord your God with all your heart and with all your soul and with all your might." If they obey God's laws, avoid other gods, and do what is right and good, they will possess the land promised by God—him who rescued them from Egypt and has brought them thus far. They are to avoid marriage and all other intercourse with the peoples of the land, utterly destroying them and their idolatrous altars and cultic places, for they are a special, holy people chosen by God out of all the peoples because of his love, not because of their greatness or power. This marvellous love will continue to be exercised, and the people will be blessed with all good things—prosperity, fertility, health, and success in battle—if they obey God's ordinances. They are urged to remember the 40-year period of wilderness wandering, in which they were tested (disciplined) by God through hardship and hunger (to find out whether or not they would keep his commands) and saved by him: man does not live by bread alone but, rather, by whatever God provides (*e.g.,* manna from heaven). Another time of testing will come when they live in the rich, fertile land of Canaan and eat their fill and perhaps forget the Lord and his laws, ascribing their wealth to their own power and might and even venturing into idolatrous worship of the gods of the land. If they do so they shall perish, just as the idolatrous nations of the land shall.

A long list of the apostasies of Israel is presented in chapter 9 to demonstrate the point that Israel is going in to possess the land of Canaan not through any virtue of

their own but because of God's promise to the patriarchs. This is followed in chapter 10 by a moving declaration of what God requires of Israel—fear (reverence), walking in his ways, love, wholehearted service, and keeping his commandments—and an extolling of the wondrous, unique, powerful God who liberated them from Egypt. Chapter 11 extols the richness of the land of Canaan and describes how it will bloom for them if they are observant of God's commandments and promises that they will hold the territory from the wilderness to Lebanon and from the Euphrates to the western sea (Mediterranean). It closes with the choice set before them by Moses of "a blessing and a curse"—the former if they obey the commandments, the latter if they do not. This choice is posed to them immediately before the presentation of the laws and norms beginning in chapter 12.

The lawbook. The laws are the central core and purport of the book of Deuteronomy. They are couched in a hortatory, sermonic style that has led to their being categorized as preached law. Emphatic statements of what must or must not be done are connected with exhortations to fulfill these injunctions, pointing to the motivations and spirit in which they should be carried out. There is a wide variety of laws here—ritual, criminal, social—but they are all set within this preaching context and aimed at the service of God. This is no dry legal code but, rather, a book written in fluent and moving prose. Scholars have seen duplications and parallels between the laws presented here and those in the Covenant Code in chapters 21–23 of Exodus; but to this a common source may be ascribed, and Deuteronomy may be considered a work in its own right and not a mere expansion of the Covenant Code.

The basic injunction: a central sanctuary

The lawbook comprises chapters 12–26, supplemented by chapters 27–28. After an initial order to destroy the pagan cultic places and idols, the lawbook goes to its basic injunction: to set up a single central sanctuary in Canaan, where all Israel is to make their offerings, as distinct from the present unregulated practice, "every man doing whatever is right in his own eyes." The spot is designated only "the place which the Lord your God will choose," which some interpreters, following King Josiah, have understood to be Jerusalem and which others understand to be Shechem. (The blessing and curse passage immediately preceding in chapter 11 specifies Mts. Gerizim and Ebal, on either side of Shechem, as the places of blessing and curse, respectively; and an even more elaborate ritual is prescribed for the same locality in chapter 27.) Instructions are given for the proper killing of animals for food, previously connected with the sacrificial cult, and the people are admonished when they settle in Canaan not to inquire about how other nations serve their gods, possibly to follow their abominable practices. Inserted at this point is the striking exhortation, "Everything that I command you you shall be careful to do; you shall not add to it or take from it."

Chapter 13 warns the people to beware of the temptations to apostasy arising from the urging or example of prophet-diviners, kinfolk or friends, or a whole town; they are to kill the tempters and destroy the towns. Chapter 14 is devoted mainly to a list of living things that may or may not be eaten, the "clean" and "unclean," similar to the list in Leviticus, chapter 11; and to laws for tithes and first fruits to be brought annually to the central sanctuary and triennially to the Levites in the towns, who are specified as having no "portion" of their own (two years to the centre, the third year to the town Levites). Chapter 15 deals mainly with the releases to be granted every seventh year to debtors of their debts and Hebrew slaves of their bondage; lenders are exhorted and commanded not to refuse loans to the poor in the sabbatical year of release, and God's redemption of Israel from Egypt is given as the reason for freeing one's Hebrew slaves in the sabbatical release. The first section of chapter 16, verses 1–17, gives the rules for celebrating the three main festivals of the religious year: Unleavened Bread, Weeks, and Booths, which are to be observed at the central sanctuary (hence later called the three pilgrim festivals).

Beginning with verse 18 of chapter 16 there is a discussion of the appointment and character of judges, and of judicial procedures and punishments for apostasy, homicide, and other crimes; similarly, beginning with verse 14 of chapter 17 there are rules on the selection of a king and for his conduct, and the injunction that he read from "a copy of this law," so that he may be edified and chastened. The first portion of chapter 18 deals with the office and support of priests, referred to here as "the Levitical priests . . . all the tribe of Levi," not distinguishing the Aaronic priests from the lesser Levites. This is followed—after a passage inveighing against abominable cultic and divinatory practices of the nations of the land—by a promise that God will raise up prophets among the people and instructions on how to tell true from false prophets. Thus the offices of judge, king, priest, and prophet are considered in chapters 16–18.

Chapter 19 deals again with crime and punishment. It distinguishes between unintentional manslaughter and murder, setting up cities of refuge for the manslayer and ordering the murderer to be killed by the blood avengers. It also lays down the rules for witnesses and the punishment for perjury. It closes with the famous lex talionis: "Life for life, eye for eye, tooth for tooth, hand for hand, foot for foot," which in context may spell out what is to happen to the false witness and even could be interpreted as a moderating, rather than an inhumane, precept (no more than an eye for an eye, etc.). Chapter 20 gives the rules for holy war, listing the situations that exempt men from military service (*e.g.*, a newly married man) and distinguishing the treatment of non-Canaanite and Canaanite cities; the latter are to be utterly destroyed, yet it is forbidden to destroy fruit-bearing trees. There are also rules on holy war in 21:10–14; 23:9–14; 24:5; and 25:17–19. Chapters 20–25 contain a great variety of laws; the just treatment of women captives, sexual offenses, exclusions from the religious community, public hygiene in campgrounds, and many other things.

The lex talionis

The last of the laws are set forth in chapter 26, dealing with the first fruits offering and tithes. At the annual offering (or soon after entering Canaan), in the central sanctuary, the worshipper is to recite a piece beginning, "A wandering Aramaean was my father," affirming his link with the patriarchs and extolling God's wondrous deeds on behalf of Israel. And every third year he is to set aside his tithe "to the Levite, the sojourner, the fatherless, and the widow" and make an affirmation "before the Lord" that he has complied and avoided any ritual stain.

The final passage in chapter 26 proclaims that "this day" God has proclaimed his law, Israel has affirmed its commitment to God and his law, and God has affirmed his choice of Israel as his special, holy people, to be set up high above all the nations. This is the hortatory conclusion to chapters 12–26 and to the "second law," or Covenant, contained therein.

Covenant ratification and renewal ceremonies

The emphasis on the laws given on "this day" is continued in the supplementary chapters 27–28, which deal with Covenant ratification and renewal ceremonies, apparently a reference to an original ceremony in Moab, one in Canaan on the first day in the land, and subsequent, possibly annual, renewal ceremonies. Blessings and curses are to be pronounced from Mts. Gerizim and Ebal for respectively fulfilling or disobeying the Covenant: all good things or all bad things will befall the people, as they keep or fail to keep the Covenant. Some of the curse consequences in chapter 28, referring to siege, subjugation, and exile, are believed by some scholars to reflect late pre-exilic or exilic situations. The curse consequences fill up the bulk of these chapters and are recounted in powerful, moving language, ending with a threat to return the people to Egypt.

Concluding exhortation and traditions about the last days of Moses. Chapters 29–31 comprise the third and last address of Moses to the people of Israel. They are preceded by an introductory verse referring to "these words" as a covenant made in Moab, in addition to the one made at Horeb (Sinai). After reminding them of all that God has done for them, Moses calls on the whole people to enter into the sworn Covenant made this day that they may be his people and he may be their God, warning the secret apostate of the calamities that will befall him. Yet the possibility of a return to God and the land is held out to

those who will suffer exile and persecution as punishment for their apostasy, again presumably a reflection of the exilic situation (chapter 30 verses 1–10 seems clearly to be an interpolation inspired by the actual experience of exile). This law, it is emphasized, is no recondite, remote thing up in the sky but is, rather, very close to men, "in your mouth and in your heart"; what is revealed is made plain, it is not the secret things of God. Moses sets before them the classic Deuteronomic choice: "life and good" over "death and evil." The people are given that choice and told the consequences of loving the Lord and keeping the Covenant or of going the other way.

The last words and acts of Moses

The final chapters are concerned with the last words and acts of Moses: directing Joshua to lead Israel after his death, writing down "this law," calling for a sabbatical renewal ceremony of it on the Feast of Booths, ordering that it be put beside the ark of the Covenant, and uttering two poems. The first, "The Song of Moses" (chapter 32), praises the faithfulness and power of the Lord, decries the faithlessness and wickedness of Israel, and predicts the consequent divine punishment; it adds, however, that in the end the Lord will relent and will vindicate his people. The second poem, "The Blessing of Moses" (chapter 33), blesses each of the tribes of Israel, one by one, and the blessings are associated with God's love, the law commanded by Moses, and the kingship of God over his people. There are indications in both poems of a considerably later date (after Joshua's time, perhaps in the period of the Judges); Moses is spoken of in the third person in "The Blessing" poem.

The narrative of Deuteronomy, and thus of the Pentateuch, ends with Moses' ascent to the top of Mt. Pisgah, his being shown the Promised Land by God, and his death there in the land of Moab, buried by God in an unknown grave. It is emphasized in the closing words that Moses was a unique prophet "whom the Lord knew face to face" and through whom the Lord wrought unique "signs and wonders" and "great and terrible deeds." Thus end the Five Books of Moses. (S.C.)

THE NEVI'IM (THE PROPHETS)

The canon of the Prophets. The Hebrew canon of the section of the Old Testament known as the Nevi'im, or the Prophets, is divided into two sections: the Former Prophets and the Latter Prophets. The Former Prophets contains four historical books—Joshua, Judges, Samuel, and Kings; the Latter Prophets includes four prophetic works—the books of Isaiah, Jeremiah, Ezekiel, and the Twelve (Minor) Prophets. The Twelve Prophets, formerly written on a single scroll, include the books of Hosea, Joel, Amos, Obadiah, Jonah, Micah, Nahum, Habakkuk, Zephaniah, Haggai, Zechariah, and Malachi. Thus, in the Hebrew canon of the Prophets there are, in effect, eight books.

Variations in the canon of the Prophets

The Christian canon of the Prophets does not include the Former Prophets section in its division of the Prophets; instead, it calls the books in this section Historical Books. In addition to Isaiah, Jeremiah, and Ezekiel, the Christian canon of the Prophets includes two works from the division of the Hebrew canon known as the Ketuvim (the Writings): the Lamentations of Jeremiah and the Book of Daniel. The Twelve (Minor) Prophets are separated into individual books. The number of works in the Christian canon, however, varies. The Protestant canon contains all the books of the Latter Prophets and the two books from the Ketuvim, thus listing 17 works among the prophetic writings. The Roman Catholic canon accepts one other book as a canonical prophetic work, namely, Baruch (including the Letter of Jeremiah); the number of prophetic writings in the Roman Catholic canon is, therefore, 18. The Greek Orthodox Synod of Jerusalem in 1672 did not accept Baruch as canonical.

As far as the Former Prophets is concerned, the Protestant canon, following the Septuagint, separates Samuel and Kings into two sections each: I and II Samuel, and I and II Kings. The Roman Catholic and Orthodox churches in the past divided these two works into I, II, III, and IV Kings, but most Roman Catholic translations now follow the listing as it is in the Septuagint.

Hebrew prophecy. Hebrew prophecy was rooted in the prophetic activities of various individuals and groups from the nations and peoples of the ancient Near East. Though prophecy among ancient Egyptians, Mesopotamians, and Canaanites—as well as among the peoples of the Aegean civilization—generally was connected with "foretelling" (or predicting) the future, the Hebrew view of prophecy centred on "forthtelling" (or proclaiming), though it included predictive aspects. Thus, in Hebrew prophecy the phrase "Thus says the Lord" is repeated constantly to emphasize the "forthtelling" motif. The Hebrew prophets were very conscious of the absolute holiness (separateness) of God and the purpose of God for his chosen people, Israel. Because of this consciousness, they developed an acute awareness of sin and its effects on man and society and, in consequence of such an awareness, a radical ethical outlook that applied to both the individual and the community.

Emphasis on "forthtelling"

The Hebrew term for prophet (*navi'*) is probably related etymologically to the Akkadian verb *nabū*, meaning "to call" or "to name." The Hebrew prophet may thus be viewed as a "caller," or spokesman, for God. Other designations for prophet in the Old Testament are *ro'e*, or "seer," and *ḥoze*, or "visionary," the two latter terms indicating that the predictive element was operative in Hebrew prophecy. The distinctive element of Hebrew prophecy, however, was the relationship of the prophet to God, the Lord of the Covenant, and to Israel, the covenant people. He spoke for the sovereign Lord to remind, cajole, castigate, reprove, comfort, and give hope to the people of the covenant, constantly reminding them that they were chosen to witness to the nations of the love, mercy, and goodness of God.

Some of the Hebrew prophets, from the 11th to the 8th century BCE, belonged to bands or guilds of ecstatic prophets. Such prophets were spokesmen for God whose uncontrollable actions and words caused them to be feared and, sometimes, held in contempt. In II Kings, chapter 9, verse 11, a prophet—who came to Jehu, the 9th-century-BCE army commander who became king of Israel, in order to anoint him—was called a "madman" (*meshugga'*). Other Hebrew prophets were more independent, such as Nathan and Elijah, though they continued to maintain the quality of being uncontrollable—at least as far as the political authorities were concerned. Both of these early nonwriting prophets spoke out against the oppression of the weak by the strong, a theme that came to be expressed constantly in Judaism throughout the centuries. The activities of such early prophets, including also Micaiah and Elisha in the 9th century BCE, are described in the Former Prophets.

In the 8th century BCE, the writing prophets—*i.e.*, the Latter Prophets—began their activities. Though all the books that bear their names probably have been edited by schools of a prophet or by individuals or groups that were influenced by their ideas, the editors or disciples of the prophets preserved as well as was possible the words, activities, and idiosyncratic themes of the prophetic personalities. Some of the Latter Prophets may have been connected with the priestly class, such as Isaiah, Jeremiah, and Ezekiel; most of the Latter Prophets, however, were independent of priestly connections. All of the Latter Prophets stood out in contrast to the court prophets who, in the tradition of court prophets of most ancient Near Eastern peoples, seldom contradicted what they believed was expected of them by their sovereigns or the people.

Joshua. The Book of Joshua takes its name from the man who succeeded Moses as the leader of the Hebrew tribes—Joshua, the son of Nun, a member of the tribe of Ephraim. In post-biblical times Joshua himself was credited with being the author of the book, though internal evidence gives no such indication. According to the views of the German biblical scholar Martin Noth, which have been accepted by many contemporary biblical critics, the Book of Joshua was the second of a series of five books (Deuteronomy, Joshua, Judges, Samuel, and Kings) written by a Judaean oriented historian after the fall of Jerusalem in 586 BCE. This writer (called the Deuteronomist and designated D) constructed the history

The work of the Deuteronomic historian

of Israel from the death of Moses to the beginning of the Babylonian Exile (586–538 BCE). The Deuteronomist, according to this view, used sources, both oral and written, from various periods to produce the history of Israel in these five books. The Book of Joshua probably contains elements from the J and E documents, as well as local and tribal traditions, all of which were modified by additions and editing until the book assumed its present form. The main theme of the Deuteronomist historian was that under the guidance of and in obedience to Yahweh, Israel would persevere and conquer its many enemies.

This theme is especially and dramatically presented in Joshua. Under the guidance of Yahweh, the people of Israel entered and conquered Canaan in fulfillment of the promise of God to Abraham and his descendants in Genesis, chapter 12. Joshua is interpreted as a second Moses—*e.g.,* he sent out spies, led the people in crossing the Jordan River on dry land as Moses had crossed the Sea of Reeds, and ordered the males to be circumcised with flint knives as Zipporah, Moses' wife, had earlier circumcised the son of Moses (and probably Moses himself). He was obedient to the will of Yahweh, and because of this obedience he was able to lead the Israelite tribes in their battles against the Canaanites. As long as they were faithful to their covenant promise, the land would be theirs as a trust.

The book may be divided into three parts: the story of the conquest of Canaan (chapters 1–12); the division of the land among the tribes of Israel (chapters 13–22); and Joshua's farewell address, the renewal of the Covenant, and Joshua's death (chapters 23–24).

The conquest of Canaan. As told by the Deuteronomist, the conquest of Canaan by Joshua and the Israelite tribes was swift and decisive. No conquest of central Canaan (in the region of Shechem), however, is mentioned in the book; and some scholars interpret this to mean that the central hill country was already occupied either by ancestors of the later Israelite tribes prior to the time of Moses or by portions of Hebrew tribes that had not gone to Egypt. Because these people made peace with the tribes under Joshua, a conquest of the area apparently was not necessary. Archaeological evidence supports portions of Joshua in describing some of the cities (*e.g.,* Iachish, Debir, and Hazor) as destroyed or conquered in the late 13th century BCE, the approximate time of the circumstances documented in Joshua. Some of the cities so reported, however, apparently were devastated at some time prior to or later than the 13th century. Jericho, for example, was razed at the end of the Middle Bronze Age (*c.* 1550 BCE) and most likely had not been rebuilt as a strongly fortified town by the time of Joshua, though the site may well have been inhabited during this period. The city of Ai was destroyed about 600 years before; but it may have been a garrison site for the city of Bethel, which was destroyed later by the "house of Joseph." Though many of the cities of Canaan were conquered by the Israelites under Joshua, historical and archaeological evidence indicates that the process of conquering the land was lengthy and not completed until David conquered the Jebusite stronghold of Jerusalem in the early 10th century BCE. At any rate, the 13th century was an ideal time for a conquest of the area because of the international turmoil involving the great powers of the time: Egypt and Babylonia. A political vacuum existed in the area, permitting small powers to strengthen or to expand their holdings.

Archaeological evidence supporting the biblical narrative

The introductory section of Joshua (chapters 1 and 2), in dealing with the Deuteronomist's view of the ideal man of faith—one who is full of courage and faithful to the law that was given to Moses—relates the story of spies sent to Jericho, where they were sheltered by Rahab, a harlot, whose house was spared by the Israelites when they later destroyed the city. In the Gospel According to Matthew, in the New Testament, Rahab is listed as the grandmother of Jesse, the father of David (the architect of the Israelite empire), which may be the reason why this story was included in Joshua. Also in the New Testament, in the Letter to the Hebrews, Rahab is depicted as an example of a person of faith. After the return of the spies, who reported that the people of Canaan were "fainthearted" in the face of the Israelite threat, Joshua launched the invasion of Canaan; the Israelite tribes crossed the Jordan River and encamped at Gilgal, where the males were circumcised after a pile of stones had been erected to commemorate the crossing of the river. They then attacked Jericho and, after the priests marched around it for seven days, utterly destroyed it in a *ḥerem; i.e.,* a holy war in which everything is devoted to destruction. Prior to the Israelites' further conquests it was discovered that Achan, a member of the tribe of Judah, had broken the *ḥerem* by not devoting everything taken from Jericho to Yahweh. Because he had thus sinned in keeping some of the booty, Achan, his family, and all of his household goods were destroyed and a mound of stones was heaped upon them. The Israelite tribes next conquered Ai, made agreements with the people of the region of Gibeon, and then campaigned against cities to the south, capturing several of them, such as Lachish and Debir, but not Jerusalem or the cities of Philistia on the seacoast. Joshua moved north, first conquering the city of Hazor—a city of political importance—and then defeating a large number (31) of the kings of Canaan, though the conquests of their cities did not necessarily follow.

The significance of the *ḥerem*

Division of the land and renewal of the Covenant. The division of the land among the tribes is recounted in chapters 13–22. Two sources were apparently used by the Deuteronomist in dealing with the division of the land: a boundary list from the pre-monarchical period (*i.e.,* before the late 11th century BCE) and a list of cities occupied by several tribes from the 10th to the 7th century BCE. The tribes who occupied territories were: Reuben, Gad, Manasseh, Caleb, Judah, the Joseph tribes (Ephraim and Manasseh), Benjamin, Simeon, Zebulun, Issachar, Asher, Naphtali, and Dan. Certain cities (*e.g.,* Hebron, Shechem, and Ramoth) were designated Levitical cities. Though the Levites probably did not control the cities politically, as the priestly class they were of cultic significance—and therefore feared and respected—in cities that were the sites of sanctuaries.

As Moses had before him, Joshua gave a farewell address (chapter 23) to his people, admonishing them to be loyal to the Lord of the Covenant; and in the closing chapter (24), the Israelites reaffirmed their loyalty to Yahweh at Shechem: first having heard the story of God's salvatory deeds in the past, they were asked to swear allegiance to Yahweh and to repudiate all other gods, after which they participated in the Covenant renewal ceremony. After the people were dismissed, Joshua died and was buried in the hill country of Ephraim; the embalmed body of Joseph that had been carried with the Hebrews when they left Egypt more than a generation earlier was buried on purchased land; and Eleazar, the priestly successor to Aaron (Moses' brother), was buried at Gibeah.

The Covenant renewal ceremony

Besides the obvious emphases on the conquest of Canaan and the division of the land, the Deuteronomist gave special attention to the ceremony of Covenant reaffirmation. By means of a regularly repeated Covenant renewal the Israelites were able to eschew Canaanite religious beliefs and practices that had been absorbed or added to the religion of the Lord of the Covenant, especially the fertility motifs that were quite attractive to the Hebrew tribes as they settled down to pursue agriculture, after more than a generation of the nomadic way of life.

Judges. The Book of Judges, the third of the series of five books that reflect the theological viewpoint of the Deuteronomic historian, covers the history of the Israelite tribes from the death of Joshua to the rise of the monarchy, a period comprising nearly 200 years (*c.* 1200–*c.* 1020 BCE). Though the internal chronology of Judges points to a period of about 400 years, the editor may have arbitrarily used the formula of 40 years for a generation of rule by a judge; and he may have compiled the list in the form of a series of successive leaders who actually may have led only a particular tribe or a group of tribes during the same generation as another judge. In other words, the reign of two or more judges may well have overlapped.

The Deuteronomic "theology of history." The Deuteronomic "theology of history" shows through very clearly in Judges: unless the people of the Covenant remain faithful and obedient to Yahweh, they will suffer the due consequences of disobedience, whether it be an overtly willful

act or an unthinking negligence in keeping the Covenant promise. The Deuteronomist worked out a formula for his theology of history that was based in a very dramatic way on the historical events of the period: (1) obedience to Yahweh brings peace and well-being; (2) a period of well-being often involves a slackening of resolve to keep the commandments of Yahweh or outright disobedience; (3) disobedience leads to a weakness of the faith that had bound the community together and thus leaves the community open to repression and attacks from external enemies; and (4) external repression forces the community to reassess its position and ask the cause of the calamities, thus leading to repentance and eventual strength to resist all enemies.

Canaanite culture and religion. The Israelite tribes during the period of the guidance and leadership of Moses and Joshua mainly had to contend with nomadic tribes; in their contacts with such groups they absorbed some of the attitudes and motifs of the nomadic way of life, such as independence, a love of freedom to move about, and fear of or disdain for the way of life of settled, agricultural, and urban peoples.

Canaanite cultural accomplishments and religious beliefs and practices

The Canaanites, with whom the Israelites came into contact during the conquest by Joshua and the period of the Judges, were a sophisticated agricultural and urban people. The name Canaan means Land of Purple (a purple dye was extracted from a murex shellfish found near the shores of Palestine). The Canaanites, a people who absorbed and assimilated the features of many cultures of the ancient Near East for at least 500 years before the Israelites entered their area of control, were the people who, as far as is known, invented the form of writing that became the alphabet, which, through the Greeks and Romans, was passed on to many cultures influenced by their successors—namely, the nations and peoples of Western civilization.

The religion of the Canaanites was an agricultural religion, with pronounced fertility motifs. Their main gods were called the Baalim (Lords) and their consorts, the Baalot (Ladies), or Asherah (singular), usually known by the personal plural name Ashtoret. The god of the city of Shechem, which city the Israelites had absorbed peacefully under Joshua, was called Baal-berith (Lord of the Covenant) or El-berith (God of the Covenant). Shechem became the first cultic centre of the religious tribal confederacy (called an amphictyony by the Greeks) of the Israelites during the period of the judges. When Shechem was excavated in the early 1960s, the temple of Baal-berith was partially reconstructed; the sacred pillar (generally a phallic symbol or, often, a representation of the *ashera,* the female fertility symbol) was placed in its original position before the entrance of the temple.

The Baalim and the Baalot, gods and goddesses of the Earth, were believed to be the revitalizers of the forces of nature upon which agriculture depended. The revitalization process involved a sacred marriage (*hieros gamos*), replete with sexual symbolic and actual activities between men, representing the Baalim, and the sacred temple prostitutes (*qedeshot*), representing the Baalot. Cultic ceremonies involving sexual acts between male members of the agricultural communities and sacred prostitutes dedicated to the Baalim were focussed on the Canaanite concept of sympathetic magic. As the Baalim (through the actions of selected men) both symbolically and actually impregnated the sacred prostitutes in order to reproduce in kind, so also, it was believed, the Baalim (as gods of the weather and the Earth) would send the rains (often identified with semen) to the Earth so that it might yield abundant harvests of grains and fruits. Canaanite myths incorporating such fertility myths are represented in the mythological texts of the ancient city of Ugarit (modern Ras Shamra) in northern Syria; though the high god El and his consort are important as the first pair of the pantheon, Baal and his sexually passionate sister-consort are significant in the creation of the world and the renewal of nature.

Attraction of the Israelites toward Canaanite religion

The religion of the Canaanite agriculturalists proved to be a strong attraction to the less sophisticated and nomadic-oriented Israelite tribes. Many Israelites succumbed to the allurements of the fertility-laden rituals and practices of the Canaanite religion, partly because it was new and different from the Yahwistic religion and, possibly, because of a tendency of a rigorous faith and ethic to weaken under the influence of sexual attractions. As the Canaanites and the Israelites began to live in closer contact with each other, the faith of Israel tended to absorb some of the concepts and practices of the Canaanite religion. Some Israelites began to name their children after the Baalim; even one of the judges, Gideon, was also known by the name Jerubbaal ("let Baal contend").

As the syncretistic tendencies became further entrenched in the Israelite faith, the people began to lose the concept of their exclusiveness and their mission to be a witness to the nations, thus becoming weakened in resolve internally and liable to the oppression of other peoples.

The role of the judges. Under these conditions, the successors to Joshua—the judges—arose. The Hebrew term *shofet,* which is translated into English as "judge," is closer in meaning to "ruler," a kind of military leader or deliverer from potential or actual defeat. In a passage from the so-called Ras Shamra tablets (discovered in 1929) the concept of the judge as a ruler is well illustrated:

> Our king is Triumphant Baal,
> Our judge, above whom there is no one!

The magistrates of the Phoenician-Canaanite city of Carthage, which competed with Rome for supremacy of the Mediterranean world in the 3rd century BCE, were called *suffetes,* thus pointing toward the political authority of the judges.

The office of judgeship in the tribal confederacy of the Israelites, which was centred at a covenant shrine, was not hereditary. The judges arose as Yahweh saw fit, in order to lead an erring and repentant people to a restoration of a right relationship with him and to victory over their enemies. The quality that enabled a person selected by Yahweh to be a judge was charisma, a spiritual power that enabled the judge to influence, lead, and control the people caught between the allurements of the sophisticated Canaanite culture and the memory of the nomadic way of life with its rugged freedom and disdain for "civilization." Though many such leaders are mentioned, the Book of Judges focusses attention upon only a few that are singled out as especially significant: Deborah and Barak, Gideon, Abimelech, Jephthah, and Samson. In spite of the Israelites' repeated apostasy, such leaders, under the guidance and spiritual powers granted to them by Yahweh, were able to lead their tribes in successfully defeating or driving back their opponents.

The significance of the office of the judge

The Book of Joshua may be divided into four parts: (1) the conquests of several tribes (chapter 1); (2) a general background for the subsequent events according to the interpretation of the Deuteronomic historian—"And the people of Israel did what was evil in the sight of the Lord and served the Baals"—(chapter 2 through chapter 3, verse 6); (3) the exploits of the judges of Israel (chapter 3, verse 7, through chapter 16); and an appendix (chapters 17 through 21).

Judges, chapter 1, shows that the conquest of Canaan, in contradistinction to the view presented in Joshua, was incomplete, inconclusive, and lengthy. Though conquests of some of the tribes (Judah, Simeon, Caleb, and the "house of Joseph") are noted, the main emphasis is on the cities and areas that the tribes had *not* conquered—*e.g.,* "And Ephraim did not drive out the Canaanites who dwelt in Gezer, but the Canaanites dwelt in Gezer among them" (chapter 1, verse 29).

The second section gives the Deuteronomic interpretation of the consequences of such a policy:

> they forsook the Lord, the God of their fathers, who had brought them out of the land of Egypt; they went after other gods, from among the gods of the peoples who were round about them; and they provoked the Lord to anger. They forsook the Lord, and served the Baals and the Ashtaroth. (chapter 2, verses 12–13)

The purpose of allowing the Canaanites to continue to exist

In chapter 3, an explanation is given as to why the Canaanites had not been annihilated and were allowed to remain with the Israelites: they enabled the Israelites to be tested in the techniques of warfare; the Philistines, for

example, had a monopoly on the smelting of iron in the area—and the iron used in their weapons was far superior to the bronze used by the Israelites for their swords, shields, and armaments—until the secret had been wrested from them by the first king of Israel, Saul, in the latter part of the 11th century BCE. The Canaanites also served to test the faith of the Israelites in the one, true God, Yahweh.

The role of certain lesser judges. The third section relates the exploits of the various judges. Othniel, a member of the tribe of Caleb, delivered the erring Israelites from eight years of oppression by Cushan-rishathaim, king of Mesopotamia. The king, however, was most likely an area ruler, rather than a king of the Mesopotamian Empire. Another judge, Ehud, a left-handed Benjamite, delivered Israel from the oppression of the Moabites. Ehud, a fat man who had hidden a sword under his garments on his right side so that when a search of his person was made it would be overlooked, brought tribute to Eglon, the Moabite king. Upon Ehud's claiming to have a secret message for the king, Eglon dismissed the other people carrying tribute. Ehud then said to the King, "I have a message from God to you," assassinated him, locked the doors to the chamber, and escaped. Rallying the Israelites around him, Ehud led an attack upon the Moabites that was decisive in favour of the Israelites. Shamgar, the third judge, is merely noted as a deliverer who killed 600 Philistines.

The roles of Deborah, Gideon, and Jephthah. The first notably important judge of the tribal confederacy was Deborah, who was primarily a seer, poet, and interpreter of dreams but still a person endowed with the kind of charisma that identified her as a judge sent from Yahweh. The story of the victory of the Israelites under the charismatic leadership of Deborah and the military leadership of Barak, her commander, is related in prose (chapter 4) and repeated in poetry (chapter 5, which is known as the "Song of Deborah"). The Canaanites, under the leadership of Jabin, king of a reestablished Hazor, and his general Sisera, had oppressed an apostate Israel. Deborah sent word to all the tribes to unite against the Canaanites, but only about half the tribes responded. The Canaanites had asserted control over the Valley of Jezreel, which was an important commercial thoroughfare and was commanded by the city of Megiddo. In this valley dominated by the hill of Megiddo (Armageddon)—a site of many later crucial military battles and which later became the symbolic name for the final battle between the forces of good and the forces of evil in apocalyptic literature—the Israelites met the Canaanites near the river Kishon in open battle. A cloudburst occurred, causing the river to flood, thus limiting the manoeuvrability of the Canaanite chariots. The Canaanite general Sisera, seeing defeat for his forces, fled, seeking refuge in the tent of a Kenite woman, Jael. A supporter of the cause of Israel, Jael gave Sisera a drink of milk (fermented?) and he fell asleep "from weariness." Jael pounded a tent peg through his temple, thus ending decisively the threat of the Canaanites of Hazor. The victory song of Deborah in chapter 5 is one of the oldest literary sections of the Old Testament. It is a hymn that incorporates the literary forms of a confession of faith, a praise of Yahweh's theophany (manifestation), an epic, a curse, a blessing, and a hymn of victory.

The significance of Deborah and Gideon

Another important judge, perhaps the most important other than Samuel, was Gideon, whose exploits are related in chapters 6–8. The oppressors of Israel during the time of Gideon were the camel-borne raiders from Midian, roving bands that pillaged the farms and unfortified villages for seven years. A prophet appeared among the Israelites and denounced them for their apostasy, after which, according to the account, an angel of Yahweh visited and then commissioned Gideon, a member of the tribe of Manasseh, to lead the Israelites against the enemies from the Transjordan. After sacrificing to Yahweh, building an altar to the Lord (which he named Yahweh Shalom, or "Yahweh is peace"), and destroying an altar of Baal and an *ashera* (most likely a wooden pole symbolizing the goddess) beside it, he sent out messengers to gather together the tribes in order to meet an armed force of the Midianites and Amalekites that had crossed the Jordan River and were encamped in the Valley of Jezreel. He went to a threshing floor (a common place to seek divinatory advice) and sought a sign from Yahweh—dew on a fleece of wool placed overnight on the threshing floor, with the rest of the area remaining dry. After receiving the positive divinatory sign, Gideon assembled a large force, reduced it to 300 men, and infiltrated the outposts of the Midianite camp with his servant—overhearing a Midianite telling another of his dream about a barley cake rolling into the camp of the Midianites and striking a tent so that it fell down and was flattened (which Gideon interpreted as a sign of victory for the forces under him). He encircled the camp of the Midianites about midnight. On signal, the men broke jars, shouted, waved torches, blew rams' horns, and attacked the encampment. The Midianites, in the confusion, were routed and harassed in their flight. In their pursuit of the fleeing Midianites, Gideon and his forces were refused aid by the cities of Succoth and Penuel, which was a violation of the tribal confederacy agreements. The Midianites, however, were again the objects of a surprise attack and their two kings (Zebah and Zalmunna) were captured and later executed by Gideon because they had killed his brother. The leaders of Succoth were punished and the men of Penuel were killed in retaliation for their refusal to aid the forces of Gideon.

After the victory, the people, recognizing their need for centralized leadership of the confederacy, petitioned to Gideon that he establish a hereditary monarchy, with himself as the first king. Gideon refused, however, on the basis that "the Lord will rule over you."

The request for a hereditary monarchy

After Gideon died, the people returned to worshipping the gods of the Canaanites, especially Baal-berith. Abimelech, one of the 70 sons of the wives and concubines of Gideon, went to Shechem to solicit support for his attempt to establish a monarchy. After receiving financial support from those who controlled the treasury of the shrine of Baal-berith, he hired a band of assassins—who killed all of his brothers except Jotham, the youngest of Gideon's sons. Abimelech was declared king by the Shechemites. The surviving Jotham told a parable about trees that sought a king—after all the larger trees refused the kingship, the bramblebush, which was highly inflammable, accepted the offer. The point of the parable was that as the bramblebush is highly inflammable, so also would the reign of Abimelech be the source of fires of rebellion and revolution. Revolution did occur, and after being wounded at Thebez by a millstone dropped by a woman from a tower, Abimelech asked his armour bearer to kill him. The attempt of Abimelech and the Shechemites to establish a monarchy thus proved to be abortive and premature.

After a brief account of the rule of two judges, Tola of the tribe of Issachar and Jair from Gilead, the Deuteronomist describes the apostasy of the Israelites and the consequent oppression of the tribes by the Philistines from the seacoast and the Ammonites from the Transjordan. The Israelites looked for a leader and found Jephthah, the son of a harlot, who had been rejected by the sons of his father and who had gathered about him a band who made their living by raiding others. Jephthah made several attempts to negotiate with the Ammonites and Moabites; when the Ammonites did not cooperate, Jephthah moved against them. Seized by the Spirit of the Lord—*i.e.*, ecstatically inspired—he began his campaign with a vow to sacrifice the first person he saw upon his return home as a burnt offering to Yahweh. He was victorious over the Ammonites, but the first person he saw on return home was his only child, a daughter. Upon learning of her destined fate, she requested a two-month period to be with her friends to bewail her virginity and approaching death. The story is reminiscent of the fertility myths of the ancient Near East. After she was sacrificed, Jephthah subdued a contingent of the Ephraimites in the Transjordan to bring peace to the area. A password was used to separate the Ephraimites from the men under Jephthah: "shibboleth." Because the Ephraimites could not pronounce the word correctly, in that their dialect was different from the others, they were thus identified and killed.

The judgeship of Jephthah

In chapter 12, three judges are given cursory treatment: Izban of Bethlehem, Elon the Zebulunite, and Abdon the Ephraimite.

The exploits of Samson

The role of Samson. The exploits of the great Israelite strongman judge, Samson (a member of the tribe of Dan), are related in chapters 13–16. Dedicated from birth by his mother to Yahweh, Samson became a member of the Nazirites, an anti-Canaanite reform movement. As a Nazirite, he was required never to cut his hair, drink wine, or eat ritually unclean food. He married a Philistine woman whom he then left when she helped her fellow Philistines avoid payment to Samson in a riddle contest by giving them the answer. Returning later to find her given to another man, he burned the grainfields of the Philistines. They sought revenge by killing Samson's wife and her father. The exploits of Samson against the Philistines from then on are numerous. After he met the temptress Delilah, who wrested from him the secret of his great strength (*i.e.,* his long uncut hair because of his vow), Samson was captured by the Philistines after his hair had been cut short. After imprisonment, blinding, and humiliation, Samson finally avenged his loss of self-respect by pulling down the main pillars of the temple of the Philistine god Dagon, after which the temple was destroyed, along with numerous Philistines. Though Samson was more a folk hero than a judge, he was probably included in the list of judges because his ventures against the Philistines slowed their movements inland against the Israelite towns and villages. The Philistines were a group of "sea peoples" united in a confederacy of five city-states: Gaza, Ashkelon, Ashdod, Gath, and Ekron. To the area they gave their name, which has endured to the 20th century: Palestine.

The final section of the Book of Judges is an appendix divided into two parts: (1) the story of Micah, the repentant Ephraimite, a Levite priest who deserted him to be priest of the tribe of Dan, and the establishment of a shrine at the conquered city of Laish (renamed Dan) with the cult object taken from the house of Micah; and (2) the story of the Benjamites who were defeated in a holy war after they had killed a concubine of a Levite. The book ends with a critique of the period: "In those days there was no king in Israel; every man did what was right in his own eyes" (chapter 21, verse 25).

Samuel. The book of Samuel covers the period from Samuel, the last of the judges, through the reigns of the first two kings of Israel, Saul and David (except for David's death). The division of Samuel and its succeeding book, Kings (Melakhim), into four separate books first appeared in the Septuagint, the Greek translation of the Old Testament from the 3rd to 2nd centuries BCE.

The two main sources of Samuel

Theological and political biases. Containing two primary sources, the book of Samuel is the result of the editorial skill of the Deuteronomic historians of the post-exilic period. The early source, which is pro-monarchical and may have been written by a single author, is found in I Samuel, chapter 9, verse 1, through chapter 10, verse 16, as well as chapter 11 and most of II Samuel. The chapters just noted were probably written by a chronicler during the reign of Solomon; possible authors of these chapters were Abiathar, a priest of the line of Eli (who was Samuel's predecessor at the shrine of Shiloh), or Ahimaaz, a son of Zadok (who originally may have been a priest of the Jebusite city of Jerusalem that David made his capital). The chapters in I Samuel are sometimes called the "Saul" source because it is in them that Saul's charismatic leadership is legitimized in the form of kingship. The chapters of II Samuel, also displaying a pro-monarchical bias—as far as content is concerned—are the "book of David." In the early source, Samuel, a seer, prophetic figure, and priest of the shrine at Shiloh, is viewed mainly as the religious leader who anointed Saul to be king. The later source, which displays a somewhat anti-monarchical bias and shows the marks of disillusionment on the part of the Deuteronomic historians of the post-exilic period, is found in I Samuel, chapter 7, verse 3, to chapter 8, verse 22, chapter 10, verses 17–27, and chapter 12. Sometimes called the Samuel source, the later source interprets the role of Samuel differently; he is viewed as the last and most important judge of the whole nation, whose influence extended to the shrines at Bethel, Gilgal, and Mizpah. The two sources illustrate the two opposing tendencies that lasted for centuries after the conquest of Canaan.

The international and area situation during the 11th–10th centuries BCE

During the period of Samuel, Saul, and David (the 11th–10th century BCE), the Israelites were still threatened by various local enemies. The great nations—Egypt, Assyria, and the Hittite Empire—were either involved in domestic crises or concerned with areas other than Palestine in their expansionist policies. Of the various peoples pressing to break up the Israelite confederacy, the Philistines (the "sea peoples") of the Mediterranean coast proved to be the most dangerous. Expanding eastward with their iron-weapon equipped armies, the Philistines threatened the commercial routes running north and south through Israelite territory. If they captured and controlled such areas as the Valley of Jezreel, they would eventually strangle the economic life of the Israelite confederacy.

To meet this threat, the tribal confederacy had four options open to it. First, the tribes could continue as before, loosely held together by charismatic leaders, who served only as temporary leaders. Second, they could create a hereditary hierocracy (rule by priests), which the priest of the shrine at Shiloh, Eli, apparently attempted to inaugurate. A third possible course of action was to establish a hereditary judgeship, which was the aspiration of the judge Samuel. But in either of these two possibilities, the sons of Eli and Samuel were not of the same stature as their fathers; and the apparent hopes of their fathers could not be realized. The fourth alternative was a hereditary monarchy. The book of Samuel is an account of the eventual success of those who supported the monarchical position, along with the Deuteronomic interpretation that pointed out the weaknesses of the monarchy whenever it departed from the concept of Israel as a covenant people and became merely one kingdom among other similar kingdoms.

The book of Samuel may be divided into four sections: (1) the stories of Samuel, the fall of the family of Eli, and the rise of Saul (I Samuel, chapters 1–15); (2) the accounts of the fall of the family of Saul and the rise of David (I Samuel, chapter 16, to II Samuel, chapter 5); (3) the chronicles of David's monarchy (II Samuel, chapter 6, to chapter 20, verse 22); and (4) an appendix of miscellaneous materials containing a copy of Psalm 18, the "last words of David," which is a psalm of praise, a list of heroes and their exploits, an account of David's census, and other miscellaneous materials.

The early life and "call" of Samuel

The role of Samuel. The first section (chapters 1–15) begins with the story of Samuel's birth, after his mother Hannah (one of the two wives of the Ephraimite Elkanah) had prayed at the shrine at Shiloh, the centre of the tribal confederacy, for a son. She vowed that if she bore a son, he would be dedicated to Yahweh for lifetime service as a Nazirite, as indicated by the words "and no razor shall touch his head."

Three years after she had borne a son, whom she named Samuel—which is interpreted "asked of God," a phrase that fits the meaning of Saul's name but may actually mean "El has heard"—Hannah took the boy to the shrine at Shiloh. Hannah's song of exultation (chapter 12, verses 1–10) probably became the basis of the form and content of the Magnificat, the song that Mary, the mother of Jesus, sang in Luke, chapter 1, verses 46–55, in the New Testament. Eli, the priest at Shiloh (who had heard Hannah's vow), trained the boy to serve Yahweh at the shrine, which Samuel's mother and father visited annually. The sons of Eli, Hophni and Phinehas, are depicted as corrupt, misusing their positions as servants of the shrine to take offerings the people gave to Yahweh for their own gratification, in contrast to Samuel, who "continued to grow in stature and favour with the Lord and with men." Because the sons of Eli failed to heed the admonition of their father, the house of Eli was condemned by a "man of God," who told Eli that his family was to lose its position of trust and power. This condemnation, an interruption of the later source, is the Deuteronomic historian's answer as to why Abiathar, a priest of the family of Eli at the time of David, was excluded from the priesthood at Jerusalem, which became the central shrine of the monarchy.

While a youth (about 12 years old), Samuel experienced a revelation from Yahweh in the shrine at night. First going to Eli three times after hearing his name called, Samuel responded to Yahweh at Eli's suggestion. What

was revealed to him was the fall of the house of Eli, a message that Samuel hesitatingly related to Eli. After this religious experience, Samuel's reputation as a prophet of Yahweh increased.

The fall of Shiloh and the house of Eli

In chapter 4 is an account of the fall of Shiloh and the loss of the ark of the Covenant to the Philistines. Leaving the ark, the symbol of Yahweh's presence, at Shiloh, the Israelites go out to battle against the Philistines near the Mediterranean coast but are defeated. The Israelites return to Shiloh for the ark; but even though they carry it back to the battleground, they are again defeated at great cost—the sons of Eli are killed, and the ark is captured by the enemy. When Eli, old and blind, hears the news of the disaster, he falls over backward in the chair on which he is sitting, breaks his neck, and dies. The wife of his son Phinehas gives birth to a son at this time; and, upon hearing of what had happened to Israel and her family, names the boy Ichabod, meaning "where is the glory?"—because, as she says, "The glory has departed from Israel."

Though the Philistines had captured the ark, they eventually discovered that it did not bring them good fortune. Their god Dagon, an agricultural fertility deity probably meaning "grain," fell to the ground whenever the ark was placed in close proximity to it; and, even more calamitous to them, the Philistines suffered from "tumours," probably the bubonic plague, wherever they carried the ark. After experiencing such disasters for seven months, the Philistines returned the ark to Beth-shemesh in Israelite territory, along with a guilt offering of five golden tumours and five golden mice carried in a cart drawn by two cows. Because many Israelite men in Beth-shemesh also died—"because they looked into the ark of the Lord"—the ark was taken to Kiriath-jearim (the "forest of martyrs" in modern Israel), where it was placed in the house of Abinadab, whose son Eleazar was consecrated to care for it. The ark was not returned to Shiloh, probably because that shrine centre had been destroyed, along with other Israelite towns, by the Philistines.

The request for a monarchy

In chapter 7, verse 3, to chapter 12, verse 25, the Deuteronomic historian depicts the way in which Samuel assumed leadership as judge and Covenant mediator of Israel. The Philistines continued to oppress Israel, though under Samuel's leadership the Israelites were able to reconquer territory lost to their western enemies. When Samuel grew old, his sons were trained to take his place; but they—like the sons of Eli—were corrupt ("they took bribes and perverted justice"), so that the Israelites demanded another form of government—a monarchy. Samuel attempted to dissuade them, pointing out that if they had a highly centralized form of government (*i.e.,* a monarchy), they would have to give up much of their freedom and would be heavily taxed in goods and services. Samuel obeyed both the elders of the people, who demanded a king, and Yahweh, who said, "make them a king."

The rise and fall of Saul. The man selected to become the first monarchical ruler of Israel was Saul, son of Kish, a wealthy Benjamite landowner. Because Kish had lost some donkeys, Saul was sent in search of them. Unsuccessful in his search, he went to the seer-prophet Samuel at Ramah. In the early source, from which this narrative comes, he did not know Samuel's name. The day before Saul went to Ramah, Samuel the seer (*ro'e*), who was depicted by the Deuteronomic historian as a prophet (*navi'*), received notice from Yahweh that Saul was the man chosen to reign over Israel. At the sacrificial meal, Saul, a tall young man, was given the seat of honour, and the next day Samuel anointed him prince (*nagid*) of Israel in a secret ceremony. Before returning home, Saul joined a band of roving ecstatic prophets and prophesied under the influence of the spirit of Yahweh. In chapter 10, verses 17–27, generally accepted as part of the later source, the Deuteronomic historian's views are depicted—Saul was chosen by lot at Mizpah. The early source picks up the story of Saul in chapter 11, which illustrates Saul's military leadership abilities and describes his acclamation as king at Gilgal. Samuel's farewell address, a Deuteronomic reworking of the later source, recapitulates the history of the Israelite tribes from the time of the patriarch Jacob through the period of the judges and forcefully presents the conservative view that the request for a monarchy will bring about adversity to Israel.

The reign of Saul

The early reign of Saul and his confrontations with Samuel until the last judge's death is the subject of chapters 13–15. Saul's early acts as king centred about battles with the Philistines. Because his son Jonathan had defeated one of their garrisons at Geba, the Philistines mustered an army to counterattack near Beth-aven (probably another name for Bethel). Saul issued a request for volunteers, who gathered together for battle but awaited the performance of the sacrifice before the battle by Samuel. Because Samuel did not come for seven days, Saul, acting on his own, presided at the sacrifice. Immediately after the burnt offering had been completed, Samuel appeared (perhaps waiting for such an opportunity to reassert his leading position) and castigated Saul for overstepping the boundaries of his princely prerogatives—even though Saul had been more than patient. Samuel warned him that this type of act (which Saul, in the early source, and later David and Solomon also often performed) would cost Saul his kingdom. In spite of Samuel's apparent animosity, Saul continued to defend the interests of the newly formed kingdom.

The tragedy of Saul was that he was a transitional figure who had to bear the burden of being the man who was of an old order and at the same time of a new way of life among a people composed of disparate elements and leading figures. Both Samuel, the last judge of Israel, and David, the future builder of the small Israelite empire, opposed him. Saul was more a judge—a charismatic leader—than a monarch. Unlike most kings of his time and area, he levied no taxes, depended on a volunteer army, and had no harem. He did not construct a court bureaucracy but relied rather on the trust of the people in his charismatic leadership and thus did not alter the political boundaries or structure of the tribal confederacy.

The dispute between Samuel and Saul

The issue between Saul and Samuel came to a head in the events described in chapter 15 (a section from the later source). Samuel requested Saul to avenge the attacks by the Amalekites on the Israelite tribes during their wanderings in the wilderness after the Exodus from Egypt about 200 years earlier. Saul defeated the Amalekites in a holy war but did not devote everything to destruction as was required by the ban (*herem*). Because Saul had not killed Agag, the Amalekite king, and had saved sheep and cattle for a sacrifice, Samuel informed Saul that he had disobeyed Yahweh and was thus rejected by God, for "to obey is better than to sacrifice." Samuel then asked that Agag be brought to him, and he hacked the Amalekite king to pieces. After that, Saul and Samuel saw each other no more.

The rise and significance of David. The next section contains the account of Saul's fall from power and David's rise to the position of king over all Israel. Samuel, still a charismatic and political power of great consequence, received from Yahweh the message that he was to go to Bethlehem to anoint a new ruler. Because he feared reprisal from Saul, Samuel went to Bethlehem (whose elders had the same fears) under the pretense of presiding at a sacrifice. There he anointed David, son of Jesse, to be future king. David then went to the court of Saul to be the king's armour bearer and court singer.

In a battle with the Philistines David is reported to have killed the 10-foot-tall Philistine champion Goliath of Gath. In II Samuel, chapter 21, verse 19, however, Goliath is killed in a later period by one of David's warriors, Elhanan. According to some biblical scholars, the name of Goliath may have been inserted for an unnamed philistine warrior killed by David apparently while he was armour bearer to Saul and was unrecognized by Saul, thus indicating the reworking of more than one source by the Deuteronomic historian.

The rise of David and the death of Saul

Chapters 18 through 26 depict the rise of David in the court of Saul, his friendship with Jonathan, the beginning of Saul's jealousy of David, the young David's winning of Saul's daughter Michal in marriage for killing a large number of Philistines, Saul's attempt on David's life, David's escape and formation of an outlaw band in the Judaean hills, his acceptance by the priests of the house of Eli at Nob (all of whom were killed by Saul except

Abiathar, who became David's priest), Samuel's death, and other incidents.

Because he feared for his life, David, along with 600 of his men, fled to the Philistine city of Gath, where he became a supposed leader of one of their military contingents against the Israelites. The last four chapters of I Samuel depict the final futile effort of Saul to retain control of his throne and thwart the Philistines: Saul attempted to receive advice from the spirit of the dead Samuel through the necromancer (sometimes called the witch or medium) of Endor, even though he had earlier banned such practices in his realm. Through her mediumship, Samuel foretold the death of Saul and his sons by the Philistines. The armies of the Philistines poured into the Valley of Jezreel. Some of the Philistine leaders distrusted David, who was sent back to his garrison town of Ziklag, which the Amalekites had overrun and in which they had taken many prisoners. Thus, David did not witness the defeat of the Israelites under Saul, who was mortally wounded by the Philistines and whose sons were killed. In an act of heroism so that he, the king of Israel, would not be captured, Saul committed suicide by falling on his own sword. Thus ended the career of the tragic hero who tried to serve Yahweh and Israel but was caught between the old, conservative ways (led by Samuel) and the new, liberal views (championed by David).

The early reign of David

The Second Book of Samuel, as noted earlier, relates the exploits of David and the events of his monarchy. After mourning the death of Saul and executing an Amalekite who claimed to have killed the former king, David began to consolidate his position as the successor to Saul. He was anointed king of Judah at Hebron while Ishbosheth ("man of shame," originally Ishbaal, or "man of Baal"), Saul's son, reigned in the rest of Israel under the guidance of Abner, Saul's general. After seven years, the army of Israel, under Abner, and the army of Judah, under Joab, David's general and nephew, met at Gibeon—each chose 12 champions to fight each other, and all were killed. After the minor battle, a major engagement ensued, with the forces of Judah emerging victorious. A long war of attrition developed between the house of Saul and the house of David. Abner attempted to deliver Israel to David but was killed by Joab to avenge his brother Asahel's death at Abner's hand in the first engagement between the two reigning houses. With Abner dead, Ishbosheth's position became exceedingly insecure, and he was beheaded by two of his own captains, whom David, in turn, executed for murdering the last ruler of the house of Saul.

Because of the course of events, the Israelites asked David to become king over all of Israel, and David made a covenant with the elders of northern Israel. He next engaged in a war with the Jebusite (Canaanite) stronghold of Jerusalem, which he captured. He selected this city as his new capital because it was a neutral site and neither the northerners nor the southerners would be adverse to the selection. From the very beginning of his reign, David showed the political astuteness and acumen that made for him a reputation that has continued for 3,000 years. He built at his new capital a palace, fortified the defenses, and established a harem. The Philistines, concerned about the man whom they had considered a former vassal, decided to move against David, which proved to be their undoing. David effectively contained them in a small area of the Mediterranean coast.

The expansion of the Davidic Empire. The third section of Samuel (II Samuel, chapter 6 through chapter 20, verse 22) contains the account of the reign of David from Jerusalem, ruling over a minor empire that stretched from Egypt in the south to Lebanon in the north and from the Mediterranean Sea in the west to the Arabian Desert in the east. He thus controlled the crossroads of the great empires of the ancient Near East. His second act of political astuteness was to bring theark of the Covenant to Jerusalem; but because of pressures from conservative elements who wanted to retain the tent that housed the ark (which had symbolic value from the days of the Exodus), David was not able to build a temple. Because the ark was now in Jerusalem, however, the city became both the political and the religious cult centre of his kingdom. In chapter 8 is a summary account of David's extension of his kingdom by military means and of the military, administrative, and priestly leaders of Israel.

II Samuel, chapters 9 through 20, verse 22—together with I Kings, chapters 1 and 2, the so-called Succession History, or the Family History of David, which, according to many scholars, forms the oldest section of historiography in Scripture—contains accounts of the domestic problems of David's reign. Though he showed generosity to Mephibosheth, the sole surviving son of the house of Saul, he showed his weakness for the charms of Bathsheba, the wife of Uriah, one of his generals. After ensuring Uriah's death by sending him into the front lines in a battle with the Ammonites, David married Bathsheba, who had become pregnant by the King. When the prophet Nathan came to David and told him of a rich man's unjust actions toward a poor man, David's response was one of anger and a demand for justice, whereupon Nathan said, "You are the man," and that Yahweh would exact retribution by not allowing the child to live. David then repented. He later went to Bathsheba and she conceived and bore another child, Solomon, who was to be the future king of Israel.

Domestic problems of the house of David

Though David was viewed as a master in the art of governing a nation, he was depicted as an unsuccessful father of his family. One son, Amnon (half-brother to Absalom and his sister Tamar), raped Tamar, for which act Absalom later exacted revenge by having Amnon assassinated at a feast. Absalom then fled to Geshur, stayed there three years, was taken back to Jerusalem by Joab, and two years later was reconciled to his father. Absalom's ambition to succeed his father as king caused him to initiate a revolt so that David had to flee from Jerusalem. Absalom was crowned king at Hebron, went to the concubines of David's harem in the palace, and decided to raise a massive army to defeat David. If he had then heeded the advice of Ahithophel, one of David's former counsellors, and attacked David's forces while they were disorganized, he probably would have been successful in retaining the throne. The forces of David under Joab, however, defeated Absalom's army "in the forest of Ephraim." While in flight on a mule, Absalom caught his head in an oak tree, and when Joab heard of his predicament he killed the hanging son of David. When David heard of the death of his rebellious son, he uttered one of the most poignant laments in literature: "O my son Absalom, my son, my son Absalom! Would I had died instead of you, O Absalom, my son, my son!" David then returned to Jerusalem and settled some of the quarrels that had erupted in his absence. A revolt led by the conservative Benjaminite Sheba, under the old rallying cry "every man to his tents, O Israel," was thwarted by Joab, who had to kill David's newly appointed commander Amasa to accomplish this end.

The appendix (chapter 20; verse 23, through chapter 24) has been noted earlier in this section.

Kings. The fourth book of the Former Prophets (I and II Kings in the Septuagint) continues the history of the nation Israel from the death of David, the reign of Solomon, and the divided monarchy through the collapse of both Israel (the northern kingdom) and Judah (the southern kingdom). Whereas Samuel was composed primarily of the early and the later sources with some editing on the part of the Deuteronomic historians, the Deuteronomic editors of Kings, in addition to these two sources, used other sources—such as the book of the acts of Solomon, the Book of the Chronicles of the Kings of Israel, the Book of the Chronicles of the Kings of Judah, temple archives, and traditions centring on certain major kings and prophets. The Deuteronomic historians wrote from the vantage points of the reign of King Josiah of Judah, who died in 609 BCE and was the ruler who accepted the Deuteronomic reform that began in 621 BCE, and of the Babylonian Exile, which traditionally lasted 70 years, though it began in 597 BCE, the temple was destroyed in 586, some exiles returned in 538, and the temple was restored in 516. The Deuteronomic view that national apostasy was the cause of the covenant people's predicament pervades this work.

The sources of the Book of Kings

(The history of the 10th through the early 6th century BCE is covered in the article JUDAISM, and therefore this

article will concentrate only on the reigns of important monarchs and their relationships to the rising power of the prophetic movement in Israel.)

The Book of Kings may be divided into four sections: (1) the last years of David and Solomon's succession to the throne (I Kings, chapter 1, to chapter 2, verse 11); (2) the reign of Solomon (I Kings, chapter 2, verse 12, to chapter 11, verse 43); (3) the beginning of the divided monarchy to the fall of Israel (I Kings, chapter 12, to II Kings, chapter 17); and (4) the last years of Judah (II Kings, chapters 18–25).

The succession of Solomon to the throne. I Kings (chapters 1 and 2) continues the story of David and the struggle for the succession of his throne. The sides were drawn between Adonijah, David's eldest living son, and Solomon, the son of David and Bathsheba. Supporting Adonijah were the "old guard"—the general Joab and the priest Abiathar—and supporting Solomon were the priest Zadok, the prophet Nathan, and the captain of David's bodyguard, Benaiah. With David close to death, Adonijah prepared to seize control of the kingdom; Nathan, however, requested Bathsheba to go to David and persuade David to proclaim Solomon the next monarch. Following the advice of Nathan, David then appointed Solomon the heir to his throne; and Zadok the priest and Nathan the prophet anointed the son of Bathsheba king in Gihon.

The appointment of Solomon as the future king of Israel

After David died, however, Adonijah attempted to regain some semblance of prestige by asking Solomon to give him Abishag, a young Shunammite woman who had been given to David in his old age, as his wife. To this request Solomon answered by ordering Adonijah's execution, which Benaiah carried out. Solomon also ordered the execution of the old general Joab for having killed Abner and Amasa years earlier as a loyal supporter of David, an execution again carried out by Benaiah, who also executed Shimei, a man who had cursed David a long time earlier. Prior to these executions, which David—before he had died—had requested of Solomon, the new king banished the priest Abiathar of the house of Eli to Anathoth, an act that confirmed the position of Zadok as the principal priest of Jerusalem.

The reign of Solomon. David had reigned from about 1000 to 962 BCE, a period in which he consolidated a federation of tribes that had been united under the charismatic leadership of Saul, who had reigned for about two decades before David began to construct his minor empire. Solomon, who inherited a strong monarchy, reigned for 40 years. His reputation as a monarch centred about his great wisdom (chapter 3), his reorganization of the administrative bureaucracy (chapter 4), and his building of the magnificent Temple (chapters 3–8). Though two sons of the prophet Nathan served Solomon, one as a court official and another as a priest, the prophetic movement apparently was little encouraged by the united monarchy's third king. Solomon is perhaps one of the most overrated figures in the Old Testament, in spite of his achievements in wisdom, construction, and commerce; he is recorded as having 1,000 wives and concubines—some of them merely guarantees of commercial treaties, to be sure—and as building a fleet of ships for a nearly landlocked Israel. To accommodate his desire for a seaport, he built the port of Ezion-geber at the head of the Gulf of Aqaba of the Red Sea. A son of the harem, Solomon had had little contact with the people of his realm, and he used many of them in labour battalions in his vast building programs to the economic disadvantage of Israel. By fostering social discontent in such ventures, Solomon prepared the way for the disintegration of the united kingdom and the resurgence of the prophetic movement that reflected the indigenous covenant concept peculiar to Israel.

Whereas David secured Israel's borders and property by military means, Solomon sought to extend Israel's influence through commercial treaties. To secure diplomatic and commercial treaties Solomon contracted marriage with various princesses—who brought with them their native deities. This defection from the Covenant obligations to Yahweh is viewed by the Deuteronomic historian as a continuance of Israel's constant flirting with apostasy, which had occurred under the judges, and the beginning of a long process of internal religious and political disintegration under the monarchical system. Solomon's oppressive taxation and commercial expansion also brought about retaliation and rebellion.

The divided monarchy. After Solomon died (922 BCE), he was succeeded by Rehoboam, who proved to be unfit for the task of reigning. Prior to Solomon's death, Jeroboam the Ephraimite, a young overseer of the forced labour battalions of the "house of Joseph" in the north, had encountered Ahijah, a prophet from the old shrine of the confederacy at Shiloh, and Ahijah had torn a new garment into 12 pieces, prophesying that 10 pieces (tribes) would be given to Jeroboam and only two pieces (tribal political units) would be retained by the house of David. The dismemberment of the united monarchy was to be brought about by Yahweh because Solomon had "not walked in my ways, doing what is right in my sight and keeping my statutes and my ordinances, as David his father did." Though Solomon had worshipped the Sidonian goddess Ashtoreth, the Moabite god Chemosh, and the Ammonite god Milcom, his reign over Israel continued. Jeroboam's initial rebellion proved to be abortive, and he sought political asylum in Egypt under the protection of the pharaoh Sheshonk I (Shishak).

The rise of the divided kingdom: Israel and Judah

Rehoboam, having been crowned king of the united monarchy in Jerusalem, went north to Shechem, a shrine centre of the 10 northern tribes of the old confederacy, to have his position ratified by the northern units of the kingdom. Using this gathering as an opportune time to present their grievances against Solomon's oppressive domestic policies, the northerners, under the leadership of the returned political fugitive Jeroboam, asked the king from Jerusalem to lighten their load. Requesting three days to take their grievances under advisement, Rehoboam sought counsel from his advisers. The older counsellors advised moderation, the younger, retaliation. Assenting to the latter, Rehoboam returned to the people with an answer that was to lead to the disintegration of the united monarchy that had lasted for only about a century under three kings: "My father made your yoke heavy, but I will add to your yoke; my father chastised you with whips, but I will chastise you with scorpions." The response of the northerners was the ancient battle cry, "To your tents, O Israel." Rehoboam, ruling from the cities, sent Adoram, the leader of the forced labour battalions, to Israel (the name to be used henceforth for the northern area); but he was stoned to death. The uncrowned king of the north, unable to quell the rebellion, returned to Jerusalem in rapid flight. Heeding the advice of the prophet Shemaiah, Rehoboam allowed the situation to remain that of a stalemate, thus inaugurating the period of the divided monarchy that lasted in Israel in the north from 922–721 BCE and in Judah in the south until 586 BCE.

Turmoil in the monarchy of the northern kingdom

Though the Davidic monarchy continued in Judah until the fall of Jerusalem in 586 BCE, the monarchial situation in Israel was one of constant turmoil and confusion, except for the periods of a few dynasties. Jeroboam I of Israel (reigned 922–901 BCE) attempted to bring about religious and political reforms. Establishing his capital at Shechem, he set aside two pilgrimage sites (Dan in the north and Bethel in the south) as shrine centres. Though the Deuteronomic historian—with an anti-north prejudice—interpreted Jeroboam's use of golden bulls in the high place sanctuaries as a sin against Yahweh, Jeroboam's actions may have merely been an incorporation of religious symbols similar to the cherubim (winged animals) that guarded the empty throne of Yahweh in the temple of Solomon in Jerusalem. Jeroboam would not have been so politically and religiously naïve as to introduce polytheistic practices among the conservative-minded tribes of northern Israel. Thus, the golden bulls may have been meant to serve as pedestals for the invisible Yahweh just as the ark (throne) may have been the seat of the invisible Yahweh in the Holy of Holies (inner sanctuary) of the Temple in Jerusalem. Gods (such as the storm god Hadad) of other Syrian and Palestinian religions also were represented as standing on the backs of bulls.

Jeroboam remained true to Yahwistic religion, however, in that the God of the Israelites was not represented icono-

graphically. The first king of the northern kingdom also inaugurated other religious reforms or reinstituted ancient practices that were interpreted as decadent by the Deuteronomic historian of the southern kingdom of Judah. He instituted a harvest thanksgiving festival on the 15th day of the eighth month, a change in the religious calendar that would preclude the journey of many northern Israelites to a similar festival in Jerusalem; he reformed the priesthood by installing non-Levites (the traditional shrine functionaries) to serve Yahweh at the shrines, an action that had been carried out in Jerusalem by David but without the opprobrium inferred by the Deuteronomic historian on a similar action by Jeroboam.

The dynasties of the northern kingdom were shortlived. Jeroboam was succeeded by his son Nadab, who reigned for two years before he was overthrown by Baasha, who decimated the house of Jeroboam. Reigning for 24 years, Baasha (who "did what was evil in the sight of the Lord" like all of the northern kings, according to the interpretation of the Deuteronomists) had to concern himself not only with charismatic leaders who were traditionally powerful in the north but also with the rising power of antimonarchical prophets, such as Jehu—who prophesied the end of the house of Baasha (chapter 16). Elah, Baasha's son, ruled only two years before he was assassinated while in a drunken state by Zimri, a chariot commander, who exterminated all of the members of the house of Baasha. Reigning for the brief period of seven days, Zimri was besieged in the citadel at Tirzah by Omri, commander of the army. Zimri burned to death in the king's house. Much of this political turmoil and confusion in the north occurred during the reign of Asa, king of Judah from *c.* 913 to 873 BCE, who inaugurated religious reforms, such as banning male cult prostitutes and the worship of the Canaanite goddess Asherah that had been sponsored by his mother, Maachah, the queen regent.

The dynasty of Omri and the career of Elijah

The significance of Elijah. With the dynasty of Omri (*c.* 876–842), the prophetic movement begins to assume a position of tremendous importance in Israel and Judah. Omri (reigned *c.* 876–869) reestablished Israel's economic and military significance among the Syrian and Palestinian minor kingdoms, so much so that years after his death the Assyrians referred to the northern kingdom as "the land of Omri." He is mentioned in the Moabite Stone of King Mesha (9th century BCE) as a king who "humbled Moab many years." To strengthen an alliance with the Phoenicians, Omri contracted a marriage between Jezebel, princess of Sidon, and his son Ahab. The marriage proved to be fateful for Israel and was a catalyst that brought the prophetic movement into a course of action and a form that became Israel's contribution to Near Eastern prophecy.

The reign of Omri's son Ahab coincided with the activities of the prophet Elijah, as recorded in I Kings, chapter 16, verse 29, to chapter 22, verse 40. Ahab, under the influence of his queen Jezebel, allowed her to foster the worship of the fertility god Baal in Samaria—the capital that Omri had built—and in all Israel, even though he himself remained a worshipper of Yahweh. A temple was built for Baal in Samaria; Jericho was rebuilt (even though the ban against its existence still remained) by Hiel of Bethel, who sacrificed two of his own sons and placed them in the foundation and the gates of the walls of the city. During these apostate activities the great prophet Elijah the Tishbite appeared. A man of erratic behaviour, wearing a garment of hair with a leather belt around his waist, using uncouth language, and preferring the wilderness areas to the towns, Elijah bore many of the outward signs of social rebels. At odds with the court authorities, he began his prophetic career just prior to a retreat in the wilderness during a drought, which he had announced to Ahab, thus pointing out that Yahweh, rather than Baal, is the Lord of nature. In the desert he performed two miracles: he ensured a widow and her son of continuous food for her act of generosity to him and cured her son, apparently dead, who had stopped breathing, by stretching himself on top of the boy three times. Elijah then went to the court of Ahab at Samaria, after having met one of the leading prophets (Obadiah) who had escaped Jezebel's attempt to destroy the leaders of the cult of Yahweh, and stood before Ahab, accusing the king of being the "troubler of Israel" for having followed the cult of Baal. Elijah hurled a challenge to the Baalists, supported by Jezebel, to meet him in a contest on Mt. Carmel.

The Mt. Carmel contest

The contest between Elijah and the 450 prophets of Baal was dramatic. Elijah first taunted the spectators, "How long will you go limping with two different opinions? If the Lord is God, follow him; but if Baal, then follow him." Elijah then laid the ground rules: two bulls were to be sacrificed, one each on an altar, on which firewood was to be laid, but no one was to light the fire—only the God "who answers by fire." The prophets of Baal had the first opportunity, and they prayed to Baal loudly for a full half day, until noon. During this time, Elijah, in coarse language, taunted them. Eliminating the euphemisms in most English versions of the Bible, Elijah mocked the Baalists by saying that Baal might not be responding because he was out urinating ("gone aside"), on a trip, or sleeping. The Baalists then attempted to use sympathetic magic. By cutting themselves they hoped that as their life blood flowed on the ground Baal would send rain, the life blood of the Earth.

When the Baalists had failed, Elijah rebuilt an old altar of Yahweh, poured water on the wood three times (perhaps a remnant of an ancient rainmaking ceremony?), and prayed to Yahweh to answer his servant; "the fire of the Lord fell, and consumed the burnt offering, and the wood, and the stones and the dust, and licked up the water that was in the trench." Though some authorities explain the action by suggesting that Elijah poured naphtha on the wood, this does not explain the ignition of the wood at that particular time and that particular place even if by a bolt of lightning. The Deuteronomic historian emphasized the miracle wrought by Yahweh. The people, upon witnessing the miracle, cried out, "Yahweh, he is God," and proceeded to annihilate the prophets of Baal.

Elijah told Ahab to complete the festivities while he went to the top of Mt. Carmel to perform another rainmaking ceremony. When the rains came in a cloudburst, Ahab was riding in his chariot in the Valley of Jezreel. Elijah, in fear of retaliation from Jezebel, fled to the southern wilderness. At Mt. Horeb (Sinai) after a storm, wind, and an earthquake, Yahweh spoke to Elijah through silence and then revealed that he should anoint Hazael to be king of Syria, Jehu to be king of Israel, and Elisha to be his successor as prophet. I Kings, chapter 20, records a war between Ben-hadad, king of Syria, and Ahab. Though Ahab was victorious, he did not kill Ben-hadad according to the provisions of the *ḥerem* (ban); and a prophet then informed Ahab that he would suffer for his inaction.

The affair of Naboth's vineyard

Upon Ahab's return to Samaria Jezebel attempted to coerce the king into confiscating the vineyards of Naboth of Jezreel, which was a Canaanite centre. Naboth asserted that as an Israelite the land was not his own but was a trust from Yahweh and that he could not sell it. Taken to court on trumped-up charges of blasphemy, Naboth was convicted and stoned to death. Ahab, following Jezebel's advice, then went to Naboth's vineyard and took possession of it. Upon hearing of Ahab's unjust act as king, Elijah proclaimed to him, "In the place where dogs licked up the blood of Naboth shall dogs lick your own blood." The prophet also announced, "The dogs shall eat Jezebel within the bounds of Jezreel."

In I Kings, chapter 22, another prophet, Micaiah, prophesied to Ahab and to King Jehoshaphat of Judah who were preparing for battle against the Syrians that in a vision he saw "all Israel scattered upon the mountains, as sheep that have no shepherd." Micaiah was put in prison to test the validity of his vision. It turned out to be true—Ahab, even though he disguised himself, was mortally wounded by an arrow shot by a Syrian archer. In 850 he was succeeded by his son Ahaziah, who reigned for only two years.

The Second Book of Kings continues the history of the monarchies of Israel and Judah and of the prophetic movement. Ahaziah fell from an upper chamber of his palace in Samaria and sought help from Baalzebub, the god of Ekron. Elijah met the messengers to castigate them for not seeking aid from Yahweh, the God of Israel, and

told a third delegation that had been sent out to return to tell Ahaziah that because of his apostasy he would die. After the death of Ahaziah, Elijah conferred his mantle, the symbol of his prophetic authority, on Elisha, and "Elijah went up by a whirlwind into heaven."

The significance of Elisha. The stories of Elijah and his successor, Elisha, are of a different literary genre from the historical accounts of the political developments of the 9th century. The historical accounts are based on the viewpoints and biases of the monarchy, nobility, and military leaders. The stories of Elijah and Elisha are legendary, popular accounts, probably having arisen among the common people. They demonstrate the predilection of the common people to accent what appears to them as the miraculous and the supernatural, much as has been the case among many Roman Catholics and Eastern Christians in stories of their saints. Elijah was depicted, in several instances, as a second Moses—*e.g.,* he fled to the wilderness to escape the retaliation of a ruler, and he encountered a theophany (manifestation of a deity) of Yahweh on Mt. Horeb. As Moses appointed Joshua as his successor, so also Elijah passed on his prophetic mantle to Elisha. Elisha is depicted in typical folk story embellishments and legendary motifs. The original beginning and ending of the Elijah story apparently was lost, but the Deuteronomic historian incorporated the popular accounts of Elijah and Elisha into the court history that gives scholars significant insights into the religious movements of the 9th century.

The prophetic career of Elisha and the end of the Omri dynasty

During the reigns of King Jehoshaphat of Judah (*c.* 873–849 BCE) and King Jehoram (Joram) of Israel (*c.* 849–842), Elisha began his prophetic career. Elisha was unlike his mentor Elijah in many ways: he did not use uncouth language, he did not shun towns, he wore more fashionable clothing, and he used music to bring about the prophetic spirit—much as Saul had done earlier. A cycle of miracle stories arose around Elisha; he was said to have made bitter water sweet, revived the son of a Shunammite woman from death by breathing into his mouth and lying on top of him, helped a woman to avoid giving up her two sons to a creditor who would make them slaves, informed the Syrian captain Naaman how to be cured from his skin disease, and many other similar actions. In addition to being a miracle worker, Elisha was a political power. He prophesied the defeat of the Moabites as a result of a huge rainfall and advised Joram how to defeat Ben-hadad, king of Syria. By performing this last act Elisha instigated a revolt in Syria; Hazael murdered the sick and dying Ben-hadad.

Elisha sent "one of the sons of the prophets" to anoint Jehu, an army commander, to be the future king of Israel. Rushing in his chariot to Jezreel, Jehu exterminated Jehoram, the last king of the Omri dynasty, his nephew Ahaziah (king of Judah), who was visiting him, and the queen mother Jezebel, who "had painted her eyes, and adorned her head" before she was thrown out of the window and so mangled by the trampling of horses that "they found no more of her than the skull and the feet and the palms of her hands." Jezebel's end had come about in a manner similar to the way in which Elijah had prophesied.

The revolution of Jehu was not only politically inspired. A driving force behind him was the arch conservative Rechabite faction, led by Jehonadab. Despising the Canaanites and their agricultural way of life, the Rechabites—descendants of the ancient Kenites of Midian where Moses had experienced the theophany of the burning bush—lived in tents, refused to drink wine, and attempted to retain as many of the accoutrements of the "good old life" of ancient nomadism as possible. With excessive revolutionary zeal they helped Jehu to annihilate the worshippers of Baal, who were tricked into coming to their temple and there murdered. To further emphasize their revolutionary intent, the followers of Jehu, in addition to the holocaust, made the site of the temple of Baal a latrine.

Because the king of Judah (Ahaziah) had been killed in the revolution—along with the remaining northern members of the house of Omri—the southern kingdom was ruled over by the queen mother, Athaliah, the daughter of Ahab and Jezebel. In her zeal to propagate the faith of her mother, Athaliah seized the opportunity to destroy the line of David that tended to be loyal to Yahweh. Liquidating all the male heirs to the throne of David—except the infant Joash (Jehoash) who received asylum in "the house of the Lord"—Athaliah ruled for six years. With support from the priests led by Jehoiada, the army and "the people of the land" revolted, killing Athaliah and her high priest of Baal, Mattan, and destroying the temple of Baal.

The reign of Jeroboam II and the demise of the northern kingdom

In the north, Jehu was succeeded by his son Jehoahaz (reigned *c.* 815–*c.* 801), who, in turn, was followed by his son Joash, or Jehoash. During the latter king's reign, the prophet Elisha died. Though the Deuteronomic historian says little about Israel's next king, Jeroboam II, he was a major monarch, reestablishing the northern kingdom's ancient boundaries and fostering a period of economic prosperity. During the reign of Jeroboam II (*c.* 786–*c.* 746 BCE), a time of both economic advances and social injustice, Amos, the great prophet of social justice, arose. During Jeroboam's last years another great prophet, Hosea, whose message centred on Covenant love, arose to call an apostate people back to their Covenant responsibilities.

The fall of Israel. After the death of Jeroboam II, however, Israel faced a period of continuous disaster; and no prophetic figure was able to arrest the steady internal decay. From 746–721, when Samaria finally fell to the Assyrians, there were six kings, the last being Hoshea, a conspirator who had assassinated the previous king. The Assyrian king Sargon II deported the leading citizens of Samaria to Persia and imported colonists from other lands to fill their places.

The fall of Judah. The southern kingdom of Judah, under the Davidic monarchy, was able to last about 135 years longer, often only as a weak vassal state. Hezekiah (reigned *c.* 715–*c.* 687), with the advice of the prophet Isaiah, managed to avoid conflict with or outlast a siege of the Assyrians. Hezekiah was succeeded by his son Manasseh, an apostate king who stilled any prophetic outcries, reintroduced Canaanite religious practices, and even offered his son as a human sacrificial victim. Soothsaying, augury, sorcery, and necromancy were also reintroduced. The Deuteronomic historian also notes that many innocent persons were killed during his reign. Manasseh was succeeded by his son Amon, who was assassinated in a palace revolution after a reign of only two years. His son Josiah, who succeeded him, reigned from 640 to 609 BCE, when he was killed in a battle with the pharaoh Necho II of Egypt. During his reign, one of the most significant events in the history of the Israelite people occurred—the Deuteronomic reform of 621 BCE. Occasioned by the discovery of a book of the Law in the Temple during its rebuilding and supported not only by Hilkiah, a high priest, and Huldah, a prophetess, but also by the young prophet Jeremiah, the Deuteronomic Code—or Covenant—as it has been called, became the basis for a far-reaching reform of the social and religious life of Judah. Though the reform was short-lived, because of the pressure of international turmoil, it left an indelible impression on the religious consciousness of the people of the Covenant, Israel, whether they were from the north or the south.

Reforms in Judah and the Babylonian Exile

From 609 to 586 Judah felt the coming oppression of Babylon under King Nebuchadrezzar. After the death of Josiah, four kings ruled in Jerusalem, the last being Zedekiah, who failed to heed the advice of the prophet Jeremiah—who had attempted to persuade the king not to trust the Egyptians in a rebellion against Babylon because there would be only one loser, the House of David. Jehoiachin, the predecessor of the puppet king Zedekiah, had been carried off into exile to Babylon in 598; but about 560 he was released from prison, thus leaving a hope that the Davidic line had not become extinct. Despite this small element of hope, the year 586 BCE marked the beginning of a tragic period for the people of Judah—the Babylonian Exile. During this period of rethinking Covenant faith, the prophet Ezekiel preached, both in Jerusalem and Babylon, offering the people hope for a restoration of the symbols and cultic acts of their covenant religion.

Isaiah. The Book of Isaiah, comprising 66 chapters, is one of the most profound theological and literarily expressive works in the Bible. Compiled over a period of

The division of Isaiah into two or three distinct sections

about two centuries (the latter half of the 8th to the latter half of the 6th century BCE), the Book of Isaiah is generally divided by scholars into two (sometimes three) major sections, which are called First Isaiah (chapters 1–39), Deutero-Isaiah (chapters 40–55 or 40–66), and—if the second section is subdivided—Trito-Isaiah (chapters 56–66).

The prophecies of First Isaiah. First Isaiah contains the words and prophecies of Isaiah, a most important 8th-century BCE prophet of Judah, written either by himself or his contemporary followers in Jerusalem (from *c.* 740 to 700 BCE), along with some later additions, such as chapters 24–27 and 33–39. The first of these two additions was probably written by a later disciple or disciples of Isaiah about 500 BCE; the second addition is divided into two sections—chapters 33–35, written during or after the exile to Babylon in 586 BCE, and chapters 36–39, which drew from the source used by the Deuteronomic historian in II Kings, chapters 18–19. The second major section of Isaiah, which may be designated Second Isaiah even though it has been divided because of chronology into Deutero-Isaiah and Trito-Isaiah, was written by members of the "school" of Isaiah in Babylon: chapters 40–55 were written prior to and after the conquest of Babylon in 539 by the Persian king Cyrus II the Great, and chapters 56–66 were composed after the return from the Babylonian Exile in 538. The canonical Book of Isaiah, after editorial redaction, probably assumed its present form during the 4th century BCE. Because of its messianic (salvatory figure) themes, Isaiah became extremely significant among the early Christians who wrote the New Testament and the sectarians at Qumrān near the Dead Sea, who awaited the imminent messianic age, a time that would inaugurate the period of the Last Judgment and the Kingdom of God.

Themes peculiar to Isaiah and his call to become a prophet

Isaiah, a prophet, priest, and statesman, lived during the last years of the northern kingdom and during the reigns of four kings of Judah: Uzziah (Azariah), Jotham, Ahaz, and Hezekiah. He was also a contemporary of the prophets of social justice: Amos, Hosea, and Micah. Influenced by their prophetic outcries against social injustice, Isaiah added themes peculiar to his prophetic mission. To kings, political and economic leaders, and to the people of the land, he issued a message that harked back nearly five centuries to the period of the judges: the holiness of Yahweh, the coming Messiah of Yahweh, the judgment of Yahweh, and the necessity of placing one's own and the nation's trust in Yahweh rather than in the might of ephemeral movements and nations. From about 742 BCE, when he first experienced his call to become a prophet, to about 687, Isaiah influenced the course of Judah's history by his oracles of destruction, judgment, and hope as well as his messages containing both threats and promises.

Intimately acquainted with worship on Mt. Zion because of his priest-prophet position, with the Temple and its rich imagery and ritualistic practices, and possessed of a deep understanding of the meaning of kingship in Judah theologically and politically, Isaiah was able to interpret and advise both leaders and the common people of the Covenant promises of Yahweh, the Lord of Hosts. Because they were imbued with the following beliefs—God dwelt on Mt. Zion, in the Temple in the city of Jerusalem, and in the person of the King—the messianic phrase "God is with us" (Immanuel) Isaiah used was not a pallid abstraction of a theological concept but a concrete living reality that found its expression in the Temple theology and message of the great prophet.

In chapters 1–6 are recorded the oracles of Isaiah's early ministry. His call, a visionary experience in the temple in Jerusalem, is described in some of the most influential symbolic language in Old Testament literature. In the year of King Uzziah's death (742 BCE), Isaiah had a vision of the Lord enthroned in a celestial temple, surrounded by the seraphim—hybrid human-animal-bird figures who attended the deity in his sanctuary. Probably experiencing this majestic imagery that was enhanced by the actual setting and the ceremonial and ritualistic objects of the Jerusalem Temple, Isaiah was mystically transported from the earthly temple to the heavenly temple, from the microcosm to the macrocosm, from sacred space in profane time to sacred space in sacred time.

Yahweh, in the mystical, ecstatic experience of Isaiah, is too sublime to be described in other than the imagery of the winged seraphim, which hide his glory and call to each other:

> "Holy, holy, holy is the Lord of hosts;
> The whole earth is full of his glory."

With smoke rising from the burning incense, Isaiah was consumed by his feelings of unworthiness ("Woe is me! for I am lost"); but one of the seraphim touched Isaiah's lips with a burning coal from the altar and the prophet heard the words, "Your guilt is taken away, and your sin forgiven." Isaiah then heard the voice of Yahweh ask the heavenly council, "Whom shall I send, and who will go for us?" The prophet, caught up as a participant in the mystical dialogue, responded, "Here am I! Send me." The message to be delivered to the Covenant people from the heavenly council, he is informed, is one that will be unheeded.

The early oracles of Isaiah

The oracles of Isaiah to the people of Jerusalem from about 740 to 732 BCE castigate the nation of Judah for its many sins. The religious, social, and economic sins of Judah roll from the prophet's utterances in staccato-like sequence: (1) "Bring no more vain offerings; incense is an abomination to me. New moon and sabbath and the calling of assemblies—I cannot endure iniquity and solemn assembly," against religious superficiality; (2) "cease to do evil, learn to do good; seek justice, correct oppression; defend the fatherless, plead for the widow," against social injustice; and (3) "Come now, let us reason together, says the Lord: though your sins are like scarlet, they shall be as white as snow," a call for obedience to the Covenant. The prophet also cried out for peace: "and they shall beat their swords into plowshares, and their spears into pruning hooks; nation shall not lift up sword against nation, neither shall they learn war anymore." The sins of Judah, however, are numerous: the rich oppress the poor, the nation squanders its economic resources on military spending, idolatry runs rampant in the land, everyone tries to cheat his fellowman, women flaunt their sexual charms in the streets, and there are many who cannot wait for a strong drink in the morning to get them through the day. One of Isaiah's castigations warns: "Woe to those who are heroes at drinking wine, and valiant men in mixing strong drink, who acquit the guilty for a bribe, and deprive the innocent of his right!"

Isaiah's prophetic attacks on Judah's foreign policy

During the Syro-Ephraimitic war (734–732 BCE), Isaiah began to challenge the policies of King Ahaz of Judah. Syria and Israel had joined forces against Judah. Isaiah's advice to the young King of Judah was to place his trust in Yahweh. Apparently Isaiah believed that Assyria would take care of the northern threat. Ahaz, in timidity, did not want to request a sign from Yahweh. In exasperation Isaiah told the King that Yahweh would give him a sign anyway: "Behold, a young woman shall conceive and bear a son, and shall call his name Immanuel." Thus, by the time this child is able to know how to choose good and refuse evil, the two minor kings of the north who were threatening Judah will be made ineffective by the Assyrians. The name Immanuel, "God is with us," would be meaningful in this situation because God on Mt. Zion and represented in the person of the king would be faithful to his Covenant people. Ahaz, however, placed his trust in an alliance with Assyria under the great conqueror Tiglath-pileser III. In order to give hope to the people, who were beginning to experience the Assyrian encroachments on Judaean lands in 738 BCE, Isaiah uttered an oracle to "the people who walked in darkness": "For to us a child is born, to us a son is given; and the government will be upon his shoulder, and his name will be called Wonderful Counselor, Mighty God, Everlasting Father, Prince of Peace." Isaiah trusted that Yahweh would bring about a kingdom of peace under a Davidic ruler.

From 732 to 731 BCE, the year the northern kingdom fell, Isaiah continued to prophesy in Judah but probably not in any vociferous manner until the Assyrians conquered Samaria. The king of the Assyrians is described as the rod of God's anger, but Assyria also will experience the judgment of God for its atrocities in time of war. During

one of the periods of Assyrian expansion towards Judah, Isaiah uttered his famous Davidic messianic (salvatory figure) oracle in which he prophesies the coming of a "shoot from the stump of Jesse," upon which the Spirit of the Lord will rest and who will establish the "peaceable kingdom" in which "the wolf shall dwell with the lamb." A hymn of praise concludes this first section of First Isaiah.

Chapters 13–23 include a list of oracles against various nations—Babylon, Assyria, Philistia, Moab, Syria, Egypt, and other oppressors of Judah. These probably came from the time when Hezekiah began his reign (*c.* 715). In 705 BCE, Sargon of Assyria died, however, and Hezekiah, a generally astute and reform-minded king, began to be caught up in the power struggle between Babylon, Egypt, and Assyria. Isaiah urged Hezekiah to remain neutral during the revolutionary turmoil. Though Sennacherib of Assyria moved south to crush the rebellion of the Palestinian vassal states, Isaiah—contrary to his previous advocacy of neutrality—urged his king to resist the Assyrians because the Lord, rather than the so-called Egyptian allies, who "are men, and not God," will protect Jerusalem. He then prophesied a coming age of justice and of the Spirit who will bring about a renewed creation.

Second Isaiah (chapters 40–66), which comes from the school of Isaiah's disciples, can be divided into two periods: chapters 40–55, generally called Deutero-Isaiah, were written about 538 BCE after the experience of the Exile; and chapters 56–66, sometimes called Trito-Isaiah (or III Isaiah), were written after the return of the exiles to Jerusalem after 538 BCE.

Deutero-Isaiah and the Servant Songs

The prophecies of Deutero-Isaiah. Second Isaiah contains the very expressive so-called Servant Songs—chapter 42, verses 1–4; chapter 49, verses 1–6; chapter 50, verses 4–9; chapter 52, verse 13; and chapter 53, verse 12. Writing from Babylon, the author begins with a message of comfort and hope and faith in Yahweh. The people are to leave Babylon and return to Jerusalem, which has paid "double for all her sins." As creator and Lord of history, God will redeem Israel, his chosen servant. Through the Servant of the Lord all the nations will be blessed: "I have put my Spirit upon him, he will bring forth justice to the nations." The Suffering Servant, whether the nation Israel or an individual agent of Yahweh, will help to bring about the deliverance of the nation. Though Second Isaiah may have been referring to a hoped-for rise of a prophetic figure, many scholars now hold that the Suffering Servant is Israel in a collective sense. Christians have interpreted the Servant Songs, especially the fourth, as a prophecy referring to Jesus of Nazareth—"He was despised and rejected by men; a man of sorrows and acquainted with grief . . . ," but this interpretation is theologically oriented and thus open to question, according to many scholars.

The oracles of Trito-Isaiah. Chapters 56–66 are a collection of oracles from the restoration period (after 538 BCE). Emphasis is placed upon cultic acts, attacks against idolatry, and a right motivation in the worship of Yahweh. Repentance and social justice are themes that have been retained from the earlier Isaiah traditions, and the ever-present element of hope in the creative goodness of Yahweh that pervaded II Isaiah remains a dominant theme in the last chapters of the Book of Isaiah.

Jeremiah. The prophet Jeremiah began to prophesy about 626 BCE during the reign of the Judaean king Josiah. From the town of Anathoth and probably from the priestly family of Eli, this prophet, who may have been instrumental in the Deuteronomic reform, dictated his oracles to his secretary Baruch. Only a youth in his late teens when he experienced the call by Yahweh to be a "prophet to the nations," Jeremiah was a hesitant reforming prophet, experiencing deep spiritual struggles regarding his adequacy from the very beginning of his call and throughout his prophetic ministry. After the death of Josiah in 609 BCE, however, he became an outspoken prophet against the national policy of Judah, a policy that he knew would lead to the disaster that came to be called the Babylonian Exile. Because of his prophecies, which were unpopular with the military and the revolutionists against the Babylonians, Jeremiah was kidnapped by conspirators after 586 and taken to Egypt, where he disappeared.

The call of Jeremiah and his difficulties with political and revolutionary leaders

The Book of Jeremiah is a collection of oracles, biographical accounts, and narratives that are not arranged in any consistent chronological or thematic order. One 20th-century German biblical scholar, Wilhelm Rudolph, has attempted to arrange the chapters of the book according to certain chronological details. He has divided the work into five sections: (1) prophecies against Judah and Jerusalem, chapters 1–25, during the reigns of kings Josiah (640–609) and Jehoiachim (609–598), and the period after Jehoiachim (597–586); (2) prophecies against foreign nations, chapters 25 and 66–61; (3) prophecies of hope for Israel, chapters 26–35 (probably after the death of Josiah in 609); (4) narratives of Jeremiah's sufferings, chapters 36–45 (from a post-586 period), and (5) an appendix, chapter 52. Jeremiah's own prophetic oracles are found particularly in chapters 1–36 and 46–52. Baruch's writings about Jeremiah are found primarily in chapters 37–45, 26–29, and 33–36.

During the reign of Josiah, after his call, Jeremiah preached to the people of Jerusalem and warned them against the sin of apostasy. Recalling the prophecies of the 8th-century Israelite prophet Hosea, Jeremiah reproached the Judaeans for playing harlot with other gods and urged them to repent. He prophesied that enemies from the north would be the instruments of Yahweh's judgment on the apostate land and Jerusalem would suffer the fate of a rejected prostitute. The idolatry and immorality of the Judaeans would inevitably lead to their destruction. Because of the impending threat from the north, Jeremiah warned the people to flee from the wrath that was to come.

At the beginning of Jehoiachim's reign, Jeremiah preached in the temple that because of Judah's apostasy "death shall be preferred to life by all the remnant that remains of this evil family in all the places where I have driven them, says the Lord of hosts." Because he spoke words that were unpopular, his own townsmen of Anathoth plotted against his life. To symbolize the fate of Judah, Jeremiah adopted some rather bizarre techniques. He buried a waist cloth and wore it when it was spoiled to illustrate the fate of Jerusalem, which had worshipped other gods than Yahweh.

Throughout his career Jeremiah had moments of deep depression, times when he lamented that he had become a prophet. Because of the uncertainty of the times, Jeremiah did not marry.

Jeremiah's depression and allegorical messages

A master of symbolic actions and the use of symbolic devices, Jeremiah used a potter's wheel to show that Yahweh was shaping an evil future for Judah; and he bought a flask, after which he broke it on the ground to illustrate again the fate of Judah. Because of such words and actions, Jeremiah often found himself in trouble. Pashur, a priest, had Jeremiah beaten and placed in stocks. When released, Jeremiah told Pashur he would go into captivity and die. Despite the plots against him, Jeremiah continued to rely on the grace of Yahweh. He was brought to trial for prophesying the destruction of Jerusalem, but his defense attorneys—"certain of the elders"—pointed out that King Hezekiah had not punished the prophet Micah of Moresheth in the 8th century for similar statements.

Continuing to prophesy against the moral and religious corruption of Jerusalem during the reign of Zedekiah (597–586), Jeremiah became even more unpopular for his advocacy to surrender to Babylon.

In spite of his apparent failure to win over the people to his cause, Jeremiah inaugurated a reform that had lasting effects. He helped to bring about a change in religion from the view that primarily accepted corporate responsibility to one that held that religion is more individualistic in terms of responsibility. His words in chapter 31, verse 33, are a summation of his reform: "But this is the covenant which I will make with the house of Israel after those days, says the Lord: I will put my law within them, and I will write it upon their hearts; and I will be their God, and they shall be my people."

Ezekiel. The Book of Ezekiel, written by the prophet-priest Ezekiel, who lived both in Jerusalem prior to the Babylonian Exile (586 BCE) and in Babylon after the Exile, and also by an editor (or editors), who belongs to a "school" of the prophet similar to that of the prophet Isaiah, has captured the attention of readers for centuries

Stylistic and literary problems in Ezekiel

because of its vivid imagery and symbolism. The book has also attracted the attention of biblical scholars who have noticed that, although Ezekiel appears to be a singularly homogeneous composition displaying a unity unusual for such a large prophetic work, it also displays, upon careful analysis, the problem of repetitions, certain inconsistencies and contradictions, and questions raised by terminological differences. Though the book itself indicates that the prophecies of Ezekiel occurred from about 593–571 BCE, some scholars—who are in a minority—have argued that the book was written during widely divergent periods, such as in the 7th century and even as late as the 2nd century BCE. Most scholars, however, accept that the main body of the book came from the 6th century BCE, with the inclusion of some later glosses by redactors who remained loyal to the theological traditions of their master-teacher.

Containing several literary genres, such as oracles, mythological themes, allegory, proverbs, historical narratives, folk tales, threats and promises, and lamentations, the Book of Ezekiel may be divided into three main sections: (1) prophecies against Judah and Jerusalem (chapters 1–24); (2) prophecies against foreign countries (chapters 25–32); and (3) prophecies about Israel's future.

Ezekiel—the man and his message. The man who wrote this book—at least the main body of the work—was undoubtedly one of the leaders of Jerusalem because he was among the first group of exiles to go into captivity—those who were forced to leave their homeland about 597 BCE in a deportation to Babylon on the orders of the conquering king Nebuchadrezzar. Belonging to the priestly class, perhaps of the line of Zadok, Ezekiel was a spiritual leader of his fellow exiles at Tel-abib, which was located near the river Chebar, a canal that was part of the Euphrates River irrigation system. According to his own account, Ezekiel, the priest without a temple, received the call to become a prophet during a vision "In the thirtieth year, in the fourth month, on the fifth day"—perhaps July 31, 593 BCE, if the dating is based on the lunar calendar, though the exact meaning of "thirtieth year" remains obscure. A married man who was often consulted by elders among the exiles, Ezekiel carried out his priestly and prophetic career during two distinct periods: (1) from 593–586 BCE, a date that was doubly depressing for the prophet because it was the period when his wife died and his native city was destroyed; and (2) from 586–571 BCE, the date of his last oracle (chapter 29, verse 17).

The personality of the prophet shows through his oracles, visions, and narrations. Frustrated because the people would not heed his messages from Yahweh, Ezekiel often exhibited erratic behaviour. This need not mean that he was psychologically abnormal. Like many great spiritual leaders, he displayed qualities and actions that did not fall within the range of moderation, and to perform an ex post facto psychological postmortem examination on any great historical figure in the face of a paucity of necessary details may be an interesting game but is hardly scientifically respectable or accurate. To be sure, Ezekiel did engage in erratic behaviour: he ate a scroll on one occasion, lost his power of speech for a period of time, and lay down on the ground "playing war" to emphasize a point, an action that would certainly draw attention to him, which was his purpose. In spite of these peculiarities, Ezekiel was a master preacher who drew large crowds and a good administrator of his religious community of exiles. He held out hope for a temple in a new age in order to inspire a people in captivity. He also initiated a form of imagery and literature that was to have profound effects on both Judaism and Christianity all the way to the 20th century: apocalypticism (the view that God would intervene in history to save the believing remnant and that this intervention would be accompanied by dramatic, cataclysmic events).

Ezekiel's mystical call and symbolic acts

Prophetic themes and actions. The first section of the book (chapters 1–24) contains prophecies against Judah and Jerusalem. Ezekiel's call is recorded in chapter 1 to chapter 3, verse 15. It came in a vision of four heavenly cherubim, who appeared in a wind from the north, a cloud, and flashing fire (lightning?)—traditional symbolic elements of a theophany (manifestation of a god) in ancient Near Eastern religions. These winged hybrid throne bearers—with the faces of a man, a lion, an ox, and an eagle (which became iconographic symbols of the four Gospel writers of the New Testament)—bore the throne chariot of Yahweh. The cherubim, symbolizing intelligence, strength, and—especially—mobility, had beside them four gleaming wheels, or "a wheel within a wheel" (*i.e.,* set at right angles to each other), which further emphasized the omnimobility of the throne chariot. This vision harks back to Isaiah's mystical experience (Isaiah, chapter 6) in which that prophet envisioned the throne of the ark, which symbolized the omnipresence of the invisible Yahweh. High above the cherubim was a firmament, or crystal platform, above which was the throne of Yahweh, who—in a "likeness as if it were of a human form"—spoke to Ezekiel. The Spirit of Yahweh entered him, and he was commissioned to preach to the people of Israel a message of doom to an apostate people. The significance of this vision is that it occurred not to a priest in the holy Temple at Jerusalem but to an exiled prophet-priest in a foreign land. The God of Israel was the God of the nations. The impact of his visionary experience so overwhelmed Ezekiel that he simply sat at Tel-abib for seven days.

Commissioned by Yahweh to be "a watchman for the house of Israel," Ezekiel performed a series of symbolic acts to illustrate the impending fate of the city from which he had been banished: he placed a brick on the ground to symbolize Jerusalem's future siege, lay down on the ground, bound himself to indicate capture, ate food first cooked on fuel composed of human feces and then animal excrement, and then cut his hair and beard. Though these acts were performed in Babylon, news of them was most likely communicated to the people of Jerusalem. Just as Jeremiah had tried to repress the false hopes that the residents of Jerusalem harboured concerning the downfall of Babylon, which had been predicted by the popular nationalistic prophet Hananiah (Jeremiah, chapter 28, verses 5–17), Ezekiel attempted to quash the ill-founded aspirations of the exiles for an immediate return to Jerusalem.

In chapters 6 and 7 Ezekiel prophesies that Jerusalem's "altars shall become desolate," its people will be "scattered through the countries," and "because the land is full of bloody crimes and the city full of violence," Yahweh "will put an end to their proud might and their holy places shall be profane." In chapter 8 he attacked the people of Jerusalem for their idolatry, as manifest by the women sitting before the entrance to the north gate of the Temple of Yahweh weeping in cultic despair for the Mesopotamian fertility deity Tammuz's "annual death."

After prophesying the fall of Jerusalem in chapters 9–11 because "the guilt of the house of Israel and Judah is exceedingly great," Ezekiel performed other symbolic acts such as packing baggage for an emergency exile, digging a hole in his house to illustrate the fact that some will try to escape, and eating and drinking with trembling actions to show the future fear that the Jerusalemites will experience; he also attacked prophets who gave the people false hopes. "Woe to the foolish prophets who follow their own spirit, and have seen nothing. Your prophets have been like foxes among ruins, O Israel." He tried to underline his message of urgency by relating the problem of apostasy to similar situations in Israel's past history.

The death of Ezekiel's wife and the fall of Jerusalem

About the time that Nebuchadrezzar besieged Jerusalem, Ezekiel's wife became ill. Though Ezekiel could mourn her impending death "but not aloud" (*i.e.,* only by himself so that the people would notice his unusual reaction and thus receive the full impact of his prophetic message), he was not to mourn her death publicly. When he did not eat the "bread of mourners" the people asked him for an explanation. He told them, and it was a shattering exposure: Jerusalem would be destroyed "and your sons and daughters whom you left behind shall fall by the sword"; when this happens—in spite of their pining and groaning—they will know the meaning of Ezekiel's actions.

In order to show that Yahweh was the Lord of the whole creation and of all nations, Ezekiel issued prophecies of impending disasters that would be experienced by many neighbouring Near Eastern countries. Nations that exulted

in Judah's defeat—*i.e.,* Ammon, Moab, Edom, Philistia, and Phoenicia—would all suffer the same fate, as well as Egypt, the formerly great empire that had manoeuvred Judah into its disastrous foreign policy of opposing Babylon.

Ezekiel's oracular imagery

Oracles of hope. In the third section, chapters 33–48, Ezekiel proclaimed, in oracles that have become imprinted in theological discourse and folk songs, the hope that lies in the faith that God cares for his people and will restore them to a state of wholeness. As the good shepherd, God will feed his flock and will "seek the lost," "bring back the strayed," "bind up the crippled," and "strengthen the weak." He will also "set up over them one shepherd, my servant David, and he shall feed them." This Davidic ruler will be a *nasi* (prince), the term used for a leader of the tribal confederacy before the inauguration of the monarchy. In chapter 37, Ezekiel had a now-famous vision of the valley of dry bones, which refers not to resurrection from the dead but rather to the restoration of a scattered Covenant people into a single unity. To further emphasize the restoration of the scattered people of Yahweh, Ezekiel uttered the oracle of the two sticks joined together into one, which prophesied the re-unification of Israel and Judah as one nation. Chapters 38 and 39 contain a cryptic apocalyptic oracle about the invasion of an unidentified Gog of Magog. Who this Gog is has long been a matter of speculation; whoever he is, his chief characteristic is that he is the demonic person who leads the forces of evil in the final battle against the people of God. Gog and Magog have thus earned a position in apocalyptic literature over the centuries. Chapters 40–48 are a closing section in which Ezekiel has a vision of a restored Temple in Jerusalem with its form of worship reestablished and a restored Israel, with each of the ancient tribes receiving appropriate allotments. Ezekiel's prophecies while in exile in Babylon were to have a significant influence on the religion of Judaism as it emerged from a time of reassessment of its religious beliefs and cultic acts during the Babylonian Exile (586–538 BCE).

The Twelve. *Hosea.* The Book of Hosea, the first of the canonical Twelve (Minor) Prophets, was written by Hosea (whose name means "salvation," or "deliverance"), a prophet who lived during the last years of the age of Jeroboam II in Israel and the period of decline and ruin that followed the brief period of economic prosperity. The Assyrians were threatening the land of Israel and the people of the Covenant acted as though they were oblivious to the stipulations of their peculiar relation to Yahweh. The Book of Hosea is a collection of oracles composed and arranged by Hosea and his disciples. Like his contemporary Amos, the great prophet of social justice, Hosea was a prophet of doom; but he held out a hope to the people that the Day of Yahweh contained not just retribution but also the possibility of renewal. His message against Israel's "spirit of harlotry" was dramatically and symbolically acted out in his personal life.

The symbolism of Hosea's marriage and the emphasis on Covenant love and knowledge of God

The Book of Hosea may be divided into two sections: (1) Hosea's marriage and its symbolic meaning (chapters 1–3); and (2) judgments against an apostate Israel and hope of forgiveness and restoration (chapters 4–14).

In the first section, Hosea is commanded by Yahweh to marry a prostitute by the name of Gomer as a symbol of Israel's playing the part of a whore searching for gods other than the one true God. He is to have children by her. Three children are born in this marriage. The first, a son, is named Jezreel, to symbolize that the house of Jehu will suffer for the bloody atrocities committed in the Valley of Jezreel by the founder of the dynasty when he annihilated the house of Omri. The second, a daughter, is named Lo Ruḥama (Not pitied), to indicate that Yahweh was no longer to be patient with Israel, the northern kingdom. The third child, a son, is named Lo ʿAmmi (Not my people), signifying that Yahweh was no longer to be the God of a people who had refused to keep the Covenant. In chapter 2, Hosea voiced what probably was a divorce formula—"she is not my wife, and I am not her husband"—to indicate that he had divorced his faithless wife Gomer, who kept "going after other lovers." The deeper symbolism is that Israel had abandoned Yahweh for the cult of Baal, celebrating the "feast days of Baal." Just as Yahweh will renew his Covenant with Israel, however, Hosea buys a woman for a wife—probably Gomer. The woman may have been a sacred prostitute in a Baal shrine, a concubine, or perhaps even a slave. He confines her for a period of time so that she will not engage in any attempt to search for other paramours and thus commit further adulteries.

The second section, chapters 4–14, does not refer to the marriage motif; but the imagery and symbolism of marriage constantly recur. The Israelites, in "a spirit of harlotry," have gone astray and have left their God. Their infidelity emphasized their lack of trustworthiness and real knowledge of love, a love that could not be camouflaged by superficial worship ceremonies. Thus, Hosea emphasized two very significant theological terms: *ḥesed,* or "Covenant love," and "knowledge of God." In attacking the superficiality of much of Israel's worship, Yahweh, through Hosea, proclaimed: "For I desire steadfast (Covenant) love and not sacrifice, the knowledge of God, rather than burnt offerings." Because they have broken Yahweh's Covenant and transgressed his law, however, the Lord's anger "burns against them." For "they sow the wind and they shall reap the whirlwind." Israel will be punished for its rebellion and iniquities, but Hosea's message holds out the hope that the holiness of Yahweh's love—including both judgment and mercy—will effect a triumphant return of Israel to her true husband, Yahweh.

Joel. The Book of Joel, the second of the Twelve (Minor) Prophets, is a short work of only three chapters. The dates of Joel (whose name means "Yahweh is God") are difficult to ascertain. Some scholars believe that the work comes from the Persian period (539–331 BCE); others hold that it was written soon after the fall of Jerusalem in 586 BCE. His references to a locust plague may refer to an actual calamity that occurred; the prophet used the situation to call the people to repentance and lamentation, perhaps in connection with the festival of the New Year, the "Day of Yahweh." " 'Yet even now,' says the Lord, 'return to me with all your heart, with fasting, with weeping, and with mourning; and rend your hearts and not your garments.' " Some scholars, however, believe that the plague of locusts refers to the armies of a foreign power (Babylonia?). In the remaining section of the book (chapter 2, verse 30 to chapter 3, verse 21), Joel, in apocalyptic imagery, predicts the judgment of the nations—especially Philistia and Phoenicia—and the restoration of Judah and Jerusalem.

Amos. The Book of Amos, the third of the Twelve (Minor) Prophets, has been one of the most significant and influential books of the Bible from the time it was written (8th century BCE) down to the 20th century. Comprising only nine chapters of oracles, it was composed during the age of Jeroboam II, king of Israel from 786 to 746 BCE. His reign was marked by great economic prosperity, but the rich were getting richer and the poor poorer. Social injustice ran rampant in the land. The economically weak could find no redress in the courts and no one to champion their cause—until the coming of Amos, a shepherd from Tekoa in Judah, who also said that he was "a dresser of sycamore trees." Amos, thus, was no professional prophet nor a member of a prophetic guild.

The call for social justice by Amos

The book may be divided into three sections: (1) oracles against foreign nations and Israel (chapters 1–2); (2) oracles of indictment against Israel for her sins and injustices (chapters 3–6); and (3) visions and words of judgment (chapters 7–9). Amos was the first of the writing prophets, but his work may be composed of oracles issued both by himself and by disciples who followed his theological views.

His prophetic oracles begin with a resounding phrase: "The Lord roars from Zion." He then goes on to indict various nations—Syria, Philistia, Tyre, Ammon, and Moab—for the crimes and atrocities they have committed in times of peace: "Because they sell the righteous for silver, and the needy for a pair of shoes—they . . . trample the head of the poor into the dust of the earth, and turn aside the way of the afflicted" (chapter 2, verses 6–7).

The second section (chapters 3–6) contains some of the most vehement and cogent invectives against the social injustices perpetrated in Israel. Though the Israelites have

prided themselves on being the elect of God, they have misinterpreted this election as privilege instead of responsibility. In chapter 4, Amos, in language that was sure to raise the ire of the privileged classes, attacked unnecessary indulgence and luxury. To the wealthy women of Samaria he said: "Hear this word, you cows of Bashan, who are in the mountain of Samaria, who oppress the poor, who crush the needy, who say to their husbands, 'Bring, that we may drink!' " (chapter 4, verse 1). After a series of warnings of punishment, Amos proclaimed the coming of the day of Yahweh, which is "darkness, and not light." His attacks against superficial pretenses to worship have become proverbial: "I hate, I despise your feasts, and I take no delight in your solemn assemblies" (chapter 5, verse 21). Another verse from Amos has become a rallying cry for those searching for social justice: "But let justice roll down like waters, and righteousness like an ever-flowing stream" (chapter 5, verse 24).

The third section (chapters 7–9) contains visions of locusts as a sign of punishment, a summer drought as a sign of God's wrath, and a plumb line as a sign to test the faithfulness of Israel. The priest of the shrine at Bethel, Amaziah, resented Amos' incursion on his territory and told him to go back to his home in the south. In reply to Amaziah, Amos prophesied the bitter end of Amaziah's family. Another vision in chapter 8, that of a basket of ripe fruit, pointed to the fact that Israel's end was near. A fifth vision, depicting the collapse of the Temple in Samaria, symbolized the collapse of even the religious life of the northern kingdom. He ended his work with a prophecy that the Davidic monarchy would be restored.

Obadiah. The Book of Obadiah, the fourth book of the Twelve (Minor) Prophets, contains only 21 verses. Nothing is known about the prophet as a person or about his times. It may have been written before the Exile, though many scholars believe that it was composed either some time after 586 BCE or in the mid-5th century, when the Jews returned to the area around Jerusalem. The prophet concentrates on the judgment of God against Edom and other nations, with the final verses referring to the restoration of the Jews in their native land.

Jonah. The Book of Jonah, containing the well-known story of Jonah in the stomach of a fish for three days, is actually a narrative about a reluctant prophet. This fifth book of the Twelve (Minor) Prophets contains no oracles and is thus unique among prophetic books. In II Kings, chapter 14, verses 25–27, there is a reference to a prophet Jonah who lived during the early part of the reign of Jeroboam II (8th century BCE).

Jonah and the universal reign of Yahweh

The story, however, probably comes from a time after the fall of Jerusalem in 586 BCE. Probably living during the Exile, the author used the memory of the hated Assyrians to proclaim the mission of Israel—to teach all nations about the mercy and forgiveness of God. In the short book of four chapters, Jonah, Amittai's son, is commissioned by Yahweh to go to Nineveh, the capital of Assyria, to preach repentance. Attempting to avoid the command of Yahweh, Jonah boarded a ship, which soon was caught up in a storm. The frightened sailors drew lots to discover who was the cause of their unfortunate and calamitous condition. Jonah drew the unlucky lot and was thrown overboard, after which he was swallowed by a fish and stayed in that uncomfortable place for three days and nights. After he cried to the Lord to let him out, the fish vomited Jonah out onto dry land. Jonah, though still reluctant, went to Nineveh to preach repentance. His efforts were successful, which did not please him—because of his hatred for the Assyrians. In the end, however, Jonah realized that God was a universal God, and not the sole property of Israel.

Probably written sometime between 500 and 350 BCE (or perhaps 250 BCE), the message of Jonah protested the exclusiveness of a post-exilic Judaism, with its policy of a pure blood race of Jews that the reformers Ezra and Nehemiah had implemented in the 5th century.

Micah. The Book of Micah, the sixth book of the Twelve (Minor) Prophets, was written by the prophet Micah in the 8th century BCE. Composed of seven chapters, the book is similar in many ways to the Book of Amos. Micah attacked the corruption of those in high places and social injustice, and the book is divided into two sections: (1) judgments against Judah and Jerusalem (chapters 1–3); and (2) promises of restoration for Judah and judgments against other nations (chapters 4–7).

Micah's attacks on corruption and his summation of the prophetic message

In the first section, Micah of Moresheth utters oracles against the corrupt religious and political leaders of Israel and Judah. He also attacks the prophets who attempted to give the people false hopes: "Thus says the Lord concerning the prophets who lead my people astray, who cry 'Peace' when they have something to eat, but declare war against him who puts nothing into their mouths . . . the seers shall be disgraced, and the diviners put to shame" (chapter 3, verses 5–7). In the second section, Israel's future is predicted as being glorious, and it is told that out of Bethlehem will come a ruler of the line of David who will bring peace to the earth. Though he issues an indictment against Judah for its idolatries, Micah proclaims what is necessary to renew the Covenant relationship between God and Israel; "and what does the Lord require of you but to do justice, and to love kindness, and to walk humbly with your God?" (chapter 6, verse 8). In this verse, Micah has given a brief summation of the messages of Amos, Hosea, and Isaiah.

Nahum. The Book of Nahum, seventh of the Twelve (Minor) Prophets, contains three chapters directed against the mighty nation of Assyria. Probably written between 626–612 BCE (the date of the destruction of Nineveh, the Assyrian capital), the book celebrates in oracles, hymns, and laments the fact that Yahweh has saved Judah from potential devastation by the Assyrians.

He begins with the words "The Lord is a jealous God and avenging . . . is slow to anger and of great might, and the Lord will by no means clear the guilty" (chapter 1, verses 2–3). From that beginning he predicts the overthrow of Assyria and the devastating manner in which Nineveh will be destroyed.

Habakkuk. The Book of Habakkuk, the eighth book of the Twelve (Minor) Prophets, was written by a prophet difficult to identify. He may have been a professional prophet of the Temple from the 7th century BCE (probably between 605–597 BCE). Containing three chapters, Habakkuk combines lamentation and oracle. In the first chapter, he cries out for Yahweh to help his people: "O Lord, how long shall I cry for help, and thou wilt not hear?" (chapter 1, verse 2). Though Yahweh will send mighty nations (*e.g.,* the neo-Babylonians will be the executors of his judgment), Habakkuk wonders who will then stop these instruments of God's justice, who use great force. The answer comes in a brief, almost cryptic verse, "but the righteous shall live by his faith." The rest of chapter 2 pronounces a series of woes against those who commit social injustices and engage in debauchery. The last chapter is a hymn anticipating the deliverance to be wrought by Yahweh.

"The righteous shall live by faith"

Zephaniah. The Book of Zephaniah, the ninth book of the Twelve (Minor) Prophets, is written in three chapters. Composed by the prophet Zephaniah in the latter part of the 7th century BCE, the book is an attack against corruption of worship in Judah, probably before the great Deuteronomic reform took place. He attacked the religious syncretism that had become established, especially the worship of Baal and astral deities, and predicted the coming catastrophe of the "Day of the Lord." He denounced both foreign nations and Judah, but issued a promise of the restoration of Israel: "Sing aloud, O daughter of Zion; shout, O Israel! Rejoice and exult with all your heart, O daughter of Jerusalem" (chapter 3, verse 14). The reason for exultation is that Yahweh will deliver his people.

Haggai. The Book of Haggai, the 10th book of the Twelve (Minor) Prophets, is a brief work of only two chapters. Written about 520 BCE by the prophet Haggai, the book contains four oracles. The first oracle calls for Zerubbabel, the governor of Judaea, and Joshua, the high priest, to rebuild the Temple (chapter 1, verses 1–11). A drought and poor harvests, according to Haggai, had been caused because the returnees from the Exile had neglected or failed to rebuild the Temple. The second oracle, addressed to the political and religious leaders and the peo-

ple, sought to encourage them in their rebuilding efforts (chapter 2, verses 1–9). Apparently they were disappointed that the new Temple was not as splendid as the former one, so Haggai reassured them: "My Spirit abides among you, fear not." The third oracle was issued against the people for not acting in a holy manner (chapter 2, verses 10–19), and the fourth proclaimed that Zerubbabel would be established as the Davidic ruler (chapter 2, verses 20–23). His promise, however, remained unfulfilled.

Zechariah. The Book of Zechariah, the 11th book of the Twelve (Minor) Prophets, dates from the same period as that of Haggai—about 520 BCE. Though the book contains 14 chapters, only the first eight are oracles of the prophet; the remaining six probably came from a school of his disciples and contain various elaborations of Zechariah's eschatological themes.

The visions of Zechariah and messianic overtones

Though little is known about Zechariah's life, he probably was one of the exiles who returned to Jerusalem from Babylon. After an initial call to repentance (chapter 1, verses 1–6), Zechariah had a series of eight visions (chapter 1, verse 7 to chapter 6, verse 15). The first is of four horsemen who have patrolled the Earth to make sure that it is at rest. The second vision is of four horns (*i.e.,* nations that have conquered Israel and Judah), which will be destroyed. The third vision is of a man with a measuring line, but Jerusalem will be beyond measurement. The fourth vision shows Joshua the high priest in the heavenly court being prosecuted by Satan (the celestial adversary) and the high priest's eventual acquittal and return to his high position. The fifth vision is of a golden lampstand and an olive tree to emphasize the important positions of Joshua and Zerubbabel, which these two figures symbolize. The sixth and seventh visions—of a flying scroll and a woman of wickedness—symbolize the removal of Judah's previous sins. The eighth vision of four chariots probably refers to the anticipated messianic reign of Zerubbabel, a hope that was thwarted. Chapters 7 and 8 concern fasting and the restoration of Jerusalem.

The remaining chapters—9–14—are additions that contain messianic overtones. Chapter 9, verses 9–10, with its reference to a king riding on the foal of an ass and to a vast kingdom of peace, was used by New Testament Gospel writers in reference to Jesus' entrance into Jerusalem prior to his crucifixion. The book closes on the note of the suffering Good Shepherd, the final battle between Jerusalem and the nations and eventual victory under God, and the universal reign of Yahweh, "king over all the earth."

Malachi. The Book of Malachi, the last of the Twelve (Minor) Prophets, was written by an anonymous writer called Malachi, or "my messenger." Perhaps written from about 500–450 BCE, the book is concerned with spiritual degradation, religious perversions, social injustices, and unfaithfulness to the Covenant. Priests are condemned for failing to instruct the people on their Covenant responsibilities, idolatry is attacked, and men are castigated for deliberately forgetting their marriage vows when their wives become older. In chapter 3, the message is that Yahweh will send a messenger of the Covenant to prepare for, and announce, the day of judgment. If the people turn from their evil ways, God will bless them, and those who "feared the Lord" will be spared. The book ends with a call to remember the Covenant and with a promise to send Elijah, the 9th-century prophet who ascended into heaven in a whirlwind on a chariot, "before the great and terrible day of the Lord comes." (L.F.)

THE KETUVIM

Contents of the Ketuvim

The Ketuvim (the Writings or the Hagiographa), the third division of the Hebrew Bible, comprises a miscellaneous collection of sacred writings that were not classified in either the Torah or the Prophets. The collection is not a unified whole: it includes liturgical poetry (Psalms and Lamentations of Jeremiah), secular love poetry (Song of Solomon), wisdom literature (Proverbs, Book of Job, and Ecclesiastes), historical works (I and II Chronicles, Book of Ezra, and Book of Nehemiah), apocalyptic, or vision, literature (Book of Daniel), a short story (Book of Ruth), and a romantic tale (Book of Esther); it ranges in content from the most entirely profane book in the Bible (Song of Solomon) to perhaps the most deeply theological (Job); it varies in mood from a pessimistic view of life (Job and Ecclesiastes) to an optimistic view (Proverbs). Psalms, Proverbs, and Job constitute the principal poetic literature of the Hebrew Bible and, in many respects, represent the high point of the Hebrew Bible as literature; in fact, Job must be considered one of the great literary products of man's creative spirit.

Although portions of some of the books of the Ketuvim (*e.g.,* Psalms and Proverbs) were composed before the Babylonian Exile (586–538 BCE), the final form was post-exilic, and Daniel was not written until almost the middle of the 2nd century BCE. The books were not included in the prophetic collection because they did not fit the content or the historical-philosophical framework of that collection, because they were originally seen as purely human and not divine writings, or simply because they were written too late for inclusion. Although some of the books individually were accepted as canonical quite early, the collection of the Ketuvim as a whole, as well as some individual books within it, was not accepted as completed and canonical until well into the 2nd century CE. As noted above, there are several indications that the lapse of time between the canonization of the Prophets and of the Ketuvim was considerable; *e.g.,* the practice of entitling the entire Scriptures "the Torah and the Prophets" and the absence of a fixed name.

The needs of the Hellenistic Jews in Alexandria and elsewhere in the Greek-speaking Diaspora led to the translation of the Bible into Greek. The process began with the Torah about the middle of the 3rd century BCE and continued for several centuries. In the Greek canon, as it finally emerged, the Ketuvim was eliminated as a corpus, and the books were redistributed, together with those of the prophetic collection, according to categories of literature, giving rise to a canon with four divisions: Torah, historical writings, poetic and didactic writings, and prophetic writings. Also, the order of the books was changed, and books not included in the Hebrew Bible were added. The early Christians of both the East and West generally cited and accepted as canonical the Scriptures according to the Greek version. When Protestants produced translations based upon the Hebrew original text and excluded or separated (as Apocrypha) the books not found in the Hebrew Bible, they retained the order and the divisions of the Greek Bible. Thus the Ketuvim is not to be found as a distinct collection in the Christian Old Testament.

Order of the books of the Ketuvim

An ancient tradition, preserved in the Babylonian Talmud, prescribed the following order for the Ketuvim: Ruth, Psalms, Job, Proverbs, Ecclesiastes, Song of Solomon, Lamentations, Daniel, Esther, Ezra (which included Nehemiah), and I and II Chronicles. This sequence was chronological according to rabbinic notions of the authorship of the books. Ruth relates to the age of the judges and concludes with a genealogy of David; the Psalms were attributed, for the most part, to David; Job was assigned to the time of the Queen of Sheba, although the rabbis differed among themselves about the date of the hero; Proverbs, Ecclesiastes, and Song of Solomon were all attributed to Solomon; Lamentations, which was ascribed to Jeremiah, refers to the destruction of Jerusalem and the beginning of the Babylonian Exile; the heroes of Daniel were active until early in the reign of Cyrus II, the king of Persia who ended the exile; Esther pertains to the reign of Xerxes I, later than that of Cyrus but earlier than that of Artaxerxes I, the patron of Ezra, reputed also to have written I and II Chronicles.

Despite this tradition, however, it would appear that the sequence of the Ketuvim was not completely fixed, and there is a great variety in ordering found in manuscripts and early printed editions. The three larger books—Psalms, Job, and Proverbs—have always constituted a group, with Psalms first and the other two interchanging. The order of the five Megillot, or Scrolls (Song of Solomon, Ruth, Lamentations, Ecclesiastes, and Esther), has shown the greatest variations. The order that has crystallized has a liturgical origin; the books are read on certain festival days in Jewish places of worship and are printed in the calendar order of those occasions. Chronicles always appears

at either the beginning or the end of the corpus. Its final position is remarkable because the narrative of Ezra and Nehemiah follows that of Chronicles. The final position may have resulted from an attempt to place the books of the Hebrew Bible in a framework (Genesis and Chronicles both begin with the origin and development of the human race, and both conclude with the theme of the return to the land of Israel), but it was more probably the result of the late acceptance of Chronicles into the canon.

Psalms. The Psalms (from Greek *psalmas,* "song") are poems and hymns, dating from various periods in the history of Israel, that were assembled for use at public worship and that have continued to play a central role in the liturgy and prayer life of both Jews and Christians. Known in Hebrew as Tehillim (Songs of Praise), the Psalter (the traditional English term for the Psalms, from the Greek *psalterion,* a stringed instrument used to accompany these songs) consists of 150 poems representing expressions of faith from many generations and diverse kinds of people. These unsystematic poems epitomize the theology of the entire Hebrew Bible.

Characteristics of Hebrew poetry

Hebrew poetry has much in common with the poetry of most of the ancient Near East, particularly the Canaanite poetic literature discovered at Ras Shamra. Its main features are rhythm and parallelism. The rhythm, which is difficult to determine precisely because the proper pronunciation of ancient Hebrew is unknown, is based upon a system of stressed syllables that follows the thought structure of the poetic line. The line, or stich, is the basic verse unit, and each line of verse is normally a complete thought unit. The most common Hebrew line consists of two parts with three stresses to each part (3/3); thus:

Have-mercy-on-me,/O-God, in-your-goodness;
in-your-great-tenderness/wipe-away-my-faults.

(Ps.51:1)

Lines with three or four parts and parts with two, four, or five stresses also occur.

The lines present various kinds of parallelism of members, whereby the idea expressed in one part of a line is balanced by the idea in the other parts. The classical study on Hebrew parallelism was done by Robert Lowth, an 18th-century Anglican bishop, who distinguished three types: synonymous, antithetic, and synthetic. Synonymous parallelism involves the repetition in the second part of what has already been expressed in the first, while simply varying the words.

Yahweh, do not punish me in your rage,
or reprove me in the heat of anger.

(Ps. 38:1)

In antithetic parallelism the second part presents the same idea as the first by way of contrast or negation.

For Yahweh takes care of the way the virtuous go,
but the way of the wicked is doomed.

(Ps. 1:6)

Synthetic parallelism involves the completion or expansion of the idea of the first part in the second part.

As a doe longs for running streams,
so longs my soul for you, my God.

(Ps. 42:1)

Synthetic parallelism is a broad category that allows for many variations, one of which has the picturesque name "staircase" parallelism and consists of a series of parts or lines that build up to a conclusion.

Pay tribute to Yahweh, you sons of God,
tribute to Yahweh of glory and power,
tribute to Yahweh of the glory of his name,
worship Yahweh in his sacred court.

(Ps. 29:1-2)

Although it is evident that Hebrew poetry groups lines into larger units, the extent of this grouping and the principles on which it is based are uncertain. The acrostic poems are a notable exception to this general uncertainty.

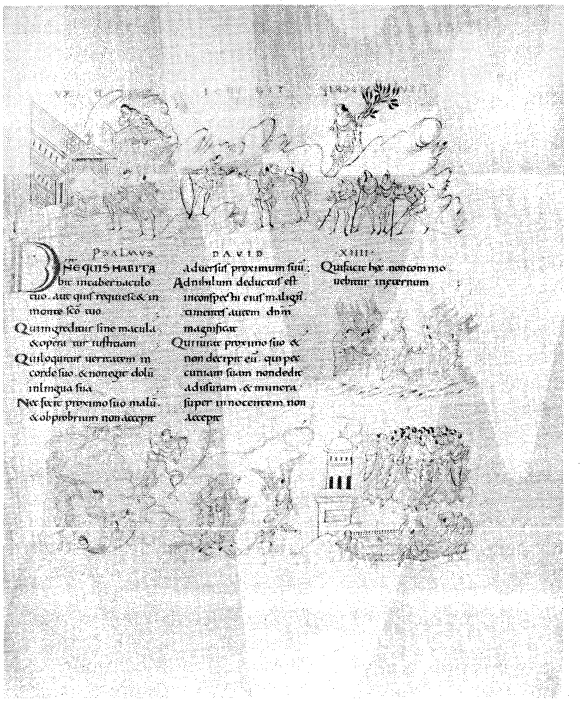
The numeration of the Psalms found in the Hebrew Bible and those versions derived from it differs from that in the Septuagint, the Vulgate, and the versions derived from them. The latter two join Psalms 9 and 10 and 114 and 115 but divide both 116 and 147 into two. The following scheme shows the differences:

Hebrew	Septuagint–Vulgate
1–8	1–8
9–10	9
11–113	10–112
114–115	113
116	114–115
117–146	116–145
147	146–147
148–150	148–150

Although Roman Catholic versions in the past have used the Septuagint–Vulgate way of numbering, recent translations have followed the Hebrew tradition.

The present form of the Psalter is the result of a lengthy literary history. It is divided into five books (Psalms 1–41; 42–72; 73–89; 90–106; and 107–150), probably in imitation of the five books of the Pentateuch. Psalm 1 serves as an introduction to the whole Psalter, while Psalm 150 is a final doxology (an expression of praise to God); the books are divided from each other by short doxologies that form the conclusions of the last psalm of each of the first four books. This division, however, appears to be artificial. There are indications, cutting across the present divisions, that the book was a compilation of existing collections. That there were several collections existing side by side is seen in the way that certain psalms (*e.g.,* Psalms 14 and 53) duplicate each other almost word for word. At some phase of the Psalter's development there must have been an Elohistic collection (Psalms 42–83) distinguished by the use of the divine name Elohim in place of Yahweh,

Compilation of existing collections



Illustrated text of Psalm 15 (Vulgate Psalm 14) from the Utrecht Psalter of Reims, 9th–12th century. In the British Museum (Harley, MS.603).

which is far more common in the rest of the psalms. There appear to be two distinct collections of psalms ascribed to David, one Yahwistic (Psalms 3–41) and the other Elohistic (Psalms 51–72). Further evidence of the book's gradual growth may be seen in the editorial gloss following Psalm 72; it purports to conclude the "prayers of David," although there are more Davidic psalms.

The superscriptions found on most of the psalms are obscure but point to the existence of earlier collections. Psalms are attributed to David, Asaph, and the sons of Korah, among others. It is generally held that Asaph and the sons of Korah indicate collections belonging to guilds of temple singers. Other possible collections include the Songs of Ascents, probably pilgrim songs in origin, the

Hallelujah Psalms, and a group of 55 psalms with a title normally taken to mean "the choirmaster."

It is evident that the process whereby these various collections were formed and then combined was extremely complex. The investigation of the process is made difficult because individual psalms and whole collections underwent constant development and adaptation. Thus, for example, private prayers became liturgical, songs of local sanctuaries were adapted to use in the Temple, and psalms that became anachronistic by reason of the fall of the monarchy or the destruction of the Temple were reworked to fit a contemporary situation. Such problems complicate the determination of the date and original occasion of the psalm.

Date and authorship

For centuries both Jews and Christians ascribed the whole Psalter to David, just as they ascribed the Pentateuch to Moses and much of the wisdom literature to Solomon. This was thought to be supported by the tradition that David was a musician, a poet, and an organizer of the liturgical cult and also by the attribution of 73 psalms to David in the superscriptions found in the Hebrew Bible. These superscriptions, however, need not refer to authorship. Moreover, it is clear that David could not have written all the psalms attributed to him because some of them presuppose the existence of the Temple in Jerusalem, which was not constructed until later. Contrary to the long-established Davidic authorship tradition, at the end of the 19th century most biblical critics spoke of a Persian date (539–333 BCE) and even of the Maccabean era (mid-2nd century BCE) for the majority of the psalms. In the 20th century the Psalter has been considered to be a collection of poems that reflect all periods of Israel's history from before the monarchy to the post-exilic restoration, and it is thought that David played a central role in the formation of the religious poetry of the Jewish people. Scholars, however, are reluctant to assign precise dates.

The most important contribution to modern scholarship on the Psalter has been the work of Hermann Gunkel, a German biblical scholar, who applied form criticism to the psalms. Form criticism is the English name for the study of the literature of the Bible that seeks to separate its literary units and classify them into types or categories (*Gattungen*) according to form and content, to trace their history, and to reconstruct the particular situation in life or setting (*Sitz im Leben*) that gave rise to the various types. This approach does not ignore the personal role of individual composers and their dates, but it recognizes that Hebrew religion, conservative in faith and practice, was more concerned with the typical than with the individual and that it expressed this concern in formal, conventional categories. The study is aided by viewing them in the context of similar literary works in the earlier or contemporary cultures of the ancient Near East.

Major types of psalms

Gunkel identified five major types of psalms, each cultic in origin. The first type is the Hymn, which is a song of praise, consisting of an invitation to praise Yahweh, an enumeration of the reasons for praise (*e.g.*, his work of creation, his steadfast love), and a conclusion in which frequently the invitation is repeated. The life setting of the hymns was generally some occasion of common worship. Two subgroups within the hymn type are the Songs of Zion, which glorify Yahweh's presence in the city of Jerusalem, and the Enthronement Songs, which—though their number, setting, and interpretation have been the subject of much debate—acclaim Yahweh's kingship over the whole world.

The second type is the Communal Lament. Its setting was some situation of national calamity, when a period of prayer, fasting, and penitence would be observed. In such psalms Yahweh is invoked, the crisis is described, Yahweh's help is sought, and confidence that the prayer has been heard is expressed.

The Royal Psalms are grouped on the basis not of literary characteristics but of content. They all have as their life setting some event in the life of the pre-exilic Israelite kings; *e.g.*, accession to the throne, marriage, departure for battle. Gunkel pointed out that in ancient Israel the king was thought to have a special relationship to Yahweh and thus played an important role in Israelite worship. With the fall of the monarchy, these psalms were adapted to different cultic purposes.

In the Individual Lament an individual worshipper cries out to Yahweh in time of need. The structure of these psalms includes: an invocation of Yahweh, the complaint, the request for help, an expression of certainty that Yahweh will hear and answer the prayer, and in many cases a vow to offer a thanksgiving sacrifice. Three aspects have been the subject of extensive study: the identity of the "enemies" who are often the reason for the complaint; the meaning of the term poor, which is frequently used to describe the worshipper; and the sudden transition in mood to certainty that the prayer has been heard. Psalms of this type form the largest group in the Psalter.

The final major type is the Individual Song of Thanksgiving, which presumably had its setting in the thanksgiving sacrifice offered after a saving experience. These psalms begin and conclude with an exclamation of praise to Yahweh. The body of the psalm contains two elements: the story of the one who has been saved and the recognition that Yahweh was the rescuer.

Gunkel also distinguished several minor types of psalms, including Wisdom Poems, Liturgies, Songs of Pilgrimage, and Communal Songs of Thanksgiving.

For Gunkel, although the types of the psalms were originally cultic, the majority of the poems in the existing Psalter were composed privately in imitation of the cultic poems and were intended for a more personal, "spiritualized" worship. Most biblical scholars since Gunkel have accepted his classifications, with perhaps some modifications, but have focussed increased attention on the setting, the *Sitz im Leben,* in which the psalms were sung. Sigmund Mowinckel, a Norwegian scholar, explained the psalms as wholly cultic both in origin and in intention. He attempted to relate more than 40 psalms to a hypothetical autumnal New Year festival at which the enthronement of Yahweh as the universal king was commemorated; the festival was associated with a similar Babylonian celebration. Artur Weiser, a German scholar, sought the cultic milieu of the Hebrew psalms especially in an annual feast of covenant renewal, which was uniquely Israelite.

Psalms is a source book for the beliefs contained in the entire Hebrew Bible. Yet, doctrines are not expounded, for this is a book of the songs of Israel that describe the way Yahweh was experienced and worshipped. Yahweh is creator and saviour; Israel is his elected people to whom he remains faithful. The enemies of this people are the enemies of Yahweh. In these songs are found the entire range of basic human feelings and attitudes before God—praise, fear, trust, thanksgiving, faith, lament, joy. The book of Psalms has thus endured as the basic prayerbook for Jews and Christians alike.

Proverbs. Proverbs is probably the oldest extant document of the Hebrew wisdom movement, of which King Solomon was the founder and patron. Wisdom literature flourished throughout the ancient Near East, with Egyptian examples dating back to before the middle of the 3rd millennium BCE. It revolved around the professional sages, or wise men, and scribes in the service of the court, and consisted primarily in maxims about the practical, intelligent way to conduct one's life and in speculations about the very worth and meaning of human life. The most common form of these wise sayings, which were intended for oral instruction especially in the schools run by the sages for the young men at the court, was the *mashal* (Hebrew: "comparison" or "parable," although frequently translated "proverb"). Typically a pithy, easily memorized aphoristic saying based on experience and universal in application, the *mashal* in its simplest and oldest form was a couplet in which a definition was given in two parallel lines related to each other either antithetically or synthetically. Verse 5 of the 15th chapter of Proverbs is an example of a simple antithetic saying:

Wisdom literature in the ancient Near East

> He who spurns his father's discipline is a fool,
> he who accepts correction is discreet.

Other forms of the *mashal,* such as parables, riddles, allegories, and ultimately full-scale compositions developed later. The word *mashal* was derived from a root that

meant "to rule," and thus a proverb was conceived as an authoritative word.

The two principal types of wisdom—one practical and utilitarian, the other speculative and frequently pessimistic—arose both within and outside Israel. Practical wisdom consisted chiefly of wise sayings that appealed to experience and offered prudential guidelines for a successful and happy life. Such wisdom is found in a collection of sayings bearing the name of Ptahhotep, a vizier to the Egyptian pharaoh about 2450 BCE, in which the sage counsels his son that the path to material success is by way of proper etiquette, strict discipline, and hard work. Although such instructions were largely materialistic and political, they were moral in character and contributed to a well-ordered society.

Speculative wisdom went beyond maxims of conduct and reflected upon the deeper problems of the value of life and of good and evil. Examples are found in ancient Egyptian and Mesopotamian texts—particularly *Ludlul bel nemeqi,* often called the "Babylonian Job"—in which sensitive poets pessimistically addressed such questions as the success of the wicked, the suffering of the innocent, and, in short, the justice of human life.

Hebrew wisdom, which owed much to that of its neighbours, appeared with the establishment of the monarchy and a royal court and found a patron in Solomon. Through the following centuries the wise men were at times the object of rebuke by the prophets, who disliked their pragmatic realism. The exile, however, brought a change in Hebrew wisdom; it became deeply religious. The wise men were convinced that religion alone possessed the key to life's highest values. It was this mood that dominated the final shaping of the Hebrew wisdom literature. Though dependent on older materials and incorporating documents from before the exile, the wisdom books in their present form were produced after the exile. In the Hebrew Bible the book of Proverbs offers the best example of practical wisdom, while Job and Ecclesiastes give expression to speculative wisdom. Some of the psalms and a few other brief passages are also representative of this type of literature. Among the Apocrypha, the Wisdom of Solomon and Ecclesiasticus are wisdom books.

Collections in the book of Proverbs

The book of Proverbs is a collection of units originally independent, some of which can be traced back to the era of Solomon. The present form of the book was the result of a long process of growth that was not completed until post-exilic times. It consists of two principal collections of early origin called "the proverbs of Solomon" and "proverbs of Solomon which the men of Hezekiah king of Judah copied." Appendixes were added to each of the collections. The whole book was preceded by a long introduction and concludes with a poem praising the ideal wife. In addition to sectional titles, changes in literary form and in subject matter help to mark off the limits of the various units, which can be ordered into nine sections.

The introduction (chapters 1–9) constitutes the youngest unit in the book. It consists of a series of poems or discourses in which a father exhorts his son to acquire wisdom and in which wisdom personified intervenes. These chapters have a more speculative quality than the remainder of the book. They do not treat wisdom simply as a human quality and achievement or as a cultural legacy imparted by teachers and parents; they present it as a universal and abiding reality, transcending the human scene. Wisdom is the first of God's works and participated with him in the creation of the world. A constantly debated aspect of this section concerns the identity of "the loose [strange] woman" who is set over against Wisdom.

The "proverbs of Solomon" (10:1–22:16) consist entirely of parallelistic couplets—the *mashal* in its primitive form. There are 375 aphorisms each complete in itself and arranged in no apparent order. The motivation of this section, in contrast to the preceding, is strongly practical: wisdom is a human achievement by means of which man's life can be fulfilled. The wise are contrasted with fools, and the just with the wicked. It is difficult, however, to establish the nature of the difference, if any, between the wicked and the fool or between the just and the wise.

The "sayings of the wise" (22:17–24:22) consist of longer units or sayings introduced by a preface. The most distinctive feature of this section is its close relationship to a piece of Egyptian writing, "The Instruction of Amenemope," which has been dated within the broad limits of 1000–600 BCE. The Hebrew author apparently used this work as a model—the Egyptian work comprises 30 chapters, and the Hebrew text refers to its "thirty sayings"—and as one of the sources in compiling his own anthology. An additional collection of four wise sayings (24:23–34) forms a supplement to the "sayings of the wise."

The second collection of "proverbs of Solomon" (chapters 25–29) consists of 128 sayings that closely resemble the earlier collection, although quatrains as well as couplets are included. The scribes of Hezekiah's court (*c.* 700 BCE) are credited with assembling this collection.

The book concludes with four independent units or collections. The "words of Agur" (30:1–14) differs sharply in spirit and substance from the rest of Proverbs; it has much closer affinities with the book of Job, stressing the inaccessibility of wisdom for man. There is no internal evidence, such as a continuous theme, to show that these 14 verses are a single unit; but in the Septuagint they stand together between the "sayings of the wise" and its supplement. The "numerical sayings" (30:15–33) contain elements of riddle and show a special interest in the wonders of nature and the habits of animals. The "instruction of Lemuel" (31:1–9) is an example of the importance of maternal advice to a ruler in the ancient Near East. Lemuel seems to have been a tribal chieftain of northwest Arabia, in the region of Edom. The final section (31:10–31) is an alphabetical poem in praise of the "perfect wife," who is celebrated for her domestic virtues.

Distinctive character of wisdom literature within Hebrew Scriptures

The wisdom movement constituted a special aspect of the religious and cultural development of ancient Israel. As the primary document of the movement, Proverbs bears a clear impress of this distinctive character, so that in many respects it presents a sharp contrast to the outlook and emphases of Israel's faith as attested in the Hebrew Scriptures generally. This contrast also marks Job and Ecclesiastes, however greatly they may differ from Proverbs in other respects.

Proverbs never refers to Israel's history. In the Hebrew Bible as a whole, this history is constantly recalled not so much for social or political reasons as to declare the faith of Israel that God has acted in its history to redeem his people and make known to them the character of his rule. The great themes of the promise to the patriarchs, the deliverance from slavery, the making of the Covenant at Mt. Sinai, the wilderness wandering, and the inheritance of Canaan were celebrated in Israel's worship to tell the story of God's revelation of himself and of his choice of Israel. None of this is alluded to in Proverbs. The implication seems to be that for Proverbs God's revelation of himself is given in the universal laws and patterns characteristic of nature, especially human nature, rather than in a special series of historical events; that is, the revelation of God is in the order of creation rather than in the order of redemption. Moreover, the meaning of this revelation is not immediately self-evident but must be discovered by men. This discovery is an educational discipline that trusts human reason and employs research, classifying and interpreting the results and bequeathing them as a legacy to future generations. The wise are those who systematically dedicate themselves to this discovery of the "way" of God.

Unlike Job and Ecclesiastes, Proverbs (with the exception of the "words of Agur") is optimistic in that it assumes that wisdom is attainable by those who seek and follow it; that is, man can discover enough about God and his law to ensure the fulfillment of his personal life. This character of God is conceived almost entirely in terms of ethical laws, and the rewards for their observance are defined in terms of human values; *e.g.,* health, long life, respect, possessions, security, and self-control.

Because God is apprehended in static terms, rather than dynamic as elsewhere in the Bible, the viewpoint of Proverbs is anthropocentric. Man's destiny depends upon his responsible action. There is no appeal to divine mercy, intervention, or forgiveness; and the divine judgment is simply the inexorable operation of the orders of life as God

has established them. Implicit in the book is an aristocratic bias. The wise constitute an elite nurtured by inheritance, training, and self-discipline; fools are those who can never catch up, because of either the determinism of birth or the wasted years of neglect. In its social and cultural attitudes, the book is probably the most conservative in the Bible: wealth and status are most important; obedience to the king and all authorities is inculcated; industry and diligence are fostered, for hunger, poverty, and slavery are the fate of the lazy; and age and accepted conventions are accorded great respect.

Job. The Book of Job is not only the finest expression of the Hebrew poetic genius; it must also be accorded a place among the greatest masterpieces of world literature. The work is grouped with Proverbs and Ecclesiastes as a product of the wisdom movement, even though it contains what might be called an anti-wisdom strain in that the hero protests vehemently against the rationalistic ethics of the sages. Yet it is the supreme example among ancient texts of speculative wisdom in which a man attempts to understand and respond to the human situation in which he exists.

The Book of Job consists of two separate portions. The bulk of the work is an extended dialogue between the hero and his friends and eventually Yahweh himself in poetic form. The poem is set within the framework of a short narrative in prose form. The book falls into five sections: a prologue (chapters 1 and 2); the dialogue between Job and his friends (3–31); the speeches of Elihu (32–37); the speeches of Yahweh and Job's reply (38–42:6); and an epilogue (42:7–17).

Prose narrative in Job

The prologue and epilogue are the prose narrative. This is probably an old folktale recounting the story of Job, an Edomite of such outstanding piety that he is mentioned by the prophet Ezekiel in conjunction with Noah and Daniel. The name Job was common in antiquity, being found in texts ranging from the 19th to the 14th century BCE. Whether the folktale is preserved in its original oral form or whether it has been retold by the poet of the dialogue is not known. The fact that an Edomite sheikh is commended by the Hebrew God, however, suggests a date before the 6th century BCE, for Jewish distrust of Edomites became intense during the exile, and the archaic language makes a date in the 8th century probable.

Job is pictured as an ideal patriarch who has been rewarded for his piety with material prosperity and happiness. The Satan (Accuser), a member of the heavenly council of Yahweh, acts with Yahweh's permission as an *agent provocateur* to test whether or not Job's piety is rooted in self-interest. Faced with the appalling loss of his worldly possessions, his children, and finally his own health, Job refuses to curse Yahweh. His capacity for trusting Yahweh's goodness has made him an unsurpassed model of patience. Three of Job's friends, whose names identify them also as Edomites, now arrive to comfort him. At this point the poetic dialogue begins. The conclusion of the tale, as given in the epilogue, describes the restoration of Job, who receives double his original possessions and lives to a ripe old age.

The dialogue between Job and his friends

The picture of Job that is presented in the poetic portion is radically different. Instead of the patient and loyal servant of Yahweh, he is an anguished and indignant sufferer, who violently protests the way Yahweh is treating him and displays a variety of moods ranging from utter despair, in which he cries out accusingly against Yahweh, to bold confidence, in which he calls for a hearing before Yahweh. Most scholars have dated this section to the 4th century BCE, but there is a growing tendency to regard it as two centuries earlier, during the period of the exile. This precise dating is based on the fact that the dialogue shows clear literary dependence on Jeremiah, whereas equally obvious connections with Deutero-Isaiah suggest the dependence of the latter on Job.

The poem opens with a heartrending soliloquy by Job in which the sufferer curses the day of his birth. The shocked friends are roused from their silence, and there follow three cycles of speeches (chapters 4–14, 15–21, and 22–27) in which the friends speak in turn. To each such speech Job makes a reply. The personalities of the friends are skillfully delineated, Eliphaz appearing as a mystic in the prophetic tradition, Bildad as a sage who looks to the authority of tradition, and Zophar as an impatient dogmatist who glibly expounds what he regards as the incomprehensible ways of God.

Eliphaz begins the first cycle by recounting a mystical vision that revealed to him the transcendence of God and the fact that all men are by nature morally frail. He suggests that suffering may be disciplinary, although this is irrelevant to Job's plight. Finally, he urges contrite submission to Yahweh. Job chides his friends for failing him in his hour of need and charges God with being his tormentor.

Bildad suggests that the fault may have lain in Job's children and reiterates Eliphaz' call to humble submission. Job then retorts that the doctrine of Yahweh's omnipotence is no answer but a serious problem, because Yahweh appears to be merely omnipotent caprice. He is convinced that if he could only meet Yahweh in open debate he would be vindicated, but he recognizes the need for an impartial third party who could intervene and protect him from Yahweh's overpowering might.

Zophar re-echoes his predecessors' views on Yahweh but goes the full length of accusing Job himself of sin and once more urges Job to a contrition that for him could only be hypocritical. Job continues to insist that Yahweh is capricious and defiantly challenges him but is bewildered when no reply is forthcoming. His longing for death as a welcome release leads him to ask whether man might not hope for a revival after death, but this daring hope is immediately rejected.

The second cycle opens with Eliphaz accusing Job of blasphemy and almost exultantly describing the fate of the wicked. In his reply Job returns to the idea of a third party to the debate. Now, however, this umpire or judge has become an advocate, a counsel for the defense. After Bildad has again elaborated on the fate of the wicked, Job states that a Vindicator, or Redeemer (Go'el), will establish his innocence. The Vindicator of this crucial but sadly corrupted passage (19:25–27) has long been identified with God himself, so that according to some scholars Job "appeals away from the God of orthodox theology to God as He must be." A few scholars, however, recognize the Vindicator as the third party (the "umpire" or "witness") of earlier chapters. It is also unclear whether this vindication will take place before or after Job's death. Then Zophar, though freely admitting that the wicked may indeed enjoy some prosperity, describes how they fall victim to inevitable nemesis. Job maintains that the wicked do not end thus but live on to an old age.

Eliphaz begins the third cycle by accusing Job at last of specific sins and again counsels Job to humble himself before Yahweh. But Job cannot find this God, who seems to be completely indifferent to him. The conclusion of the dialogue is in serious disorder, with speeches placed in Job's mouth that could only have been uttered by the friends. The final speech of Zophar, which is omitted, seems to be represented by a fragment preserved within the third reply of Job.

Chapter 28 is regarded as a later addition by most scholars, because it is hardly in place at this juncture in the dialogue, especially in the mouth of Job. It is a magnificent hymn in praise of wisdom. Chapters 29–31 contain a monologue by Job; in them occurs an adumbration of the highest moral ideal to be found in the Hebrew Bible.

The speeches of Elihu and the speeches of Yahweh

Although a few scholars have maintained that the speeches of Elihu formed part of the original work, most reject this section as a later insertion. The speeches merely reiterate the dogmas of the friends and unduly delay the appearance of Yahweh. Although the section is in poetic form, its style is different from that of the dialogue. Significantly, there is no mention of Elihu in the dialogue or anywhere else in the book, yet the Elihu speeches are familiar with the dialogue, frequently quoting verbatim from it. Chapter 32 is of interest, because it appears to contain the writer's notes and comments on the dialogue, often citing passages from it. Worthy of notice is the writer's emphasis on the disciplinary value of suffering.

The climax of the poem is reached in the speeches of

Yahweh, who appears in a majestic theophany—a whirlwind—and reveals himself to Job in three speeches interspersed with two short speeches by Job. Biblical scholars have often questioned whether this section—especially the descriptions of Behemoth (the hippopotamus) and Leviathan (the crocodile) in the second Yahweh speech—is a genuine part of the original poem, but there is no doubt that their presence at this point in the book is a dramatic triumph. Throughout these speeches Yahweh does not offer rational answers to Job's questions and accusations; he raises the discussion to a new perspective. With heavy irony Yahweh puts to Job a series of unanswerable questions about the mysteries of the universe; if, the writer is asking, Job is unable to answer the simple questions about the divine activity in the marvels of nature, how can Yahweh explain to him the deeper mystery of his dealings with men. Job's personal problem is ignored, yet he finds his answer in this direct encounter with Yahweh:

> I had heard of thee by the hearing of the ear,
> but now my eye sees thee;
> therefore I despise myself,
> and repent in dust and ashes.

Job stands in a new relationship to Yahweh, one no longer based on hearsay but the result of an act of personal faith expressed in repentance.

A few scholars, beginning in the mid-18th century, have attempted to demonstrate the influence of Greek tragedy upon the form of the book. This has not met with acceptance by most critics; its long monologues are not truly dramatic in nature. Neither is it a philosophical discussion in the style of the Platonic dialogues. It is a deeply religious poem with dramatic possibilities. It skillfully blends many genres: folktale, hymn, individual lament, prophetic oracle, and didactic poem.

The author remains quite unknown except for a few hints provided by the book itself. That he was a Jew is assumed because of his familiarity with much of the Hebrew literature. Nevertheless, the book does not have a Hebrew setting, it is pervaded with foreign elements, and it shows a special knowledge of Egypt, thus leading many to believe that he was well travelled or lived outside the Holy Land. He was a keen observer of the natural world, and his feeling for the agony of the sufferer is a compelling argument that he had known anguish.

The book touches on many subjects, such as disinterested obedience to God under testing, innocent suffering, social oppression, religious experience and pious suffering, a man's relation to God, and the nature of God. Scholars have attempted to discover the basic message of the author. Because of the greater difficulty in understanding the Job of the poetic portion, the traditional interpretation looked to the narrative and saw the message as the need for patient bearing and faith despite tribulation. When certain poetic passages were thought to point to a belief in the resurrection of the body, Job became not only a patient sufferer but also a prophet of the resurrection. This view, however, does not account for the Job of the poetic portion. Thus, in the 19th century, with the advancement of biblical criticism, scholars began to claim that the author was dealing with the problem of unmerited suffering. The book presents a deep view of suffering, and Job's experience teaches that man must rest in faith and resign himself to the incomprehensible ways of God.

It would seem, however, that the question raised by Job is both deeper and broader than the question of how to account for the infliction of physical adversity on the innocent. Job's physical suffering is the outward symbol of his intense inward agony, the agony of a man who feels himself lost in a meaningless universe and abandoned even by God. What torments Job—and the author—is the question of the justice of God and the justice and honour of man before God. His passionate pleading of his own righteousness and his calling upon God for a hearing lead him to an encounter with God. This encounter does not answer the question of why the innocent suffer, but it is the only answer to the plea of a man seeking to find his God and to justify himself to him. The complacent believer who has been shattered by suffering, doubt, and despair is confirmed in faith and repents.

The Megillot (the Scrolls). The five books known as the Megillot or Scrolls are grouped together as a unit in modern Hebrew Bibles according to the order of the annual religious festivals on which they are read in the synagogues of the Ashkenazim (central and eastern European Jews and their descendants). They did not originally form a unit and were found scattered in the Bible in their supposed historical position. In the so-called Leningrad Codex of the year 1008 CE, on which the third and subsequent editions of *Biblica Hebraica* edited by Rudolf Kittel are based, the five are grouped together but in a historical order. Nevertheless, their appearance usually follows the order of the liturgical calendar:

Song of Solomon	Pesah (pass over)	March–April
Ruth	Shavuot (Feast of Weeks	May–June
Lamentations	Tisha be-Av (Fast of Av 9)	July–August
Ecclesiastes	Sukkot (Feast of Tabernacles)	September–October
Esther	Purim (Feast of Lots)	February–March

The five books have little in common apart from their roles in the liturgy. Although the Song of Solomon and Lamentations are poetic in form and Ruth and Esther are stories of heroines, the contrast in the moods and purposes of both pairs sharply distinguishes the books. Ecclesiastes is a product of the Hebrew wisdom movement and exhibits the most pessimistic tone of any book in the Hebrew Bible.

Song of Solomon. The Song of Solomon (also called Song of Songs and Canticle of Canticles) consists of a series of love poems in which lovers describe the physical beauty and excellence of their beloved and their sexual enjoyment of each other. The Hebrew title of the book mentions Solomon as its author, but this seems improbable, primarily because of the late vocabulary of the work. Although the poems may date from an earlier period, the present form of the book is late, perhaps as late as the 3rd century BCE, and its author remains unknown.

Interpretations of the Song of Solomon

The Song of Solomon has been interpreted in different ways, four of which are noteworthy. The allegorical interpretation takes the book as an allegory of God's love for Israel or of Christ's love for the church. Such a view seems gratuitous and incompatible with the sensuous character of the poems. The dramatic interpretation is based on the dialogue form of much of the book and attempts to find a plot involving either a maiden in Solomon's court and the King or the maiden, the King, and a shepherd lover. The absence of drama in Semitic literatures and the episodic character of the book make this theory highly improbable. The cultic-mythological interpretation connects the book with the fertility cults of the ancient Near Eastern world. The condemnation in the Hebrew Bible of such rituals makes it difficult to accept this view, unless it is assumed that the original meaning of the poems was forgotten. The literal interpretation considers it to be a collection of secular love poems, without any religious implications, that may have been sung at wedding festivities. According to this commonly accepted view, the poems were received into the biblical canon despite their secular nature and their lack of mention of God because they were attributed to Solomon and because they were understood as wedding songs and marriage was ordained by God.

The reasons for the Song of Solomon being read at Passover, which celebrates the Exodus from Egypt, are not entirely clear. Possibly, they include the fact that spring is referred to in the book and that according to the allegorical interpretation the book could refer to God's love for Israel, which is so well evidenced by the events of the Exodus and especially the Covenant at Mt. Sinai.

Ruth. The Book of Ruth is a beautiful short story about a number of good people, particularly the Moabite great-grandmother of David. Though events are set in the time of the judges, linguistic and other features suggest that the present form dates from post-exilic times. But it gives the impression of being based on an ancient tradition, perhaps on written source. It was certainly grounded on a solid core of fact, for no one would have invented a Moabite ancestress for Israel's greatest king.

The book describes how, during a time of famine, Elimelech, a Bethlehemite, travelled to Moab with his wife, Naomi, and his two sons, Mahlon and Chilion. After his

death, the sons married Moabite women, and then they too died, leaving no children. There was thus no one to keep the family line alive and no one to provide for Naomi. Ruth, the widow of Mahlon, dedicated herself to the care of Naomi and insisted on returning with her to her native land and adopting her God. They arrived in Bethlehem during the harvest, and Ruth went out to work for the two women in the field of Boaz, a wealthy landowner. Naomi urged Ruth to seek marriage with Boaz because he was a kinsman of her late husband, and the firstborn son of such a marriage would count as a son of the deceased. (This resembles the levirate marriage that obliged a man to marry the widow of his deceased brother if the brother died without male issue.) Ruth crept under Boaz' cloak while he slept, and he accepted the implied proposal of marriage. After a nearer kinsman forfeited his claim to Ruth, Boaz married her and a son was born. Thus, loyal Ruth was provided with an excellent husband, the dead Mahlon with a son to keep his name alive, and Naomi with a grandson to support her in her old age.

Many purposes have been assigned to the book: to entertain, to delineate the ancestry of David, to uphold levirate marriage as a means of perpetuating a family name, to commend loyalty in family relationships, to protest the narrowness of Ezra and Nehemiah, the leaders of the post-exilic restoration in relation to marriages with non-Jews, to inculcate kindness toward converts to Judaism, to teach that a person who becomes a worshipper of Yahweh will be blessed by him, and to illustrate the providence of God in human affairs. The book may have served all these "purposes," but the author's objective cannot be determined with certainty.

Lamentations of Jeremiah. The Lamentations of Jeremiah consists of five poems (chapters) in the form of laments for Judah and Jerusalem when they were invaded and devastated by the Babylonians in 586 BCE, for the sufferings of the population, and for the poet himself during and after the catastrophe. These grief-stricken laments are intermingled with abject confessions of sin and prayers for divine compassion. The first four poems are alphabetic acrostics; the fifth is not, although like the others it has 22 stanzas, which is the number of letters in the Hebrew alphabet. The formal structure served as a mnemonic device and perhaps was meant to convey the note of wholeness, of Israel's total grief, penitence, and hope. The moving quality of these elegies has suited them for liturgical use. Besides their place in the Jewish liturgy commemorating the anniversary of the destruction of Jerusalem, the laments are employed by the Christian Church to pour out its grief over the Passion and death of Jesus Christ.

Dating the composition of Lamentations

Most critics place the composition of the book before the return of the Jews from exile in 537/536 BCE. Certain passages appear to be word pictures by an eyewitness and would, therefore, have been written shortly after the destruction of Jerusalem. Until the 18th century, the work was universally ascribed to the prophet Jeremiah, and this was supported by a prologue found in the Septuagint and in some manuscripts of the Vulgate. Since that time, however, many scholars have rejected the attribution to Jeremiah chiefly because the ideas and sentiments expressed in Lamentations are unlike those in Jeremiah. Moreover, it is unlikely that the spontaneity and naturalness so characteristic of Jeremiah's utterances could be accommodated to a poetic form as complicated and artificial as that in Lamentations. It is probable that the laments were the product of more than one poet.

Ecclesiastes. The book of Ecclesiastes is a work of the Hebrew wisdom movement, associated by its title and by tradition with King Solomon. It is evident, however, that the book is of much later composition; the author may have identified himself with the famous king and wise man of the past to give greater authority to his work. The language of the book, including the relatively large number of Aramaic forms, and its content point to a date in the early Greek period (later 4th or early 3rd century BCE). That the book was written prior to the 2nd century BCE, however, is shown by its influence on Ecclesiasticus, which was written early in that century, and its appearance among the manuscripts discovered at Khirbat Qumrān, on the northwestern shore of the Dead Sea, where a Jewish community existed in the mid-2nd century.

The name Ecclesiastes is a transliteration of the Greek word used in the Septuagint to translate the Hebrew Qohelet, a word connected with the noun *qahal* ("assembly"). Qohelet seems to mean the one who gathers or teaches an assembly; the author used the word as a pseudonym. He appears to be a wisdom teacher writing late in life expressing skeptical personal reflections in a collection of popular maxims of the day and longer compositions of his own. The book has been described as a sage's notebook of random observations about life. Some interpreters have questioned the unity of authorship, but, given the notebook character of the work, there seems to be little need for questioning its basic integrity.

Although the phrase "vanity of vanities! all is vanity" stressed at both the beginning and the end of the book sums up its theme, it does not convey the variety of tests that the skeptical Qohelet applies to life. He examines everything—material things, wisdom, toil, riches—and finds them unable to give meaning to life. He repeatedly returns to life's uncertainties, to the hidden and incomprehensible ways of God, and to the stark and final fact of death. The only conclusion to this human condition is to accept gratefully the small day-to-day pleasures that God gives to man.

Qohelet stands in sharp contrast to the conventional wisdom schools. He recognizes the relative value of wisdom as against foolishness, but he rejects the oversimplified and optimistic view of wisdom as security for life. He offers a religious skepticism that rejects all facile answers to life's mysteries and God's ways.

Book of Esther. The Book of Esther is a romantic and patriotic tale, perhaps with some historical basis but with so little religious purpose that God, in fact, is not mentioned in it. The book may have been included in the Hebrew canon only for the sake of sanctioning the celebrations of the festival Purim, the Feast of Lots. There is considerable evidence that the stories related in Esther actually originated among Gentiles (Persian and Babylonian) rather than among the Jews. There is also reason to believe that the version given in the Septuagint goes back to older sources than the version given in the Hebrew Bible.

Origin of Esther

Laying the scene at Susa, a residential city of the Persian kings, the book narrates that Haman, the vizier and favourite of King Ahasuerus (Xerxes I; reigned 486–465 BCE), determined by lot that the 13th of Adar was the day on which the Jews living in the Persian Empire were to be slain. Esther, a beautiful Jewess whom the King had chosen as queen after repudiating Queen Vashti, and her cousin and foster father Mordecai were able to frustrate Haman's plans. Haman then schemed to have Mordecai hanged; instead, he was sent to the gallows erected for Mordecai, and Jews throughout the empire were given permission to defend themselves on the day set for their extermination. The governors of the provinces learned in time that Mordecai, who had saved the King from being assassinated by two discontented courtiers, had succeeded to Haman's position as vizier; thus, they supported the Jews in the fight against their enemies.

In the provinces, the Jews celebrated their victory on the following day, but at Susa, where, at Esther's request, the King permitted them to continue to fight on the 14th of Adar, they rested and celebrated their success a day later. Therefore, Esther and Mordecai issued a decree obligating the Jews henceforth to commemorate these events on both the 14th and 15th of Adar.

Theme and language characterize Esther as one of the latest books of the Hebrew Bible, probably dating from the 2nd century BCE. Nothing is known of its author. According to the postbiblical sources, its inclusion in the canon, as well as the observance of the feast of 14th and 15th Adar, still met with strong opposition on the part of the Jewish authorities in Jerusalem as late as the 3rd century CE; yet, despite its lack of specific religious content, the story has become in popular Jewish understanding a magnificent message that the providence of God will preserve his people from annihilation.

Daniel. The Book of Daniel presents a collection of

popular stories about Daniel, a loyal Jew, and the record of visions granted to him, with the Babylonian Exile of the 6th century BCE as their background. The book, however, was written in a later time of national crisis—when the Jews were suffering severe persecution under Antiochus IV Epiphanes (reigned 175–164 BCE), the second Seleucid ruler of Palestine.

The exiled Jews had been permitted to return to their homeland by Cyrus II the Great, master of the Medes and Persians, who captured Babylon in 539 BCE from its last king, Nabonidus, and his son Belshazzar. The ancient Near East was then ruled by the Persians until Alexander the Great brought it under his control in 331. After Alexander's death in 323, his empire was divided among his generals, with Palestine coming under the dominion of the Ptolemies until 198, when the Seleucids won control. Under the Persian and Ptolemaic rulers the Jews seem to have enjoyed some political autonomy and complete religious liberty. But under Antiochus IV Jewish fortunes changed dramatically. In his effort to Hellenize the Jews of Palestine, Antiochus attempted to force them to abandon their religion and practice the common pagan worship of his realm. Increasingly sterner restrictions were imposed upon the Jews, the city of Jerusalem was pillaged, and, finally, in December 167 the Temple was desecrated. The outcome of this persecution was the open rebellion among the Jews, as described in the books of Maccabees. This period of Hellenistic Judaism is treated more fully in JUDAISM.

The conflict between the religion of the Jews and the paganism of their foreign rulers is also the basic theme of the Book of Daniel. In Daniel, however, it is regarded as foreseen and permitted by God to show the superiority of Hebrew wisdom over pagan wisdom and to demonstrate that the God of Israel will triumph over all earthly kings and will rescue his faithful ones from their persecutors.

Apocalyptic literature

To develop this theme the author makes use of a literary and theological form known as apocalypse (from the Greek *apokalypsis,* "revelation" or "unveiling"), which was widely diffused in Judaism and then in Christianity from 200 BCE to 200 CE. Apocalyptic literature professes to be a revelation of future events, particularly the time and manner of the coming of the final age when the powers of evil will be routed in bloody combat and God's kingdom will be established. This revelation usually occurs as a vision expressed in complicated, often bizarre symbolism. The literature is generally pseudonymous, proposed under the name of some authoritative figure of the distant past, such as Daniel, Moses, Enoch, or Ezra. This allows the author to present events that are past history to him as prophecies of future happenings.

The Book of Daniel, the first of the apocalyptic writings, did not represent an entirely new type of literature. Apocalypse had its beginnings in passages in the works of the prophets. In fact, it has been said that the apocalyptic was really an attempt to rationalize and systematize the predictive side of prophecy. There were significant differences, however. The prophet, for the most part, declared his message by word of mouth, which might subsequently be recorded in writing. The apocalyptist, on the other hand, remained completely hidden behind his message, which he wrote down for the faithful to read. The prophets normally spoke in their own name a message for their own day. The apocalyptists normally wrote in the name of some notable man of the past a message for the time of the age to come.

Like the prophets before them, the apocalyptists saw in the working out of history, which they divided into well-defined periods, a purpose and a goal. The evil in the world might lead men to despair, but the predetermined purpose of God could not be frustrated. A future age of righteousness would replace the present age of ungodliness, and God's purpose would at last be fulfilled. This literature, then, is a mixture of pessimism—times would become worse and worse, and God would destroy this present evil world—and of optimism—out of turmoil and confusion God would bring in his kingdom, the goal of history.

For many centuries the apocalyptic character of the Book of Daniel was overlooked, and it was generally considered to be true history, containing genuine prophecy. In fact, the book was included among the prophetic books in the Greek canon. It is now recognized, however, that the writer's knowledge of the exilic times was sketchy and inaccurate. His date for the fall of Jerusalem, for example, is wrong; Belshazzar is represented as the son of Nebuchadrezzar and the last king of Babylon, whereas he was actually the son of Nabonidus and, though a powerful figure, was never king; Darius the Mede, a fictitious character perhaps confused with Darius I of Persia, is made the successor of Belshazzar instead of Cyrus. By contrast, the book is a not inconsiderable historical source for the Greek period. It refers to the desecration of the Temple in 167 and possibly to the beginning of the Maccabean revolt. Only when the narrative reaches the latter part of the reign of Antiochus do notable inaccuracies appear—an indication of a transition from history to prediction. The book is thus dated between 167 and 164 BCE.

Date, hero, and languages of Daniel

Other considerations that point to this 2nd-century date are the omission of the book from the prophetic portion of the Hebrew canon, the absence of Daniel's name in the list of Israel's great men in Ecclesiasticus, the book's linguistic characteristics, and its religious thought, especially the belief in the resurrection of the dead with consequent rewards and punishments.

The name Daniel would appear to refer to a legendary hero who was used in different ways at different times and who became particularly popular in the storytelling of the Persian and Greek Diaspora as a personification of the practical and theological problems faced by the Jews in that environment. Whether there is any connection between the Daniel of this book and the one mentioned as a wise man without equal in the Book of Ezekiel and as a righteous man in the tale of Aqhat, a Ugaritic text dated from about the middle of the 14th century, is uncertain.

The book is written in two languages: the beginning (1:1–2:4a) and the final chapters (8–12) in Hebrew and the rest in Aramaic. This offers no proof of multiple authorship, however, because the linguistic divisions do not correspond to the division by literary form: chapters 1–6 are stories of Daniel and his friends in exile, and chapters 7–12 are Daniel's apocalyptic visions. Furthermore, there is a singleness of religious outlook, spirit, and purpose throughout. Nevertheless, the problem of the languages has never been satisfactorily answered.

The stories and visions of Daniel

The stories of the first six chapters, which probably existed in oral tradition before the author set them down, begin with the account of how Daniel and his three companions (Hananiah, Mishael, and Azariah, who were given the names Shadrach, Meshach, and Abednego by the Babylonians) came to be living at the Babylonian court and how they remained faithful to the laws of their religion. This is followed by five dramatic episodes calculated to demonstrate the wisdom and might of Israel's God and the unconquerable steadfastness of his loyal people. Thus, through God's gift of wisdom, Daniel excels the professional sages of the pagan court by revealing and interpreting Nebuchadrezzar's dream of a great image, made of four metals, which was shattered by a stone cut without human hand, and then the King's further dream of a tree reduced to a stump, which presaged the punishment of his arrogance by madness, and, finally, the writing on the wall, which spelled Belshazzar's doom at his sacrilegious feast. By trust in God, Daniel's companions, who refused to worship Nebuchadrezzar's golden idol, are miraculously delivered from a fiery furnace, and Daniel himself, thrown into a den of lions for holding fast to his tradition of prayer, is divinely protected.

The last six chapters of the book are apocalyptic. In chapter 7 Daniel is granted a vision of four beasts from the abyss, which are brought under divine judgment, and of "one like a son of man," who is brought before God to be invested with his universal and everlasting sovereignty. The mythological beasts are interpreted as four empires (the Babylonian Empire, the kingdom of the Medes, the Persian Empire, and the empire of Alexander) and the manlike figure as Israel. The vision of a battle between the ram (Medes and Persians) and the goat (the Greek

Empire) in chapter 8 introduces the iniquities of Antiochus IV Epiphanes and is an assurance to the stricken Jews that the end of their tribulation is near. In chapter 9 the author reinterprets the prophecy of Jeremiah that Jerusalem's desolation would end after 70 years. By making these 70 years mean 70 "weeks of years" (*i.e.,* 490 years), the author is again able to focus attention on the period of Antiochus' persecution in the 2nd century and on the imminence of his determined doom. A precise understanding of the author's scheme is not possible, however, because 490 years calculated from the beginning of the exile extends far beyond the time of Antiochus. The remaining chapters provide the fourth commentary on the crisis provoked by the Seleucid tyrant. The greater part of this vision is a sketch of the events that affected the Jews from the Persian period to the time of Antiochus and prepared for his reign of terror. After chapter 11, verse 39, the account of Antiochus' life ceases to correspond with historical fact; an inaccurate prediction of his end is the prelude to the announcement of the end of Israel's tribulation and the inauguration of God's kingdom.

The purpose of the whole book, stories and visions alike, is to encourage Israel to endure under the threat of annihilation and to strengthen its faith that "the Most High rules the kingdom of men" and will in the end give victory to his people and establish his kingdom.

The Chronicler's History

Ezra, Nehemiah, and Chronicles. The final books of the Hebrew Bible are the books of Chronicles and Ezra–Nehemiah, which once formed a unitary history of Israel from Adam to the 4th century BCE, written by an anonymous Chronicler. That these books constituted a single work—referred to as the Chronicler's history, in distinction to the Deuteronomic history and the elements of history from the priestly code of the Torah—appears evident because the same language, style, and fundamental ideas are found throughout and because the concluding verses of II Chronicles are repeated at the beginning of Ezra. The purpose of this history seems to have been to trace the origin of the Temple and to show the antiquity and authenticity of its cult and of the formal, legalistic type of religion that dominated later Judaism.

The history that these books record has already been treated in the historical section of this article and is found in greater detail in JUDAISM. The concern in this section will be chiefly with the literary and theological aspects of the books, but their contents can be summarized. In I and II Chronicles the author repeats much of the material from earlier historical books, concentrating upon the history of the kingdom of Judah. The First Book of the Chronicles begins with an extensive genealogy of Israel from Adam to the restoration but is primarily a biography of David that adds further facts to the story as given in Samuel. The Second Book of the Chronicles begins with Solomon and goes through the division of the kingdom to the reign of Zedekiah; once again the Chronicler had access to materials that supplemented the account in I and II Kings. In the Book of Ezra he describes the return of the Jews from the Babylonian Exile and the reconstruction of the Temple. He includes lists of the families who returned and the texts of the decrees under which they returned. In the Book of Nehemiah the reconstruction of the city walls of Jerusalem becomes the basis for a meditation upon the relation between God and his people. This book, too, contains lists of those who participated in the reconstruction, but much of it concentrates upon the description of Nehemiah and his persistence in performing his assignment.

Divisions, Author, Date, and Sources

The fourfold division of the books derives from the Greek and Latin versions; the more basic twofold division into Chronicles and Ezra–Nehemiah is more complex. This original division apparently resulted from the inclusion of the material known as Ezra–Nehemiah in the Hebrew canon before that known as Chronicles because it contained fresh information not found in any other canonical book. When Chronicles was later admitted to the canon, it was placed in order after Ezra–Nehemiah; although the book has retained this position in the Hebrew Bible, the Greek version restored it to its proper sequence. That Chronicles was thus "left aside" may account for the choice of *Paraleipomena* ("Things Omitted") as the Greek title of the book, but the usual and perhaps correct explanation is that Chronicles contains stories, speeches, and observations that were omitted from the parallel accounts in earlier books.

Jewish tradition has identified Ezra as the author of these books, and some modern scholars concur. According to many critics, however, the Chronicler was a Levite cantor in Jerusalem. This position is supported by the author's concern with the Levites and cultic musicians. The date of the work is more difficult to pinpoint. In its final form it has to be later than Ezra, who came to Judah about 400 BCE. An indication of the latest date at which the entire work could have been completed is its silence about the Hellenizing of Judaism that took place after Alexander the Great. This, together with language considerations that point to the late Persian period, has led the majority of commentators to postulate a 4th-century date. Some scholars, however, claim that a time before 300 BCE would be too short to account for the genealogy at the beginning of I Chronicles, which is carried down to the eighth generation after Zerubbabel, one of the leaders of the band that returned from Babylon. Thus, they push the final date to about 200 BCE or even slightly later. It is possible that the 4th-century work of the Chronicler went through a series of minor additions and adaptations until sometime early in the 2nd century, when it reached its final form.

The Chronicler had numerous historical sources—both biblical and extrabiblical—at his disposal. He was closely dependent on the books of Samuel and Kings for all of Chronicles except the first nine chapters. Sometimes he even repeated the actual words of his model, though slight textual variations suggest to some that the Hebrew copy he had before him differed a little from that of the canon and corresponded to that which lay behind the Septuagint. But he was also able to consult the final version of the Torah and the whole of the Deuteronomic history. His use of the personal memoirs of Nehemiah is undisputed; the nature of his Ezra source is less clear, but some have regarded a portion of narrative written in the first person as an autobiographical source. He included many lists, genealogies, census reports, and other official documents that may have been preserved as Temple records. The text refers by name to certain documents representing royal histories and prophetic writings about which, as they have not survived, only speculation is possible.

Theological purpose

The Chronicler made use of all these sources, but he was not shackled by them. Although his work has won increasing respect as a historical document, especially as an indispensable source for the restoration period, his purpose was chiefly theological, not historical. He was convinced of the definitiveness of the divine covenant with David. The holy community that was brought into existence by this covenant, that has been maintained by God through the vicissitudes of history, and that has its worship centred on the Temple in Jerusalem is the true kingdom of God. It is the true Israel and is the Chronicler's only concern. Thus, he mentions the northern kingdom and the kings of Israel only to the extent that they figure in the events of Judah. Loyalty to the Davidic line of succession, to Jerusalem, and to the Temple worship were the central elements in the life of God's people according to this writer. All success and failure were the result of such loyalty or disloyalty. Thus, if a king's reign was long and successful, the Chronicler saw it as the reward of God for a life led in obedience to his will; conversely, a king suffered misfortune only if he had sinned. Significantly, the Chronicler devotes much attention to David's part in the development of the liturgy, especially the organization and functions of the Levites, and omits important but uncomplimentary stories about the King that are found in the Deuteronomic history.

In short, the Chronicler traced the reformed liturgy of his day back to David and laid a solid foundation for the acceptance and conservation of the religious community that he envisioned—a devout community that worshipped joyfully in the Temple with sacrifice and praise and obeyed the Law of Moses. He knew well that the realization of that community in his day was not perfect and that the future had something better in store, but he seems to

have been content to accept the existing Davidic leaders in order not to abandon the dynastic hope because of their shortcomings. These books thus provided an apologia for orthodox Judaism (perhaps in the face of opposition from the Samaritans, the inhabitants of the former northern kingdom), and they offer to the modern reader some insight into the post-exilic community in Jerusalem, withdrawn into itself and trying to justify, explain, and preserve its existence and its spirituality. (R.F.)

Intertestamental literature

NATURE AND SIGNIFICANCE

Definitions. A vast amount of Jewish literature written in the intertestamental period (mainly 2nd and 1st centuries BCE) and from the 1st and 2nd centuries CE was preserved, for the most part, through various Christian churches. A part of this literature is today commonly called the Apocrypha (Hidden; hence, secret books; singular apocryphon). At one time in the early church this was one of the terms for books not regarded by the church as canonical (scripturally acceptable), but in modern usage the Apocrypha is the term for those Jewish books that are called in the Roman Catholic Church deuterocanonical works—*i.e.*, those that are canonical for Catholics but are not a part of the Jewish Bible. (These works are also regarded as canonical in the Eastern Orthodox churches.) When the Protestant churches returned to the Jewish canon (Hebrew Old Testament) during the Reformation period (16th century), the Catholic deuterocanonical works became for the Protestants "apocryphal"—*i.e.*, non-canonical.

Meaning of Apocrypha and Pseudepigrapha among Roman Catholics, Protestants, and Jews

In 19th-century biblical scholarship a new term was coined for those ancient Jewish works that were not accepted as canonical by either the Catholic or Protestant churches; such books are now commonly called Pseudepigrapha (Falsely Inscribed; singular pseudepigraphon), *i.e.*, books wrongly ascribed to a biblical author. The term Pseudepigrapha, however, is not an especially well suited one, not only because the pseudepigraphic character is not restricted to the Pseudepigrapha alone—and, indeed, not even all Pseudepigrapha are ascribed to any author, since there are among them anonymous treatises—but also because the group of writings so designated by this name necessarily varies in the different modern collections. Theoretically, the name Pseudepigrapha can designate all ancient Jewish writings that are not canonical in the Catholic Church. The writings of the philosopher Philo of Alexandria (1st century BCE–1st century CE) and the historian Josephus (1st century CE) and fragments of other postbiblical Hellenistic Jewish historians and poets, however, usually are excluded. Rabbinic literature (2nd century BCE–2nd century CE) also is generally excluded; such literature existed for centuries only in oral form. The edition of the Pseudepigrapha edited by the British biblical scholar R.H. Charles in 1913, however, contains a translation of *Pirqe Avot* ("Sayings of the Fathers"), an ethical tractate from the Mishna (a collection of oral laws), and even the non-Jewish *Story of Aḥikar* (a folklore hero), though other genuine Jewish writings from antiquity are omitted. Some of the Jewish Pseudepigrapha were discovered only in the last two centuries, and the Dead Sea Scrolls (the first of them discovered in the 1940s), most of which belong to this category, are not yet all published. Thus, in the broader meaning of the terms, the Apocrypha and Pseudepigrapha are a bloc of Jewish literature written in antiquity from the later Persian period (*c.* 4th century BCE) and not canonized by the Jews.

Texts and versions. A small portion of this literature is preserved in the original languages: Hebrew, Aramaic, and Greek. Most of the Hebrew or Aramaic works, however, exist today only in various translations: Greek, Latin, Syriac, Ethiopian, Coptic, Old Slavonic, Armenian, and Romanian. All the works of the Apocrypha are preserved in Greek, because they have for the Greek Church a canonical value. Those books not considered canonical by the early church have often fallen into oblivion, and their Greek text was often lost; many of the ancient Jewish Pseudepigrapha are today preserved only in fragments or quotations in various languages, and sometimes only their titles are known from old lists of books that were rejected by the church.

Of this literature only the Apocrypha (contained in Latin and Greek Bibles) were read in the liturgical services of the church. The Pseudepigrapha, in their various versions, were in most cases nearly forgotten; and manuscripts of most of them were rediscovered only in modern times, a process that continues. The discovery of the Dead Sea Scrolls at Qumrān in the Judaean desert not only furnished new texts and fragments of unknown and already known Pseudepigrapha but also contributed solutions to problems concerning the origin of other Jewish religious writings (including some Old Testament books), the connection between them, and even their composition and redaction from older sources. The new original texts also strengthened interest in the Jewish literature of the intertestamental period because of its importance for the study of both ancient Judaism and early Christianity. As a result of such discoveries, better critical editions of the Apocrypha and Pseudepigrapha have been published, as well as new studies of their content.

Rediscoveries and new discoveries of texts

The Apocrypha, whose texts originated mostly before the rise of Christianity, were regarded as canonical in the early church but contain no Christian interpolations. Many of the Pseudepigrapha, however, were interpolated by Christian writers. The nature and the extent of these Christian interpolations is often difficult to define since a Christian interpolator not only changes the text according to his Christian views or introduces specific Christian terminology, but he also may introduce in a Jewish text ideas, motifs, or terminology that are common to both Judaism and Christianity. For these reasons it is sometimes difficult to decide if a passage in a pseudepigraphon, or even sometimes the whole work, is Jewish or Christian.

Persian and Hellenistic influences. Some of the Apocrypha (*e.g.*, Judith, Tobit) may have been written already in the Persian period (6th–4th century BCE), but with these possible exceptions, all the Apocrypha and Pseudepigrapha were written in the Hellenistic period (*c.* 300 BC–*c.* AD 300). Yet the influence of Persian culture and religion sometimes can be detected even in comparatively late Jewish works, especially in Jewish apocalyptic literature (see below *Apocalypticism*). The Persian influence was facilitated by the fact that both the Jewish and Persian religions are iconoclastic (against the veneration or worship of images) and opposed to paganism and display an interest in eschatology (doctrines of last times).

Although such an affinity did not exist between Judaism and Hellenistic culture, literary activity among Hellenistic Jews was generally Greek in character: the Greek-writing Jewish authors thought mainly in Greek concepts, used genuine Greek terminology, and wrote many of their works in Greek literary forms.

Though Hellenistic Jewish authors sometimes imitated biblical forms, they learned such forms from their Greek Bible (the Septuagint). Many Greek products written by Jews served as religious propaganda and probably influenced many pagans to become proselytes, or at least to abandon their heathen faith and to become "God fearing." Thus, the Jewish literature written in Greek could be later used by Christianity for similar purposes.

Greek influence

Greek influence on Jewish writings written in Hebrew or Aramaic in Palestine in the intertestamental period was by no means as significant as upon Jewish works written in Greek among the Hellenistic Diaspora (Jews living outside Palestine). In Palestine, religion and culture formed a unity, and the Hellenization of the upper classes in Jerusalem before the Maccabean wars (168–142 BCE) was restricted to some families who had accepted Greek civilization for practical purposes. Jews in Palestine developed a flourishing autonomous culture based upon religious ideals. Living without interruption in their powerful religious tradition and with their own non-Greek education, the Palestinian Jews were able to produce literary works without significant evidences of Greek influence. The language of this literature was both Aramaic and Hebrew. Under the national revival in the Maccabean period, Hebrew became prevalent as the language of Jewish literature in Palestine; but since Aramaic was a spoken language in Palestine

during the whole period, some of the extant literary works of Palestinian Jews in the Maccabean and Roman period probably were originally written also in Aramaic.

Apocalypticism. In intertestamental Jewish literature a special trend developed: namely, apocalypticism. *Apokalypsis* is a Greek term meaning "revelation of divine mysteries," both about the nature of God and about the last days (eschatology). Apocalyptic writings were composed both in Judaism and Christianity; one of them (the Book of Daniel) was accepted in the Jewish canon and another (the book of Revelation) in the New Testament. Other apocalypses form a part of the Pseudepigrapha, and influences of apocalypticism or similar approaches are found in some of the Apocrypha. The sectarian Dead Sea Scrolls are the works of an apocalyptic movement, though not all are written in the style of apocalypses. *The Sibylline Oracles* are, in their Jewish passages, a part of Jewish Hellenistic literature; inasmuch as they contain eschatological prophecies of future doom and salvation, they are apocalyptic, but in their polemics against idolatry and their apology for Jewish faith, they are a product of Jewish Hellenistic propagandistic literature. Because one of the central themes of apocalypticism is that of future salvation, messianic hopes involving the advent of a deliverer are usually the object of intertestamental Jewish apocalypticism.

APOCRYPHAL WRITINGS

Apocryphal works indicating Persian influence. *Esdras.* The "Greek Ezra," sometimes named I (or II or III) Esdras, enjoyed considerable popularity in the early church but lost its prestige in the Middle Ages in the Latin Chruch. At the reforming Council of Trent (1545–63), the Roman Catholic Church no longer recognized it as canonical and relegated it in the Latin Bible to the end, as an appendix to the New Testament. One of the reasons for its noncanonicity in the West is that the "Greek Ezra" contains parallel material to the biblical books of Chronicles, Ezra, and Nehemiah but differs in textual recension (points of critical revision) and occasionally in the order of the stories. The content of the book is a history of the Jews from the celebration of the Passover in the time of King Josiah (7th century BCE) to the reading of the Law in the time of Ezra (5th century BCE). Though written in an idiomatic Greek, "Greek Ezra" is probably a Greek translation from an unknown Hebrew and Aramaic redaction of the materials contained in the biblical books of Chronicles, Ezra, and Nehemiah. An important part of this book (3:1–5:6), the story of the three youths at the court of Darius, has no parallel in the canonical books. This story concerns a debate between three guardsmen before Darius, king of Persia, about the question of what they consider to be the strongest of all things; the first youth asserts that it is wine, the second says that it is the king, and the third, who is identified with the biblical Zerubbabel (a prince of Davidic lineage who became governor of Judah under Darius), expresses his opinion that "women are strongest, but truth is victor over all things." He is acclaimed as the victor, and, as a reward, he requests that Darius rebuild Jerusalem and its Temple. The story evidently was written in two stages: originally, the competition was about wine, the king, and women, but later, truth was added. Truth is one of the central concepts of Persian religion and the competition itself is before a Persian king; thus it seems likely that the story is Persian in origin and that it became Jewish by the identification of the third youth with Zerubbabel.

The three youths at the court of Darius

Judith. The book of Judith is similar to the biblical Book of Esther in that it also describes how a woman saved her people from impending massacre by her cunning and daring. The name of the heroine occurs already in Gen. 26:34 as a Gentile wife of Esau, but in the book of Judith it evidently has symbolic value. Judith is an exemplary Jewess. Her deed is probably invented under the influence of the account of the 12th-century-BCE Kenite woman Jael (Judg. 5:24–27), who killed the Canaanite general Sisera by driving a tent peg through his head.

The story is clearly fiction, and the anachronisms in it are intentional: they show that the story itself is a mere fiction. The book speaks about the victory of Nebuchadnezzar, "who reigned over the Assyrians at Nineveh" (the name is of the 7th–6th century BCE king of Babylon, Nebuchadrezzar) in the time of an unknown Arphaxad, king of the Medes. Since the western nations of Nebuchadnezzar's empire had refused to come to his aid, the King ordered his commander in chief, Holofernes (a Persian name), to force submission upon the rebellious nations. In subduing these nations Holofernes destroyed their sanctuaries and proclaimed that Nebuchadnezzar alone should henceforth be worshipped as a god. Thus, the Jews, who had recently returned from the Babylonian Captivity (6th century BCE) and rebuilt the Temple, were compelled to prepare for war. Holofernes laid siege to Bethulia (otherwise unknown), described as an important strategic point on the way to Jerusalem. Because of a long siege, the inhabitants wanted to surrender their city, but Judith persuaded the people to delay the surrender for five days. Judith was a virtuous, pious, and beautiful widow. She removed her mourning garments, left the city, entered Holofernes' camp, and was brought before him. On the fourth day, Holofernes decided to seduce Judith and invited her to come into his tent; he then drank more wine than ever before. After he fell into a drunken stupor, Judith cut off his head with his sword and returned with the head to Bethulia. The Jews put Holofernes' head outside the city wall, and the following morning, upon learning of the death of their commander in chief, the Assyrian soldiers dispersed and were pursued by the Jews of Bethulia, who took abundant spoil. The Jews were not threatened again during Judith's lifetime—she lived to be 105—or for long thereafter.

The killing of Holofernes

Many suggestions have been made about the book of Judith's date of composition. Though current scholarly opinion is that the book was written in the warlike patriotic atmosphere of the early Maccabean period (*c.* 150 BCE) by a Palestinian Jew, there are no Maccabean elements in the book. It shows no direct or indirect Greek influences, the deification of kings existed already in the ancient Near East, and the political situation described in the book has nothing in common with the Maccabean period. All the apparently intentional historical mistakes, however, can be understood if it is suggested that the book of Judith was written under Persian rule. Holofernes is, as noted above, a typical Persian name; and the whole political and social situation described in the book fits the Persian world, as do the Jewish life and institutions reflected in the book. Thus, there are no serious indications that the book of Judith is a Maccabean product, and there are many allusions to the time of the Persian rule over Palestine. Only a Greek translation of the book is extant, but, from its style, it is clear that the book was originally written in Hebrew. In his preface to the book of Judith, the Latin biblical scholar Jerome (*c.* 347–419/420 CE) states that he used for his translation a "Chaldaean" (*i.e.,* Aramaic) text and that he also used an older Latin translation from Greek. His translation differs in many points from the original text.

Tobit. The other Jewish short story possibly dating from Persian times is the book of Tobit, named after the father of its hero. From the fragments of the book discovered at Qumrān, scholars now know that the original form of the name was Tobi. Tobit was from the Hebrew tribe of Naphtali and lived as an exile in Nineveh; his son was Tobias. Obeying the tenets of Jewish piety, Tobit buried the corpses of his fellow Israelites who had been executed. One day, when he buried a dead man, the warm dung of sparrows fell in his eyes and blinded him. His family subsequently suffered from poverty, but then Tobit remembered that he had once left a deposit of silver at Rages (today Teheran) in Media. He sent his son Tobias along with a companion, who was in reality the angel Raphael under the guise of an Israelite, to retrieve the deposit. During the journey, while Tobias was washing in the Tigris, a fish threatened to devour his foot. Upon instructions from Raphael, Tobias caught the fish and removed its gall, heart, and liver, since it was believed that the smoke from the heart and liver had the power to exorcise demons and that ointment made from the gall would cure blindness. On the way he stopped at Ecbatana (in Persia), where Raguel, a member of Tobias' family, lived. His daughter Sarah had been

married seven times, but the men had been slain by the demon Asmodeus on the wedding night, before they had lain with her. On the counsel of Raphael, Tobias asked to marry Raguel's daughter, and on the wedding night Tobias put Asmodeus to flight through the stench of the burning liver and heart of the fish. Raphael went to Rages and returned with the deposit. When he returned with his young wife and Raphael to Nineveh, Tobias restored his father's sight by applying the gall of the fish to his eyes. Raphael then disclosed that he was one of God's seven angels and ascended into heaven.

"The Grateful Dead"

The story of the book of Tobit is a historicized and Judaized version of the well-known folktale of "The Grateful Dead" (or "The Grateful Ghost"), in which a young man buries the corpse of a stranger despite injunctions against such an act; later the youth wins a bride through the intercession of the dead man's spirit. Asmodeus (in Persian, Aeshma Daeva, the demon of wrath) occurs as a powerful demon in rabbinic literature as well as in folktales. In the Jewish form of the story, "The Grateful Dead" is replaced by the angel Raphael. According to the *Ethiopic Enoch* (20:3; 22:3), Raphael is appointed over the spirits of the souls of the dead (for *Enoch,* see below). Because the cause of this situation is not mentioned in the book of Tobit, the story itself in its Jewish form probably existed before it became the subject of the book of Tobit. The present work is a literary product; the interesting plot gave to the author many occasions to insert religious and moral teachings in the manner of wisdom literature, which is concerned with practical, everyday issues. The book contains prayers, psalms, and aphorisms, most of them put in the mouth of Tobit. It is the oldest Jewish witness of the golden rule (4:15): "And what you hate, do not do to anyone." Eschatological hopes are also described: at the end of time, all Jewish exiles will return, Jerusalem will be rebuilt of precious stones and gold, and all nations will worship the true God. In these eschatological images, however, the figure of the Messiah does not occur.

The religious, social, and literary atmosphere of the book does not contain elements from the Greek period. Thus, the book probably was written already in the Persian period or in the early days of Greek rule (3rd century BCE). The book exists today in three principal recensions, and it is often difficult to determine, in a particular passage, what was the original text. The book was written in Hebrew or Aramaic; the Greek recensions differ, perhaps because they are based on different Semitic versions. These questions may be answered when the Hebrew and Aramaic fragments of the book, which were found among the Dead Sea Scrolls, are published.

The Story of Ahikar. According to the book of Tobit, Ahikar, the cupbearer of the Assyrian king Esarhaddon, was Tobit's nephew; he is a secondary personage in the plot, and his own story is mentioned. Ahikar is the hero of a Near Eastern non-Jewish work, *The Story of Ahikar.* The book exists in medieval translations, the best of them in Syriac. The story was known in the Persian period in the Jewish military colony in Elephantine Island in Egypt, a fact demonstrated by the discovery of fragmentary Aramaic papyri of the work dating from 450–410 BCE. Thus, the author of the book of Tobit probably knew *The Story of Ahikar,* in which, as in the book of Tobit, the plot is a pretext for the introduction of speeches and wise sayings. Some of Tobit's sayings have close parallels in the words of the wise Ahikar.

Baruch. The apocryphon of Baruch, which is extant in Greek and was included in the Septuagint, is attributed to Baruch, secretary to the Old Testament prophet Jeremiah (7th–6th century BCE). It was Baruch who read Jeremiah's letter to the exiles in Babylon. After hearing his words, the Jews repented and confessed their sins. The first part of the book of Baruch (1:1–3, 8), containing a confession of sins by the Jews following the destruction of Jerusalem and the exiles' prayer for forgiveness and salvation, may date from the Persian or at least from the pre-Maccabean period. This early section was originally written in Hebrew and seems to be very ancient. The other two parts (3:9–4:4 and 4:5–5:9) were written in Greek or freely translated from Hebrew or Aramaic. The first is a praise of wisdom: only Israel received wisdom from God, which is the Law of Moses. The last part of the book of Baruch contains Jerusalem's lament over her desolation and her consolation.

Apocryphal works lacking strong indications of influence. *The Letter of Jeremiah.* The Letter of Jeremiah, like the book of Baruch, was conserved—together with the Greek translation of the Book of Jeremiah—in the Septuagint. The oldest witness of the letter is a fragment of a Greek papyrus, written about 160 BCE and found among the Dead Sea Scrolls at Qumrān. Whether the letter was originally written in Greek or is a translation from Hebrew or Aramaic is difficult to decide. The letter attacks the folly of idolatry as did Jeremiah's letter "to those who were to be taken to Babylon as captives." Though, according to some experts, the idolatry described in the book fits Babylonian cults, the only clear indication of its date is that of the Qumrān fragment.

Prayer of Manasseh. In some manuscripts of the Septuagint and in two later Christian writings, a pseudepigraphic Prayer of Manasseh is contained. This prayer was composed with reference to II Chron. 33:11–18, according to which the wicked Judaean king Manasseh repented and prayed. In the present form the prayer is Greek in origin, but it may have existed in a Hebrew version, of which the Greek is a free adaptation. The prayer was probably composed (or translated) in the 1st century BCE.

Additions to Daniel and Esther. Two of the Old Testament Hagiographa (Ketuvim; see above *The Hebrew canon*)—Daniel and Esther—contain, in their Greek translations, numerous additions.

The Prayer of Azariah and the Song of the Three Young Men. The first addition to Daniel (in Greek and Latin translations Dan. 3:24–68) contains the Prayer of Azariah and the Song of the Three Young Men. These are the prayers of Hananiah, Mishael, and Azariah, the three young men who praised God after they had been placed in the midst of the fiery furnace during a persecution of Jews in Babylon, as told in the Book of Daniel. The first prayer is said by Azariah alone; the second, a thanksgiving prayer, is said by all three after having been saved by God. The two poems are not found in the original Daniel and were never a part of it. They were translated from Hebrew originals or adapted from them. A passage from the second, a liturgical hymn of praise, is a poetic expansion of the doxology that was sung in the Temple when the holy name of God was pronounced. Like the other additions to Daniel, the two prayers were probably composed before 100 BCE.

Susanna. The second addition to Daniel, the story of Susanna, and the third one, Bel and the Dragon, are preserved in two Greek versions. In both stories the hero is the wise Daniel. Susanna was the pious and beautiful wife of Joakim, a wealthy Jew in Babylon. Two aged judges became inflamed with love for her. They tried to force her to yield to their lust, and, when she refused, they accused her of committing adultery with a young man, who escaped. She was condemned to death, but when Daniel cross-examined the two elders separately, the first stated that Susanna had been surprised under a mastic tree, the other under a holm tree. Susanna was thus saved and the two false witnesses executed.

The wisdom of Daniel

The short story, perhaps invented even before the extant Book of Daniel was composed, could very well be added to Daniel (whose name means God is my Judge). The story was written in its present form in Greek, since it contains two Greek puns, but a written Semitic prototype may have existed.

Bel and the Dragon. The third Greek addition to the Book of Daniel is the story of Bel and the Dragon. The Babylonians worshipped the idol of the god Bel and daily provided him with much food, but Daniel proved to the King that the food was in reality eaten by the priests. The priests were punished by death and Bel's temple destroyed. The Babylonians also worshipped a dragon, but Daniel declined to worship him. To destroy the beast, Daniel boiled pitch, fat, and hair together: the dragon ate it and burst asunder. After Daniel's sacrilege of slaying the dragon, the King was forced to cast Daniel into the lions' den, but nothing happened to him. Indeed, he was given

a dinner by the prophet Habakkuk, who was brought there by the hair of his head by an angel. On the seventh day the King found Daniel sitting in the den; so he led Daniel out and cast his enemies into the den, where they were devoured.

The two stories are an attack against idolatry. As the addition ends with the story about Daniel in the lions' den, which is also narrated in the canonical Book of Daniel with another motivation, it is probable that this short treatise originated in a tradition that was parallel to the canonical Book of Daniel and that the two stories were translated from a Hebrew or Aramaic original.

Greek and Roman anti-Semitism

Greek additions to Esther. The Hebrew Book of Esther had a religious and social value to the Jews during the time of Greek and Roman anti-Semitism, though the Hebrew short story did not directly mention God's intervention in history—and even God himself is not named. To bring the canonical book up-to-date in connection with contemporary anti-Semitism and to stress the religious meaning of the story, additions were made in its Greek translation. These Greek additions are (1) the dream of Mordecai (Esther's uncle), a symbolic vision written in the spirit of apocalyptic literature; (2) the edict of King Artaxerxes (considered by some to be Artaxerxes II, but more probably Xerxes) against the Jews, containing arguments taken from classical anti-Semitism; (3) the prayers of Mordecai and of Esther, containing apologies for what is said in the Book of Esther—Mordecai saying that he refused to bow before Haman (the grand vizier) because he is flesh and blood and Esther saying that she strongly detests her forced marriage with the heathen king; (4) a description of Esther's audience with the King, during which the King's mood was favourably changed when he saw that Esther had fallen down in a faint; (5) the decree of Artaxerxes on behalf of the Jews, in which Haman is called a Macedonian who plotted against the King to transfer the kingdom of Persia to the Macedonians; and (6) the interpretation of Mordecai's dream and a colophon (inscription at the end of a manuscript with publication facts), where the date, namely, "the fourth year of the reign of Ptolemy and Cleopatra" (*i.e.*, 114 BCE), is given. This indicates that the additions in the Greek Esther were written in Egypt under the rule of the Ptolemies.

I and II Maccabees. *I Maccabees.* The first two of the four books of Maccabees are deuterocanonical (accepted by the Roman Catholic Church). The First Book of the Maccabees is preserved in the Greek translation from the Hebrew original, the original Hebrew name of it having been known to the Christian theologian Origen of Alexandria. At the beginning, the author of the book mentions Alexander the Great, then moves on to the Seleucid king of Syria, Antiochus Epiphanes (died 164/163 BCE), and his persecution of the Jews in Palestine, the desecration of the Jerusalem Temple, and the Maccabean revolt. After the death of the priest Mattathias, who had refused to obey Antiochus, his son Judas Maccabeus succeeded him and led victorious wars against the Syrian Greeks. Exactly three years after its profanation by Antiochus, Judas captured the Temple, cleansed and rededicated it, and in honour of the rededication initiated an annual festival (Ḥanukka) lasting eight days. After Judas later fell in battle against the Syrian Greeks, his brother Jonathan succeeded him and continued the struggle. Only in the time of Simon, Jonathan's brother and successor, did the Maccabean state become independent. A short mention of the rule of Simon's son John Hyrcanus I (135/134–104 BCE) closes the book. The author, a pious and nationalistic Jew and an ardent adherent of the family of Maccabees, evidently lived in the time of John Hyrcanus. The book imitates the biblical style of the historical books of the Old Testament and contains diplomatic and other important—though not necessarily authentic—official documents.

Origin of Ḥanukka

II Maccabees. The Second Book of the Maccabees, or its source, was probably written in the same period as I Maccabees. The book is preceded by two letters to the Jews of Egypt: the first from the year 124 BCE and the second one written earlier (164 BCE) commemorating the rededication of the Temple. In the preface of the book, the author indicates that he has condensed into one book the lost five-volume history compiled by Jason of Cyrene. II Maccabees describes the persecution under Antiochus Epiphanes and the Maccabean wars until the victory of Judas Maccabeus over Nicanor, the commander of the Syrian elephant corps, in 161 BCE. The book, written in Greek, is an important document of Hellenistic historiography. Descriptions of the martyrdom of the priest Eleazar and of the seven brothers under Antiochus, in which Greek dramatic style is linked with Jewish religious spirit, became important for Christian martyrology. The book also furnished proof texts for various Jewish and subsequently Christian doctrines (*e.g.*, doctrines of angels and the resurrection of the flesh).

Wisdom literature. *Ecclesiasticus (or Sirach).* There are two deuterocanonical works of the genre known as wisdom literature, one Hebrew and one Greek. The Hebrew work is called Ecclesiasticus, in the Latin Bible and in Greek manuscripts Sophia Iēsou hyiou Sirach (the Wisdom of Jesus the Son of Sirach); the original Hebrew title was probably Ḥokhmat Yeshua' Ben-Sira, the Wisdom of Ben-Sira. Written in Hebrew about 180–175 BCE, it was translated into Greek by the author's grandson in Egypt. A Syriac translation also was made. Portions (about three-fifths) of the Hebrew text were found in medieval copies in a synagogue of Cairo and a part of the book in a fragment of a scroll from Massada in Palestine (written *c.* 75 BCE). Small Hebrew fragments also were found among the Dead Sea Scrolls; one of them, the Psalms scroll, contains a large part of a poem about wisdom that is a part of the appendix (chapter 51) and that was not written by the author. The Proverbs of Ben-Sira are often quoted in rabbinic literature.

The book is written in the poetical style of the wisdom books of the Old Testament (*e.g.*, Proverbs, Job) and deals with the themes of practical and theoretical morality. The religious and moral position of the author is conservative—he does not believe in the afterlife, but he reflects the contemporary religious positions. He identifies wisdom, the origin of which is divine, with "the Law which Moses commanded," an idea that became important for later Judaism. He also reflects contemporary debates about freedom of will and determinism, and, though realistic in his basic opinions, he sometimes expresses eschatological hopes of salvation for his people. His piety is ethical, though lacking in asceticism; and he invites his readers to enjoy life, which is short (in this point some Greek influence is palpable, but it is not very deep). At the end of the book the author praises, in chronological order, "the fathers of old," from the beginning of history to his contemporary, the high priest Simon, whose appearance in the Temple is poetically described. After some verses comes the colophon with the author's name—the last chapter being an appendix not composed by the author.

The themes of intertestamental wisdom literature

The Wisdom of Solomon. The other deuterocanonical wisdom book, the Wisdom of Solomon, was written in Greek, though it purports to have been written by King Solomon himself. The hypothesis that the first half of the book was translated from Hebrew seems to be without foundation and probably came into existence because, in this section, the author imitated in Greek the Old Testament poetical style. The Wisdom of Solomon was probably written in Alexandria (Egypt) in the 1st century BCE.

The book has three parts. The first (chapters 1–5) concerns the contrast between pious and righteous Jews and the wicked, sinful, and mundane Jews who persecute the righteous; the lot of the righteous is preferable to the sorrows and final condemnation of the sinners. In the second part (chapters 6–9) Solomon speaks about the essence of wisdom and how he attained it. In the third part (chapters 10–19) the author proves the value of wisdom by telling—not in an exact chronological order—how, in the history of Israel from the beginning until the conquest of Palestine, God exalted Israel and punished the heathens, the Egyptians, and the Canaanites. He also describes the folly of heathenism and its origins in human aberrations.

The author fuses Judaism and Hellenism both in style and in thought. Though he imitates biblical style, he is also influenced by Greek rhetoric. He also freely uses Greek philosophical and other terms and is influenced by

Jewish apocalyptic literature. Some close parallels to the Dead Sea sect (at Qumrān), both in eschatology and in anthropology (doctrines about man), can be found in the Wisdom of Solomon.

THE PSEUDEPIGRAPHAL WRITINGS

Works indicating a Greek influence. *The Letter of Aristeas.* An important document of Jewish Hellenistic literature is *The Letter of Aristeas,* a pseudepigraphon ascribed to Aristeas, an official of Ptolemy II Philadelphus, a Greek monarch of Egypt in the 3rd century BCE. The letter is addressed to his brother and gives an account of the translation of the Pentateuch (first five books of the Old Testament) into Greek, by order of Ptolemy. According to the legend, reflected in the letter, the translation was made by 72 elders, brought from Jerusalem, in 72 days. The letter, in reality written by an Alexandrian Jew about 100 BCE, attempts to show the superiority of Judaism both as religion and as philosophy. It also contains interesting descriptions of Palestine, of Jerusalem with its Temple, and of the royal gifts to the Temple.

Translation of the Pentateuch into Greek

IV Maccabees. Another Jewish Hellenistic work combining history and philosophy is *The Fourth Book of Maccabees.* The theme of the book, reflecting the views of the Greek Stoics, is "whether the Inspired Reason is supreme ruler over the passions." This thesis is demonstrated by the martyrdom of the elderly scribe Eleazar and the unnamed seven brothers and their mother, taken from II Macc. 6:18–7:41. The idea of the expiatory force of martyrdom is stressed more in *IV Maccabees* than in its source. The author probably lived in the 1st century BCE and may have been from Antioch (in Syria), where the tombs of the Maccabean martyrs were venerated by the Jews.

III Maccabees. The Greek book called *The Third Book of Maccabees* itself has nothing to do with the Maccabean period. Its content is a legend, a miraculous story of deliverance, which is also independently told—in another historical context—by Josephus (*Against Apion* II, 5). In III Maccabees the story takes place during the reign of Ptolemy IV Philopator (reigned 221–203 BCE). The central episode of the book is the oppression of Egyptian Jews, culminating with an anti-Jewish decree by the King. The Jews who were registered for execution were brought into the hippodrome outside of Alexandria; the King had ordered 500 elephants to be drugged with incense and wine for the purpose of crushing the Jews, but by God's intercession "the beasts turned round against the armed hosts [of the king] and began to tread them under foot and destroy them." The Jews fixed annual celebrations of this deliverance. The book was probably written at the end of the 1st century BCE by an Alexandrian Jew in a period of high anti-Jewish tension.

The Lives of the Prophets. The little book called the *Lives of the Prophets* is a collection of Jewish legends about Old Testament prophets. It is preserved in Greek and in versions and recensions in various languages, all based on the Greek. The purpose of the work was to furnish to the readers of the Bible further information about the prophets. The collection evidently passed through Christian hands since it includes an assumed prophecy of Jeremiah about the birth of Christ. Thus, the date of composition of the supposed original Jewish work and the question as to whether it was originally written in Hebrew or Greek are difficult to resolve. Scholars are inclined toward a 1st-century-CE date in Palestine—with the exception of the life of "Jeremiah," which is Egyptian in origin.

The Ascension of Isaiah. According to the *Lives of the Prophets,* Jeremiah was stoned to death and Isaiah was sawn asunder. These two legends are reflected in two originally Jewish works. The *Ascension of Isaiah,* in which the martyrdom of Isaiah is narrated, is as a whole extant only in Ethiopic, translated from a Greek original, which itself is also known from fragments. The book contains important Christian passages from the 1st century CE, but the story about Isaiah's martyrdom is most likely based upon a Jewish written source. According to this legend, Isaiah was killed by the wicked king Manasseh, who served Beliar-Sammael, the chief of the evil spirits, instead of God. Isaiah, with his followers, had fled to the wilderness, but upon being captured he was sawn asunder with a wooden saw, and his followers fled to the region of Tyre and Sidon. The activity of Beliar is known also from the writings of the sect that preserved the Dead Sea Scrolls and similar writings, and the story itself resembles in some way the history of the Dead Sea sect; but no fragment of the Jewish part of the book was found among the Dead Sea Scrolls. The original *Martyrdom of Isaiah* was written probably in Hebrew or Aramaic before the 1st century CE.

The legendary death of Isaiah

Paralipomena of Jeremiah. In the last chapter of the Greek text of the *Paralipomena* (additional stories) *of Jeremiah,* there is a hint of the Christian part of the *Ascension of Isaiah:* the people stoned Jeremiah to death because he, like Isaiah before him, prophesied the coming of Christ. In a parallel legend (preserved in Arabic), both the violent death of Jeremiah and the Christian motif are lacking. The book begins shortly before and ends shortly after the Babylonian Exile and contains mostly otherwise unknown legends. The legend about the long sleep of Abimelech (the biblical Ebed-melech—an Ethiopian eunuch who rescued Jeremiah from a cistern), who slept and so did not see the destruction of Jerusalem by the Babylonians—is based upon a legendary understanding of Psalm 126:1; a similar legend about another person is preserved in the Talmud (the authoritative rabbinical compendium of Jewish law, lore, and commentary). The book is basically Jewish, and the last chapter was Christianized. The Jewish work was probably written at the end of the 1st century CE or at the beginning of the 2nd, originally in either Hebrew, Aramaic, or Greek.

The Testament of Job. Though there are scholars who think that the *Testament of Job* was once written in Hebrew or Aramaic, it is more probable that the existing Greek text of the book is the original or even a rewritten later version of a Greek work; a fragment of an older form is probably preserved in the Greek translation of Job (2:9). Job is identified, according to some Jewish traditions, with the biblical Jobab (king of Edom), and his (second) wife is Dinah, Jacob's daughter. Job knew by revelation that, for destroying an idol, he would undergo suffering but that a happy end would be the final outcome. Thus, in contrast to the biblical Book of Job, this work does not deal with the question of God's righteousness but places great emphasis on resurrection and eternal life. These special motifs in the book indicate that the book probably was written by a member of an unknown Jewish group that upheld a high mystical spirituality. The extreme "pietistic" tendency of the book is noted in the exaggeration of Job's love for suffering and of his charity to the poor. At the end of the book Job's soul was taken to heaven in a heavenly chariot. The book was probably written before 70 CE.

Life of Adam and Eve. The many Christian legends in many languages about the lives of Adam and Eve probably have their origin in a Jewish writing (or writings) about the biblical first man and woman. The most important of these works are the Latin *Vita Adae et Evae* (*Life of Adam and Eve*) and a Greek work closely parallel to it, named erroneously by its first editor the *Apocalypse of Moses.* The narrative runs from the Fall to the deaths of Adam and Eve. The religious message in the story involves the repentance of Adam and Eve after their expulsion from paradise—and the description of their deaths does not show any traces of the idea of original sin, which was important in later Christian theology. Nonetheless, there are definitely Christian passages in the various versions, and the treatment of Adam in the literature of the Ebionites (an early Jewish Christian sect) shows an affinity for the story. Thus, the Jewish source probably was composed in the 1st century CE in Jewish circles that influenced the Ebionites. The original language of this supposed source is unknown.

Apocalyptic and eschatological works. *III Baruch.* Apocalyptic literature was much concerned about sources of information about the heavenly world and about the places of the damned and saved souls. In later Jewish and early Christian apocalypses, in which the hero undertakes a heavenly trip and sees the secrets that are hidden from others, these sources of information are highly significant. *III Baruch,* a book written in Greek—in which Baruch,

Interests of apocalyptic literature

the disciple of the prophet Jeremiah, visits the universe and sees its secrets and the places of the souls and of the angels—is such an apocalypse. In the Greek text the number of heavens visited by Baruch is five, but it is possible that originally he was said to have seen seven heavens. There are Christian passages in the book, but it seems to have been a Jewish work from the 1st century CE later rewritten by a Christian.

II Enoch. Similar in content is *II Enoch,* or *The Book of the Secrets of Enoch,* which is preserved only in an Old Slavonic translation. The oldest text does not contain any Christian additions nor any passage from which it could be concluded that the book was written in Greek. Thus, the book could have been written originally in Hebrew or Aramaic, probably in the 1st century CE. The hero who visits the heavens is the biblical Enoch (son of Jared). The author of the book knew at least some of the treatises contained in *I Enoch.* The book also contains the story of the miraculous birth of the biblical priest-king Melchizedek.

The Psalms of Solomon. Other Jewish apocalypses or books containing eschatological elements did not deal with the mysteries of celestial worlds but rather with the political aspect of apocalyptic thought and with the last days and the messianic age. This latter theme is one of the important motifs of the *Psalms of Solomon,* a book written originally in Hebrew; only the Greek translation of the *Psalms* is preserved. The title is evidently a later addition—the author himself apparently had no intention to give the impression that his 18 psalms were composed by the biblical king Solomon. The *Psalms of Solomon* were written in Jerusalem about the middle of the 1st century BCE, and, though persons are not named, they reflect the dramatic events of the Jewish history of that period, especially the Roman general Pompey's conquest of Jerusalem in 63 BCE and his violent death in Egypt. In Psalm 17, the author denounces the Hasmonean dynasty as illegal and describes the coming of the Davidic Messiah (a kingly saviour from the line of David). His religious opinion resembles the teachings of the Pharisees (a sect that espoused a reinterpretation of Jewish laws and customs), especially in his faith in the resurrection of the body and in the question of free will, though he most likely was not a Pharisee but rather a member of the community of Ḥasidim, a Jewish pietistic group that had joined the Maccabean revolt from its beginning.

The Assumption of Moses. The *Assumption of Moses* originally contained apocalyptic material—no longer extant—in the form of a legend. According to Origen, the dispute between the archangel Michael and the devil for the body of Moses was narrated in the *Assumption of Moses.* This legend, which has parallels in the rabbinic literature, probably formed the end of the *Assumption of Moses,* the first part of which was discovered in a Latin manuscript. The Latin version was translated from Greek, but the original language was Semitic, probably Hebrew.

The coming of the Kingdom of Heaven

The main content of the preserved part is Moses' prophecy about the future, from his time until the Kingdom of Heaven will be revealed. According to the custom of apocalyptic literature, names of persons and groups are not mentioned, but from the last events hinted at in the book it can be assumed that it was written at the beginning of the 1st century CE, while Jesus was alive. In its older version, the book apparently was written at the beginning of the Maccabean revolt, some years before the Book of Daniel; after a description of the pre-Maccabean Hellenistic priests (chapter 5) and before the description of the persecutions by Antiochus Epiphanes (chapter 8), chapters 6–7 contain Jewish history from the time of the later Hasmonean rulers to the time of the sons of Herod—as well as polemics against leading religious circles, which are accused of religious hypocrisy, as are the Pharisees in the Christian Gospels. The author of these chapters (6–7), a contemporary of Jesus, evidently erroneously identified the wicked pre-Maccabean priests with the wicked late Maccabean priestly rulers and also interpreted Antiochus Epiphanes as a kind of eschatological Antichrist. No messianic figure is mentioned in the eschatological description of the Kingdom of God: God himself and his angel will bring the salvation.

The Sibylline Oracles. *The Sibylline Oracles* is a collection of oracles in Greek verse containing pagan, Jewish, and Christian material from various periods. It comprised 15 books (books IX, X, and XV are lost), of which 4,240 verses are extant. Sibyl is the name (or title) of a legendary ancient pagan prophetess. In the Hellenistic period, eastern nations fabricated Sibylline oracles as propagandistic literature against Greek and, later, against Roman occupation. The political anti-Roman and anti-pagan tone is typical of the Jewish and Christian parts of Sibylline oracles; they also contain religious propaganda for the respective religion. Because Jewish parts used pagan material and Christian authors interpolated Jewish parts or used Jewish material, it is sometimes difficult to decide what verses are pagan, Jewish, or Christian. *The Sibylline Oracles* perhaps became a part of Jewish (and Christian) apocalyptic literature because of their emphasis on eschatology. The oldest Jewish "Sibyl" is contained in the third book: it dates from about 140 BCE and describes the coming of the Messiah. Book IV was written by a Jew about 80 CE: the eruption of Vesuvius (79) is viewed as a divine punishment for the massacre of Jews in the Roman war (70). Book V was written by a Jew about 125.

II Esdras (or IV Esdras). Two important apocalyptic pseudepigrapha (II Esdras and the *Apocalypse of Baruch*), in which the political and eschatological aspects are central to the aim of the books, were written in Palestine at the end of the 1st century CE as a consequence of the catastrophic destruction of the Second Temple in Jerusalem (70). Both were written as if they reflected the doom that befell the people of Israel after the destruction of the First Temple (586 BCE) by the Babylonians. II Esdras (or IV Esdras) was written in Hebrew, but only various translations from a lost Greek version are preserved. The Latin version (in which chapters 1–2 and 15–16 have been added by a Christian hand) at one time was printed at the end of the Latin Bible. The book consists of six visions attributed to the biblical Ezra (who is, at the beginning of the book, erroneously identified with Salathiel, the father of Zerubbabel, a leader of the returning exiles from Babylon). The tragedy of his nation evokes in the heart of the author questions about God's righteousness, the human condition, the meaning of history, and the election of Israel; "Ezra" does not find consolation and full answer in the words of the angel who was sent to him, which also contain revelations about the last days. In the fourth vision "Ezra" sees a mourning woman; she disappears and a city (the New Jerusalem) stands in her place. In the fifth vision a monstrous eagle appears, the symbol of the Roman Empire, and a lion, the symbol of the Messiah. The final victory of the Messiah is described in the last vision of the man (Son of man) coming from the sea. In chapter 14 "Ezra" is described as dictating 94 books: 24 are the books of the Hebrew Bible, and the other 70 are esoteric.

Questions about the meaning of history

The Apocalypse of Baruch. The *Apocalypse of Baruch* was written about the same time as II (IV) Esdras, and the less profound *Apocalypse* probably depends much upon II Esdras. The *Apocalypse of Baruch* survives only in a Syriac version translated from Greek; originally the book was composed in Hebrew or Aramaic and is ascribed to Baruch, the disciple of Jeremiah and a contemporary of the destruction of the First Temple. If II Esdras asks questions about important problems of human history and the tragic situation of Israel after the destruction of the Second Temple, the *Apocalypse of Baruch* apparently was written to give a positive, traditional answer to these doubts.

Pseudepigrapha connected with the Dead Sea Scrolls. There are three Pseudepigrapha that are closely connected with the writings of the Dead Sea sect: the *Book of Jubilees,* the Ethiopic *Book of Enoch,* and the *Testaments of the Twelve Patriarchs.* It is not accidental that fragments of the two first books and of two sources of the third were found among the Dead Sea Scrolls.

The Book of Jubilees. From the fragments of the *Book of Jubilees* among the Dead Sea Scrolls, scholars note that the book was originally written in biblical Hebrew. The whole book is preserved in an Ethiopic version translated from Greek.

The book is written in the form of a revealed history of

Israel from the creation until the dwelling of Moses on Mt. Sinai, where the content of the book was revealed to Moses by "the angel of the presence." The *Book of Jubilees* in fact is a legendary rewriting of the book of Genesis and a part of Exodus. One of the main purposes of the author is to promote, in the form of divine revelation, a special sectarian interpretation of Jewish law. All the legal prescriptions noted in the book were practiced by the Dead Sea sect; in connection with the solar calendar of 52 weeks, one of the Dead Sea Scrolls even mentions the *Book of Jubilees* as the source. The (unpublished) *Temple Scroll,* a book of sectarian prescriptions that paraphrases—also as divine revelation—a part of the Mosaic Law and was composed by the Dead Sea sect before 100 BCE (*i.e.,* in the same period as the *Book of Jubilees*), closely resembles some parts of the *Book of Jubilees.* Thus, the *Book of Jubilees* could be accepted by the Dead Sea sect and apparently was written in the same circles, immediately before the sect itself came into existence. The apocalyptical hopes expressed in the book are also identical to those of the Dead Sea sect.

The Book of Enoch. Another book that was written during the period of the apocalyptic movement in which the Dead Sea sect came into existence is the *Book of Enoch,* or *I Enoch.* It was completely preserved in an Ethiopic translation from Greek, and large parts from the beginning and end of the Greek version have been published from two papyri. Aramaic fragments of many parts of the book were found among the Dead Sea Scrolls, as were Hebrew fragments of the *Book of Noah,* either one of the sources of *Enoch* or a parallel elaboration of the same material. Passages of the *Book of Noah* were included in *Enoch* by its redactor (editor). Scholars generally agree that the somewhat haphazard redaction of the book was made in its Greek stage, when a redactor put together various treatises of the Enochic literature that were written at various times and reflected various trends of the movement.

The *Book of Noah*

Besides the passages from the *Book of Noah,* five treatises are included in the *Book of Enoch.* The hero of all of them is the biblical Enoch. The first treatise (chapters 1–36) speaks about the fall of the angels, who rebelled before the Flood, and describes Enoch's celestial journeys, in which divine secrets were revealed to him. It was probably written in the late 2nd century BCE.

The second part of the *Book of Enoch* is the "Parables" (or Similitudes) of Enoch (37–71). These three eschatological sermons of Enoch refer to visions; their original language was probably Hebrew rather than Aramaic. This treatise is an important witness for the belief in the coming of the Son of man, who is expressly identified with the Messiah; in chapters 70–71, which are probably a later addition, the Son of man is identified with Enoch himself. The treatise probably dates from the 1st century BCE.

As Aramaic fragments from the Dead Sea Scrolls show, the astronomical book entitled "The Book of the Heavenly Luminaries" (chapters 72–82) is in the present form abbreviated in the *Book of Enoch.* All these astronomical mysteries were shown to Enoch by the angel Uriel. The treatise propagates the same solar calendar that is also known from the *Book of Jubilees* and from the Dead Sea sect. This treatise was probably written before the year 100 BCE.

The fourth treatise (chapters 83–90) contains two visions of Enoch: the first (chapters 83–84), about the Flood, is in reality only a sort of introduction to the second one ("the vision of seventy shepherds"), which describes the history of the world from Adam to the messianic age; the personages of the visions are allegorically described as various kinds of animals. The symbolic description of history continues to the time of Judas Maccabeus; then follows the last assault of Gentiles and the messianic period. Thus, the treatise was written in the early Hasmonean period, some time after the biblical Book of Daniel.

The fifth treatise (chapters 91–107) contains Enoch's speech of moral admonition to his family. The moral stress and the social impact is similar to parts of Jesus' teaching; even the form of beatitudes (blessings) and woes is present. The treatise shows some affinities to the Dead Sea Scrolls, but the author was not a member of the Dead Sea sect; he opposes the central teaching of the sect, the doctrine of predestination (98: 4–5). The treatise apparently was written at the end of the 1st century BCE. Chapter 105, lacking in the Greek version, is a late interpolation, probably of Christian origin.

The author of the treatise himself apparently incorporated into it a small apocalypse, the "Apocalypse of Weeks" (93:1–10; 91:12–17); in it the whole of human history is divided into ten weeks; seven of them belong to the past and the last three to the future.

Testaments of the Twelve Patriarchs. The third pseudepigraphon that shows important affinities with the Dead Sea sect is the *Testaments of the Twelve Patriarchs,* the last speeches of the 12 sons of the Hebrew patriarch Jacob. In its extant form, containing Christian passages, the book was written in Greek. Fragments of two original Semitic sources of the book were found among the Dead Sea Scrolls: the Aramaic "Testament of Levi" (fragments of it were also discovered in Aramaic in the medieval Geniza, or synagogue storeroom, in Cairo) and a Hebrew fragment of the "Testaments of Naphtali." A Hebrew "Testament of Judah," which was used both by the *Book of Jubilees* and the *Testaments of the Twelve Patriarchs* in their description of the wars of the sons of Jacob, also probably existed.

Whether Hebrew and Aramaic prototypes for all the 12 testaments of the patriarchs existed is difficult to ascertain. The present book was originally written in Greek. In it each of the sons of Jacob before his death gives moral advice to his descendants, based upon his own experience. All the testaments, with the exception of Gad, also contain apocalyptic predictions.

Between the *Testaments of the Twelve Patriarchs* and the Dead Sea sect there is a historical and ideological connection. The sources of the book were found among the scrolls, the source of the "Testament of Levi" is quoted in a sectarian writing (the Damascus Document), a dualistic outlook is common to the book and the sect, and the devil is named Belial in both. There are, however, important differences: in regard to the nature of the dualism between good and evil, there is in the *Testaments* the concept of the good and bad inclination, known from rabbinical literature, which does not exist in the scrolls; though the sect believed in an afterlife of souls, the *Testaments* reflect the belief in the resurrection of the body; there are no traces of the doctrine of predestination in the testaments, a doctrine that is so important for the sect. Only the "Testament of Asher" preaches, as did the Dead Sea sect, hatred against sinners; the other testaments stress, as does rabbinic literature and especially Jesus, the precept of love for God and neighbour. Thus, it is probable that the testaments of the patriarchs were composed in circles in which doctrines of the Dead Sea sect were mitigated and combined with some rabbinic doctrines. A similar humanistic position, founded both on doctrines of the Dead Sea sect and of the Pharisees, is typical of Jesus' message, and there are important parallels between his message and the *Testaments of the Twelve Patriarchs.*

Connection between the *Testaments of the Twelve Patriarchs* and the Dead Sea sect

QUMRĀN LITERATURE (DEAD SEA SCROLLS)

New literary documents from the intertestamental period were found in the caves of Qumrān in the vicinity of the Dead Sea in the 1940s, but only a portion of them has yet been published. All the Dead Sea Scrolls were written before the destruction of the Second Temple; with the exception of small Greek fragments, they are all in Hebrew and Aramaic. The scrolls formed the library of an ancient Jewish sect, which probably came into existence at the end of the 2nd century BCE and was founded by a religious genius, called in the scrolls the Teacher of Righteousness. Scholars have tried to identify the sect with all possible groups of ancient Judaism, including the Zealots and early Christians, but it is now most often identified with the Essenes; all that the sectarian scrolls contain fits previous information about the Essenes, and the Dead Sea Scrolls help scholars to interpret the descriptions about the Essenes in ancient sources.

Apocryphal and pseudepigraphal writings. The importance of the discovery is very great; the scrolls of books

of the Old Testament caused a new evaluation of the history of the text of the Hebrew Bible; fragments of the Apocrypha (Sirach and Tobit) and of already known and unknown Pseudepigrapha enlarge knowledge about Jewish literature of the intertestamental period, and the properly sectarian scrolls are important witnesses about an ancient sect that influenced, in some points, the origins of Christianity.

Among the previously unknown Pseudepigrapha were large parts of an Aramaic scroll, the *Genesis Apocryphon,* which retells stories from Genesis in the manner of a number of apocryphal books. The chapters that are preserved are concerned with Lamech, his grandfather Enoch, Noah, and Abraham, and the narrators in the scroll are the respective biblical heroes. There is a close affinity between this scroll and the *Book of Jubilees* and *Book of Enoch,* fragments of these books having been also found among the Dead Sea Scrolls. Another pseudepigraphon that resembles the Dead Sea sect in spirit is the *Testaments of the Twelve Patriarchs;* fragments of two of its sources, namely, the Aramaic "Testament of Levi" and a Hebrew "Testament of Naphtali," are extant in the Qumrān library. All these books were composed in an apocalyptic movement in Judaism, in the midst of which the Dead Sea sect originated. It is sometimes difficult to ascertain if a work was written within the sect itself or if it represents the broader movement. The largest scroll, the *Temple Scroll,* is as yet unpublished. It describes—by the mouth of God himself and in Hebrew—not the Temple of the last days but the Temple as it should have been built. There are strong ties between the *Temple Scroll* and the *Book of Jubilees* and the prescriptions in it fit the conceptions of the sect; the work was composed by the sectarians themselves.

The Temple Scroll

Pesharim. An important source of knowledge about the history of the Dead Sea sect is the *pesharim* ("commentaries"; singular *pesher*). The sectarian authors commented on the books of Old Testament prophets and the book of Psalms and in the commentaries explained the biblical text as speaking about the history of the sect and of events that happened in the time of its existence. According to the manner of apocalyptic literature in the *pesharim,* persons and groups are not named with their proper names but are described by symbolic titles—*e.g.,* the Teacher of Righteousness for the founder of the sect. The most important sectarian commentaries are the *pesharim* on Habakkuk and on Nahum.

The War of the Sons of Light Against the Sons of Darkness. One of the most interesting Dead Sea Scrolls is *The War of the Sons of Light Against the Sons of Darkness,* a description of the eschatological war between the Sons of Light—*i.e.,* the sect—and the rest of mankind, first with the other Jews and then with the Gentiles. At the end the Sons of Light will conquer the whole world, and in this war they will be helped by heavenly hosts; the Sons of Darkness, aided by the devil Belial and his demonic army, and, finally, all wicked ones will be destroyed. The work contains prayers and speeches that will be uttered in the eschatological war as well as military and other ordinances. Thus, the book also could be called the *Manual of Discipline* for the last war.

Books of ordinances. Other books of ordinances of the sect have been preserved, containing prescriptions and other material. Three such compositions are written on one scroll: the *Manual of Discipline,* the *Rule of the Congregation,* and the manual of *Benedictions.* The *Manual of Discipline* is the rule (or statement of regulations) of the Essene community; the most important part of this work is a treatise about the special theology of the sect. The *Rule of the Congregation* contains prescriptions for the eschatological future when the sect is expected to be the elite of the nation. The manual of *Benedictions,* preserved only in a fragmentary state, contains benedictions that are to be said in the eschatological future.

Another sectarian book of ordinances is the Damascus Document (the Zadokite Fragments). The work was already known from two medieval copies before the discovery of the Dead Sea Scrolls, but fragments of it also were found in Qumrān, and the connection between this work and the Dead Sea sect is evident. The Damascus Document was written in a community in Damascus, which was not as rigidly organized as the Essenes. The work contains the rules of this community and reminiscences of the sect's history. Some scholars think that "Damascus" is only a symbolical name for Qumrān.

Hodayot. One of the most important Essene works is the *Hodayot* ("Praises")—a modern Hebrew name for the *Thanksgiving Psalms.* This scroll contains sectarian hymns of praise to God. In its view of the fleshly nature of man, who can be justified only by God's undeserved grace, it resembles St. Paul's approach to the same problem. Some scholars think that the work, or a part of it, was written by the Teacher of Righteousness.

The Thanksgiving Psalms

Among other fragments of scrolls liturgical texts of prayers were found, as well as fragments of horoscopes written in a cryptic script.

(D.Fl.)

New Testament canon, texts, and versions

THE NEW TESTAMENT CANON

Conditions aiding the formation of the canon. The New Testament consists of 27 books, which are the residue, or precipitate, out of many 1st–2nd-century AD writings that Christian groups considered sacred. In these various writings the early church transmitted its traditions: its experience, understanding, and interpretation of Jesus as the Christ and the self-understanding of the church. In a seemingly circuitous interplay between the historical and theological processes, the church selected these 27 writings as normative for its life and teachings—*i.e.,* as its canon (from the Greek *kanōn,* literally, a reed or cane used as a measuring rod and, figuratively, a rule or standard). Other accounts, letters, and revelations—*e.g.,* the *Didachē* (Teaching of the Twelve Apostles), *Gospel of Peter, First Letter of Clement, Letter of Barnabas, Apocalypse* (Revelation) *of Peter, Shepherd of Hermas*—exist, but through a complex process the canon was fixed for both the Eastern and Western churches in the 4th century. The canon contained four Gospels (Matthew, Mark, Luke, and John), Acts, 21 letters, and one book of a strictly revelatory character, Revelation. These were not necessarily the oldest writings, not all equally revelatory, and not all directed to the church at large.

The Old Testament in its Greek translation, the Septuagint (LXX), was the Bible of the earliest Christians. The New Covenant, or Testament, was viewed as the fulfillment of the Old Testament promises of salvation that were continued for the new Israel, the church, through the Holy Spirit, which had come through Christ, upon the whole people of God. Thus, the Spirit, which in the Old Testament had been viewed as resting only on special charismatic figures, in the New Testament became "democratized"—*i.e.,* was given to the whole people of the New Covenant. In postbiblical Judaism of the first Christian centuries, it was believed that the Spirit had ceased after the writing of the Book of Malachi (the last book of the Old Testament canon) and that no longer could anyone say "Thus saith the Lord," as had the prophets, nor could any further holy writ be produced.

Significance of the Old Testament

The descent of the Spirit on the community of the Messiah (*i.e.,* the Christ) was thus perceived by Christians as a sign of the beginning of the age to come, and the church understood itself as having access to that inspiration through the Spirit. Having this understanding of itself, the church created the New Testament canon not only as a continuation and fulfillment of the Old Testament but also as qualitatively different, because a new age had been ushered in. These 27 books, therefore, were not merely appended to the traditional Jewish threefold division of the Old Testament—the Law (Torah), the Prophets (Nevi'im), and the Writings (Ketuvim)—but rather became the New Testament, the second part of the Christian Bible, of which the Old Testament is the first.

Because of a belief that something almost magical occurs—with an element of secrecy—when a transmitted oral tradition is put into writing, there was, in both the Old and New Testaments, an expression of reluctance about committing sacred material to writing. When such

sacred writings are studied to find the revealed word of God, a settled delimiting of the writings—*i.e.,* a canon—must be selected. In the last decade of the 1st century, the Synod of Jamnia (Jabneh), in Palestine, fixed the canon of the Bible for Judaism, which, following a long period of flux and fluidity and controversy about certain of its books, Christians came to call the Old Testament. A possible factor in the timing of this Jewish canon was a situation of crisis: the fall of Jerusalem and reaction to the fact that the Septuagint was used by Christians and to their advantage, as in the translation of the Hebrew word *'alma* ("young woman") in chapter 7, verse 14, of Isaiah—"Behold, a young woman shall conceive and bear a son, and shall call his name Immanuel"—into the Greek term *parthenos* ("virgin").

As far as the New Testament is concerned, there could be no Bible without a church that created it; yet conversely, having been nurtured by the content of the writings themselves, the church selected the canon. The concept of inspiration was not decisive in the matter of demarcation because the church understood itself as having access to inspiration through the guidance of the Spirit. Indeed, until *c.* AD 150, Christians could produce writings either anonymously or pseudonymously—*i.e.,* using the name of some acknowledged important biblical or apostolic figure. The practice was not believed to be either a trick or fraud. Apart from letters in which the person of the writer was clearly attested—as in those of Paul, which have distinctive historical, theological, and stylistic traits peculiar to Paul—the other writings placed their emphases on the message or revelation conveyed, and the author was considered to be only an instrument or witness to the Holy Spirit or the Lord. When the message was committed to writing, the instrument was considered irrelevant, because the true author was believed to be the Spirit. By the mid-2nd century, however, with the delay of the final coming (the Parousia) of the Messiah as the victorious eschatological (end-time) judge and with a resulting increased awareness of history, increasingly a distinction was made between the apostolic time and the present. There also was a gradual cessation of "authentically pseudonymous" writings in which the author could identify with Christ and the Apostles and thereby gain ecclesiastical recognition.

Acceptance of anonymous or pseudonymous writings

The process of canonization. The process of canonization was relatively long and remarkably flexible and detached; various books in use were recognized as inspired, but the Church Fathers noted, without embarrassment or criticism, how some held certain books to be canonical and others did not. Emerging Christianity assumed that through the Spirit the selection of canonical books was "certain" enough for the needs of the church. Inspiration, it is to be stressed, was neither a divisive nor a decisive criterion. Only when the canon had become self-evident was it argued that inspiration and canonicity coincided, and this coincidence became the presupposition of Protestant orthodoxy (*e.g.,* the authority of the Bible through the inspiration of the Holy Spirit).

The need for consolidation and delimitation. Viewed both phenomenologically and practically, the canon had to be consolidated and delimited. Seen historically, however, there were a number of reasons that forced the issue of limiting the canon. Oral tradition had begun to deteriorate in post-apostolic times, partly because many or most of the eyewitnesses to the earliest events of Jesus' life and death and the beginning of the church had died. Also, the oral tradition may simply have suffered in transmission. Papias (died *c.* 130), a bishop of Hieropolis, in Asia Minor, was said by Irenaeus (died *c.* 200), a bishop of Lugdunum (now Lyon, France) to have been an eyewitness of the Apostle John. Papias had said, "For I did not suppose that the things from the books would aid me so much as the things from the living and continuing voice." Eusebius (*c.* 260–*c.* 340), a church historian, reported these comments in his *Ecclesiastical History* and pointed out inconsistencies in Papias' recollections, doubted his understanding, and called him "a man of exceedingly small intelligence." Large sections of oral tradition, however, which were probably translated in part from Aramaic before being written down in Greek—such as the Passion (suffering of Christ) narrative, many sayings of Jesus, and early liturgical material—benefitted by the very conservativism implicit in such traditions. But because the church perceived its risen Lord as a living Lord, even his words could be adjusted or adapted to fit specific church needs. Toward the end of the 1st century, there was also a conscious production of gospels. Some gospels purported to be words of the risen Lord that did not reflect apostolic traditions and even claimed superiority over them. Such claims were deemed heretical and helped to push the early church toward canonization.

Faced with heresy and claims to late revelations, the early church was constrained to retain the historical dimension of its faith, the *ephapax,* or the "once for all," revelation of God in Jesus Christ.

Impulse toward canonization from heretical movements. Gnosticism (a religious system with influence both on Judaism and Christianity) tended to foster speculation, cutting loose from historical revelation. In defense the orthodox churches stressed the apostolic tradition by focussing on Gospels and letters from apostolic lives and distinguished them from Gnostic writings, such as the *Gospel of Truth* (mentioned by Irenaeus) and now found in Coptic translation in a collection of Gnostic writings from Egypt; it is a Coptic manuscript of a Valentinian Gnostic speculation from the mid-2nd century—*i.e.,* a work based on the teachings of Valentinus, a Gnostic teacher from Alexandria. In the same collection is the *Gospel of Thomas* in Coptic, actually a collection of sayings purporting to be the words of the risen Christ, the living Lord. This "gospel" also occurred in Greek (*c.* 140), and warnings against it as heretical were made by the Church Fathers in the 2nd to the 4th centuries.

Gnosticism

In a general prophetic apocalyptic mood, another heresy, Montanism, arose. This was an ecstatic enthusiastic movement claiming special revelation and stressing "the age of the spirit." Montanus (died *c.* 175) and two prophetesses claimed that their oracular statements contained new and contemporary authoritative revelations. This break with the apostolic time caused vigorous response. An anti-Montanist reported that "the false prophet is one who speaks in ecstasy after which follow freedom . . . and madness of soul."

The single most decisive factor in the process of canonization was the influence of Marcion (flourished *c.* 140), who had Gnostic tendencies and who set up a "canon" that totally repudiated the Old Testament and anything Jewish. He viewed the Creator God of the Old Testament as a cruel God of retribution and the Jewish Law. His canon consisted of *The Gospel,* a "cleaned up" Luke (the least Jewish), and the *Apostolikon* (ten Pauline letters with Old Testament references and analogies edited out, without Hebrews, I and II Timothy, and Titus). This restrictive canon acted as a catalyst to the formation of a canon more in line with the thought of the church catholic (universal).

Late-2nd-century canons. By the end of the 2nd century, Irenaeus used the four canonical Gospels, 13 letters of Paul, I Peter, I and II John, Revelation, *Shepherd of Hermas* (a work later excluded from the canon), and Acts. Justin Martyr (died *c.* 165), a Christian apologist, wrote of the reading of the Gospels, "the memoirs of the Apostles," in the services, in which they were the basis for sermons. In his writings he quoted freely from the Gospels, Hebrews, the Pauline Letters, I Peter, and Acts. Justin's Syrian pupil, Tatian (*c.* 160), although he quotes from John separately, is best known for his *Diatessaron* (literally, "through four" [gospels], but also a musicological term meaning "choral" "harmony"), which was a life of Christ compiled from all four Gospels but based on the outline and structure of John. This indicates both that Tatian was aware of four gospel traditions and that their canonicity was not fixed in final form at his time in Syria. Although Tatian was later declared a heretic, the *Diatessaron* was used until the 5th century and influenced the Western Church even after four separated gospels were established.

The influence of Tatian's *Diatessaron*

The first clear witness to a catalog of authoritative New Testament writings is found in the so-called Muratorian Canon, a crude and uncultured Latin 8th-century manuscript translated from a Greek list written in Rome *c.* 170–

180, named for its modern discoverer and publisher Lodovica Antonio Muratori (1672–1750). Though the first lines are lost, Luke is referred to as "the third book of the Gospel," and the canon thus contains [Matthew, Mark] Luke, John, Acts, 13 Pauline letters, Jude, two letters of John, and Revelation. Concerning the *Apocalypse of Peter,* it notes that it may be read, although some persons object; it rejects the *Shepherd of Hermas* as having been written only recently in Rome and lacking connection with the apostolic age. The Wisdom of Solomon (a Jewish intertestamental writing), is included in the accepted works as written in Solomon's honour.

Criteria of canonicity

Some principles for determining the criteria of canonicity begin to be apparent: apostolicity, true doctrine (*regula fidei*), and widespread geographical usage. Such principles are indicated by Muratori's argument that the Pauline Letters are canonical and universal—the Word of God for the whole church—although they are addressed to specific churches, on the analogy of the letters to the seven churches in Revelation; in a prophetic statement to the whole church, seven specific churches are addressed, then the specific letters of Paul can be read for all. Thus, the catholic status of the Pauline letters to seven churches is vindicated on the basis of the revelation of Jesus Christ to John, the seer and writer of Revelation. Wide usage in the church is indicated in calling Acts the Acts of *all* the Apostles and in the intention of the "general address"—*e.g.,* "To those who are called," in Jude—of the Catholic (or general) Letters—*i.e.,* I and II Peter, I, II, and III John, James, and Jude. The criterion of accordance with received teaching is plain in the rejection of heretical writings. The Muratorian Canon itself may have been, in part, a response to Marcion's heretical and reductive canon.

The criteria of true doctrine, usage, and apostolicity all taken together must be satisfied, then, in order that a book be judged canonical. Thus, even though the *Shepherd of Hermas,* the *First Letter of Clement,* and the *Didachē* may have been widely used and contain true doctrines, they were not canonical because they were not apostolic nor connected to the apostolic age, or they were local writings without support in many areas.

During the time of the definitive formation of the canon in the 2nd century, apparent differences existed in the Western churches (centred in or in close contact with Rome) and those of the East (as in Alexandria and Asia Minor). It is not surprising that the Roman Muratorian Canon omitted Hebrews and accepted and held Revelation in high esteem, for Hebrews allows for no repentance for the baptized Christian who commits apostasy (rejection of faith), a problem in the Western Church when it was subjected to persecution. In the East, on the other hand, there was a dogmatic resistance to the teaching of a 1,000-year reign of the Messiah before the end time—*i.e.,* chiliasm, or millenarianism—in Revelation. There was also a difference in the acceptance of Acts and the Catholic Letters. With the continued expansion of the church, particularly in the 2nd century, consolidation was necessary.

Canonical standards of the 3rd and 4th centuries. Clement of Alexandria, a theologian who flourished in the late 2nd century, seemed to be practically unconcerned about canonicity. To him, inspiration is what mattered, and he made use of the *Gospel of the Hebrews,* the *Gospel of the Egyptians,* the *Letter of Barnabas,* the *Didachē,* and other extracanonical works. Origen (died *c.* 254), Clement's pupil and one of the greatest thinkers of the early church, distinguished at least three classes of writings, basing his judgment on majority usage in places that he had visited: (1) *homologoumena* or *anantirrhēta,* "undisputed in the churches of God throughout the whole world" (the four Gospels, 13 Pauline Letters, I Peter, I John, Acts, and Revelation); (2) *amphiballomena,* "disputed" (II Peter, II and III John, Hebrews, James, and Jude); and (3) *notha,* "spurious" (*Gospel of the Egyptians, Thomas,* and others). He used the term "scripture" (*graphē*) for the *Didachē,* the *Letter of Barnabas,* and the *Shepherd of Hermas,* but did not consider them canonical. Eusebius shows the situation in the early 4th century. Universally accepted are: the four Gospels, Acts, 14 Pauline Letters (including Hebrews), I John, and I Peter. The disputed writings are of two kinds:

Standards of Origen and Eusebius

(1) those known and accepted by many (James, Jude, II Peter, II and III John, and (2) those called "spurious" but not "foul and impious" (*Acts of Paul, Shepherd of Hermas, Apocalypse of Peter, Letter of Barnabas, Didachē* and possibly the *Gospel of the Hebrews*); finally there are the heretically spurious (*e.g., Gospel of Peter, Acts of John*). Revelation is listed both as fully accepted ("if permissible") and as spurious but not impious. It is important that Eusebius feels free to make authoritative use of the disputed writings. Thus canon and authoritative revelation are not yet the same thing.

Determination of the canon in the 4th century. Athanasius, a 4th-century bishop of Alexandria and a significant theologian, delimited the canon and settled the strife between East and West. On a principle of inclusiveness, both Revelation and Hebrews (as part of the Pauline corpus) were accepted. The 27 books of the New Testament—and they only—were declared canonical. In the Greek churches there was still controversy about Revelation, but in the Latin Church, under the influence of Jerome, Athanasius' decision was accepted. It is notable, however, that, in a mid-4th-century manuscript called Codex Sinaiticus, the *Letter of Barnabas* and the *Shepherd of Hermas* are included at the end but with no indication of secondary status, and that, in the 5th-century Codex Alexandrinus, there is no demarcation between Revelation and I and II Clement.

The Syriac canon

In the Syriac Church, Tatian's *Diatessaron* was used until the 5th century, and in the 3rd century the 14 Pauline Letters were added. Because Tatian had been declared a heretic, there was a clear episcopal order to have the four separated Gospels when, according to tradition, Rabbula, bishop of Edessa, introduced the Syriac version known as the Peshitta—also adding Acts, James, I Peter, and I John—making a 22-book canon. Only much later, perhaps in the 7th century, did the Syriac canon come into agreement with the Greek 27 books.

Developments in the 16th century. With the advent of printing and differences between Roman Catholics and Protestants, the canon and its relationship to tradition finally became fixed. During the Counter-Reformation Council of Trent (1545–63), the canon of the entire Bible was set in 1546 as the Vulgate, based on Jerome's Latin version. For Luther, the criterion of what was canonical was both apostolicity, or what is of an apostolic nature, and "was Christum treibet"—what drives toward, or leads to, Christ. This latter criterion he did not find in, for example, Hebrews, James, Jude, and Revelation; even so, he bowed to tradition, and placed these books last in the New Testament.

TEXTS AND VERSIONS

Textual criticism. *The physical aspects of New Testament texts.* To establish the reliability of the text of ancient manuscripts in order to reach the text that the author originally wrote (or, rather, dictated) involves the physical aspects of the texts: collection, collation of differences or variant readings in manuscripts, and comparison in matters of dating, geographical origins, and the amount of editing or revision noted, using as many copies as are available. Textual criticism starts thus with the manuscripts themselves. Families of manuscripts may be recognized by noting similarities and differences, degrees of dependence, or stages of their transmission leading back to the earliest text, or autograph. The techniques used in textual studies of ancient manuscripts are the same whether they deal with secular, philosophical, or religious texts. New Testament textual criticism, however, operates under unique conditions because of an abundance of manuscripts and the rather short gap between the time of original writing and the extant manuscripts, shorter than that of the Old Testament.

Significance of the large number of New Testament manuscripts

Compared with other ancient manuscripts, the text of the New Testament is dependable and consistent, but on an absolute scale there are far more variant readings as compared with those of, for example, classical Greek authors. This is the result, on the one hand, of a great number of surviving manuscripts and extant manuscript fragments and, on the other, of the fact that the time gap be-

tween an oral phase of transmission and the written stage was far shorter than that of many other ancient Greek manuscripts. The missionary message—the kerygma (proclamation)—with reports of the Passion, death, Resurrection, and Ascension of Jesus Christ and collections of his deeds and sayings was, at first, oral tradition. Later it was written down in Gospel form. The letters of Paul, Apostle to the Gentiles who founded or corresponded with churches, were also collected and distributed as he had dictated them. All autographs of New Testament books have disappeared. In sharp contrast to the fact that the oldest extant full manuscript of a work by the Greek philosopher Plato (died 347 BC) is a copy written in 895—a gap of more than 1,000 years bridged by only a few papyrus texts—there was a time gap of less than 200 or 300 years between the original accounts of the New Testament events and extant manuscripts. In fact, a small (about 2.5 inches by 3.5 inches [6.4 by 8.9 centimetres]) papyrus fragment with verses from the 18th chapter of the Gospel According to John can be dated *c.* 120–130; this earliest known fragment of the New Testament was written 40 years or less after the presumed date of the production of that Gospel (*c.* 90).

Excluding papyri found preserved in the dry sands, as in Egypt (where the Gospel According to John was evidently popular judging from the large number of fragments found there), the approximate number of New Testament manuscripts dating from the 3rd to 18th centuries are: 2,000 of the four Gospels; 400 of Acts, Pauline, and Catholic letters together; 300 of Pauline letters alone; 250 of Revelation; and 2,000 lectionaries—*i.e.,* collections of gospel (and sometimes Acts and letter) selections, or pericopes, meant to be used in public worship. Quotations from the Church Fathers—some of which are so extensive as to include almost the whole New Testament—account for more than 150,000 textual variants. Of the quotations in the Fathers, however, it is difficult to make judgments because the quotations may have been intended to be exact from some particular text traditions, but others may have been from memory, conflations, harmonizations, or allusions. Of the many New Testament manuscripts to date, however, only about 50 contain the entire 27 books of the New Testament. The majority have the four Gospels, and Revelation is the least well attested. Prior to the printing press (15th century), all copies of Bibles show textual variations.

Types of writing materials and methods. In Hellenistic times (*c.* 300 BC–*c.* AD 300), official records were often inscribed on stone or metal tablets. Literary works and detailed letters were written on parchment or papyrus, though short or temporary records were written or scratched on potsherds (ostraca) or wax tablets. Scrolls were made by gluing together papyrus sheets (made from the pith of the papyrus reed) or by sewing together parchment leaves (made from treated and scraped animal skins); they were written in columns and read by shifting the roll backward and forward from some wooden support on one or both ends. Such scrolls were used for literary or religious works and seldom exceeded 30 feet (nine metres) in length because of their weight and awkwardness in handling.

Scrolls and codices

In contrast, the church used not scrolls but the codex (book) form for its literature. A codex was formed by sewing pages of papyrus or parchment of equal size one upon another and vertically down the middle, forming a quire; both sides of the pages thus formed could be written upon. In antiquity, the codex was the less honourable form of writing material, used for notes and casual records. The use of the book form testifies to the low cultural and educational status of early Christianity—and, as the church rose to prominence, it brought "the book" with it. Not until the time of the Roman emperor Constantine in the 4th century, when Christianity became a state religion, were there parchment codices containing the whole New Testament.

Some very early New Testament manuscripts and fragments thereof are papyrus, but parchment, when available, became the best writing material until the advent of printing. The majority of New Testament manuscripts from the 4th to 15th centuries are parchment codices. When parchment codices occasionally were deemed no longer of use, the writing was scraped off and a new text written upon it. Such a rewritten (*rescriptus*) manuscript is called a palimpsest (from the Greek *palin,* "again," and *psaō,* "I scrape"). Often the original text of a palimpsest can be discerned by photographic process.

In New Testament times there were two main types of Greek writing: majuscules (or uncials) and minuscules. Majuscules are all capital (uppercase) letters, and the word uncial (literally, 1/12 of a whole, about an inch) points to the size of their letters. Minuscules are lowercase manuscripts. Both uncials and minuscules might have ligatures making them into semi-connected cursives. In Greco-Roman times minuscules were used for the usual daily writing. In parchments from the 4th to the 9th centuries, both majuscules and minuscules were used for New Testament manuscripts, but by the 11th century all the manuscripts were minuscules.

In these early New Testament manuscripts, there were no spaces between either letters or words, rarely an indication that a word was "hyphenated," no chapter or verse divisions, no punctuation, and no accents or breathing marks on the Greek words. There was only a continuous flow of letters. In addition, there were numerous (and sometimes variable) abbreviations marked only by a line above (*e.g.,* $\overline{\text{IC}}$ for IHCOUC, or Jesus, and $\overline{\text{KC}}$ for *kyrios,* or Lord. Not until the 8th–9th century was there any indication of accents or breathing marks (both of which may make a difference in the meaning of some words); punctuation occurred sporadically at this period; but not until the Middle Ages were the texts supplied with such helps as chapters (*c.* 1200) and verses (*c.* 1550).

Problems of the continuous flow of letters

Occasionally, the parchment was stained (*e.g.,* purple), and the ink was silver (*e.g.,* Codex Argenteus, a 5th–6th-century Gothic translation). Initial letters were sometimes illuminated, often with red ink (from which comes the present English word rubric, based on the Latin for "red," namely *ruber*).

Types of manuscript errors. Since scribes either copied manuscripts or wrote from dictation, manuscript variants could be of several types: copying, hearing, accidental, or intentional. Errors in copying were common, particularly with uncial letters that looked alike. In early manuscripts OC (for *hos,* "[he] who"), for example, might easily be mistaken for the traditional abbreviation of God: $\overline{\Theta\text{C}}$ (for ΘEOC, *theos*). Dittography (the picking up of a word or group of words and repeating it) and haplography (the omission of syllables, words, or lines) are errors most apt to occur where there are similar words or syllables involved. In chapter 17, verse 15, of John, in one manuscript the following error occurs: "I do not pray that thou shouldest take *them from the* [world, but that thou shouldst keep *them from the*] evil one" becomes "I do not pray that thou shouldst take them from the evil one." This is obviously a reading that omitted the words between two identical ends of lines—*i.e.,* an error due to *homoioteleuton* (similar ending of lines).

Especially in uncial manuscripts with continuous writing, there is a problem of word division. An English example may serve to illustrate: GODISNOWHERE may be read "God is now here" or "God is nowhere." Internal evidence from the context can usually solve such problems. Corrections of a manuscript either above the line of writing or in the margin (and also marginal comments) may be read and copied into the text and become part of it as a gloss.

Errors of hearing are particularly common when words have the same pronunciation as others but differ in spelling (as in English: "their, there"; "meet, meat"). This kind of error increased in frequency in the early Christian Era because some vowels and diphthongs lost their distinctive sound and came to be pronounced alike. For example, the Greek vowels *ē, i,* and *u* and the diphthongs *ei, oi,* and *ui* all sounded like the ēē (as in "feet"). Remarkable mistranslations can occur as, for example, in I Corinthians, chapter 15, verse 54: "Death is swallowed up in victory"—becomes by itacism (pronunciation of the Greek letter ē) "Death is swallowed up in conflict" (*neikos*). Another problem of itacism is the distinction between declensions of the 1st and 2nd persons in the plural ("we" and "you") in Greek,

which can sound the same (*hemeis,* "we"; *humeis,* "you"), because the initial vowels are not clearly differentiated. Such errors can cause interpretative difficulties.

A different category of error occurs in dictation or copying, when sequences of words, syllables, or letters in a word are mixed up, synonyms substituted in familiar passages, words read across a two- (or more) column manuscript instead of down, or assimilated to a parallel. Intentional changes might involve corrections of spelling or grammar, harmonizations, or even doctrinal emendations, and might be passed on from manuscript to manuscript. Paleographers—*i.e.,* scientists of ancient writing—can note changes of hands in manuscript copying or the addition of new hands such as those of correctors of a later date.

Significance and reliability of paleography

Paleography, a science of dating manuscripts by typological analysis of their scripts, is the most precise and objective means known for determining the age of a manuscript. Script groups belong typologically to their generation; and changes can be noted with great accuracy over relatively short periods of time. Dating of manuscript material by a radioactive-carbon test requires that a small part of the material be destroyed in the process; it is less accurate than dating from paleography.

Attempts to approximate an original manuscript and critical scholarship. Textual criticism of the Greek New Testament attempts to come as near as possible to the original manuscripts (which did not survive), based on reconstructions from extant manuscripts of various ages and locales. Assessment of the individual manuscripts and their relationships to each other can produce a fairly reliable text from various readings that may have been the result of copying and recopying of manuscripts. It is not always age that matters. Older manuscripts may be corrupt, and a reading in a later manuscript may in reality be ancient. No single witness or group of witnesses is reliable in all its readings.

Erasmus' edition

When Erasmus, the Dutch Humanist, prepared the Greek text for the first printed edition (1516) of the New Testament, he depended on a few manuscripts of the type that had dominated the church's manuscripts for centuries and that had had its origin in Constantinople. His edition was produced hastily, he even translated some parts for which he did not have a Greek text from Jerome's Latin text (Vulgate). In about 1522 Cardinal Francisco Jiménez, a Spanish scholarly churchman, published his Complutensian Polyglot at Alcalá (Latin: Complutum), Spain, a Bible in which parallel columns of the Old Testament are printed in Hebrew, the Vulgate, and the Septuagint (LXX), together with the Aramaic Targum (translation or paraphrase) of Onkelos to the Pentateuch with a translation into Latin. The Greek New Testament was volume 5 of this work, and the text tradition behind it cannot be determined with any accuracy. During the next decades new editions of Erasmus' text profited from more and better manuscript evidence and the printer Robert Estienne of Paris produced in 1550 the first text with a critical apparatus (variant readings in various manuscripts). This edition became influential as a chief witness for the *Textus Receptus* (the received standard text) that came to dominate New Testament studies for more than 300 years. This *Textus Receptus* is the basis for all the translations in the churches of the Reformation, including the King James Version.

Large extensive New Testament critical editions prepared by the German scholars C. von Tischendorf (1869–72) and H. von Soden (1902–13) had Sigla (signs) for the various textual witnesses; they are complex to use and different from each other. The current system, a revision by an American scholar, C.R. Gregory (adopted in 1908), though not uncomplicated has made uniform practice possible. A more pragmatic method of designation and rough classification was that of the Swiss scholar J.J. Wettstein's edition (1751–52). His textual apparatus was relatively uncomplicated. He introduced the use of capital Roman, Greek, or Hebrew letters for uncials and Arabic numbers for minuscules. Later, a Gothic P with exponents came into use for papyri and, in the few cases needed, Gothic or Old English O and T with exponents for ostraca and talismans (engraved amulets). Lectionaries are usually designated by an italicized lowercase *l* with exponents in Arabic numbers.

Known ostraca—*i.e.,* broken pieces of pottery (or potsherds) inscribed with ink—contain short portions of six New Testament books and number about 25. About nine talismans date from the 4th to 12th centuries; they are good-luck charms with a few verses on parchment, wood, or papyrus. Four of these contain the Lord's Prayer. These short portions of writing, however, are hardly of significance for a study of the New Testament textual tradition.

Texts and manuscripts. In referring to manuscript text types by their place of origin, one posits the idea that the major centers of Christendom established more or less standard texts: Alexandria; Caesarea and Antioch (Eastern); Italy and Gallia plus Africa (Western); Constantinople, the home for the Byzantine text type or the *Textus Receptus.* While such a geographical scheme has become less accurate or helpful, it still serves as a rough classification of text types.

Characteristics of major codices

Uncials. The main uncials known in the 17th and 18th centuries were: A, D, D^p, E^a, and C.

A, Codex Alexandrinus, is an early-5th-century manuscript containing most of the New Testament but with lacunae (gaps) in Matthew, John, and II Corinthians, plus the inclusion of the extracanonical I and II Clement. In the Gospels, the text is of the Byzantine type, but, in the rest of the New Testament, it is Alexandrian. In 1627 the A uncial was presented to King Charles I of England by the Patriarch of Constantinople; it has been in the British Museum, in London, since 1751.

D, Codex Bezae Cantabrigiensis, is a 5th-century Greco-Roman bilingual text (with Greek and Latin pages facing each other). D contains most of the four Gospels and Acts and a small part of III John and is thus designated D^{ea} (e, for *evangelia,* or "gospels"; and a for *acta,* or Acts). In Luke, and especially in Acts, D^{ea} has a text that is very different from other witnesses. Codex Bezae has many distinctive longer and shorter readings and seems almost to be a separate edition. Its Acts, for example, is one-tenth longer than usual. D represents the Western text tradition. D^{ea} was acquired by Theodore Beza, a Reformed theologian and classical scholar, in 1562 from a monastery in Lyon (in France). He presented it to the University of Cambridge, England, in 1581 (hence, Beza Cantabrigiensis).

D^p, Codex Claromontanus, of the same Western text type although not remarkably dissimilar from other known texts, contains the Pauline Letters including Hebrews. D^p (p, for Pauline epistles) is sometimes referred to as D_2. Beza acquired this 6th-century manuscript at about the same time as D^{ea}, but D^p was from the Monastery of Clermont at Beauvais (hence, Claramontanus). It is now in the Bibliothèque Nationale, in Paris.

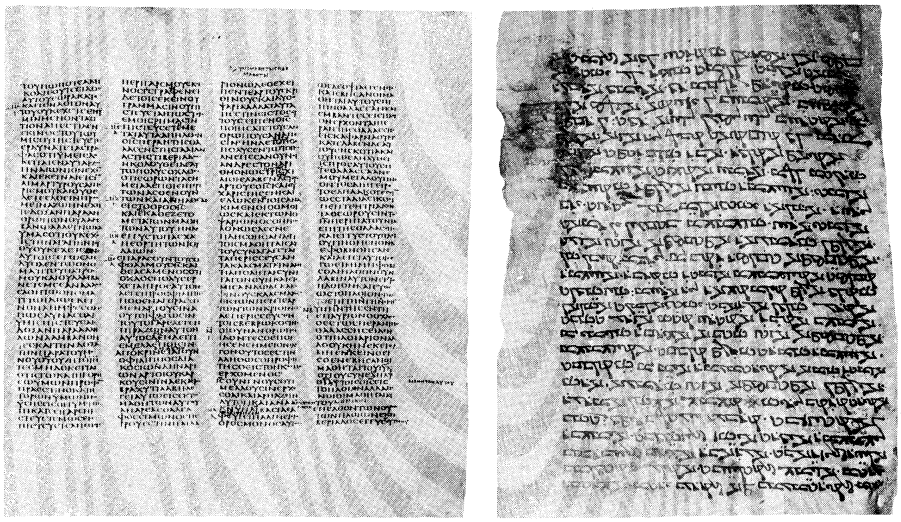
E^a, Codex Laudianus, is a bilingual Greco-Latin text of Acts presented in 1636 by Archbishop Laud, an Anglican churchman, to the Bodleian Library at Oxford. It is a late-6th- or early-7th-century manuscript often agreeing with D^{ea} and its Western readings but also having a mixture of text types, often the Byzantine.

C, Codex Ephraemi Syri rescriptus, is a palimpsest. Originally written as a biblical manuscript in the 5th century, it was erased in the 12th century, and the treatises or sermons of Ephraem Syrus, a 4th-century Syrian Church Father, were written over the scraped text. It was found *c.* 1700 by the French preacher and scholar Pierre Allix; and Tischendorf, using chemical reagents, later deciphered the almost 60 percent of the New Testament contained in it, publishing it in 1843. The text had two correctors after the 5th century but is, on the whole, Byzantine and reflects the not too useful common text of the 9th century.

Although there are numerous minuscules (and lectionaries), their significance in having readings going back to the first six centuries AD was not noted until textual criticism had become more refined in later centuries.

Newer uncial codices

The main uncials and some significant minuscules that were discovered and investigated in the 19th century changed the course of the textual criticism and led the way to better manuscript evidence and methods of dealing with it. This has continued into the 20th century. The



(Left) Gospel According to John 5:38–6:24, from the Codex Sinaiticus. In the British Museum. (Right) Palimpsest in which verses from chapter 5 of the Gospel According to John are overwritten with the story of St. Pelagia in Syriac, from the Codex Palimpsestus Sinaiticus.

main new manuscript witnesses are designated ℵ or S, B, W, and Θ.

ℵ or S, Codex Sinaiticus, was discovered in 1859 by Tischendorf at the Monastery of St. Catherine at the foot of Mt. Sinai (hence, Sinaiticus) after a partial discovery of 43 leaves of a 4th-century biblical codex there in 1844. Though some of the Old Testament is missing, a whole 4th-century New Testament is preserved, with the *Letter of Barnabas* and most of the *Shepherd of Hermas* at the end. There were probably three hands and several later correctors. Tischendorf convinced the monks that giving the precious manuscript to Tsar Alexander II of Russia would grant them needed protection of their abbey and the Greek Church. Tischendorf subsequently published ℵ (S) at Leipzig and then presented it to the Tsar. The manuscript remained in Leningrad until 1933, during which time the Oxford University Press in 1911 published a facsimile of the New Testament from photographs of the manuscript taken by Kirsopp Lake, an English biblical scholar. The manuscript was sold in 1933 by the Soviet regime to the British Museum for £100,000. The text type of ℵ is in the Alexandrian group, although it has some Western readings. Later corrections representing attempts to alter the text to a different standard probably were made about the 6th or 7th century at Caesarea.

B, Codex Vaticanus, a biblical manuscript of the mid-4th century in the Vatican Library since before 1475, appeared in photographic facsimile in 1889–90 and 1904. The New Testament lacks Hebrews from chapter 9, verse 14, on, the Pastorals, Philemon, and Revelation. Because B has no ornamentation, some scholars think it slightly older than ℵ. Others, however, believe that both B and ℵ, having predominantly Alexandrian texts, may have been produced at the same time when Constantine ordered 50 copies of the Scriptures. As an early representation of the Alexandrian text, B is invaluable as a most trustworthy ancient Greek text.

W, Codex Washingtonianus (or Freerianus), consists of the four Gospels in the so-called Western order (Matthew, John, Luke, and Mark, as D^{ca}). It was acquired in Egypt by C.L. Freer, an American businessman and philanthropist (hence, the Freer-Gospels), in 1906 and is now in the Freer Gallery of Art of the Smithsonian Institution, in Washington, D.C. Codex Washingtonianus is a 4th–5th-century manuscript probably copied from several different manuscripts or textual families. The Byzantine, Western (similar to Old Latin), Caesarean, and Alexandrian text types are all represented at one point or another. One of the most interesting variant readings is a long ending to the Gospel According to Mark following a reference to the risen Christ (not found in most manuscript traditions).

Θ, Codex Koridethianus, is a 9th-century manuscript taking its name from the place of the scribe's monastery, Koridethi, in the Caucasus Mountains, near the Caspian Sea. Θ contains the Gospels; Matthew, Luke, and John have a text similar to most Byzantine manuscripts, but the text of Mark is similar to the type of text that Origen and Eusebius used in the 3rd–4th centuries, a Caesarean type. The manuscript is now in Tiflis, capital city of the Georgian S.S.R.

Minuscules. Although there are many minuscules, most of them come from the 9th century on; a few, however, shed significant light on earlier readings, representing otherwise not well attested texts or textual "families." In the early 20th century, the English scholar Kirsopp Lake (hence, Lake group) discovered a textual family of manuscripts known as Family 1:1, 118, 131, and 209 (from the 12th to 14th centuries) that have a text type similar to that of Θ, a 3rd–4th-century Caesarean type. At the end of the 19th century, W.H. Ferrar, a classical scholar at Dublin University (hence, the Ferrar group), found that manuscripts 13, 69, 124, and 346—and some minuscules discovered later (from the 11th to 15th centuries)—also seemed to be witnesses to the Caesarean text type. Manuscript 33, the "Queen of the Cursives," is a 9th–10th-century manuscript now at the Bibliothèque Nationale, in Paris; it contains the whole New Testament except Revelation and is a reliable witness to the Alexandrian text (similar to B) but, in Acts and the Pauline Letters, shows influence of the Byzantine text type.

Textual families

Lectionaries range from the 5th to the 6th century on; some early ones are uncials, though many are minuscules. Scholarly work with lectionary texts is only at its beginning, but the textual types of lectionaries may preserve a textual tradition that antedates its compilation and serves to give examples of the various text forms.

Papyri. The earliest New Testament manuscript witnesses (2nd–8th centuries) are papyri mainly found preserved in fragments in the dry sands of Egypt. Only in the recent decades of this century have the relatively recently discovered New Testament papyri been published. Of those cataloged to date, there are about 76 New Testament manuscripts with fragments of various parts of the New Testament, more than half of them being from the 2nd to 4th centuries. All the witnesses prior to 400 are of Egyptian provenance, and their primitive text types, though mainly Alexandrian, establish that many text types existed and developed side by side. One of the most significant papyrus finds is p^{52}, from *c.* 130 to 140, the earliest extant manuscript of any part of the New Testament. P^{52} consists of a fragment having on one side John 18:31–33 and on the other John 18:37–38, indicating that it was a codex, of which the text type may be Alexandrian. It is now in the John Rylands Library at Manchester.

In the early 1930s, British mining engineer A. Chester Beatty acquired three 3rd-century papyri from Egypt; they were published in 1934–37. Known as p^{45}, p^{46}, and p^{47}, they are, for the most part, in his private library in Dublin.

The Chester Beatty papyri

P^{45}, Beatty Biblical Papyrus I (and some leaves in Vienna), contains 30 leaves of an early- or mid-3rd-century codex of Matthew, Mark, Luke, John, and Acts. Each Gospel is of a different text type, and, although the leaves are mutilated, the Alexandrian text appears to predominate (particularly in Acts, in which a short non-Western text prevails); the whole may be thought of as pre-Caesarean.

P^{46}, Beatty Biblical Papyrus II (and Papyrus 222 at the University of Michigan), consists of 86 leaves of an early-3rd-century (*c.* 200) codex quire containing the Pauline Letters in the following order: Romans, Hebrews, I and II Corinthians, Ephesians, Galatians, Philippians, Colossians, and I Thessalonians. Although some of the leaves are quite mutilated, the text type of p^{46} appears to be Alexandrian. P^{47}, Beatty Biblical Papyrus III, is from the late 3rd century. It contains Rev. 9:10–17:2. It is the oldest, but not the best, text of Revelation and agrees with A, C, and ℵ.

Other early significant papyri are: p^{66}, p^{48}, p^{72}, p^{75}, and p^{74}. P^{66}, also known as Papyrus Bodmer II, contains in 146 leaves (some of which have lacunae) almost all of the Gospel According to John, including chapter 21. This codex, written before 200, is thus merely one century removed from the time of the autograph, the original text. Its text, like that of p^{45}, is mixed, but it has elements of an early Alexandrian text. P^{66} and the other Bodmer papyri, which Martin Bodmer, a Swiss private collector, acquired from Egypt, were published 1956–61. They are in the private Bodmer library at Cologny, near Geneva. P^{48} is a late-3rd-century text of Acts now in a library in Florence. It contains Acts 23:11–17, 23–29 and illustrates a Greek form of the Western text in Egypt in the 3rd century. The papyri of p^{72}, Papyri Bodmer VII and VIII, are also from the 3rd century. VII contains a manuscript of Jude in a mixed text, and VIII contains I and II Peter. In I Peter the Greek was written by a scribe whose native language was Coptic; there are numerous examples of misspellings and itacisms that when corrected leave a text similar to the Alexandrian witnesses.

The papyri of p^{75}, Papyri Bodmer XIV and XV, are 2nd–3rd-century codices containing most of Luke and of John, with John connected to Luke on the same page (unlike the Western order of the Gospels). The text coincides most with B but also has affinities with p^{66} and p^{45} as a predecessor of Alexandrian form.

P^{74}, Bodmer Papyrus XVII, is a 6th–7th-century text of Acts and the Catholic Letters. Acts show affinities with ℵ and A and no parallels with the Western text.

These and other papyri witness to the state of the early text of the New Testament in Egypt, indicating that no *one* text dominated and that text types of different origin flourished side by side.

Versions. *Early versions.* Even with all these witnesses, there remain problems in the Greek text. These include variants about which there is no settled opinion and some few words for which no accurate meaning can be found because they occur only once in the New Testament and not in prior Greek works. Very early translations of the New Testament made as it spread into the non-Greek-speaking regions of the missionary world, the so-called early versions, may provide evidence for otherwise unknown meanings and reflections of early text types.

The Koine, Latin, Syriac, Coptic, and other versions

In the Eastern half of the Mediterranean, Koine (common, vernacular) Greek was understood, but, elsewhere, other languages were used. Where Roman rule dominated, Latin came into use—in North Africa, perhaps in parts of Asia Minor, Gaul, and Spain (*c.* 3rd century). Old Latin versions had many variants, and these translations, traditionally known as the *Itala,* or Old Latin (O.L.), are designated in small letters of the Roman alphabet. The African versions were further from the Greek than were those made in Europe.

In dealing with the New Testament, Jerome prepared a Latin recension of the Gospels using a European form of the Old Latin and some Greek manuscripts. Though the completed Latin translation at the end of the 4th century was produced by no one editor or compiler—a commonly accepted Latin text, the Vulgate, emerged. A reworked official critical edition was a concern of the Council of Trent (1545–63), and in 1592 the Clementine Vulgate, named after Pope Clement VIII, became the authoritative edition. Since Vatican II (1962–65), an ecumenical group of biblical scholars using the best available manuscript witnesses has been engaged in the preparation of a critically sound revision of the Vulgate.

At Edessa (in Syria) and western Mesopotamia neither Latin nor Greek was understood. Therefore, Syriac (a Semitic language related to Aramaic) was used. Old Syriac was probably the original language of the *Diatessaron* (2nd century), but only fragments of Old Syriac manuscripts survive. The Peshitta (common, simple) Syriac (known as syr^{pesh}) became the Syrian 22-book Vulgate of the New Testament, and, at the end of the 4th century, its text was transmitted with great fidelity. The Philoxenian (syr^{phil}) and Harclean (syr^{harc}) versions followed in the 6th–7th centuries and contained all 27 of the New Testament books. The Palestinian (similar to Palestinian Aramaic) Syriac (syr^{pal}) may date to the 5th century but is known chiefly from 11th- to 12th-century lectionaries and is quite independent of other Syriac versions, reflecting a different text type.

In Egypt, in the later Hellenistic period, the New Testament was translated into Coptic—in the south (Upper Egypt) the Sahidic (cop^{sah}), and in the north (Lower Egypt) the Bohairic (cop^{boh}), the two principal dialects. By the 4th century, the Sahidic version was known, and the Bohairic somewhat later. The Coptic versions are fairly literal and reflect a 2nd–3rd-century Alexandrian Greek text type with some Western variants.

A Gothic version was made from the Byzantine text type by a missionary, Ulfilas (late 4th century); an Armenian version (5th century) traditionally was believed to have been made from the Syriac but may have come from a Greek text. Related perhaps to the Armenian was a Georgian version; and an Ethiopic version (*c.* 6th–7th century) was influenced by both Coptic and later Arabic traditions. In the various versions there is evidence of geographical spread, of the history of the underlying text traditions used, and of how they were interpreted in the early centuries.

The many readings in the Greek, Latin, and Syriac Fathers, who can be dated and located, can, to some extent, shed light on the underlying New Testament texts they quoted or used.

Another use both of the versions and of the patristic quotations is elucidation of the meaning of hitherto unknown Greek words in the New Testament.

Elucidation of meanings of unknown Greek words

An example is *epiousios* in the Lord's Prayer as given in verse 11 of chapter 6 of Matthew and verse 3, chapter 11, of Luke. The traditional translation in the Western Church is "daily" (referring to bread). From the Old Latin, Jerome, the early Syriac versions, and a retroversion of the Lord's Prayer into a proposed Aramaic substratum, the meaning is either "daily" or, more likely, "for the morrow"; and modern translations include this meaning in footnotes, including the suggestion that it may refer to eucharistic bread. The Greek is possibly a coined compound word that, on the basis of its component parts, yields "for the morrow" or "that which is coming soon." Such latter treatment is not conjectural emendation but rather creative analysis in context, where no Greek variants help. The biblical scholar, in possession of many variants, usually uses conjecture only as a means of last resort, and any conjecture must be both intrinsically suitable and account for the reading considered corrupt in the transmitted text.

Later and modern editions. New Testament editions in the 18th century did not question the *Textus Receptus (T.R.),* despite new manuscript evidence and study, but its limitations became apparent. E. Wells, a British mathematician and theological writer (1719), was the first to edit a complete New Testament that abandoned the *T.R.* in favour of more ancient manuscripts; and English scholar Richard Bentley (1720) also tried to go back to early manuscripts to restore an ancient text, but their work

Modern criteria and classifications of texts

was ignored. In 1734 J.A. Bengel, a German Lutheran biblical theologian, stressed the idea that not only manuscripts but also families of manuscript traditions must be differentiated, and he initiated the formulation of criteria for text criticism. J.J. Wettstein's edition (1730–51) had a wealth of classical and rabbinic quotations, but his theory on text was better than the text itself. A German Lutheran theologian, J.S. Semler (1767), further refined Bengel's classification of families.

J.J. Griesbach (1745–1812), a German scholar and student of Semler, adapted the text-family classification to include Western and Alexandrian text groups that preceded the Constantinopolitan groupings. He cautiously began to alter texts according to increasingly scientific canons of text criticism. These are, with various refinements, still used, as, for example, that "the difficult is to be preferred to the easy reading," and "the shorter is preferable to a longer"—both of which reason (with many other factors) that correction, smoothing, or interpretation leads to clearer and longer readings.

In the 19th century, classical philologist Karl Lachmann's critical text (1831) bypassed the *T.R.*, using manuscripts prior to the 4th century. C. von Tischendorf's discovery of ℵ (S) and his New Testament text (8th edition, 1864) collated the best manuscripts and had the richest critical apparatus thus far.

Two English biblical scholars, B.F. Westcott and F.J.A. Hort of Cambridge, using ℵ and B, brought out an edition in 1881–82 and classified the text witnesses into four groupings: Neutral (B, ℵ, the purest and earliest Eastern text); Alexandrian (a smoothed Neutral text as it developed in Alexandria); Western (D, Old Syrian, O.L., the Western Fathers with glosses that caused many readings to be rejected); and Syrian (A^c and the Byzantine tradition as it later developed). Such a "family tree" clearly showed the *T.R.* (Syrian) and, hence, the King James Version based upon it as an inferior text type; and the Revised Standard Version is based on such superior text types as B and ℵ.

Another critical edition (1902–13) was made by H. von Soden, a German biblical scholar who presupposed recensions to which all manuscripts can lead back. The importance of his work is in his enormous critical apparatus rather than in his theoretical groupings. B.H. Streeter, an English scholar, revised Westcott and Hort's classification in 1924. Basically, he challenged the concept of any uncontaminated descent from originals and made the observation (already alluded to in the evolution of papyrus evidence) that even the earliest manuscripts are of mixed text types. Yet, Streeter grouped texts in five families: Alexandrian, Caesarean, Antiochene, European Western, and African Western—parts of which all led into the Byzantine text and had become the *T.R.*

Unlikelihood of reconstructing an autograph

Despite grouping, it is clear that no reading backward from text families can reach an autograph. A strictly local text theory is useless in view of the papyrus evidence that there were no "unmixed" early texts. The use of external evidence cannot push beyond the boundary of the 3rd century. This insight brought about a new perspective. Only by using the canons of the internal evidence of readings can the best texts be determined, evaluating the variants from case to case—namely, the eclectic method. In modern times, therefore, the value of text families is primarily that of a step in the study of the history of the texts and their transmission. The eclectic method of reconstruction of an earliest possible New Testament text will yield the closest approximation of the historical texts put together into the New Testament canon. (For other, later and modern versions, see above *Old Testament canon, texts, and versions.*)

New Testament history

THE JEWISH AND HELLENISTIC MATRIX

The historical background of the New Testament and its times must be viewed in conjunction with the Jewish matrix from which it evolved and the Hellenistic (Greek cultural) world into which it expanded during a period of Jewish religious propaganda. It is difficult, however, to separate the phenomena of the Jewish and Hellenistic backgrounds, because the Judaism out of which the church arose was a part of a very Hellenized world. The conquests of Alexander the Great culminated in 331 BC, and the subtle but strong influence of Greek culture, language, and customs that was spread by his conquests united his empire. Jews in both Palestine and the Diaspora (Dispersion) were, however, affected by Hellenism, as in ideas of cosmic dualism and rich religious imagery derived in part from Eastern influence as a result of the Greek conquests. Greek words were transliterated into Hebrew and Aramaic even in connection with religious ideas and institutions as, for example, synagogue (religious assembly), Sanhedrin (religious court), and paraclete (advocate, intercessor). It could be argued that the very preoccupation with ancient texts and tradition and the interpretation thereof is a Hellenistic phenomenon. Thus, what may appear as the most indigenous element in the activity of the Jewish scribes, sages, and rabbis (teachers)—*i.e.*, textual scholarship—has its parallels in Hellenistic culture and is part of the general culture of the times. The thought worlds merged, confronted each other, and communicated with each other.

The Hasmonean kingdom. After Alexander's death the empire was split, and first the Ptolemies, an Egyptian dynasty, and then the Seleucids, a Syrian dynasty, held Palestine. Antiochus IV Epiphanes, a 2nd-century-BC Seleucid king, desecrated the Temple in Jerusalem; a successful Jewish revolt under the Maccabees, a priestly family, resulted in its purification and in freedom from Syrian domination in 164 BC. This began the Hasmonean (Maccabean) dynasty, which appropriated the powers both of king and of high priest. This reign, which created dissatisfaction on the part of other groups who considered their own claims falsely usurped, lasted until internecine strife brought it to an end. John Hyrcanus II, a 1st-century-BC Hasmonean king, appealed to Rome for help, and Pompey, a Roman general, intervened, bringing Palestine under Roman rule in 63 BC. John Hyrcanus, given the title of ethnarch, was later executed for treason (30 BC), thus ending the Hasmonean line, but Jewish independence had come to an end by Roman occupation.

Roman intervention in Palestine

Rule by the Herods. The Herods who followed were under the control of Rome. Herod the Great, son of Antipater of Idumaea, was made king of Judaea, having sided with Rome, and he ruled with Roman favour (37–4 BC). Though he was a good statesman and architect, he was hated by the Jews as a foreigner and semi-Jew. Jesus was born a few years before the end of his reign, and "the slaughter of the innocents," young children of Bethlehem who were killed as possible pretenders to Herod's throne, was attributed to Herod. After his death, Palestine was divided among three of his sons: Philip was made tetrarch of Iturea (the northeast quarter of the province) and ruled from 4 BC until AD 37. Herod Antipas became tetrarch of Galilee and Peraea until AD 39 and, like his father, was a builder, rebuilding Sepphoris and Tiberias before he was banished. Herod Antipas had John the Baptist beheaded and treated Jesus with contempt at Jesus' trial before him, before sending him back to Pontius Pilate, the Roman procurator (AD 26–36) at the time of Jesus' Crucifixion. Archelaus was made ethnarch of Judaea, Samaria, and Idumaea but was removed by AD 6 for his oppressive rule, and Judaea then became an imperial province, governed by procurators responsible to the emperor.

Two other Herods are mentioned in the New Testament: Agrippa I (called "Herod the king," AD 37–44) had James, the brother of John, killed and had Peter arrested; and the last of the Herods, Agrippa II, king of Trachonitis (*c.* AD 50–100), welcomed the procurator Festus (*c.* AD 60–62), who replaced Felix (*c.* AD 52–60) for the trial of Paul.

Roman occupation and Jewish revolts. In AD 66–70 there was a Jewish revolt while Nero was emperor of Rome (54–68). When he died and was succeeded by Vespasian, his former army commander (69–79), the siege and final destruction of Jerusalem occurred (AD 70). Before this event, Jewish Christians had fled, perhaps to Pella, and Yohanan ben Zakkai, a leading Jewish rabbi, with a group of rabbinical scholars, fled to Yavneh, where they established an academy that gave leadership to the Jews. Under the emperors Trajan (98–117) and Hadrian (117–

The effects of the fall of Jerusalem

138), Jews in Egypt and Mesopotamia rebelled and again fought unsuccessfully against Rome in Palestine for forbidding the practice of religious rites, and, under Simeon Bar Kokhba (or Bar Koziba), a Jewish revolutionary messianic figure, the final Jewish war was waged (132–135). After this defeat Jerusalem became a Roman colony; a temple to Jupiter was erected there, and Jews were prevented from entering the city until the 4th century.

When the Romans had entered Palestine in 63 BC, they practiced a relatively humane occupation until *c.* AD 66–70. They did not interfere with religious practices unless they considered them a threat to Rome, and their rights of requisition were precise and limited.

JEWISH SECTS AND PARTIES

From both the New Testament and extrabiblical material the main religious groups or parties in Palestinian Judaism may be discerned. Such descriptions, however, may be somewhat biassed or apologetic. Philo, an Alexandrian Jewish philosopher (died *c.* AD 40), Josephus, a Jewish apologist to the Romans (died *c.* 100), and sectarian writings found at Qumrān near the Dead Sea in 1947 that date back to about *c.* 200 BC and end about AD 70 all provide data about the respective Jewish religious groups in Palestine in the 1st century BC and the 1st century AD. The Pharisees (typically Jesus' opponents, although his ideas may have been close to their own), the Sadducees, and the Zealots are mentioned in the New Testament. The Essenes were described by Philo and Josephus, but new evidence from their own writings makes their group better understood (*i.e.,* the Dead Sea Scrolls from Qumrān).

The Pharisees. The Pharisees (possibly spiritual descendants of the Ḥasidim [Pious Ones], who were the exponents of Maccabean revolt) were strict adherents to the Law. Their name may come from *parush*—*i.e.,* "separated" from what is unclean, or what is unholy. They were deeply concerned with the Mosaic Law and how to keep it, and they were innovators in adapting the Law to new situations. They believed that the Law was for all the people and democratized it—even the priestly laws were to be observed by all, not only by the priestly class—so that they actually had a belief in a priesthood of all believers. They included Oral as well as Written Law in their interpretations. Though they did not accept the Roman occupation, they kept to themselves, and by pious acts, such as giving alms and burying the dead, they upheld the Law. Their interpretations of Law were sometimes considered casuistic because they believed they must find interpretations that would help all people to keep the Law. Their underlying hope was eschatological: in the day when Israel obeyed the Torah, the Kingdom would come. The Pharisees were called "smooth interpreters" by their opponents, but their hope was to find a way to make the living of the Law possible for all people. In their meal fellowship *(ḥavura)* they observed the laws strictly and formed a nucleus of obedient Israel. The Pharisees believed in the resurrection of the dead and had a developed angelology.

Pharisaic interpretations of the Law

The Sadducees. The Sadducees, more conservative and static, consisted mainly of the old priesthood and landed aristocracy and, perhaps, some Herodians. They were collaborators with Rome. They did not believe in resurrection because they found no Old Testament enunciation of such a doctrine. In a way, they seemed to respect the Pharisees in legal matters; but both the Pharisees—because they were a bourgeois rather than a popular movement—and the Sadducees—because they were aristocrats—rejected the *'am ha-aretz* (People of the Land), who were no party but simply the poor, common people whom they considered ignorant of the Law.

The Zealots. The Zealots were revolutionaries who plotted actively against the Roman oppression. That the Pharisees did not react in this way was perhaps because of their belief in Providence: what happens is the will of God, and their free will is expressed in the context of trust and piety in conjunction with an eschatological hope of winning God's Kingdom through obedience to Law.

The Essenes. Though the Essenes of the Dead Sea Scrolls are not mentioned in the New Testament, they are described by Philo, Josephus, and Eusebius, a 4th-century Christian historian. With publication of the Essenes' own sectarian writings since the 1950s, however, they have become well known. They did not have any really new ideas, but their founder, the Teacher of Righteousness, believed that he knew the interpretation of the prophets for his time in a way that was not even known to the prophets of their own day. Their withdrawal into desert seclusion was in opposition to the ruling powers in the city and the Temple of Jerusalem. They lived apart from society in constant study of the Scriptures and with a firm belief that they were the elect of Israel living in the end of days and to whom would come messianic figures—a messiah of David (royal) and a messiah of Aaron (priestly). Membership in their group and acceptance or rejection of its founder determined their place in the age to come. After a long period of probation and initiation, a man became a member of this elect community that had strict rules of community discipline that would seal or destroy his membership in their New Covenant. Ritual lustrations preceded most liturgical rites, the most important one of which was participation in a sacred meal—an anticipation of the messianic banquet, to which only the fully initiated members in good standing were admitted and which was presided over by representatives of the Davidic and Aaronic messiahs. From what is known of them, their communities were celibate, living "in the presence of the angels" and thus required to be in a state of ritual purity. Their laws were strict, their discipline severe, and—unlike Pharisees, Sadducees, and Zealots—they were not simply different parties within Judaism but a separate eschatological sect. The Pharisees did have lodges and a common meal, but membership in the Pharisaic party did not, as it did with the Essenes, guarantee a place in the age to come; and the attitude of the Pharisees to a leader or founder was not, as it was to the Essenes, one of the bases on which such place could be attained. Thus, the Essenes—as the early Jewish Christians—were an eschatological Jewish sect. They believed that they alone, among those living in the end time, would be saved. The apocalypticism of the Essenes and the early Christians had many similarities, but the Christians had a higher eschatological intensity because they already knew who the Messiah would be when he came in the future at the Parousia (the "Second" Advent), and they also had a recollection of the earthly Jesus, knowledge of the risen Lord, and the gift of the Spirit upon the church. Both communities lived in an era wherein the cosmic battle of God versus Satan-Belial was taking place, but the Christian community already had the traditions of Jesus' victory over Satan and the experience of his Resurrection. Both Essenes and Christians were sects with tightly knit organizations, but the church had a historically based messiah. The Essenes probably were killed or forced to flee from their wilderness community *c.* AD 68, yet some of their ideas can still be traced in the ministry of John the Baptist (who might have been an Essene) and in the thought world of the New Testament (see also JUDAISM).

Eschatological views of the Essenes

Similarities and differences between Essenes and Christians

THE RELIGIOUS SITUATION IN THE GRECO-ROMAN WORLD OF THE 1ST CENTURY AD

Hellenistic religions. With the expansion of Christianity into the Hellenistic world either to Jews or increasingly to Gentiles, there were various reasons why the Christian message that spread, for example by Paul, met the needs of the Hellenistic Age and world. There was no lack of religions, but there was a crisis of upheaval, unrest, and uncertainty and a desire to escape from mortality and the domination of unbending fate. There was also a desire to win personal knowledge of the universe and a dignified status within it—*i.e.,* a religious identity crisis. City-states with their cults of civic gods were unstable, because men changed from place to place and the gods of the city were distant from individual needs and anxieties. After Alexander's conquests, the resulting religious syncretism did not meet individual needs and longings that were increasingly becoming conscious. Many Gentiles turned to Judaism, at least as "god fearers," and later to Christianity. There were also "mystery religions," the secrets of which were known only to the initiate, which may have arisen from Eastern

The religious crisis of the 1st century AD

fertility cults with their dying and rising gods and were transformed in the Hellenistic Age to cults of a saviour god whose dying and rising gives personal immortality. Such mystery cults often provided meaningful relationships with fellow initiates.

Astrology. There were elements in the Greek world that may have come from the East, partly Egyptian and Babylonian, which gave rise to astrology. The basic conviction of astrology was that the heavenly bodies were deities that in a direct way control life and events on earth. An older idea of *tychē*, or "fate," originally signified the chance element in the universe, a capriciousness that increased insecurity. Astrology transformed this into a fate or destiny in which everything is strictly regulated by celestial deities. Man's problem, then, is that of finding security from overwhelming powers outside human control. One way is to "read a horoscope." Because the heavenly deities are systematic and orderly according to astronomic observation, this order and regularity can be exploited to see how and in what way events will happen and can perhaps be used or avoided. Another way is to deal with such forces through magic. From the Hellenistic period many magical papyri with formulas for dealing with sicknesses, demons, and other adverse forces have been found. Magic attempts to manipulate and control what affects the world by a kind of participation in the event.

Philosophical solutions. Solutions were also sought in philosophy. Socrates, a 5th-century-BC Greek philosopher, was largely concerned with the search for the "good," the good life. After Plato and Aristotle, however, philosophical systems sought to supply man's longing for inward security and stability. These were sought not by an in-depth understanding of reality but by ad hoc constructions—a new dogmatism for providing infallible plans and attaining immediate security—that the age demanded. Those philosophies were crude constructions that gave shelter and were defended by an unyielding dogmatism as absolute truths; if they were proved false, they would remove their promised security. Epicureanism, founded by the Greek philosopher Epicurus (341–270 BC), was basically a philosophy of escape, and its goal was serenity and tranquillity, a negative concept characterized by absence of fear, pain, and struggle. Fate, providence, and the afterlife were eliminated to deny the anxieties they provoked in terms of control, reward, or judgment. Epicurus attempted to meet this crisis by adopting a completely material view of the universe, including the soul, and thereby eliminating interference by deities both in life and after death. He did believe in the gods; but they, too, lived in their own perfect tranquillity, away from the universe. The Epicurean was both self-reliant and at peace with the absence of pain. There was also emphasis on friendship and the development of close communities.

Goals of escape or acceptance

Zeno, a 3rd-century-BC philosopher, was the founder of Stoicism. Stoicism was a rule of life that held that all reality was material but was animated by a rational principle that was at the same time both the law of the universe and of the human soul. The wise man then could accept and learn to live a life in conformity to this permeating reason without letting anything affect him. He responded to duty and accepted it.

Cynicism was a philosophy that maintained a cosmic view of life with a method of dealing with crisis by reducing man's needs to a minimum. Later in the Hellenistic period, a group of Stoic–Cynic preachers arose and, in New Testament times, wandered around calling men to repent and change their lives from sin to virtue.

ADAPTATION OF THE CHRISTIAN MESSAGE TO THE HELLENISTIC RELIGIOUS SITUATION

The Christian message adapted itself to this Hellenistic situation of crisis and proved a successful answer: Jesus was proclaimed as Lord and Saviour, Baptism was practiced as a form of initiation and a passage from death to new life, and the Lord's Supper was celebrated as a sacral meal. The obvious difference between Christianity and the mystery religions is that a historical person, Jesus, forms the center of cult and devotion; his titles came from his Jewish background. Adaptation took place out of the Jewish matrix of Christianity—and Hellenistic terms that were meaningful were also used, such as illumination and regeneration. Such terms are not to be found in the earliest origins of Christianity but in the communication of the Christian message to a new environment. Among the religious and philosophic needs of the time was that of a cult that provided for the needs of the individual along with a community of worship. Christ as Lord was viewed as universal, and his teachings made the universe understandable, as well as providing a basis for ethics. In a period of expansion, all religions are to some extent syncretistic, as is the case of Christianity in the 2nd century. Such a phenomenon belongs to a religion in a time of strength. Though universal, however, Christ was believed to have an exclusive claim, and in this there was security and relief for the anxieties of the period. The church was more than a philosophy; it had a social and enduring structure. It also reached out to all men—not only to those regarded as the best of men. It called them to a new life and gave them a new home and community, the church.

THE LIFE OF JESUS

Though the fact that Jesus was a historical person has been stressed, significant, too, is the fact that a full biography of accurate chronology is not possible. The New Testament writers were less concerned with such difficulties than the person who attempts to construct some chronological accounts in retrospect. Both the indifference of early secular historians and the confusions and approximations attributable to the simultaneous use of Roman and Jewish calendars make the establishment of a chronology of Jesus' life difficult. That the accounts of Matthew and Luke do not agree is a further problem. Thus, only an approximate chronology may be reconstructed from a few somewhat conflicting facts. The points of reference are best taken from knowledge of the history of the times reflected in the passages.

Difficulties in establishing a chronology of the life of Jesus

According to Matthew, Jesus was born near the end of the reign of Herod the Great, thus before 4 BC. In Luke, chapter 2, verses 1 to 2, Jesus is said to have been born at the time of a census when Quirinius was governor of Syria. Such a census did occur, but in AD 6–7. Because this was after Herod's death and not in agreement with a possible date of Jesus' baptism, this late date is unlikely. There may have been an earlier census under another governor; an inscription in the Lateran Museum records an unnamed governor who twice ruled Syria, and the suggestion has been made that this was, indeed, Quirinius and that in an earlier time a reported census according to Roman calculation might have been carried out *c.* 8 BC, one of a series of such. With such speculation and the combined evidence of Matthew and Luke, an approximate year of birth might be 7–6 BC.

In Luke, chapter 3, verse 23, it is stated that Jesus' ministry began when he was about 30 years of age. This would not come within the dates of the procuratorship of Pontius Pilate (AD 26–36), and the age might simply approximate a term for Jesus' having arrived at maturity. In Luke several dates are implied to assist in dating the Baptism of Jesus: the 15th year of Tiberius (*c.* 29, according to his accession as co-emperor with Augustus), while Pontius Pilate was in office (during 26–36), while Herod Antipas was tetrarch (4 BC–AD 39) and Philip tetrarch (4 BC–AD 37). These limits make a speculation of Jesus' Baptism and the start of his ministry *c.* AD 27/28.

The duration of Jesus' ministry can be an average of the one year, as indicated in the Synoptic Gospels (Matthew, Mark, and Luke) or about three years as indicated in John, based on various cycles of harvests and festivals. This would be about two years. Because Jesus was crucified before 36 and his ministry started about 27/28, he then was crucified about AD 30 (see also JESUS).

THE CHRONOLOGY OF PAUL

For the chronology of Paul's ministry, there are also some extra-biblical data: According to Josephus, Herod Agrippa I was made ruler of all Palestine by the emperor Claudius in AD 41 and reigned for three years. His death was thus in AD 44. A famine in Claudius' reign took place when

Tiberius Alexander was procurator of Judaea (*c.* 46–48), and Egyptian papyri suggest (by reference to high wheat prices) that the date of the famine was about 46. The Gallio inscription at Delphi (in Greece) gives a date for Gallio, proconsul of Achaia when Paul was at Corinth. It notes that Claudius was acclaimed emperor for the 26th time. This would bring the date of being declared emperor to about 52 and Gallio's term of office (about one year) to about 51–52.

The chronology of Paul's missionary journeys

The chronology of Paul's missionary journeys and the dates of his letters have been the object of an investigation made difficult by the fact that the account in Acts does not agree with Paul's own letters, which are, of course, more reliable.

With the help of external references, some degree of absolute chronology might be sought—with several years' margin both because of uncertainty as to extra-biblical dating and much ambiguity about internal evidence. Although Paul would be in a better position to know his own situation, often his letters are, in their present form, combined fragments from various times (see below *The Second Letter of Paul to the Corinthians; The Letter of Paul to the Phillipians*). A chronology can be reached by comparing Paul's accounts of his journeys and sojourns with those reported in Acts. Given references in Acts and the Gallio inscription, it is possible to place Paul in Corinth in AD 51, and, since he was there for 18 months, it can be assumed that he began his missionary work sometime in 49 (he had previously been in Thessalonica and Philippi and in Troas and Asia Minor). This probably fits in with the "expulsion" of Jews from Rome about AD 49, thus indicating that Paul met Priscilla and Aquila, two Roman Jewish Christians, in Corinth at this time. This indicates that he was at an "apostolic conference" at Jerusalem sometime shortly before this (a comparison of chapters 13 and 15 of Acts with chapters 1 and 2 of Galatians shows that the author of Acts made two visits out of the one recorded by Paul), which was either in 49 or 48.

Though the dates in Galatians 1 and 2 are uncertain—not indicating whether they refer to 17 years *in toto* or only 14 years, because half years were equated with whole ones—they do establish the call of Paul to become a Christian in 31 or about 34–35. Working in the other direction, it is known that Paul wrote to the Thessalonians from Corinth, thus indicating a date of about 50 as probable for the writing of I Thessalonians.

From Corinth, Paul went to Ephesus, where, according to Acts, he remained (probably in prison) for three years. This would place him in Ephesus during the period 52–55, thus allowing time for a journey from Corinth via Ephesus to Antioch and then back to Ephesus. A sequence given in Acts, chapters 16 and 18, shows two possibilities for Paul to have been in Galatia that work in agreement with Galatians, chapter 4, verse 13, demonstrating that Galatians was written from Ephesus about 53–54. Ephesus can also be the location from which came I Cor., Phil., and probably Philem.

II Corinthians appears to have been written from Macedonia during 55. From the dating of the periods of Felix and Festus in office at Caesarea (mid-50s) and from the events in Felix' time of office, it is probable that Paul was in prison under Felix by 56.

Thus, data of Acts 18 and 20 regarding the journey and sojourn at Corinth can be correlated with data in Romans 15 to place the epistle to the Romans in about the year 56, before the journey back to Jerusalem, ending in the arrest of Paul in 56. The two years of Acts 24:27 can then be explained as the time during which Paul was in prison at Caesarea, so that in 58 Paul was before Festus and was sent to Rome.

That Paul was then in Rome for two more years is established in Acts chapter 28, verse 30. It can be concluded that Paul died sometime after 60, possibly during or before the Neronian persecution of 64 (*cf.* I Clem. 5). All this does not resolve the question of a possible Spanish journey nor give precise dates and locations for II Thessalonians, Colossians, Ephesians, or the Pastoral Letters (see also PAUL).

New Testament literature

INTRODUCTION TO THE GOSPELS

Meaning of the term gospel. From the late AD 40s and until his martyrdom in the 60s, Paul wrote letters to the churches that he founded or guided. These are the earliest Christian writings that the church has, and in them he refers to "the gospel" (*euangelion*). In Romans, chapter 1, verse 1, he says: "Paul, a servant of Jesus Christ, called to be an apostle, set apart for the gospel of God . . ." and goes on to describe this "gospel" in what was already by that time traditional language, such as: "promised beforehand through his prophets in the holy scriptures, the gospel concerning his Son, who was descended . . . our Lord" (Rom. 1:1–4). This gospel is the power of God for salvation to everyone who has faith ". . . for in it the righteousness of God is revealed through faith for faith . . ." (1:17). In I Corinthians Paul had reminded his congregation in stylized terms of "the gospel" he had brought to them. It consisted of the announcement that Jesus had died and risen according to the Scriptures.

Earliest concept of "gospel"

Thus, the "gospel" was an authoritative proclamation (as announced by a herald, *kēryx*), or the kerygma (that which is proclaimed, *kērygma*). The earthly life of Jesus is hardly noted or missed, because something more glorious—the ascended Lord who sent the Spirit upon the church—is what matters.

In the speeches of Peter in Acts, the transition from kerygma to creed or vice versa is almost interchangeable. In Acts 2 Jesus is viewed as resurrected and exalted at the right hand of God and made both Lord and Christ. In Acts 3 Peter's speech proclaims Jesus as the Christ having been received in heaven to be sent at the end of time as judge for the vindication and salvation of those who believe in him. Here the proclaimed message, the gospel, is more basic than an overview of Jesus' earthly life, which in Acts is referred to only briefly as "his acting with power, going about doing good, and healing and exorcising" (10:38ff.). Such an extended kergyma can be seen as a transition from the original meaning of gospel as the "message" to gospel meaning an account of the life of Jesus.

The term gospel has connotations of the traditions of Jesus' earthly ministry and Passion that were remembered and then written in the accounts of Matthew, Mark, Luke, and John. They are written from the post-Resurrection perspective and they contain an extensive and common Passion narrative as they deal with the earthly ministry of Jesus from hindsight. And so the use of the term gospel for Matthew, Mark, Luke, and John has taken the place of the original creedal–kerygmatic use in early Christianity. It is also to be noted that, in the Evangelists' accounts, their theological presuppositions and the situations of their addressees molded the formation of the four canonical Gospels written after the Pauline Letters. The primary affirmations—of Jesus as the Christ, his message of the Kingdom, and his Resurrection—preceded the Evangelists' accounts. Some of these affirmations were extrapolated backward (much as the Exodus event central in the Old Testament was extrapolated backward and was the theological presupposition for the patriarchal narratives in Genesis). These stories were shaped by the purpose for their telling: religious propaganda or preaching to inspire belief. The kerygmatic, or creedal, beginning was expanded with material about the life and teaching of Jesus, which a reverence for and a preoccupation with the holy figure of Jesus demanded out of loving curiosity about his earthly ministry and life.

Theological presuppositions that helped to shape the Gospels

The English word gospel is derived from the Anglo-Saxon *godspell* ("good story"). The classical Greek word *euangelion* means "a reward for bringing of good news" or the "good news" itself. In the emperor cult particularly, in which the Roman emperor was venerated as the spirit and protector of the empire, the term took on a religious meaning: the announcement of the appearance or accession to the throne of the ruler. In contemporary Greek it denoted a weighty, authoritative, royal, and official message.

In the New Testament, no stress can be placed on the etymological (root) meaning of *eu* ("good"); in Luke, chap-

ter 3, verse 18 (as in other places), the word means simply authoritative news concerning impending judgment.

Form criticism. In the Pauline writings, as noted above, gospel, kerygma, and creed come close together from oral to written formulas that were transmitted about the Christ event: Jesus' death and Resurrection. In the apostolic Fathers (early 2nd century), the transition was made from oral to written tradition; the translation of the presumed Aramaic traditions had taken place before the Gospel material had been committed to writing. By the time of Justin Martyr (*c.* 155), these writings were called Gospels and referred to in the plural; they contain the words, deeds, and Passion narratives—*i.e.,* the present four Gospels compiled and edited by the Evangelists according to their various needs and theological emphases. Justin also referred to these as "memoirs of the Apostles."

Patterns noted in the Gospels

Such a Gospel began with a missionary announcement concerning a cosmic divine figure, a man with divine characteristics who would bring salvation and hope to the world. The earthly historical Jesus, however, was the criterion of the proclamation—being both the content of the church's proclamation and the object of its faith.

The identification of basic patterns in the history of oral and written traditions—the stage of tradition prior to any literary form and particularly as the traditions passed from an oral to a written form—and the determination of their creative milieu, or their situations and functions in various places and under various circumstances, are tasks of form criticism. Through such study, small independent units may be isolated in a postulated more primitive form than they were before being incorporated into more extended accounts. The term *Sitz-im-Leben* refers to the "Sitz im Leben der Kirche"—*i.e.,* the situation in the life of the church in which the material was shaped and adjusted to the needs at hand. Only through such studies is it possible to progress tentatively to an assessment of a "Sitz im Leben Jesu."

Both Jews and Gentiles could use "biographies," often for propaganda purposes. Philo and Josephus recounted the wonderful lives and deeds of Old Testament heroes such as Moses; and there are miraculous tales of the prophets Elijah and Elisha told in order that faith might be inspired or justified. A miracle worker (*theios anēr,* "divine man") and stories about him comprised an aretalogy (from *aretē,* "virtue"; also manifestation of divine power, miracle). Aretalogies were frequently used to represent the essential creed and belief of a religious or philosophical movement. *The Life of Apollonius of Tyana,* a Neo-Pythagorean philosopher and wonder-worker (transmitted by the Greek writer Philostratus), was widely read. He was depicted as having performed miracles and as being possessed of divine cosmic power not as an exception but as an example to men who have the possibility of sharing such power (*cf.* Matt. 9:8). There were tales of Heracles, the Greek hero, and a whole literature of Alexander the Great as wonder-workers, divine men.

Types of forms and genres

Though the pericopes (small units) of which the Gospels are constituted include many forms, or genres, they are mainly divided into narratives (including legends, miracle stories, exorcisms, healings, and tales) and sayings (prophetic and apocalyptic sayings, proverbs and wisdom sayings, parables, church discipline and rules for the community, Christological sayings, such as the socalled "I am" sayings [*e.g.,* "I am the bread of life"] in John, revelations, and legal sayings). Some stories may simply be the background for a pithy saying; these latter are sometimes called paradigmatic sayings, and the pronouncement stories are their vehicles of transmission. The forms have many different names, but form criticism started with Homeric form analysis (taking oral tradition into account), which was applied to Old Testament studies by Hermann Gunkel, a German biblical scholar, and applied to the New Testament, on the basis of the German classical philologist Eduard Norden's stylistic studies, by such biblical scholars as Rudolf Bultmann and Martin Dibelius.

Form criticism asks and answers questions about what shaped the preliterary tradition and the earliest written traditions into blocks as they are found in the Gospels. This may be a historical context (as a missionary situation), a need for admonition (as church-discipline sections), or for the transmission of teaching in a faithful way (as in a "school," be it Matthean, Pauline, or Johannine). One large block of the material, however, is to all intents and purposes the same (although differing in details) in all four canonical Gospels: the Passion narrative. In the Synoptic Gospels there is also a basic nucleus in the sayings about Jesus that are mysterious, prophetic, and apocalyptic and that point to the significance of Jesus as the Christ who has come in history in the person of Jesus of Nazareth.

Such form-critical studies were centred on the smaller units of tradition (pericopes) that make up the Gospels, and their intention was partly to assess relative age and authenticity of such traditions. In more recent times the tools of form criticism have been applied to a more synthetic method that could be used to determine the relation between a genre of literature and the Christological and theological perspectives that made such genres natural. A presentation of Jesus material in the form of more or less disconnected sayings (as in the so-called Q Source, composed of independent sayings, behind Matthew and Luke, and in the *Gospel of Thomas;* see below *The two- and four-source hypotheses*) tends to fit a Christology in which Jesus is viewed as a teacher of Wisdom, an envoy of Wisdom, or as Wisdom herself. The collections of wonder stories (aretalogies) grew out of a Christology of Jesus as the divine man. Another type of Jesus material with independent existence seems to have been "revelations," or "apocalypses," in which Jesus Christ speaks to his followers. This is seen, for example, in Mark 13, I Thessalonians, chapter 4, the canonical book of Revelation to John, and the noncanonical *Didache* 16.

These genres of material now represented in the canonical Gospels are amply represented also in the noncanonical writings from the first Christian centuries. The discovery of a Gnostic library of Coptic writings at Naj̱ Ḥammādī, in Egypt, in the 1940s gave scholars a new opportunity to compare the canonical Gospels with the Jesus material of these various types, some of them having been called and used as gospels (such as the *Gospel of Thomas*). In the light of such a wider spectrum of material, it appears that the gospel form for which Mark is the earliest witness became a criterion for the orthodox transmission of the Christian message about Jesus. By making the confession of Jesus as the crucified and risen Lord (the earliest kerygma and "gospel" as found in Paul and Acts) the form of an extensive Passion account prefaced by a limited amount of narrative and teaching, Mark set the stage for a faith that anchored faith in Jesus Christ in the events of the earthly life of Jesus. This form of the "gospel" became the standard within which the other commonly accepted Gospels grew. It became the criterion for later creedal statements concerning Jesus Christ as true God and true man. By such a criterion, gospels that seemed to disregard his humanity (*e.g., Gospel of Thomas,* the *Gospel of Peter*) were judged heretical.

Significance of the Passion account

THE SYNOPTIC PROBLEM

Early theories about the Synoptic problem. Since the 1780s, Matthew, Mark, and Luke have been referred to as the Synoptic Gospels (from *synoptikos,* "seen together"). The extensive parallels in structure, content, and wording of Matthew, Mark, and Luke make it even possible to arrange them side by side so that corresponding sections can be seen in parallel columns. John Calvin, the 16th-century Reformer, wrote a commentary on these Gospels as a harmony. Such an arrangement is called a "synopsis," or Gospel harmony, and, by careful comparison of their construction, compilation, and actual agreement or disagreement in wording or content, literary- or source-critical relationships can be seen. Augustine, the great 4th–5th-century Western theologian, considered Mark to be an abridged Matthew, and, until the 19th century, some variation of this solution to literary dependency dominated the scene. It still recurs from time to time.

The Synoptic problem is one of literary or of source criticism and deals with the written sources after compilation and redaction. Matthew was the Gospel most used for the selections read in the liturgy of the church, and other

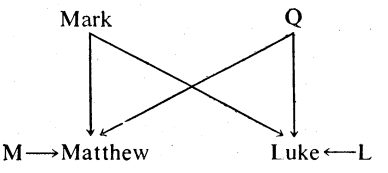
Gospels were used to fill in the picture. One attempted solution to the problem of priority was the proposed existence of an Aramaic primitive gospel, which is now lost, as the first Gospel from which a later Mark in Greek was translated and arranged. The Greek Mark would thus be first based on a prior Semitic Matthew, and later both Mark and Matthew would be translations dependent on Matthew, and Luke dependent on both. The preservation of an ecclesiastical priority of Matthew breaks down because of the literary word-for-word agreement in Matthew, Mark, and Luke. This agreement occurs to far too great an extent to be accounted for in translations and revisions, not to mention the agreement in the order of the various pericopes as they are viewed in a synoptic parallel arrangement.

For similar reasons, a fragment theory holding that the Gospels were constructed of small written collections brought together in varying sequences cannot stand the test of actual structure—but it has the merit of stressing compilation of sources.

In 1789 J.J. Griesbach, a German biblical scholar, hypothesized that the Synoptics had not developed independently, but in his "usage-hypothesis" he recognized that there must be literary dependency. He thought that Mark used Matthew as well as Luke, but this could not account for the close relationship of Matthew and Luke. His basic concept of literary dependency, however, paved the way for K. Lachmann, who observed in 1835 that Matthew and Luke agree only when they also agree with Mark and that, where material is introduced that is not in Mark, it is inserted in different places. This, it is held, can only be explained on the basis of the priority of Mark and its use as the patterning form of Matthew and Luke. This insight led to a so-called two-source hypothesis (by two German biblical scholars, Heinrich Holtzmann in 1863, and Bernhard Weiss in 1887–88), which, with various modifications and refinements of other scholars, is the generally accepted solution to the Synoptic problem.

The two- and four-source hypotheses. The two-source hypothesis is predicated upon the following observations: Matthew and Luke used Mark, both for its narrative material as well as for the basic structural outline of chronology of Jesus' life. Matthew and Luke use a second source, which is called Q (from German *Quelle,* "source"), not extant, for the sayings (logia) found in common in both of them. Thus, Mark and Q are the main components of Matthew and Luke. In both Matthew and Luke there is material that is peculiar to each of their Gospels; this material is probably drawn from some other sources, which may be designated M (material found only in Matthew's special source) and L (material found only in Luke's special source). This is known as the four-document hypothesis, which was elaborated in 1925 by B.H. Streeter, an English biblical scholar. The placement of Q material in Luke and Matthew disagrees at certain points according to the needs and theologies of the addressees of the gospels, but in Matthew the Marcan chronology is the basic scheme into which Q is put. Mark's order is kept, on the whole, by Matthew and Luke, but, where it differs, at least one agrees with Mark. After chapter 4 in Matthew and Luke, not a single passage from Q is in the same place. Q was a source written in Greek as was Mark, which can be demonstrated by word agreement (not possible, for example, with a translation from Aramaic, although perhaps the Greek has vestiges of Semitic structure form). A diagram might thus be:

The source called Q



In approximate figures, Mark's text has 661 verses, more than 600 of which appear in Matthew and 350 in Luke. Only *c.* 31 verses of Mark are found nowhere in Matthew or Luke. In the material common to all three Synoptics, there is very seldom verbatim agreement of Matthew and Luke against Mark, though such agreement is common between Matthew and Mark or Luke and Mark or where all three concur.

The postulated common saying source of Matthew and Luke, Q, would account for much verbatim agreement of Matthew and Luke when they include sayings absent from Mark. The fact that the sayings are used in different ways or different contexts in Matthew and Luke is an indication of a somewhat free way in which the editors could take material and mold it to their given situations and needs. An example of this is the parable in Matthew and Luke about the lost sheep (Matt. 18:10–14, Luke 15:3–7). The basic material has been used in different ways. In Matthew, the context is church discipline—how a brother in Christ who has lapsed or who is in danger of doing so is to be gently and graciously dealt with—and Matthew shapes it accordingly (the sheep has "gone astray"). In Luke, the parable exemplifies Jesus' attitude toward sinners and is directed against the critical Pharisees and scribes who object to Jesus' contact with sinners and outsiders (the sheep is "lost").

Variations in the use of certain sayings of Jesus

Another example of two passages used verbatim in Luke and Matthew is Jesus' lament over Jerusalem. In Luke (13:34–35; the lament over Jerusalem) Jesus refers to how they will cry "Blessed be the King who comes in the name of the Lord" when he enters Jerusalem (Lk. 19:38). In Luke, the passage is structured into the life of Jesus and refers to his triumphal entry into Jerusalem, "Blessed is he who comes in the name of the Lord"). In Matthew (23:37–39) this same lament is placed after the entry into the city (21:9) and thus refers to the fall of Jerusalem and the Last Judgment. Apparently, Luke has historicized a primarily eschatological saying.

Since the 1930s, scholars have increasingly refined sources, postulated sources behind sources, and many stages of their formation. The premise of the two- (or four-) source hypothesis is basic and provides information as to literary sources; further refinement is of interest only to the specialist. Another movement in synoptic research—and also research including John—is that which concentrates rather on the treatment of gospels as a whole, formally and theologically, with patterns or cycles to be investigated. It may be significant that the latest and best regarded Greek synopsis is that of the German scholar Kurt Aland, *Synopsis Quattuor Evangeliorum* (1964; *Synopsis of the Four Gospels,* 1972), which includes the Gospel According to John and, as an appendix, the *Gospel of Thomas,* as well as ample quotations from noncanonical gospels and Jesus' sayings preserved in the Church Fathers.

THE SYNOPTIC GOSPELS

The Gospel According to Mark. The Gospel According to Mark is the second in canonical order of the Gospels and is both the earliest gospel that survived and the shortest. Probably contemporaneous with Q, it has no direct connection with it. The Passion narrative comprises 40 percent of Mark, and, from chapter 8, verse 27, onward, there is heavy reference forward to the Passion.

Though the author of Mark is probably unknown, authority is traditionally derived from a supposed connection with the Apostle Peter, who had transmitted the traditions before his martyr death under Nero's persecution (*c.* 64–65). Papias, a 2nd-century bishop in Asia Minor, is quoted as saying that Mark had been Peter's amanuensis (secretary) who wrote as he remembered (after Peter's death), though not in the right order. Because Papias was from the East, perhaps the Johannine order would have priority, as is the case in the structure of the Syrian scholar Tatian's *Diatesseron* (harmony of the Gospels).

Traditional connection with Peter

Attempts have been made to identify Mark as the John Mark mentioned in Acts 12 or as the disciple who fled naked in the garden (Mark 14). A reference to "my son, Mark," in I Peter is part of the same tradition by which Mark was related to Peter; thus the Evangelist's apostolic guarantor was Peter.

The setting is a Gentile church. There is no special interest in problems with Jews and little precision in stating Jewish views, arguments, or terminology. Full validity is given the worship of the Gentiles. In further support of

a Gentile setting and Roman provenance is the argument that Mark uses a high percentage of so-called Latinisms—*i.e.,* Latin loanwords in Greek for military officers, money, and other such terms. Similar translations and transliterations, however, have been found in the Jerusalem Talmud, a compendium of Jewish law, lore, and commentary, which certainly was not of Roman provenance. The argument from Latinisms must be weighed against the fact that Latin could be used anywhere in the widespread Roman Empire. In addition, for the first three centuries the language of the church of Rome was Greek—so the Gentile addressees might just as well have been Syrian as Roman. The Latinisms—as well as the Aramaisms—are rather an indication of the vernacular style of Mark, which was "improved" by the other Evangelists.

Simplicity and directness of style

Mark is written in rather crude and plain Greek, with great realism. Jesus' healing of a blind man is done in two stages: first the blind man sees men, but they look like trees walking, and only after further healing activity on Jesus' part is he restored to see everything clearly. This concrete element was lost in the rest of the tradition. It is also perhaps possible that this two-stage healing is a good analogy for understanding Mark theologically: first, through enigmatic miracles and parables in secret, and only later, after recognition of Jesus as the Christ, is there a gradual clarification leading to the empty tomb. In chapter 3, verse 21, those closest to Jesus call him insane ("he is beside himself"), a statement without parallel in the other Gospels.

In Mark, some Aramaic is retained, transliterated into Greek, and then translated—*e.g.,* in the raising of Jairus' daughter (5:41) and in the healing of the deaf mute (7:34). The well-known *abba,* Father, is retained in Mark's account of Jesus' prayer in Gethsemane. In the two miracle stories, the Aramaic may have been retained to enhance the miracle by the technique of preserving Jesus' actual words. And a cry of Jesus on the Cross is given in Aramaized Hebrew.

The stories in Mark are woven together with simple stereotyped connectives, such as the use of *kai euthus* ("and immediately," "straightway"), which may be thought of as a Semitic style (as a typical simple connective in the Old Testament narrative style). More likely, however, this abruptness indicated that the compiler-redactor of Mark has used geography and people simply as props or scenes to be used as needed to connect the events in the service of the narrative.

Except for the Passion narrative, there is little chronological information. References in chapters 13 and 14 appear to presuppose that the Jerusalem Temple (destroyed in AD 70) still stood (in Matthew and Luke this is no longer the case); but the context of chapter 13, the "Little Apocalypse," is so interwoven with eschatological traditions of both the Jewish and Christian expectations in the 1st century that it cannot serve with certainty as a historical reference. To some extent, however, chapter 13 does help to date Mark—the priority of which has already been established from literary criticism—because it is in good agreement with the traditions that Mark was written after the martyrdom of Peter. Mark may thus be dated somewhere after 64 and before 70, when the Jewish war ended.

Structure of the Gospel

The organization and schematizing of Mark reveals its special thrust. It may be roughly divided into three parts: (1) 1:1–8:26—the Galilean ministry—an account of mighty deeds (an aretalogy); (2) 8:27–10:52—discussions with his disciples centred on suffering; and (3) 11:1–16:8—controversies, Passion, death, the empty tomb, and the expected Parousia in Galilee.

"The beginning of the Gospel" in the first words of Mark apparently refers to John the Baptist, who is clearly described as a forerunner of the Messiah who calls the people to repentance. Jesus never calls himself the Messiah (Christ). After Jesus' Baptism by John, the heavens open, the Spirit descends, and a heavenly voice proclaims Jesus as God's beloved son with whom He is well pleased. Already in this account there is a certain secrecy, because it is not clear whether the onlookers or only Jesus witnessed or heard. Jesus was then driven by the Spirit into the wilderness, the place of demons and struggle, to be tempted by Satan, surrounded by wild beasts (the symbols of the power of evil and persecution) and ministered to by angels. Here again he is in secret, alone. The opening of the struggle with Satan is depicted, and the attendance by angels is a sign of Jesus' success in the test.

Many references to persecution in Mark point toward Roman oppression and a martyr church that was preoccupied with a confrontation with the Satanic power behind the world's hostility to Jesus and his message. There was stress on the underlying fact that the church must witness before the authorities in a hostile world. Much of the martyrological aspect of Mark's account is grounded in his interpretation of the basic function of Jesus' Passion and death and its implication that the Christian life is a life of suffering witness.

The proximity of the Kingdom of God

What Jesus preached in Galilee at the beginning of his ministry was that the time is fulfilled and the Kingdom of God is "at hand"; *i.e.,* very very near—therefore repent! (1:15). In Matthew this same message is that of both John the Baptist (3:2) and Jesus (4:17). This sets the stage; and the miraculous ministry in Galilee about which the followers are enjoined to secrecy points not so much to Jesus as the wonder-worker as to the great scheme of pushing back the frontier of Satan. Toward the end of this first section, the Pharisees ask Jesus for a sign, and he answers in no uncertain terms that no sign will be given (8:12). In the Synoptic Gospels the miracles are never called "signs" (as in John); and no sign is to be given prior to the cosmological, eschatological signs from heaven that belong to the end: darkening of the Sun and Moon and extreme tribulations that in postbiblical Jewish eschatology—the mood of the first Christian century—is a sign of the coming of the heavenly Son of man to judge the world.

Parables are a revelatory mode of expression; they are not just illustrations of ideas or principles. Jesus, the revealer, tells his disciples that the secret of the Kingdom of God is given to them but that to the outsider everything is in parables (or riddles) *in order that* they may not hear and understand lest they repent and be forgiven (4:10–12). This mystery and hiddenness is particularly related to the parables about the coming of the kingdom. Yet, even Jesus' disciples did not recognize him as the Messiah, although his miracles were such that only a messianic figure could perform them: forgiving sins on earth, casting out demons, raising the dead, making the deaf hear and the stammerer (the dumb) speak, and the blind to see—all fulfillments of Old Testament prophecy concerning the Messiah. Only the demons, supranatural beings, recognize Jesus. There is a constant campaign against Satan from the temptation after Jesus' Baptism until his death on the Cross, and, in each act of healing or exorcism, there is anticipated the ultimate defeat of Satan and the manifestation of the power of the new age. In all this Mark stresses the need for secrecy and Peter's confession of Jesus as the Christ (8:29) is told in Mark as the opportunity to motivate an acceptance of the admonition "not to tell" by reference to the necessity of suffering.

Emphasis on suffering and the messianic secret

This strong emphasis on the necessity of suffering—in the life of Jesus and in the life of the disciples—before the hour of victory gives the best explanation to what scholars have called the secrecy motif in Mark—*i.e.,* the constant stress on not telling the world about Jesus' messianic power.

According to William Wrede, a German scholar, the messianic secret motif was a literary and apologetic device by which the Christological faith of the early church could be reconciled with the fact that Jesus never claimed to be the Messiah. According to Wrede, Mark's solution was: Jesus always knew it but kept it a secret for the inner group. After Peter's confession at Caesarea Philippi, Jesus began to speak of a *suffering* Son of man. The Son of man in Jewish apocalyptic was a glorious, transcendent, heavenly figure who would come victorious on clouds of glory to judge the world at the end of time. Suffering was not part of this picture. E. Sjöberg (1955) has interpreted the messianic secret not as a literary invention but as an understanding both that the Messiah would appear without recognition except by those who are chosen and to whom he reveals himself and that he must suffer. For

outsiders, then, he remains a mystery until the age to come. Even his disciples did not understand the necessity of suffering. Only in the light of Resurrection faith—the hope of the Parousia and final victory over Satan—could they understand that he had to suffer and die to fulfill his mission and how they, too, must suffer.

Martyrological aspects in Mark can be noted from the beginning. Already according to 2:20 Jesus' disciples are not to fast until "when the bridegroom is taken away from them and then they will fast . . . ." In Mark 8 to 10, there is great concentration on discussions with the disciples. The theme is suffering, and repeatedly they are reminded that there is no way of coming to glory except through suffering. Three Passion predictions meet either with rejection, fear, or confusion. In the Transfiguration (9:2–13; in which three disciples—Peter, James, and John—see Jesus become brighter and Elijah and Moses, two Old Testament prophets, appear) there is the same emphasis. The tension between future glory and prior suffering is the more striking when the Transfiguration is recognized as a Resurrection appearance, placed here in an anticipatory manner. The disciples are reminded of an association of Elijah with John the Baptist and his fate. This is also a hidden epiphany (manifestation)—the triumphal enthroned king closely juxtaposed with suffering and death.

After the third Passion prediction, in chapter 10, two of the disciples ask for places of honour when Jesus is glorified. He reminds them that suffering must precede glory for "The Son of man also came not to be served but to serve, and to give his life as a ransom for many." It is worth noting that this is the only reference to the death of Christ as a ransom or sacrifice but that Mark does not dwell on the Christological implications, but uses the saying for ethical purposes. Even so, the Marcan text gives one of the important building blocks for Christological growth and reflection on the suffering Son of man.

Just as Jesus' public ministry in Mark started with the calling of disciples, so the central part of the Gospel calls them to participate through suffering in his own confrontation with the power of Satan.

Emphasis on the Passion

In the last section of the Gospel, the scene is shifted to Jerusalem, where Jesus is going to die. His entry is described as triumphal and openly messianic and is accompanied by acted-out parables in a judgment of a barren fig tree, casting money changers out of the Temple, and in a parable of a vineyard in which the beloved son of the owner is killed. There is an increasing conflict and alienation of the authorities. Chapter 13, the "Little Apocalypse," made up of a complex arrangement of apocalyptic traditions, serves as instruction to the disciples and thence to the church that they must endure through tribulation and persecution until the end time. Thus, although the setting is Jerusalem, the orientation is toward Galilee, the place where the Parousia is expected. The Holy Spirit will come to those who must witness in the situation of trial before governors and authorities (13:11); in the final eschatological trials only by God's intervention can anyone endure unless the time be shortened for the elect. Because this chapter is shaped as a discourse that precedes the Passion narrative, it serves as a farewell address, a type of testament including apocalyptic sayings and warnings to the messianic community at the end of the "narrative" before the Passion—as do most testament forms (admonitions given before death to those beloved who will remain behind).

The Cross is both the high point of the Gospel and its lowest level of abject humiliation and suffering. A cry of dereliction and agony and the cosmic sign of the rending of the Temple veil bring from a Gentile centurion acknowledgment of Jesus as Son of God. The disciples reacted to the scandal of the Cross with discouragement, although already the scene is set for a meeting in Galilee. There are no visions of the risen Lord, however, in the best manuscripts (verses 9–20 are commonly held to be later additions), and Mark thus remains an open-ended Gospel. The Resurrection is neither described nor interpreted. Not exultation but rather involvement in the battle with Satan is the inheritance until the victorious coming in glory of the Lord—a continual process with the empty tomb pointing to hope of the final victory and glory, the Parousia in Galilee. The Gospel ends on the note of expectation. The mood from the last words of Jesus to the disciples remains: What I say to you, I say to all: Watch!

The Gospel According to Matthew. Matthew is the first in order of the four canonical Gospels and is often called the "ecclesiastical" Gospel, both because it was much used for selections for pericopes for the church year and because it deals to a great extent with the life and conduct of the church and its members. Matthew gave the frame, the basic shape and colour, to the early church's picture of Jesus. Matthew used almost all of Mark, upon which it is to a large extent structured, some material peculiar only to Matthew, and sayings from Q as they serve the needs of the church. This Gospel expands and enhances the stark description of Jesus from Mark. The fall of Jerusalem (AD 70) had occurred, and this dates Matthew later than Mark, *c.* 70–80.

Matthew as the "ecclesiastical" Gospel

Although there is a Matthew named among the various lists of Jesus' disciples, more telling is the fact that the name of Levi, the tax collector who in Mark became a follower of Jesus, in Matthew is changed to Matthew. It would appear from this that Matthew was claiming apostolic authority for his Gospel through this device but that the writer of Matthew is probably anonymous.

The Gospel grew out of a "school" led by a man with considerable knowledge of Jewish ways of teaching and interpretation. This is suggested by the many ways in which Matthew is related to Judaism. It is in some ways the most "Jewish" Gospel. Striking are 11 "formula quotations" ("This was to fulfill what was spoken by the prophet . . .") claiming the fulfillment of Old Testament messianic prophecies.

The structure of Matthew

The outstanding feature of Matthew is its division into five discourses, or sermons, following narrative sections with episodes and vignettes that precede and feed into them: (1) chapters 5–7—the Sermon on the Mount—a sharpened ethic for the Kingdom and a higher righteousness than that of the Pharisees; (2) chapter 10—a discourse on mission, witness, and martyrological potential for disciples with an eschatological context (including material from Mark 13); (3) chapter 13—parables about the coming of the Kingdom; (4) chapter 18—on church discipline, harshness toward leaders who lead their flock astray and more gentleness toward sinning members; and (5) chapters 23–25—concerned with the end time (the Parousia) and watchful waiting for it, and firmness in faith in God and his Holy Spirit. Each sermon is preceded by a didactic use of narratives, events, and miracles leading up to them, many from the Marcan outline. Each of the five sections of narrative and discourse ends with a similar formula: "now when Jesus had finished these sayings. . . ." The style suggests a catechism for Christian behaviour based on the example of Jesus: a handbook for teaching and administration of the church. This presupposes a teaching and acting community, a church, in which the Gospel functions. The Greek word *ekklēsia,* ("church") is used in the Gospels only in Matthew (16:18 and 18:17).

The discourses are preceded by etiological (sources or origins) material of chapters 1–2, in which the birth narrative relates Jesus' descent (by adoption according to the will of God) through Joseph into the Davidic royal line. Though a virgin birth is mentioned, it is not capitalized upon theologically in Matthew. The story includes a flight into Egypt (recalling a Mosaic tradition). Some "Semitisms" add to the Jewish flavour, such as calling the Kingdom of God the Kingdom of the Heaven(s). The name Jesus (Saviour) is theologically meaningful to Matthew (1:21). Chapter 2 reflects on the geographical framework of the Messiah's birth and tells how the messianic baby born in Bethlehem came to dwell in Nazareth.

After the five narrative and discourse units, Matthew continues from chapter 26 on with the Passion narrative, burial, a Resurrection account, and the appearance of the risen Lord in Galilee, where he gives the final "great commission," with which Matthew ends.

The setting of Matthew

Matthew is not only an original Greek document, but its addressees are Greek-speaking Gentile Christians. By the time of the Gospel According to Matthew, there had been a relatively smooth and mild transition into a Gentile

Christian milieu. The setting could be Syria, but hardly Antioch, where the Pauline mission had sharpened the theological issues far beyond what seems to be the case in Matthew. Matthew has no need to argue against the Law, or Torah, as divisive for the church (as had been the case earlier with Paul in Romans and Galatians, in which the Law was divisive among Gentile Christians and Jewish Christians), and, indeed, the Law is upheld in Matthew (5:17–19). For Matthew, there had already been a separation of Christianity from its Jewish matrix. When he speaks about the "scribes and the Pharisees," he thinks of the synagogue "across the street" from the now primarily Gentile church. Christianity is presented as superior to Judaism even in regard to the Law and its ethical demands.

The Matthean church is conscious of its Jewish origins but also of a great difference in that it is permeated with an eschatological perspective, seeing itself not only as participating in the suffering of Christ (as in Mark) but also as functioning even in the face of persecution while patiently—but eagerly—awaiting the Parousia. The questions of the mission of the church and the degree of the "coming" of the Kingdom with the person and coming of Jesus are handled by the Evangelist by a "timetable" device. The Gospel is arranged so that only after the Resurrection is the power of the Lord fully manifest as universal and continuing. Before the Resurrection the disciples are sent nowhere among the Gentiles but only to the lost sheep of the house of Israel; and the end time is expected before the mission will have gone through the towns of Israel. Even in his earthly ministry, however, Jesus proleptically, with a sort of holy impatience, heals the son of a believing Roman centurion and responds to the persistent faith of a Canaanite woman—whose heathen background is stressed even more than her geographical designation, Syro-Phoenician, given in the parallel in Mark—by healing her daughter. The Jewish origins of Jesus' teaching and the way the Evangelist presents them do not deny but push beyond them. The prophecies are fulfilled, the Law is kept, and the church's mission is finally universal, partly because the unbelief of the pious Jewish leaders left the gospel message to the poor, the sick, the sinner, the outcast, and the Gentile.

Jesus as teacher, Messiah, King, and Judge

In Matthew, because of the use of Q and Matthew's theological organization, there is stress on Jesus as teacher, his sharpening or radicalizing of the Law in an eschatological context; and Jesus is presented not in secret but as an openly proclaimed Messiah, King, and Judge. In the temptation narrative Jesus refuses Satan's temptations because they are of the devil, but he himself later in the Gospel does feed the multitude, and after the Resurrection he claims all authority in heaven and on earth. By overcoming Satan, Jesus gave example to his church to stand firm in persecution. Messianic titles are more used in Matthew than in Mark. In the exorcism of demoniacs, the demons cry out, calling him Son of God and rebuking him for having come "before the time" (8:29). Again, this shows that Jesus in his earthly ministry had power over demons, power belonging only to the Messiah and the age to come; and he pushed this timetable ahead. Yet, as in Mark, the miracles are not to be interpreted as signs. When asked for a sign, the Matthean account gives only the sign of Jonah, an Old Testament prophet—*i.e.,* the preaching of the gospel—which in later tradition took on an added interpretation as presaging the Son of man (Jesus) being three days and nights in the tomb (12:40, a later addition to Matthew).

Even the antitheses in the Sermon on the Mount are not new but demonstrate a higher ethic—one that is sharpened, strict, more immediate because the end time is perceived as coming soon. People who took this intensification of the Law upon themselves dared to do it as an example of "messianic license"—*i.e.,* to use the ethics of the Kingdom in the present in a church still under historical ambiguity and in constant struggle with Satan.

At such points the peculiar nature of Matthew comes into focus. The sharpening of the Law and the messianic license for the disciples are clearly there. At the same time Matthew presents the maxims of Jesus as attractive to a wider audience with Hellenistic tastes: Jesus is the teacher of a superior ethic, beyond casuistry and particularism. Similarly, in chapter 15, he renders maxims about food laws as an example of enlightened attitudes, not as rules for actual behaviour.

According to Matthew, the "professionally" pious were blind and unhearing, and these traits led to their replacement by those who are called in Matthew the "little ones"; in Final Judgment the King-Messiah will judge according to their response to him who is himself represented as one of "the least of these." The depiction of Jesus as Lord, King, Judge, Saviour, Messiah, Son of man, and Son of God (all messianic titles) is made in a highly pitched eschatological tone. The Lord's Prayer is presented in this context, and, for example, the "temptation" (trial, test) of "Lead us not into temptation" is no ordinary sin but the ordeal before the end time, the coming of the Kingdom for which the Matthean church prays. Martyrdom, though not to be pursued, can be endured through the help of the Spirit and the example of Jesus.

The Passion narrative is forceful and direct. Pilate's part in sentencing Jesus to be crucified is somewhat modified, and the guilt of the Jews increased in comparison with the Marcan account. In Matthew the Resurrection is properly witnessed by more than one male witness so that there can be no ambiguity as to the meaning of the empty tomb. The risen Lord directs his disciples to go to Galilee, and the Gospel According to Matthew ends with a glorious epiphany there and with Jesus' commission to the disciples—the church—to go to the Gentiles, because the risen Jesus is Lord of heaven and earth for all time.

The Gospel According to Luke. Luke is the third in order of the canonical gospels, which, together with Acts, its continuation, is dedicated by Luke to the same patron, "most excellent" Theophilus. Theophilus may have been a Roman called by a title of high degree because he is an official or out of respect; or he may have been an exemplification of the Gentile Christian addressees of the Lucan Gospel. The account in Luke–Acts is for the purpose of instruction and for establishing reliability by going back to the apostolic age. The very style of this preface follows the pattern of Greek historiography, and thus Luke is called the "historical" Gospel. Historically reliable information cannot be expected, however, because Luke's sources were not historical; they rather were embedded in tradition and proclamation. Luke is, however, a historian in structuring his sources, especially in structuring his chronology into periods to show how God's plan of salvation was unfolded in world history. That he uses events and names is secondary to his intention, and their historical accuracy is of less importance than the schematization by which he shows Jesus to be the Saviour of the world and the church in its mission (Acts) to be part of an orderly progress according to God's plan.

The purpose of Luke

The sources of the Gospel are arranged in the service of its theological thrust with definite periodization of the narrative. Approximately one-third of Luke is from Mark (about 60 percent of Mark); 20 percent of Luke is derived from Q (sometimes arranged with parts of L). Almost 50 percent is from Luke's special source (L), especially the infancy narratives of John the Baptist and Jesus, and parables peculiar to Luke (*e.g.,* the prodigal son, the good Samaritan, the rich fool). L material is also interwoven into the Passion narrative. While Matthew structured similar teaching materials in his five discourses, Luke places them in an extensive travel account that takes Jesus from Galilee to Judaea via Jericho to Jerusalem. This is similar to the ways in which Acts is structured on the principle of bringing the word from Jerusalem to Rome (see below).

The author has been identified with Luke, "the beloved physician," Paul's companion on his journeys, presumably a Gentile (Col. 4:14 and 11; cf. II Tim. 4:11, Philem. 24). There is no Papias fragment concerning Luke, and only late-2nd-century traditions claim (somewhat ambiguously) that Paul was the guarantor of Luke's Gospel traditions. The Muratorian Canon refers to Luke, the physician, Paul's companion; Irenaeus depicts Luke as a follower of Paul's gospel. Eusebius has Luke as an Antiochene physician who was with Paul in order to give the Gospel apostolic authority. References are often made to Luke's

medical language, but there is no evidence of such language beyond that to which any educated Greek might have been exposed. Of more import is the fact that in the writings of Luke specifically Pauline ideas are significantly missing; while Paul speaks of the death of Christ, Luke speaks rather of the suffering, and there are other differing and discrepant ideas on Law and eschatology. In short, the author of this gospel remains unknown.

The setting of Luke

Luke can be dated *c.* 80. There is no conjecture about its place of writing, except that it probably was outside of Palestine because the writer had no accurate idea of its geography. Luke uses a good literary style of the Hellenistic Age in terms of syntax. His language has a "biblical" ring already in its own time because of his use of the Septuagint style; he is a Greek familiar with the Septuagint, which was written for Greeks; he seldom uses loanwords and repeatedly improves Mark's wording. The hymns of chapters 1 and 2 (the Magnificat, beginning "My soul magnifies the Lord"; the Benedictus, beginning "Blessed be the Lord God of Israel"; the Nunc Dimittis, beginning "Now lettest thou thy servant depart in peace") and the birth narratives of John the Baptist and Jesus either came from some early oral tradition or were consciously modelled on the basis of the language of the Septuagint. These sections provide insight into the early Christian community, and the hymns in particular reflect the Old Testament psalms or the *Thanksgiving Psalms* from Qumrān. Though on the whole Matthew is the Gospel most used for the lectionaries, the Christmas story comes from Luke. The "old age" motif of the birth of John to Elizabeth also recalls the Old Testament birth of Samuel, the judge. All the material about John the Baptist, however, is deliberately placed prior to that of Jesus. When Mary, the mother of Jesus, visits Elizabeth, Jesus' superiority to John is already established. The Davidic royal tradition is thus depicted as superior to the priestly tradition.

Writing out of the cultural tradition of Hellenism and that of Jewish *'anawim* piety—*i.e.,* the piety of the poor and the humble entertaining messianic expectations—Luke has "humanized" the portrait of Jesus. Piety and prayer (his own and that of others) are stressed. Love and compassion for the poor and despised and hatred of the rich are emphasized, as is Jesus' attitude toward women, children, and sinners. In the Crucifixion scene, the discussion between the robbers and Jesus' assurance that one of them would be with him in Paradise, as well as the words, "Father, into thy hands I commit my spirit!"—which are in contrast to the cry of dereliction in Mark and Matthew—all point toward the paradigm of the truly pious man. Parables peculiar to Luke—among which are those of the good Samaritan, the importunate friend, the lost coin, and the prodigal son—have an element of warmth and tenderness. Thus, Luke "civilizes" the more stark eschatological emphasis of Mark (and Matthew), leading the way, perhaps, to a lessening of eschatological hopes in a time in which the imminent Parousia was not expected but pushed into the distant future.

The structure of the Gospel

The interplay between Luke and Acts reveals Luke's answer to the coming of the Kingdom. Once the church has the Holy Spirit, the delay of the Parousia has been answered for a time. Thus, Luke divides history into three periods: (1) the end of the prophetic era of Israel as a preparation for revelation, with John the Baptist as the end of the old dispensation; (2) the revelation of Jesus' ministry as the centre of time—with Satan having departed after the temptation and, until he once again appears, entering into Judas to betray Jesus; and (3) the beginning of the period of the church after Jesus' Passion and Resurrection.

Consistent with this schematization, John the Baptist's arrest occurs before Jesus' Baptism, though it is placed later in Mark and Matthew. From the beginning, the rule of the Spirit is a central theme, important in healing, the ministry, the message, and the promise of the continued guidance of the Spirit in the age of the church, pointing toward part two of Luke's work, the book of Acts of the Apostles, in which Pentecost (the receiving of the Holy Spirit by 120 disciples gathered together the 50th day after Easter) is a decisive event.

Just as Luke arranges his Gospel to show the divine plan of salvation in historical periodization, so he orders its structure in accordance with a geographical scheme. Chapter 1 (verse 8) of Acts provides the framework: after the coming of the Spirit, the church will witness in Jerusalem, in all Judaea and Samaria, and then to the end of the inhabited world. These places foreshadow the church's mission. The end of the old dispensation takes place in Jerusalem and its environs. The Resurrection appearances in Luke are placed in Jerusalem (Mark, Matthew, and John point toward Galilee). Jerusalem is also the place of the beginning of the church, and the old holy place thus becomes the centre of the new holy community. The necessity of suffering was made clear and interpreted as the fulfillment of prophecy. Rejection by people from his old home, Nazareth, and by Jewish religious leaders corresponds to the beginning of the ministry to the Gentiles—to the end of the earth.

Luke's interpretation of the Passion

Luke's account of the Crucifixion heightens the guilt of the Jews, adding a trial and mockery by Herod Antipas. The Crucifixion in Luke is interpreted as an anticipatory event: that the Christ must suffer by means of death before entering into glory. Jesus' death, therefore, is not interpreted in terms of an expiatory redemptive act. The centurion who saw the event praised God and called Jesus a righteous man, thus describing his fate as that of a martyr, but with no special meaning for salvation. The link between past salvation history and the period of the church is through the Spirit; salvation history continues in Acts.

THE FOURTH GOSPEL: THE GOSPEL ACCORDING TO JOHN

John is the last Gospel and, in many ways, different from the Synoptic Gospels. The question in the Synoptic Gospels concerns the extent to which the divine reality broke into history in Jesus' coming, and the answers are given in terms of the closeness of the new age. John, from the very beginning, presents Jesus in terms of glory: the Christ, the exalted Lord, mighty from the beginning and throughout his ministry, pointing to the Cross as his glorification and a revelation of the glory of the Father. The Resurrection, together with Jesus' promise to send the Paraclete (the Holy Spirit) as witness, spokesman, and helper for the church, is a continuation of the glorious revelation and manifestation (Greek *epiphaneia*).

Irenaeus calls John the beloved disciple who wrote the Gospel in Ephesus. Papias mentions John the son of Zebedee, the disciple, as well as another John, the presbyter, who might have been at Ephesus. From internal evidence the Gospel was written by a beloved disciple whose name is unknown. Because both external and internal evidence are doubtful, a working hypothesis is that John and the Johannine letters were written and edited somewhere in the East (perhaps Ephesus) as the product of a "school," or Johannine circle, at the end of the 1st century. The addressees were Gentile Christians, but there is accurate knowledge and much reference to Palestine, which might be a reflection of early Gospel tradition. The Jews are equated with the opponents of Jesus, and the separation of church and synagogue is complete, also pointing to a late-1st-century dating. The author of John knows part of the tradition behind the Synoptic Gospels, but it is unlikely that he knew them as literary sources. His use of common tradition is molded to his own style and theology, differing markedly with the Synoptics in many ways. Yet, John is a significant source of Jesus' life and ministry, and it does not stand as a "foreign body" among the Gospels. Confidence in some apostolic traditions behind John is an organic link with the apostolic witness, and, from beginning to end, the confidence is anchored in Jesus' words and the disciples' experience—although much has been changed in redaction. Traces of eyewitness accounts occur in John's unified Gospel narrative, but they are interpreted, as is also the case with the other Gospels. Clement of Alexandria, a late-2nd-century theologian, calls John the "spiritual gospel" that complements and supplements the Synoptics. Although the Greek of John is relatively simple, the power behind it (and its "poetic" translation especially in the King James Version) makes it a most beautiful writing. Various backgrounds for John have been suggested: Greek philosophy (especially the Stoic concept

Theories of various backgrounds of the Gospel According to John

of the *logos,* or "word," as immanent reason); the works of Philo of Alexandria, in which there is an impersonal *logos* concept that can not be the object of faith and love; Hermetic writings, comprising esoteric, magical works from Egypt (2nd–3rd centuries AD) that contain both Greek and Oriental speculations on monotheistic religion and the revelation of God; Gnosticism, a 2nd-century religious movement that emphasized salvation through knowledge and a metaphysical dualism; Mandaeanism, a form of Gnosticism based on Iranian, Babylonian, Egyptian, and Jewish sources; and Palestinian Judaism, from which both Hellenistic and Jewish ideas came. In the last source there is a Wisdom component and some ideas that possibly come from Qumrān, such as a dualism of good versus evil, truth versus falsehood, and light versus darkness. Of these backgrounds, perhaps, all have played a part, but the last appears to fit John best. In the thought world of Jewish Gnosticism, there is a mythological descending and ascending envoy of God. In the prologue of John, there is embedded what is proclaimed as a historical fact: The Logos (Word) took on new meaning in Christ. The Creator of the world entered anew with creative power. But history and interpretation are always so inextricably bound together that one cannot be separated from the other.

In John there is a mixture of long meditational discourses on definite themes and concrete events recalling the structure of Matthew (with events plus discourses); and, although the source problem is complex and research is still grappling with it, there can be little doubt that John depended on a distinct source for his seven miracles (the sign [or *sēmeia*] source): (1) turning water to wine at the marriage at Cana; (2) the healing of an official's son; (3) the healing of a paralytic at the pool at Bethzatha; (4) the feeding of the multitude; (5) Jesus walking on water; (6) the cure of one blind from birth; and (7) the raising of Lazarus from the dead. In chapter 20, verse 30, the purpose of the signs is stated: "Jesus did many other signs in the presence of the disciples, which are not written in this book; but these are written that you may believe that Jesus is the Christ, the Son of God, and that believing you may have life in his name."

The sign source for John

A major part of John is in the form of self-revelatory discourses by Jesus. Some would assign these to a distinct source, but they may rather be the work of the author.

Jesus' coming "hour"—the hour of his glorification—could not come about at any bidding but only according to a divine plan, and Jesus is obedient to it. The Paraclete is promised to come to the disciples, and it is necessary that Jesus go away in order that the Paraclete may come to the church. In John, Christ is depicted as belonging to a higher world, and his kingship is not of this world. He is said to have come into this world to his own people, and they rejected him, but this is but another example of the church's mission having passed both historically and theologically to the Gentile milieu.

The Christology in John is heightened: though the Synoptics have Jesus speaking about the Kingdom, in John, Jesus speaks about himself. This heightened Christology can be seen in many of the "I am" sayings of Jesus *(e.g.,* "I am the bread of life") in the context of their discourses and accompanying signs. This type of discourse is a concentration in terms and titles of the way in which the Messiah openly reveals his identity by a striking phenomenon: in the Old Testament the association with "I am" is the revelation of the name of God in the theophany (manifestation of God) to Moses (Exodus), and this theophanic interpretation carries over in John. Jesus says "I am" with regard to his function as Messiah, as divine. These sayings are self-revelatory pronouncements: (1) bread of life, (2) light of the world, (3) door of the sheepfold, (4) good shepherd, (5) resurrection and life, (6) way, truth, and life, and (7) true vine. Such theophanic expressions are heightened in other sayings: "I and the Father are one"; "Before Abraham was, I am"; "He who has seen me has seen the Father"; and Thomas' cry after the Resurrection "My Lord and my God."

The "I am" pronouncements

John 14 is a farewell speech, one of a series, before the Passion. In testament form, it is the bidding of farewell by one who is dying and giving comfort to those he loves. In John, however, the eons (ages) overlap. The significance of the farewell address, thus, is in the teaching that Jesus is God's representative. The fact that he must go to the Father means that the eschatological era already started in Jesus' presence as the Christ and will be intensified at his death and manifested further in the coming of the Spirit to the church. The times shift; the eschatology—here and still to come—also shifts but remains on the whole realized in John, although there is still a tension between the "already" and the "not yet."

John's allegorical thought is shown by his ending of the miracle of Jesus' walking on the sea. The frightened disciples took him into their boat, "and immediately the boat was at the land." This fits the pattern of John's Gospel, namely that, when Jesus is with his church, the new era has already arrived, and, where Jesus is, there is the Kingdom fulfilled. Similarly, the raising of Lazarus in chapter 11 is to demonstrate that the power of the Resurrection, of the fulfilled "eschaton" (last times), is already present in Jesus as Christ now, not only in some future time. Thus, there would appear to be a "realized eschatology" in John; *i.e.,* the last times are realized in the person and work of Jesus. The coming of the Spirit, the Paraclete, however, is still to come, so, even in this most eschatological Gospel, there is a building up, a crescendo, of glorification. In chapter 12, verse 32, Jesus is depicted as saying, "I, when I am lifted up . . . will draw all men to myself"—again an exaltation and glorification that points to the Cross. At the point of death on the Cross, Jesus' words "It is finished" are interpreted to mean that part of the "eschaton" is consummated, fulfilled. After the finding of the empty tomb, there is a Resurrection appearance to the disciples. This includes the "doubting Thomas" pericope, which teaches that those who have to depend on the witness of the Gospel are at no disadvantage.

In an appended chapter, 21, there is a touching story of the Apostle Peter, who, having denied his Lord thrice, is three times asked by Jesus if he loves him. Peter affirms his knowledge that Jesus knows what love is in his heart and is given the care of the church and a prediction that he himself will be persecuted and crucified.

The numerous differences between the Synoptics and John can be summed up thus: in John eternal life is already present for the believer, while in the Synoptics there is a waiting for the Parousia for the fulfillment of eschatological expectations. This Johannine theology and piety has great similarities to the views that Paul criticizes in I Cor. 15 (see below). The contrast between Paul and John is even more striking if one accepts the most plausible theory that John as we have it includes passages (added later) by which the realized eschatology has been corrected so as to fit better into the more futuristic eschatology that was stressed in defense against the Gnostics. John 5:25–28 is such a striking correction.

Differences between John and the Synoptics

The Johannine chronology also differs from the Synoptic. John starts the public ministry with the casting out of the money changers: the Synoptics have this as the last event of the earthly ministry leading to Jesus' apprehension. The public ministry in John occupies two or three years, but the Synoptics telescope it into one. In John Jesus is crucified on 14 Nisan, the same day that the Jewish Passover lamb is sacrificed; in the Synoptics Jesus is crucified on 15 Nisan. The difference in the chronologies of the Passion between John and the Synoptics may be because of the use of a solar calendar in John and a lunar calendar in the Synoptics. Nevertheless, the actual dating is of less importance than the fact that John places the Crucifixion at the time of the Passover sacrifice to emphasize Jesus as the Paschal lamb. There is no celebration of the Last Supper in John, but the feeding of the multitude in chapter 6 gives the opportunity for a eucharistic discourse. Because Jesus is regarded as the Christ from the very beginning of John, there is no baptism story—John the Baptist bears witness to Jesus as the Lamb of God—no temptation, and no demon exorcisms. Satan is vanquished in the presence of Christ. Each of the four Gospels presents a different facet of the picture, a different theology. Although in all the Gospels there is warning about persecution and the danger of discipleship, each has the retrospective comfort

of having knowledge of the risen Lord who will send the Spirit. In John, however, there is a triumphant, glorious confidence: "In the world you have tribulation; but be of good cheer, I have overcome the world."

THE ACTS OF THE APOSTLES

The relationship between Luke and Acts

As indicated by both its introduction and its theological plan (see *The Gospel According to Luke*), Acts is the second of a two-volume work compiled by the author of Luke. Both volumes are dedicated to Theophilus (presumably an imperial official), and its contents are divided into periods. In the Gospel, Luke describes first the end of the old dispensation and then the earthly life of Jesus. Near the end of the Gospel, the stage is set for the next period: the "new dispensation" of the church as presented in Acts. After the Ascension of the risen Lord in Jerusalem (Acts 1), there is Pentecost, called Shavuot in Hebrew (*i.e.*, "the 50th day" after Passover). This Jewish festival of the revelation of the Law on Mt. Sinai becomes the day when the Spirit is poured out. For Acts this event marks the beginning of a new era (Acts 2): as in Luke, Jesus, endowed by the Spirit, was led from Nazareth to Jerusalem, so in Acts, the outpouring of the Spirit at Pentecost leads the church from Jerusalem to Rome.

The purpose and style of Acts. Although the title, Acts of the Apostles, suggests that the aim of Acts is to give an account of the deeds of the Apostles, the title actually was a later addition to the work (about the end of the 2nd century). Acts depicts the shift from Jewish Christianity to Gentile Christianity as relatively smooth and portrays the Roman government as regarding the Christian doctrine as harmless. This book is the earliest "church history," viewing the church as guided by the Spirit until a future Parousia (coming of the Lord).

Probably written shortly after Luke (*c.* 85) as a companion volume, in no manuscripts or canonical lists is Acts attached to the Gospel.

Luke edited his history as a series of accounts, and thus Acts is not history in the sense of accurate chronology or of continuity of events but in the ancient sense of rhetoric with an apologetic aim. The author weaves strands of varying traditions and sources into patterns loosely clustered around a nucleus of past events viewed from the vantage point of later development.

The structuring of the material by time and geography may account for the unique way in which both the Ascension of Christ to heaven (40 days after the Resurrection) and the outpouring of the Spirit at Pentecost (50 days after the Resurrection) became fixed and dated events.

The redactor (editor) of Acts composed speeches with primary primitive material within them; about one-fifth of Acts is composed in this way. This manner of using speeches was part of the style and purpose of the work and was not unlike that of other ancient historians such as Josephus, Plutarch, and Tacitus.

The use of speeches and the "we-passages"

In the latter part of Acts are several sections known as the "we-passages" (*e.g.*, 16:10, 20:5, 21:1,8, 27:1, 28:16) that appear to be extracts from a travel diary, or narrative. These do not, however, necessarily point to Luke as a companion of Paul—as has been commonly assumed—but are rather a stylistic device, such as that noted particularly in itinerary accounts in other ancient historical works (*e.g.*, Philostratus' *Life of Apollonius of Tyana*). Though the pronoun changes from "they" to "we," the style, subject matter, and theology do not differ. That an actual companion of Paul writing about his mission journeys could be in so much disagreement with Paul (whose theology is evidenced in his letters) about fundamental issues such as the Law, his apostleship, and his relationship to the Jerusalem church is hardly conceivable.

Acts was written in relatively good literary Greek (especially where it addresses the Gentiles), but it is not consistent, and the Koinē (vernacular) Greek of the 1st century was apparently more natural to the writer. There are some Semitisms, especially when stressing Jewish backgrounds; thus, Paul is called Saul in accounts of his conversion experience on Damascus road. In chapter 17, Paul's speech on the Areopagus, a hill in Athens that traditionally was the meeting place of the city's council, for an intellectual Athenian audience is in good Greek, assimilating Gentile thought patterns, but is expressed in Old Testament universalistic terms.

The content of Acts. The outline of Acts can be roughly divided into two parts: the mission under Peter, centred in Jerusalem (chapters 1–12); and the missions to the Gentiles all the way to Rome (*cf.* chapter 1, verse 8), under the leadership of Paul (chapters 13–28). The earlier sections deal with the Jerusalem church under Peter and the gradual spread of the gospel beyond Jewish limits (in chapters 10–11, for example, Peter is led by the Spirit to baptize the Roman centurion, Cornelius). References to Peter are abruptly ended in chapter 12; James, the brother of the Lord, has become the head of the Jerusalem church, and Philip, a Greek-speaking missionary, is commanded by the Spirit to baptize an Ethiopian eunuch.

Paul's missionary journeys and primitive traditions about Jesus

Paul's missionary journeys are traditionally separated into three: (1) 13:1–14:28; followed by the Council of Jerusalem *c.* AD 49 (15:1–35); (2) 15:36–18:22 with a stop at Antioch; and (3) 18:23–21:14. After that, Paul is imprisoned and sent to Rome where Acts leaves him witnessing openly and unhindered in the capital of the Empire. These journeys may be seen as a part of the writer's "theological geography," because they form one continuous circuit—with stops on the way—between the geographical poles of Jerusalem and Rome. After the Council of Jerusalem *c.* AD 49, the situation was changed, and Paul became the spokesman for the whole Christian mission.

The earliest chapters of Acts contain some primitive traditions important both for any study of the early church and its preaching and for the church's own development of its understanding of itself and of Jesus. After Peter healed a lame man, he made a speech, in chapter 3, in which Jesus is proclaimed as the one appointed but who is now in heaven and who will come as the Christ at the Parousia (Second Coming). In his Pentecost speech in chapter 2, Peter preached that God made Jesus Lord and Christ at his Resurrection.

The titles used for Jesus show both a preservation of primitive tradition and theology and a clear differentiation made by the writer between Jesus in his earthly life (in Luke) and reflection on him in Acts. Christ (Messiah) is consciously used as the title of Jesus; the title Son of man, used frequently in Luke, is used only once in Acts, at the death of the martyr Stephen, when he is granted a vision of the Lord in glory. Early titles, "servant" and "righteous one," reflect the Old Testament background of God's "suffering servant." The Hellenistic term saviour (*sōtēr*) is used in Acts in chapters 5 and 13. The more primitive Christologies and titles show not only a flexibility of traditions but also the functional nature of New Testament Christology.

Differences between views of Paul in Acts and in Paul's Letters

Acts presents a picture of Paul that differs from his own description of himself in many of his letters, both factually and theologically. In Acts, Paul, on his way to Damascus to persecute the church, is dramatically stopped by a visionary experience of Jesus and is later instructed. In his letters, however, Paul stated that he was called by direct revelation of the risen Lord and given a vocation for which he had been born (recalling the call of an Old Testament prophet, such as Jeremiah) and was instructed by no man.

The account of Paul's relation to Judaism in Acts also differs from that in his letters. In Acts, Paul is presented as having received from the Jerusalem apostolic council the authority for his mission to the Gentiles as well as their decision—the so-called apostolic decree (15:20; *cf.* 15:29)—as to the minimal basis upon which a Gentile could be accepted into fellowship with Jewish Christians. According to this decree, Gentile converts to Christianity were to abstain from pollutions of idols (pagan cults), unchastity, from what is strangled, and from blood (referring to the Jewish cultic food laws as showing continuity with the old Israel). Circumcision, however, was not required, an important concession on the part of the Jewish Christians.

In Acts Paul is not called an Apostle except in passing, and the impression is given, contrary to Paul's letters, that he is subordinate to and dependent upon the twelve Apostles. When Paul entered a new city, he went first to the synagogue. If his message of the gospel was rejected,

he turned to the Gentiles. According to Paul's missionary practice and theology, the message had first to be spoken to the Jews as a reminder that Christianity is grounded in redemptive history; this prevents the connection with the old Israel from being forgotten. Because most Jews rejected Paul's message, the author proclaimed that salvation thus passed to the Gentiles.

Paul's relationship to the Romans and the dominance of the Holy Spirit

Roman authorities are depicted as treating Paul (and other Christians) in a just manner. The author repeatedly stressed that the Roman authorities did not find fault with the Christians but rather viewed Christian–Jewish antagonisms merely as one problem among Jewish factions. While in Corinth, during a conflict with the Jews, the Roman proconsul of Achaea in Greece, Gallio, refused to hear the charges brought against Paul because, according to Roman law, they were extralegal. On a later occasion in Ephesus, during a conflict with the silversmiths who derived their income from selling statuettes of the goddess Diana, Paul was protected from local antagonisms and a riot by Roman authorities. Toward the end of his career, after having been in the protective custody of the Judaean procurator Felix, Paul was heard by Felix's successor, Festus, and the Jewish king Agrippa II, and, had he not appealed to Caesar as a Roman citizen, he could have been set free. He thus had to go to Rome to be tried, and that is the last that is heard about him in Acts.

The doctrine of the Holy Spirit is a dominant theme in Acts, as it is in the Gospel According to Luke. Just as Jesus started his public ministry in Luke by reading from the Book of Isaiah: "The Spirit of the Lord is upon me . . ." so also in Acts the new age of the Spirit began at Pentecost, which is viewed as the fulfillment of the prophecy of Joel that in the new age the Spirit would be poured out on all men. That persons from many nations heard in their own tongues the mighty works of God has been viewed as a reversal of the Tower of Babel narrative, with languages no more confused and people no longer scattered.

Although Peter, Stephen, and Paul are central figures in Acts, the piety of the humbler members of the church also permeates the book. Church structure and organization, with apostles, disciples, elders, prophets, and teachers, exhibits great fluidity. Paul, in bidding farewell at Miletus to the elders from Ephesus, exhorted them to "take heed . . . to all the flock in which the Holy Spirit made you guardians (bishops) to feed the church. . . ." Offices may be conveyed by prayer and laying on of hands but there is little stress on distinction of office or succession, thus indicating a very early period in the life of the church.

Because Peter "departs and goes to another place" and Paul is left under house arrest awaiting trial, the readers appear to be left in suspense concerning the fates of these two leaders. The readers, however, probably knew what had happened to them—*i.e.,* that these Apostles had eventually been martyred sometime in the 60s before Acts was written. What is more, the interest in Acts is not in the fates of Peter and Paul; the gospel has finally reached Rome, the center of the *oikoumenē* ("the inhabited world"), and thus the ending is suitable to the book—Paul is left "preaching the kingdom of God and teaching about the Lord Jesus Christ quite openly and unhindered."

THE PAULINE LETTERS

In the New Testament canon of 27 books, 21 are called "letters," and even the Revelation to John starts and ends in letter form. Of the 21, 13 belong to the Pauline corpus; the Letter to the Hebrews is included in the Pauline corpus in the East but not, however, in the West. Three letters of this corpus, the Pastoral Letters, are pseudonymous and thus are not considered here. Of the remaining 10, the Letters to the Colossians and Ephesians are from the hand of a later Pauline follower and II Thessalonians is spurious. How this Pauline corpus was collected and published remains obscure, but letters as part of Holy Scripture were an early established phenomenon of Christianity.

The church was poor and widespread, and, in the early stages, expected an imminent Parousia. More formal sacred writings were thus superseded in importance by letters (*e.g.,* those of bishop Ignatius of Antioch) that answered practical questions of the early churches.

The letters of Paul, written only about 20–30 years after the crucifixion, were preserved, collected, and eventually "published." In general, they answered questions of churches that he had founded. When all the Pauline Letters as a corpus were first known is difficult to determine. Because Pauline theology and some quotations and allusions were certainly known at the end of the 1st century, the Pauline Letters probably were collected and circulated for general church use by the end of the 1st century or soon thereafter. A disciple of Paul, possibly Onesimus, may have used Ephesians as a covering letter for the whole collection.

The letters Galatians and Romans both contain an extensive discussion about the Law (Torah) and justification (in language not found in the other letters) to solve the problem of the relation of Christianity to Judaism and of the relationship of Jewish Christians with Gentile Christians. Galatians is older and differs from Romans in that it deals with Judaizers—*i.e.,* Gentile Christians who were infatuated with Jewish ways and championed Jewish ceremonial law for Gentile Christians. On the other hand, Romans speaks to the question of the Jews and the Christian faith and church in God's plan of salvation.

The significance of the Pauline Letters to the addressees

In I and II Corinthians (which may include fragments of much Corinthian correspondence preserved in a somewhat haphazard order), there is no preoccupation with either Jews or Judaizing practices. They deal with a church of Gentile Christians and are therefore the best evidence of how Paul operated on Gentile territory.

The earliest book in the New Testament is I Thessalonians, which is concerned with the problem of eschatology. Though II Thessalonians is obvious in its imitation of the style of I Thessalonians, it reflects a later time, elaborates on I Thessalonians, and is thus not viewed as genuine.

Philippians may be a composite letter in which various themes of Pauline teaching are held together by a testament form. Thus, it is a compendium without too specific a focus on the Philippian situation. Philemon, although addressed to a house church, is uniquely concerned with the fate of a slave being returned to his master, with the hope that he will be forgiven and be sent back to help Paul in prison, an example of manumission in Paul's name.

Ephesians appears to be dependent on Colossians, and both, although using the Pauline style, reflect a time and imagery sometimes different from and later than Paul's genuine letters. Ephesians covers the content of Colossians in more compact form and may be a covering letter for the entire Pauline corpus by a disciple or other later Paulinist.

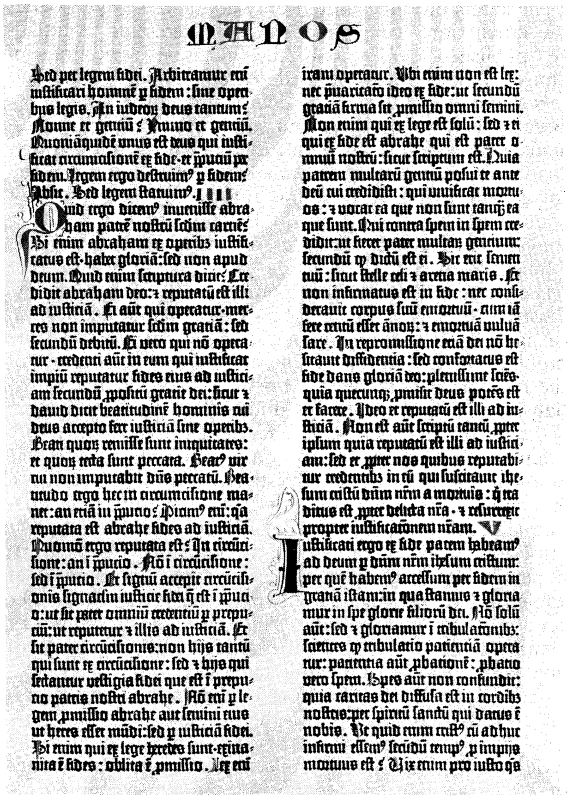
The style and form of Paul's letters

The style of Paul's letters is an admixture of Greek and Jewish form, combining Paul's personal concern with his official status as Apostle. After his own name, Paul names the addressees or congregation being addressed and adds "grace and peace." This is often followed by thanksgivings and intercession that are significantly adapted to the content and purpose of the letter. Doctrinal material usually precedes advice or exhortation (*parenesis*), and the letters conclude with personal news or admonition and a blessing: "The grace of our Lord Jesus Christ be with you." Paul's letters were probably dictated to an amanuensis (who might be named, for example, Sosthenes, I Cor. 1:2), and some greetings were written at the end of the letters in his own hand. They were obviously meant to be read aloud in the church, however, and thus their style is different from that of purely personal letters.

The reason for Paul's Letter to the Romans

The Letter of Paul to the Romans. Romans differs from all the other Pauline letters in that it was written to a congregation over which Paul did not claim apostolic authority. He stressed that he was merely going to Rome in transit, because it was his principle not to evangelize where others had worked. Because his apostolic ministry appeared to be completed in Asia Minor and Greece, Paul planned to go to Spain via Rome, a city that he had never visited. Before going westward, however, he first had to go to Jerusalem to deliver to the church there a collection of money.

Because Paul was going to a church he had not founded, his writing to the Roman Christians offered him an opportunity to present his theological views in a systematic way, which he had not done in other letters. Paul reflected



The end of chapter 3, chapter 4, and the opening of chapter 5 of the Letter of Paul to the Romans from a facsimile of Gutenberg's 42-line Bible. In the British Museum.

on how his special mission fitted into God's plan for the salvation of mankind, of both Jews and Gentiles—a theme that reached its climax in chapters 9–11. Chapters 1–8 unfold with great specificity how the coming of Jesus the Messiah has made it possible for the Gentiles to become heirs to God's promises. His argument is at first negative, stating that neither Gentile nor Jew could effect his own salvation. He then shows a new way in which eventually both can be delivered from the bondage of sin by being justified—*i.e.,* made "right with God"—not through acceptance of the Law but by faith in the crucified Lord.

The theological section (chapters 1–11) is followed (as is often the case in Pauline letters) by ethical instructions. There is little doubt about the integrity of Romans 1–15; the letter was written from Corinth *c.* 56. Chapter 16, however, seems to be a later addition. It contains numerous salutations to individuals (which is unusual in that Paul had never been to Rome) and an antinomian (antilegalistic) tone that would be more appropriate to the situation in Asia Minor. The doxology (16:25–27) is rhetorical and its vocabulary is not in keeping with that of Paul's usual thought. Because the doxology occurs in different manuscripts in varying positions in the course of textual transmission, it is probably secondary. Chapter 16 may thus preserve portions of a letter or letters from some other time or to some place other than Rome, possibly Ephesus.

The main theme of the Letter to the Romans

In chapter 1, verses 1–17, there are greetings and thanksgivings leading to the main theme of the letter: the gospel is

> the power of God for salvation to every one who has faith (*i.e.,* that Jesus is the Messiah), to the Jew first and also to the Greek. For in it the righteousness of God is revealed through faith for faith; as it is written, "The righteous shall live by faith."

Paul took this sentence from the Old Testament Book of Habakkuk, chapter 2, verse 4, not as a principle but as a prophecy now fulfilled. Thus, the translation should read "will live" rather than "shall live." This does not refer to God's faithfulness but rather to the believer's trust. Justification by faith is not, however, the answer to the question of man, plagued by conscience, about his salvation nor is it deep theology. It is rather an argument totally grounded in the problem of the relationship of Jews and Gentiles—*i.e.,* how it will be possible for the Gentiles to be fellow heirs with Jews and how both Jews and Gentiles can be members of the church. In chapters 2–3 both Gentiles and Jews are demonstrated to have fallen short of the glory of God and to be under condemnation. A turning point, however, is emphasized in chapter 3: "But now the righteousness of God has been manifested apart from law. . . ." Justification is a gift through Jesus Christ and his expiating death for the salvation and vindication of all who believe in him. Because all this is through Christ and not by works of the Law, salvation is equally available to the Gentiles as well as to the Jews. For both, the means is the same: faith in Jesus the Christ.

The central problem after chapter 8, which describes the glory of the new dispensation in Christ and the Spirit (presented in chapters 9–11), centres on the mystery revealed to Paul, namely, that the Gentiles should be incorporated and be fellow heirs with the Jews. This is what Paul yearned for with respect to his fellow Jews. What makes it equally possible for Jew or Gentile to come to Christ is justification by faith, with the Law viewed as obsolete because Christ is the end of the Law (chapter 10, verse 4). Thus, there are, in effect, no distinctions between Gentile and Jew. Paul viewed his ministry as having made possible the inclusion of the Gentiles; as an apostle to the Gentiles he never urged them to carry on a mission to the Jews. He envisaged the Jewish acceptance of Christ as a mystery beyond human planning and effort, a divine event that will be the climax of history.

The ethical section (12:1–15:13) has no special reference to a situation in Rome. A close analysis shows that Paul here repeats thoughts and admonitions that are more specific in other letters. A metaphor of the church as a body (12:5), for example, is stylized and compressed as compared with the fuller use of the same in I Corinthians, chapter 12, and the pattern of weakness and strength in matters of food is best understood in the light of the fuller exposition in I Corinthians, chapters 8 and 10.

The First Letter of Paul to the Corinthians. This letter is part of Paul's correspondence with the Corinthian congregation founded by him and composed of Gentile Christians. The problems of Galatians and Romans, written to Christians with Jewish and Roman legal concepts, are different from those of I Corinthians, and, thus, the justification language is absent.

Except for the brief communication with Philemon (see below), I Corinthians is the most specifically practical, situation-oriented of Paul's letters. No other Pauline letter is so directly devoted to the consideration of practical and theological problems, many of them apparently communicated by the congregation through correspondence or by delegations. The letter, therefore, does not tend to stand as a unit and it is not uniform in its treatment of the varying situations.

Emphasis on practical and theological problems

Literary criticism—or redaction—has traditionally split the letter into several fragments with a presumed historical development within a relatively short period in the Corinthian church. Paul's reference to a previous letter of his in chapter 5, verse 9, has been the object of scholarly efforts to restore the earlier letter. The fragmentary and not-too-uniform nature of both I and II Corinthians, however, precludes much probability of success in such searches.

Writing from Ephesus *c.* 53 or 54 upon hearing from a certain Chloe's people that the church was rent by party factions, Paul tried to bring unity to the congregation. Whether these factions actually represented outside interference (*e.g.,* Cephas [Peter], Apollos, or others) or were factions of the congregation under the influence of a widespread heresy of the time is a question perhaps best answered by the fact that the factions do not come up again after I Corinthians, chapter 1, and that I Corinthians, chapter 3, reduces the factions to Apollos and Paul, who claims he is head of no party. The Christ "party"—*i.e.,* those who claim no party at all—(1:12; *cf.* 3:23) may be the only "party" Paul advocated because Christ is not divided. Paul warned that Christians should not fashion

themselves into parties under various leaders, because all these leaders are servants of Christ and stewards of the mysteries of God through whom Christians come to belief. The church is not a society with competitive philosophical schools.

The cause of the difficulties in Corinth: proto-Gnosticism

The letter is a response to difficulties caused or increased by a relatively strong group in Corinth that may be described as "enthusiasts." This group of enthusiasts may have been proto-Gnostics (early religious dualists not yet organized into definite sects). The Corinthian enthusiasts did, however, have some characteristics that would later be found in 2nd–3rd-century Gnosticism: a belief in salvation through spiritual knowledge or wisdom communicated by a revealer (not a redeemer); an otherworldliness that could lead either to licentiousness (scorn) or asceticism (withdrawal); and a basically dualist and deliberately syncretistic system of beliefs using the mythical speculations and magical ideas of their time.

The Corinthian problems might well be traced to such enthusiasts. Their *gnōsis* ("esoteric knowledge") was a religious knowledge that gave them the feeling of superiority over more pedestrian Christians. This *gnōsis* Paul identified as false wisdom. In chapter 14 Paul describes the views and related practices of those maintaining that they have spiritual gifts of inspiration, especially speaking in tongues (glossolalia) and *gnōsis.* Such enthusiasts prized eloquent or secret wisdom; they sought a revealer who had come into the world hidden from the evil powers and known only to those, the *pneumatikoi,* or the spiritual elite, who recognize him; and they tolerated gross immorality by claiming anything to be lawful for them (especially their slogan quoted by Paul: "for me all things are lawful"). These enthusiasts also rejected marriage because it furthered the propagation of the present evil world; they claimed to possess knowledge that made them indifferent to the world; and they believed that their salvation was guaranteed by ritual and rites. Though they prized spiritual gifts, they scorned the ordinary Christian services for the community; and they did not believe in a future resurrection of the dead, which in their system had no place or was nonsense.

The concept of love and views on the resurrection

The main Pauline answer (*e.g.,* as emphasized in chapter 13) was that love, namely concern for the building up of the community, surpasses all knowledge or spiritual gifts and that love is a corrective because it demands service, edification (*i.e.,* building up) of the church, and involves Christians with one another. Those Corinthians whom Paul viewed as opponents emphasized *gnōsis* over against love. The discussion of the resurrection in chapter 15 sheds further light on this. The opponents did not deny the Resurrection of Jesus Christ about which there was common agreement, but rather they debated about the future resurrection of Christians from the dead. Their view was perhaps similar to that reported as heresy in II Timothy, chapter 2, verse 18—*i.e.,* the believer already had eternal life and that a future resurrection of the body was meaningless. In holding such a view, Paul's opponents claimed they were faithful to the received kerygma (proclamation).

Another indication that some Corinthians had no disagreement with tradition but interpreted it too enthusiastically is found in I Corinthians, chapter 11. The liturgical formula pertaining to the Lord's Supper is sound:

> The Lord Jesus on the night when he was betrayed took bread, and when he had given thanks, he broke it, and said "This is my body which is for you. Do this in remembrance of me." In the same way also the cup, after supper, saying, "This cup is the new covenant in my blood. Do this, as often as you drink it, in remembrance of me." (11:23–25.)

In a discussion of the sacraments in chapter 10, however, the enthusiasts probably believed in a rather magical efficacy of Baptism and the Eucharist, though Paul qualified such an interpretation and took exception to it. The misunderstanding of the enthusiasts points to a special reinterpretation of Scripture and tradition (which resembles that of the 1st-century Jewish philosopher Philo and also the later Gnostics)—taking Scripture, tradition, and liturgical practices as effectively bringing about an otherworldly, spiritual reality immediately for those who really understand (*i.e.,* those who have *gnōsis*). Paul also criticized these spiritualists for their disregard of the poor members of the congregation, who found no food left when they came from their work.

The question of freedom and unity

Discussions about Christian and apostolic freedom (in chapters 5, 6, 7, 9, and 11) and also a discussion about being free to eat meat that had been sacrificed to idols and leftovers of pagan sacrifices sold in the marketplace were caused by conflicts with the enthusiasts who paraded their spiritual freedom, strength, and superiority at the expense of their weaker brothers in the faith, who were not ready for this freedom. A shift in the discussion in chapter 12 (the body and its members are equal in Christ)—from a very speculative idea of the body of Christ to a more metaphorical one that is reminiscent of Stoic philosophical ideas about society as an organism—can best be understood if it is assumed that the enthusiasts actually pressed for a mythical understanding of Christianity, in which one became literally incorporated into Christ, otherworldly, and divine. Paul added some qualifications that brought the church into concrete everyday life and even provided a source of political reality. A somewhat drastic understanding of spiritual gifts that was presupposed and criticized by Paul in chapters 12–14 fits well into such a pattern.

Permeating all the discussion of individual topics in I Corinthians is the theme of Christian unity and edification, a topic introduced and underscored in the preface and thanksgiving of this letter and in its introduction. Such unity is defended as being very inclusive, real, and concrete—as over against the enthusiastic attempt to speak in terms of spiritual reality and achievement, in which the true life of the spirit is only for the few (*i.e.,* the Gnostic elitists).

Paul viewed the necessity of unity in the wisdom of God as it is evinced in the scandal of the cross. In order to deflate the exalted and to make foolish the destructive (speculative) wisdom established by men, God showed his wisdom in the "foolishness" of Jesus' crucifixion. Here, although hidden, is God's true wisdom. The opponents hailed their ideal teachers as bringers of hidden wisdom. To this Paul said that it is Christ who is the Wisdom.

Ethical questions and views on marriage

In chapters 5 and 6 Paul dealt with certain ethical scandals and difficulties in the congregation: incest and fornication; the use of pagan courts for settling disputes among Christians; traffic with prostitutes—all for the demonstration of Christian "freedom." These wrongs might have been the direct or indirect consequences of the spiritual "powers" of the enthusiasts. According to Paul, however, such immorality was impossible for the Christian because of the concreteness of his allegiance to Christ and of inspiration (with the idea of the body as the temple of the Holy Spirit).

Because Paul expected an imminent Parousia (Second Coming of Christ), he suggested (chapter 7) the unmarried state as the preferable one, but conceded that marriage can prevent fornication. Paul even advised against breaking up mixed marriages between baptized Christians (both Jews and Gentiles) and unbaptized Gentiles. He advocated the practice of ascetics living together as "virgins," male and female, although he took this as a strain that is hard to bear and thus suggested marriage in unbearable cases. Not only the imminence of the Parousia but also radical change ("the form of this world is passing away") caused Paul, on the whole, to affirm the social status quo—whether it concern circumcision, slavery, or other matters. Everybody is advised to remain—for the short time ahead—in the state in which he finds himself. Such eschatological fervour caused Paul to argue against any worldly anxiety, fear, or worries stemming from them. This is reflected in the ethical criterion of possessing things as though one did not have them.

In chapter 9, Paul used his own conduct, in contrast to that of the enthusiasts who flaunted their freedom in such a way that it often had destructive influences, as a paradigm for an understanding of responsible freedom. Here he showed by various examples from his own lifestyle that he had never made use of his rightful privileges to the fullest, that he has, rather, been guided by what serves the weaker brothers and sisters. It is in this sense

that he subdued his body and that he urged the spiritual "snobs" to imitate him.

Discussions on corporate worship

In chapters 11–14, Paul turned to problems of corporate worship. Paul did not question the right and ability of prophetically gifted women to make inspired statements in Christian worship, but he pointed out that women need protection. Arguments about a veil or long hair for a woman are in the context of the church's worship before God himself, in which the congregation worships in the presence of the angels. Paul stressed the subordination of women in chapters 11 and 14; they are forbidden to speak in worship. In chapter 14 Paul stated (perhaps) a general principle that would allow for exceptions in cases of clear prophetic inspiration of women (*cf.* however, Galatians, chapter 3, verse 28).

In discussion of proper restraint and mutual regard in celebrating the Lord's Supper, Paul seemed to presuppose a prior common meal (possibly an agape meal) as part of the eucharistic celebration. This common meal, however, had apparently been devalued because of the interest of the enthusiasts in the sacrament itself. As a result, the communal aspect showed up social differences in the community; and some brought ample food, whereas others, of lower station, had nothing. In view of this, Paul again used the criterion of love and suggested that people eat their meal at home and then come together, being sensitive to each other's needs. The Lord's Supper would then be what it is, a proclamation of the death of Christ in anticipation of his return; mutual and corporate concern and responsibility thus become a part of the Eucharist.

Similarly, mutual edification and love are linked in chapter 13 as the appropriate centre of the discussion of spiritual gifts, manifested particularly in public worship (chapter 14).

The emphasis on the communal aspect of the church is continued in chapter 15. Paul did not dwell on his own vision of Christ nor on his role in founding the church at Corinth but rather argued for the resurrection of all as a future experience, not as though each person had already had this experience. Paul viewed the resurrection as a collective phenomenon in the expectation of an end-time resurrection from the dead, with Christ as the first fruits of those who have died.

That love is to extend beyond the immediate community and be shared with all the saints (members of the church) is demonstrated in chapter 16, the closing chapter, by the collection for the Jerusalem church. The keynote might be: "Let all that you do be done in love." The final passage—including the cry: "Our Lord, come!"—may reflect or repeat a eucharistic formula or setting.

The Second Letter of Paul to the Corinthians. This letter, as is I Corinthians, is composed of a collection of fragments of Paul's correspondence with the Corinthians about a year later (*i.e., c.* 55) from Macedonia. The diversity of I Corinthians was caused by the variety of problems discussed, but the diversity of II Corinthians was the result of a reflection of the underlying, rather turbulent history of Paul and his congregation. A pattern of fragments that make up II Corinthians can be understood in terms of a development that can be reconstructed. Gaps and editorial seams in this pattern are more recognizable and abrupt than those in I Corinthians, and a more original order for II Corinthians can be restored by fitting together blocks of material that obviously belong with one another in terms of context and unity of thought.

Though historical settings can be reconstructed with a high degree of validity to account for the fragments of II Corinthians, later editorial processes account for the order in which the fragments appear in the letter as it is now written. Based on both internal and external evidence, II Corinthians probably was later than I Corinthians, which was written after Paul's first trip to Corinth. Not long before the composition of II Corinthians, Paul was in mortal danger in Asia and travelled to Macedonia, where he remained.

New apostles and heresies had apparently invaded the Corinthian congregation and Paul sent his companion Timothy to try to bring them back to the true gospel as Paul had preached it. This mission was apparently unsuccessful, and Paul, in chapters 2 to 7, wrote to the church with a defense of his apostolic office, still counting on the loyalty of the Corinthians. His letter apparently did not change things, and there is some dispute as to whether Paul himself made an intermediate second visit to Corinth that was abruptly cut short by conflict with a member of the Corinthian church who violently opposed him. He considered such a second visit, but, according to chapter 2, verse 4, and chapters 10 to 13, he sent Titus to Corinth with a strongly polemical "letter of tears" and anxiously awaited his return, going from Troas to Macedonia to meet him.

New problems within the Corinthian congregation

Paul had almost been in despair over the Corinthians, but Titus and the letter seemed to have restored the Corinthian church to order. Titus and some of his companions were then sent to take up the collection for the church at Jerusalem, a sign of Christian mutual love and unity. He took with him Paul's "letter of reconciliation," which was written from Macedonia and which can be noted in chapter 1, verse 1, to chapter 2, verse 3; chapter 7, verses 5 and 6; and chapter 8. In chapter 8 the Macedonians are held up as an example of generosity. A similar section regarding the collection is in chapter 9, and the Achaeans (and probably their capital city, Corinth) were cited as an example to the Macedonians for generous giving. This was probably sent shortly before Paul's third (and last) visit to Corinth. From Corinth Paul wrote to the Roman church a letter that shows no sign of difficulties with the Corinthians and that presumed the conveying of the collection to Jerusalem.

The problem of the "letter of tears" and the "letter of reconciliation"

If the Corinthian controversy had been smoothed out, a question is raised as to why II Corinthians ends in the "letter of tears" rather than in the "letter of reconciliation." This may be understood if the literary order of the several sections was arranged by a redactor who collected the fragments probably in the last decade of the 1st century. The redactor may have used a "form" amply illustrated in Christian writings of the late 1st and early 2nd century; one of the end-time expectations was that "false prophets would show signs and wonders to lead the elect astray," and chapters 10–13 deal with "false prophets" and "servants of Satan." Such warnings were placed at the end of writings of that time.

Several abrupt editorial seams that resulted from an arrangement of a letter of reconciliation, an apology on the nature of Paul's apostolic authority, a polemic against opponents, two letters concerning the collection, and a possible non-Pauline insertion (in chapter 6, verse 14, to chapter 7, verse 1) can thus be understood. The reconciliation of chapters 1 and 7 is hardly in agreement with Paul's elaborate defense of his ministry in chapter 2. Even more jarring to such a reconciliation is the polemic of chapters 10–13. These latter chapters are viewed as a substantial fragment of Paul's "letter of tears," after which the Corinthians disengaged themselves from outside agitators and caused them to leave. Such opponents, who are mentioned in chapter 11, verse 4, and who tried to attract the congregation away from Paul's ideas, were probably Hellenized Jewish Christians from Palestine.

The problem of outside agitators

The outside agitators (who provoked the response of chapters 10–13) probably were Christians who imitated the Hellenistic-Jewish missionaries and had developed an elaborate propagandizing missionary theology and practices analogous to the missionary movements in the pagan world. Their goal was to prove the spiritual power of their own religion in conscious and aggressive competition with other religions, thus hoping to attract others and convert them to Christianity.

The major criteria for successful competition were affinity or identity with the ancient Mosaic traditions and objective manifestations of the current power of that tradition in the form of miraculous demonstrations. The link between the ancient traditions and the current careers of the itinerant missionaries was the record of Jesus as understood from the miracle stories of the Gospels—a demonstrated epiphany of the powers of the Spirit. These missionaries were seen as "divine men," as were the heroes of old. Their miracles were to be imitated. Such traditions about Jesus as a wonder-worker might have been used by

Paul's opponents, with over-emphasis on such works as criteria of power.

Paul's attacks on the "super-apostles"

That which Paul attacks as "bragging" or "boasting," particularly the preaching of the so-called "super-apostles," in chapter 11, verse 5, was probably understood by his opponents as no more than faithful testimony to, and a demonstration of, the spiritual powers of tradition as they perceived it in their own experiences. To them faithfulness to Jesus was primarily the acknowledgment of Jesus' being the most powerful "divine man" and, secondarily, their establishment and maintenance of relationship to him through imitation in their powerful demonstrations and wondrous acts.

Paul (who in I Corinthians, chapter 1, had advocated the dialectic of the cross) would thus be discredited by miracle-working men like the opponents in II Corinthians. Paul's credibility and validity as an Apostle came into question along with his Christology, which was a "theology of the cross." Confronted with the challenge of the powerful "super-apostles," Paul's message could be distorted as hiding his own inability or incapacity—an apostle who dared not take money because, being an ineffective speaker and a weak person, he had nothing for which to ask payment. His defense was Paul's first attempt to deal with these new problems caused by invading opponents who had undercut his authority.

Paul's defense of his own apostleship

Paul centred his defense around the issue most debated; true apostleship and his own sufficiency. Because he derived his ministry from God himself as a servant preaching not himself but Jesus Christ as Lord, no "peddler of God's word or selling or recommendation is called for, but only the living record—*i.e.,* the people brought to believe in Christ. Paul quickly alluded to his own weakness and "carrying in the body the death of Jesus, so that the life of Jesus may also be manifested . . ." (chapter 4, verse 10). Paul found his weakness one of the things that made him one with the Lord and that made his ministry a true ministry of Jesus Christ, who was crucified through weakness but lives by the power of God—as does his true apostle. This weakness seems to refer to a physical handicap of Paul's (epilepsy?), the "thorn in the flesh" that interfered with his travel plans.

Paul placed his own apparent weakness, in which he proclaimed that God had manifested himself, against the boastings of the "super-apostles." Unlike them, he strikes a non-heroic note. It is confidence in the power of Jesus' Resurrection that produces glory for the Gospel message and final (eschatological) reward and recognition for the Apostle.

Though Paul may himself sound "enthusiastic," his statements are made with a realistic assessment of the world, as demonstrated not least in the sufferings of Paul himself. Emphasis on God's act of grace, however, makes Paul urge the Corinthians to accept him and to reach out to the promise of God's salvation even in the present.

Paul's defense of his apostleship and a following visit did not succeed. Agitation from outside opponents apparently increased and solidified. The "letter of tears" reflects this situation. Paul revealed himself personally, coming close to autobiographical statements. Paul spoke of himself only with theological purpose and as part of his tactical argument with his opponents concerning attitudes and conduct. His point was that a style of life is a reflection of an underlying theology. He demonstrated to his opponents that his work for the church is constructive, and that though he boasted of his ministry, he boasted only "of the Lord," of the work Christ had done through him.

Paul's use of the technique of the "fool's speech"

In his so-called fool's speech, in which he blatantly asked the Corinthians to "bear with me in a little foolishness," Paul adopted the technique of the mime of the street theatres of his times, consciously drawing on the laughter and mockery of his audience, but then he successfully reversed the scene and made his audience realize that in laughing at him they mocked themselves, thus revealing the perversion of their criteria of superiority. Paul used metaphorical images, identifying the congregation with the bride, Jesus as the bridegroom, himself as the best man, and Satan (the opponents) as the adulterer. The plot assumed a successful seduction, and the best man who recommended the bride stands disproven. Paul then pretended to try to shift this balance by bragging about himself and scolding both seducers and the seduced. He accepted no inferiority to the opponents—the seducers ("super-apostles")—and claimed that they preached another Christ than the true Christ and brought another spirit and that he would accept no support from the church that was led astray.

In chapter 11, Paul continued to boast "as a fool," claiming to have all the qualifications of his opponents, but that he was more truly a representative of Christ. This he explained ever more intensely in an ironic and almost sarcastic trend in the dialectic of the so-called fool's speech. He boasted not of strength but of weakness—though he could boast of ecstatic experience as his opponents had—and that he had learned through bitter experience (possibly a chronic illness) that he must not exalt himself, but rather that he has been told through a word of Christ that his power is made perfect in weakness. In the enumeration of his qualifications, Paul has jested "as a fool" concerning his suffering, visions, miraculous heavenly travels, and oracles. Yet, it is clear that through Christ these modes of experience and communication have been transformed. Thus, Paul establishes that he is a true apostle and not inferior to the "super-apostles."

Paul's intention to visit the congregation again

Paul expressed his intention of visiting the congregation and told them that he desired to come not as a judge but as a father. Neither he nor Titus had or would deceive or take advantage of them. At this, the end of the "letter of tears," Paul announced his possible third visit and revealed a definite fear that he might be forced to act as a judge of the congregation, which was increasingly falling away from the apostolic gospel. Paul, however, still hoped that reconciliation might be accomplished, that truth would prevail, and that his authority could be used for building up rather than destruction. He exhorted the community to keep peace and blessed them.

The "letter of reconciliation," found in chapters 1, 2, and 7, assumed that Titus had returned with good news of the Corinthians, their eagerness to prove that they had amended their ways. Paul responded with a report of the consolation this had brought him and of the grave danger he had escaped (in prison in Ephesus). He exhorted the church at Corinth to remember the Christian message in love—of Paul for them and of the congregation for him. The shadow between Paul and the Corinthians had been dispersed, and Paul reaffirmed his constant and continuous concern for them and God's love in Christ manifest in Baptism and the gift of the Spirit. Paul interceded for a man who had offended him and forgave him. Paul then told the Corinthians of his eagerness for Titus' news of them that occasioned his special trip to Macedonia. This news brought joy and consolation; therefore, Paul urged the Corinthians again to forgive the man who had offended him.

Fragments of two letters concerning the collection for Jerusalem, a sign of unity of the church (chapter 8 especially being close to the "letter of reconciliation" and chapter 9, a fragment probably later than chapter 8), are signs that Paul's relation to the Corinthians again became close and joyful. The collection was a bond of mutual and reciprocal relationship that reached its climax in thanksgiving and praise of God. For the whole church he exclaimed: "Thanks be to God for His inexpressible gift!"

The Letter of Paul to the Galatians. Paul's Letter to the Galatians is a forceful and passionate letter dealing with a very specific question: the relation of Jewish Christians and Gentile Christians in the church, the problem of justification through faith not works of the Law, and freedom in Christ. Paul probably wrote from Ephesus *c.* 53–54 to a church he had founded in the territory of Galatia in Asia Minor.

The question of the relationships between Jewish and Gentile Christians

This congregation had been "unsettled" since his last visit to Galatia. Gentile Christians, Judaizers who were fascinated with Jewish customs and festivals and who asserted that Gentiles must adhere to the Law, the Torah, had attempted to undermine Paul's message and effectiveness. The Judaizers believed that Gentile Christians should be circumcised and keep the Jewish food laws. There were

probably some Jewish Christians in this church, but the majority were Gentile Christians. Paul attacked the Judaizers vigorously by defending his own call and the independence of the revelations of his personal apostolate. This is supported by reports of agreement between him and the Jerusalem church and by argument from Scripture. In these, he proved that the Law was given only a limited role in the total history of salvation. The letter ends with Paul pointing out that through the Spirit the Christian in faith is admonished to good behaviour and brotherly love. He admonishes faith in the cross of Christ, wishes peace upon his followers, and prays for mercy on Israel.

This Pauline letter is the only one without either kindly ingression, thanksgiving, or personal greetings appended to the final blessing. It is very specific in dealing with the problems concerned. In chapter 1, an account of Paul's call, he defended his apostolic office, having received it directly from God in the revelation of Christ. He provided autobiographical data concerning his former persecution of the church and zeal in his Jewish tradition. He referred to his call on the model of that of the Old Testament prophets called by God in order that they may serve him and said that his mission had been revealed to him to be the apostle to the Gentiles. Paul viewed himself as being chosen to be an instrument to take the message of God and Christ to the Gentiles, a call rather than a "conversion experience." Handpicked as God's servant (slave), he received a revelation—not from men but by secret knowledge from God—that the Gentiles will come to the Christian faith without the Law, the Torah of the Jews. He himself could bear the Law, but he was told that the Gentiles do not need the Law in order to be accounted righteous. The conviction that the Gentiles stand equal before God was reinforced by his visit to James, Cephas (Peter), and John in Jerusalem, who confirmed his mission, enjoining him only to remember the poor (probably reference to the Jerusalem collection). Faith in Christ has thus superseded righteousness of works, and the Law is no longer needed.

The freedom of the gospel

The freedom of the gospel is the theme developed in chapters 3–4 in a series of allegorical-typological interpretations based on the Law. Paul first recalled the covenant promise to Abraham: that he "believed God and it was reckoned to him as righteousness" and that through Abraham all nations would be blessed.

In chapter 3 there is a complex line of thought: Christ has redeemed men from the curse of the Law by becoming a "curse" for men; Christ has taken away this curse by accepting it himself in order that all men by faith might receive the Spirit that was promised. But the promise had already been made to Abraham and his seed (singular), the Messiah, Christ; the Law had come only 430 years later, a sign that it is not eternal. In this chapter, Paul constructed arguments against the Law. First, the Law was added because of transgressions committed first by the people who caused Moses to shatter the first tablets of the Law and was thus not ultimate but rather time-bound, limited, and tainted by the evil reality it had to counteract; secondly, the Law was given only for a restricted time, from Moses "till the offspring should come to whom the promise had been made" (*i.e.,* Christ); thirdly, the Law came "ordained by angels through an intermediary," who is not God and thus is neither something glorious in itself nor the absolute manifestation of the salvation of God. Paul expanded on the Law in the image of a *paidagōgos* (instructor or custodian). Such a custodian is now not needed and served only as a restraint so that in God's timetable of salvation the Gentiles could be delivered after the Law has been "outgrown." Paul then showed the reasoning behind his statement that the Law was obsolete: in Christ (*i.e.,* in the church) there are no divisions between Greek and Jew, slave or free, male or female—all divisions or partitions are broken down.

Freedom from the elemental powers of the universe

Paul's arguments are bold. He even claimed that, as heirs through Christ, men were no longer bound under the elemental powers of the universe, which were apprehended as negative, as was the Law, in Paul's mind. In chapter 4 the Judaizers are said to keep themselves, like many Greeks, under astrological powers—not unlike the Jewish calendar of feasts—which kept man, according to Paul, enslaved by cosmic order. But to those free from the Law and possessing the Spirit, sonship and inheritance can come by adoption. Thus, Paul was negative in Galatians concerning the Law, and taught that freedom from it brings unity and the fruits of the Spirit.

In chapters 5–6 Paul listed catalogs of virtues and vices, fruits of the Spirit or the flesh, and stressed mutual forgiveness in the church. This is an exhortatory section that leads to the closing of the letter in Paul's own hand and to his stress on seeing his only glory in the cross of Christ.

The Letter of Paul to the Ephesians. The authenticity of Ephesians as a genuinely Pauline epistle has been doubted since the time of the Dutch Humanist Erasmus in the 16th century. It is most reasonable to consider it as "deutero-Pauline"—*i.e.,* in the tradition of Paul but not written by him. The problem of Ephesians cannot be solved apart from that of Colossians, because many similarities are noted in the style and development of Pauline thought into cosmic imagery; yet they treat different problems. In both, the heritage of Paul is preserved by a "Paulinist," and it is on this basis that Ephesians and Colossians were accepted into the canon. Both are "captivity epistles," ostensibly written by Paul from prison. Of the 155 verses in Ephesians, 73 have verbal parallels with Colossians; and when parallels to genuine Pauline letters are added, 85 percent of Ephesians is duplicated elsewhere. It would appear that Ephesians is dependent on an earlier, more specifically oriented Colossians, and it may be that Ephesians uses, combines, and condenses the material of Colossians for its own needs.

The universal appeal of Ephesians

Though Colossians is directed explicitly and strongly against a particular Judaizing proto-Gnostic heresy—*i.e.,* an incipient form of a religious dualistic system that emerged as a very attractive heretical movement in the 2nd century—Ephesians is not polemically oriented and is not clearly connected to a particular congregation, its problem, or its individuals. Though Ephesians uses a letter style with an introduction, greeting, and closing benediction, the only person mentioned in it is Tychicus, already mentioned in the same context in Colossians. The doctrinal section shows that the whole world—not only the Jews—is in a cosmic sense subjected to Christ, and Jew and Gentile are reconciled and united through him. This is the mystery of God's plan revealed to the church through Paul but expanded in scope. All are saved and reconciled through Christ, who has made both Jew and Gentile one and has "broken down the dividing wall of hostility," bringing peace and unity. The author of Ephesians continues Pauline language and makes it more Pauline than Paul himself.

After the address—which, according to the best manuscripts, lacks a reference to Ephesus—there is a hymn of praise to God in terms of a cosmic plan of redemption. Through the ascended Christ, salvation is for all, and he is the head of the body, his church. Because the address and thanksgiving are to the church in general (the place name, Ephesus, being an early gloss), it is possible that Ephesians was meant as an encyclical, to be distributed, perhaps, as a covering letter for the whole Pauline collection. The "mystery of God's will" (chapter 1, verse 9) is spelled out in chapter 2 as the reconciling act of Christ for both Gentile and Jew. In chapter 3 Paul's role in giving knowledge of this mystery in his ministry leads to a doxology. After this semi-epistolary form, the general admonitions follow in terms of gifts of grace with stress on unity: one hope, one Lord, one faith, one baptism, one God for all. A warning against a heathen way of life is given in contrast with the Christian's old nature as opposed to his new being in Christ. In chapter 6, verses 10–20, the Christian is enjoined "to put on the whole armor of God" as defense against evil and Ephesians ends as a letter, with a blessing.

The Christology and ecclesiology imply a background of a Christianized, mythological proto-Gnosticism, or a strongly Hellenized Judaism. Perhaps one of the best clues to the lateness and pseudonymity of Ephesians in comparison with the genuine Pauline letters, however, is the phrase "revealed to his (Christ's) *holy* apostles and prophets by the Spirit." Such an expression is certainly

later than Paul and looks back on the apostolic age as a time in the past.

The date and style of Ephesians

A possible date is shortly after Colossians, in the early 2nd century. Because there are so many similarities to Colossians, Asia Minor might be the place of composition, but this is merely conjecture. The non-Pauline use of the term mystery to denote that Gentiles are fellow heirs with Jews, the uniting of all in Christ, and an analogy between marriage and Christ's relation to the church, all point to a different and later time than that of Paul. The style of Ephesians builds up long, almost unmanageable, unpunctuated, excited, and abundant sentences, even longer than those of Paul when he is most provoked or, perhaps, absentminded and does not finish sentences that he begins. A comparison of the table of duties of Colossians 3 and Ephesians 5 and 6 also shows a strong development in the direction of making the relationship of Christ and his church the basis for all other relationships.

The eschatology of Ephesians is attenuated, if not far in the background, and a continuation of the church is implied. In chapter 1, verse 13, the writer sees the Spirit as the guarantee (down payment) of the Christian's inheritance—a present indication through the Spirit that the Christian can live in faith in the world looking for the Kingdom but already sure he can draw on the powers thereof without an imminent expectation of the end-time. Ephesians gives hope for universal salvation, grace as a gift of God, strength in patience, and an example of unity for the church as well as freedom in the Spirit to attain maturity as a Christian.

The Letter of Paul to the Philippians. In its present canonical form Philippians is, according to several scholars, a later collection of fragments of the correspondence of Paul with the congregation in Philippi that was founded by Paul himself. The first of the two major difficulties leading to this conclusion concerning redaction of the letter is created by a discrepancy between chapters 2 and 3—*i.e.,* an entirely unexpected polemic in chapter 3 after a calm second chapter. Another major difficulty is the relationship of chapter 4, verses 10 and following, with Paul's joyful acceptance of his suffering, and the remainder of the present letter that deals with the collection the Philippians had made and sent to Paul in prison. The place of the expression of Paul's gratitude at the end of the letter is odd, particularly because Epaphroditus, the Philippian delegate conveying the gift, is thanked as though he had just arrived; yet he has already been described as ill when he was with Paul (who apologized in chapter 2 for not having told about Epaphroditus' illness sooner and the delay in sending him back). Yet, Epaphroditus is obviously back and the sequence of events is, indeed, confusing.

The fragmentary condition of the letter in its present form

The following rearrangement of the parts of the letter is probably acceptable. Chapter 4, verses 10–20, shows Paul reacting to the gift of the Philippians and the arrival of its bearer, Epaphroditus, and seems to be the earliest fragment, written probably during Paul's imprisonment (*c.* 53–54). The portions of the letter that treat of the theme of mutual joy (1:1–3, 4:4–7, and probably 4:21–23 that refers back to chapter 1) are best taken together as fragments of a second and somewhat later letter. The third section is 3:2–4:3 and possibly 4:8–9, which addresses the danger caused by outsiders and opponents who had started to penetrate the Philippian congregation with a theology Paul considered heretical and against which he aimed his polemic. Because this is an entirely new situation, it is probably a third letter, of which only the preface is missing. This arrangement also attempts properly to account for the fact that chapter 4 actually comprises endings of several letters. Thus, chapter 3, verse 1, which is itself a summation and ending, fits in.

The reference to frequent visits between Paul and the Philippians referred to in the correspondence makes its origin in Rome unlikely and points rather toward Ephesus as the place of imprisonment. Paul's reaction to the gift of the Philippians is almost rude (although he accepted gifts from no other congregation but preferred to support himself during his apostolic mission). He actually avoided expressing direct gratitude and attempted to divert the significance of the gift from its material side to its spiritual meaning. He emphasized the sympathy proven by the Philippians, the importance of the value of the gift for them as a spiritual sacrifice for God.

The "letter of joy"

The "letter of joy" section describes Paul's enthusiasm in his mission efforts—and their success—and his joy in the energy and growth of the mission in Philippi, which Paul shared with his congregation. Paul's address to "bishops and deacons," terms unique in Paul's letters except here, are, perhaps, circumlocutions for missionaries active in Philippi, a congregation that had become a strong and stable Christian community. Paul had traditionally remained there about one week and, in chapters 1 and 2, encouraged and praised the Philippians for continuing in their faith in his absence. This is part of the thanksgiving in Philippians—an emphasis on the participation, cooperation, collaboration, and empathy of the Philippians with respect to the preaching of the gospel. Thus, the terms bishop and deacon may belong to the language of a self-supporting mission church with its own overseers (bishops) and workers (deacons) and does not carry the connotations of later ecclesiastical structures. Paul expressed his confidence in the fine beginning of this young church that sought "to become pure and blameless for the day of Christ," the final judgment.

Paul then turned to his own experience of imprisonment, which he viewed as advancing the gospel. Though he considered that not all preachers of Christ preach on the basis of selfless motives, the fact that Christ is proclaimed is a most important cause for rejoicing. Paul then exhorted the Philippians to work hard for the sake of the gospel, not minding any opposition, and to do this in a sense of unity and mutual support.

This exhortation toward a strong and active sense of community was reinforced by quoting an early Christian hymn that described the humiliation (*kenōsis*) and exaltation of Jesus who is made the Lord of the universe and confessed by all cosmic powers. A part of Jesus' humiliation, his death on the cross, can be taken as part of his manifest glorification. The verses following the hymn make clear that the incorporation of the hymn with its triumphal ending also has a missionary purpose, because Paul emphasized again the need to responsibly act out one's own calling even before non-Christians. Thus, active responsibility continuously exercised in the perspective of the approaching Parousia merges with Paul's own readiness to sacrifice himself.

The missionary emphasis

In chapters 3–4 the situation may be totally different. Paul reacted to the threat of the appearance of Jewish-Christian missionaries who are rather close in theology to the Galatian Judaizers. Paul's polemic indicates that in addition to Jewish tradition, they must have emphasized the Law in particular. Reference is made to circumcision, and Paul emphatically claimed that he could compete with heretics boasting of their Jewish tradition and, in elaborating on that, emphasized his former pious righteousness under the Law, in which he was blameless. He then stressed categorically that for him the experience of Christ has terminated his former piety completely and that he has left it behind as of no value. Such a polemic implies that for his opponents such was not the case. Paul also argued against libertinistic tendencies, which indicates that his opponents were not legalists in an ordinary sense but combined faithfulness to the Law with a strong and fanatical enthusiasm that could lead toward "mysticism" and easily be misinterpreted as libertinism. Paul's emphasis on true Christian experience as not being completed but rather still being in the state of expectation might be a further polemic against overenthusiasm. In chapter 4, verse 8, Paul reaffirms his own example, making it, in imitation of the teaching of popular philosophy, the epitome of all positive ethical values and virtues, and thus the pattern to be imitated. This tendency toward the paradigmatic, together with warnings and autobiographical material in chapter 3, verse 2, to chapter 4, verse 3, can be seen as a "testament" of Paul, consciously written with an awareness of impending death or martyrdom. Thus Paul presents himself—his life, ideas, admonitions, and an eschatological section—as his heritage and as an incorporation of the message he preached and its value.

The Letter of Paul to the Colossians. Colossians presents the problem of having, on the one hand, numerous (though superficial) affinities with the circumstances of the Letter of Paul to Philemon while, on the other hand, being addressed mainly to a different situation. In this new situation he uses ideas and expressions that seem to be rather a development of Pauline ideas about the cosmic realm than genuinely Pauline argumentation. In this latter aspect, Colossians and Ephesians share the heritage of Paul, but a later "Paulinist" changed details to meet different situations.

The purpose of Colossians

Colossians was written ostensibly by Paul from prison (in Ephesus) to a predominantly Gentile Christian congregation founded by his co-worker, Epaphras, at Colossae. The Colossian congregation was endangered by a heresy involving a "philosophy" that was connected with the elemental spirits of the universe to which men seemed to be bound, with circumcision, feast days and food laws, visions, and an asceticism that was not only false in its piety but foreign to the Christian faith.

To combat these proto-Gnostic, syncretistic, and Judaizing tendencies, the Paulinist appealed to the authority of Paul's apostolate and his thought but accented his theology in a new way, enlarging Paul's theological dimensions, so that they included the whole universe, the fate of the entire cosmos. This whole world is depicted as subject to Christ and has its meaning, aim, and goal in the church, which is Christ's body and over which he is the head. This transformation of Paul's theology would appear to be somewhat later than Paul, yet not so much later than Philemon, and its import has been forgotten. Colossians cannot be dated or placed with certainty, but the end of the 1st century or the beginning of the 2nd century has been suggested.

In a first edition, before the Paulinist changed or added to it, Colossians seems close to the situation of Philemon. In both letters Paul is in prison. Onesimus appears in Colossians, chapter 4, and the readers of Colossians are asked to transmit a special injunction through the church of the Laodiceans to Archippus—possibly that the former slave, Onesimus, now referred to as a "beloved brother," be freed for service of the gospel. The same five names appear in Philemon and Colossians (Col. 4:10 ff.; *cf.* Philem. 23), which is unusual because the church at Colossae is strange to Paul. The lost letter to the Laodiceans may possibly be the Letter to Philemon, and the request to the slave owner would, by being read aloud in a neighbouring large church (Colossae), reinforce Paul's request that the slave be freed.

Later substantial redaction has obviously taken place, however, and it is the heresy at Colossae rather than the situation of Philemon that is mainly addressed in Colossians. Though Paul asserted that he did not preach and exhort where another has founded a church, here the Paulinist, using and amplifying Pauline theology, taught, gave thanks, and interceded for a church that he did not found and that was in danger of accepting heretical Judaizing teachings, thus falling away from Christ. The doctrinal section of Colossians sets forth in a hymn Christ's preeminence over the whole cosmos, all principalities and powers, to bring redemption through the cross and to be the head of the body, the church.

From this cosmological beginning, the style and imagery differ from the authentic Pauline letters. Colossians is wider and broader in scope, with long, almost breathless sentences. There is a hierarchy in Christ being head of the body, his church, which differs from the Pauline expression of equality of all the members, although with differing functions (*cf.* I Corinthians, chapter 12, and Romans, chapter 12).

Christological and ethical emphases

The Christology is applied to the situation of the church and Paul's role in behalf of the church—his suffering with Christ and knowledge of God's mystery, Christ—is used to bolster his defense against heresy. This polemic is based first on tradition and then proceeds to specific warnings against false teaching, cult, or practice. An admonition "to set your minds on the things that are above," because in Baptism the Christian has died and been raised with Christ, is followed by the conclusion that the Christian's conduct should be ruled by love and be thus free from all wrongdoing.

Another difference from the genuine Pauline letters can be noted in this latter section. When Paul referred to the resurrection of Christians he used the future tense in most cases, but Colossians, chapter 2, verse 12, and chapter 3, verse 1, presuppose that because the Christian is risen with Christ, ethical demands can be made.

In Colossae, such Christian ethics apparently were lacking, thus the inclusion of a table of duties—*i.e.,* a list of household duties and of relations between members of a household. General exhortations to prayer and right conduct are followed by the conclusion of the letter with its list of greetings. There are some similarities in Colossians to Paul's polemic against Judaizers in Galatians, but Colossians seems to reflect a later time and a more developed "cosmic" theology of a later deutero-Pauline writer.

The First Letter of Paul to the Thessalonians. In all probability I Thessalonians is the earliest of Paul's letters, particularly because the memory of the events that led to the founding of that congregation are still fresh in the mind of the Apostle. The letter was written from Corinth. According to I Thessalonians, chapter 3, verse 2, Paul had sent Timothy to Thessalonica from Athens during his brief stay there, had just experienced the delegate's return, and had received reports about the congregation to which he is reacting in this letter. I Thessalonians gives expression to Paul's surprise over the rapid growth of the Christian mission at Thessalonica, which was achieved despite immediate persecutions from pagan contemporaries. Paul acknowledged that the successful development had been wrought in the Thessalonians by their own acceptance, fully recognizing the human frailty of the Apostle, their founder (2:1–12), and not by a mistaken understanding that he himself was divine.

The rapid growth of the church at Thessalonica and Paul's response to eschatological expectations

Paul's surprise results, therefore, in overwhelming gratitude, and the customary Pauline thanksgivings here exceed the usual limits. A second reason for this unusually long thanksgiving—which actually makes thanksgiving the theme of the letter—is Paul's intent to undergird the encouragement he gives in 4:13–5:11. After having dwelt so extensively on his being moved by the change in the Thessalonians, Paul continues to state that therefore they have no reason for giving up faith in the face of the death of some fellow Christians, who had died between their conversion and the expected imminent Parousia of Christ. Apparently, they had expected the Parousia and final salvation as the promise of the Christian message. Paul encouraged his congregation that he had a "word of the Lord" that the dead and the living in Christ will rise together. "Word of the Lord" could refer to a word of Jesus known to Paul but could instead be a direct revelation to Paul.

In chapter 5 there is further thanksgiving, emphasizing the present gift and power of Christian faith and corporate Christian life. This emphasis is linked with ethical applications, with stress on brotherhood, diligence in keeping the faith, and religious industriousness. The difficulties of balancing the expectation of the Christian with God's timetable is outweighed by the hope and joy in what has already been experienced and what is hoped for. Paul's real emphasis is more on the actual description of Christian life in the face of coming salvation and vindication than on the preceding discussion of the fate of those who had died or on the actual circumstances of Christ's appearance from heaven.

The encouragement of the Thessalonians was introduced in chapter 4 by a genuinely ethical exhortation to proceed properly on the way to holiness and sanctification already begun. The brevity of this rather traditional exhortation is most unusual in Paul's letters and supports the observation that it was written in joy and confidence for a new congregation well begun in order to support it against attacks and doubts as it matured in the faith.

The Second Letter of Paul to the Thessalonians. A feature of II Thessalonians that resembles the otherwise most unusual feature of I Thessalonians is its excessively long thanksgiving. Within this thanksgiving there is an excursus dealing with the timing of the Parousia, but in

Corrections about apocalyptic expectations

II Thessalonians Paul aggressively argues against any expectation of an imminent coming of Christ that might be expected from the things he wrote in I Thessalonians. II Thessalonians perhaps presupposes I Thessalonians and intimates that believers had a false understanding of that communication of Paul. In II Thessalonians, much to the surprise of the reader of both letters, the statement is made that a letter "purporting to be from us" is "to the effect that the day of the Lord has come." II Thessalonians then presents a problem as to whether it was a self-correction of Paul or directed to the situation of a later time and thus the writing of a later author in a "Pauline" tradition. II Thessalonians does have more apocalyptically catastrophic language than I Thessalonians. Such a description not only underestimates the positive work of God and Christ for the believer but also says little about the Parousia. II Thessalonians claims that not all the events preceding the Parousia have yet occurred. The "mystery of lawlessness," opposed to the "mystery of godliness," is still at work in the world, and the full activity of Satan has not yet unfolded itself. Emphasis in II Thessalonians is on steadfastness as God's gift and promise in the days of tribulation, which makes the apostle ask for support in prayer. Criticism of people leading disorderly and idle lives follows. The perhaps casual admonition to work is thus elaborated into a major point.

Salvation seems to be sought almost exclusively in futuristic terms. Incipient or actual Gnosticism in the church could account both for the assertion that the fulfillment has already come and for the depiction of disorderly lives (because in "proto-Gnostic" terms the world is evil and provokes a response either of total renunciation or libertinism). II Thessalonians may thus reflect these problems and fit into the late 1st century. Verbal agreements between the two letters may be evidence of deliberate spurious writing, as also the suggestion in II Thessalonians that false letters may be circulating. A later author saw Paul's heritage threatened by too enthusiastic an understanding of Paul in Thessalonians and composed this letter to preserve Paul's meaning.

THE PASTORAL LETTERS: I AND II TIMOTHY AND TITUS

The Pastoral Letters as a unit. The First and Second Letters of Paul to Timothy and the Letter of Paul to Titus, three small epistles traditionally part of the Pauline corpus, are written not to churches nor to an individual concerning a special problem but to two individual addressees in their capacity as pastors, or leaders of their local churches. The purpose of the letters is to instruct, admonish, and direct the recipients in their pastoral office. Since the 18th century they have been referred to as a unit, the Pastoral Letters, and they contain common injunctions to guard the faith, to appoint qualified officials, to conduct worship, and to maintain discipline both personally and in the churches. Their similar peculiarities of style and vocabulary as well as the similarity of the heresies and other problems they faced place them in a common time and allow them to be dealt with as a unit. Their content presents a picture of the post-apostolic church when pastoral offices and tradition came to the fore and the formerly high apocalyptic tension appears attenuated.

Reasons for accepting a non-Pauline authorship

The Muratorian Canon (a list of biblical books from *c.* 180) includes references to the Pastoral Letters and notes that they were written "for the sake of affection and love." They have a place in the canon because "they have been sanctified by an ordination of the ecclesiastical discipline." These letters, however, do not appear among the Pauline letters in P 46, an early-3rd-century manuscript, and there is no clear external attestation in the primitive church concerning them until the end of the 2nd century. Not until the 19th century were doubts expressed about the Pastorals as being authentically Pauline, when German scholars and others noted discrepancies in style and vocabulary, church organization, heresies, biographical and historical situations, and theology from those found in the Pauline letters. The problems of authorship, authenticity, and dating almost paralyze investigation of the Pastorals unless discussion of these problems is seen as connected also with the literary character of the material.

Attempts have been made to apply the tools of statistical analysis in comparing these disputed letters to the rest of the New Testament (particularly to the Pauline corpus) for the purpose of establishing authorship. The studies, utilizing computer technology, point toward non-Pauline authorship with affinities to language and style of a later, possibly 2nd-century, date. More refined and complex analyses, however, are still needed.

Linguistic facts—such as short connectives, particles, and other syntactical peculiarities; use of different words for the same things; and repeated unusual phrases otherwise not used in Paul—offer fairly conclusive evidence against Pauline authorship and authenticity.

Content and problems. Church offices are more developed in the Pastoral Letters than in Paul's time. There are presbyters and bishops, but these are sometimes used interchangeably and the monarchical episcopate is not yet depicted, although church offices appear to be heading in that direction. Requirements for office are strict and leaders are chosen and ordained by laying on of hands. Such leaders must be able to teach true and sound doctrine and guard what has been entrusted to them, the *parathēkē*—*i.e.,* the deposit of teaching or the message to be carried on. They must also be able to stand firm and argue against heresy. Such offices and aims suggest an expectation of future generations of faithful witnesses to carry on the traditions, perhaps particularly necessary as some may be killed for the witness they make.

Internal organizational and theological developments

The heresies referred to appear to be Gnostic and the arguments are rather mild and reasonable, unlike Paul's urgency in combatting heresy with strenuous argumentation. The heresies taught by false teachers are an early partly Encratitic (abstaining) Gnosticism, with "higher knowledge" that emphasizes "godless and silly myth," or are statements that the resurrection has already taken place, which is a denial of future resurrection and a glorification and spiritualizing of resurrection as a rebirth, as, for example, in Baptism.

Biographical notes about Paul's journeys and situations contradict his own letters as well as the accounts in Acts. The Pauline sense of living in a time close to the end of the age is missing in these descriptions of churches; they are viewed as settling down with a succession of tradition with Hellenized expressions of salvation and a replacement of enthusiasm with bourgeois ethics. This indicates a period of de-emphasized eschatology and an expectation of a long community life in which people must live out their lives in Christian responsibility and moral behaviour.

I Timothy and Titus are more similar to each other than they are to II Timothy, but all three mark exhortations to personal lives of exemplary conduct and give rules of conduct for church order and discipline for the group as a whole and for individual parts of it—sometimes in terms of catalogs of virtues and vices recalling the Jewish two-way orders: the way of life being good, the way of death including a list of sins. Each concludes with a final blessing or salutation. They are all pseudonymous, using Paul as an epistolary model and using pseudonymous devices, such as naming individuals known to be Paul's co-workers. The authority of Paul is invoked to lend authority to the teachings contained in the letters: the avoidance of heresy, holding to sound doctrine, and piety of life. The author is anonymous, the place of writing and the addressees are unknown, but they probably are later spiritual children of Pauline teaching. The date of the letters is about the turn of the 2nd century.

II Timothy uses the background of Pauline imagery most fully. It is cast at least in part in the testament form to Timothy as his spiritual heir because Paul is depicted as suffering, fettered in prison, and awaiting the martyr's crown. He exhorts Timothy and through him the church to share in these sufferings as they will eventually share in glory. II Timothy, chapter 2, verses 1–13, is an exhortation to martyrdom with a faith that Christ, triumphant over death, will save his faithful witnesses. Recollection of the creed is followed by a direct application to bearing suffering and its meaning in God's plan of salvation. The words "faithful is the word" occur in 2:11. This "word," unlike Paul or any Christian, cannot be bound. It both

Early liturgical Christological hymns

confirms salvation described in the preceding verses and introduces a hymn that may represent liturgical usage in that it is poetic and balanced.

> Faithful is the word:
> If we have died with him, we shall also live with him;
> if we endure, we shall also reign with him;
> if we deny him, he also will deny us;
> if we are faithless, he remains faithful—for he cannot deny himself
>
> (II Tim. 2:11–13)

The hymn preserves within itself a reflection of sayings of Jesus that those who endure and persevere will reign with the Lord and that even to those who deny him (as did Peter) God will remain faithful because Christ cannot deny his own faithfulness. Even in this hymn there is allusion to a "testament" form, with Paul already martyred, as a pseudonymous device to spur the Christian on to endurance and faithfulness as a member of the redeemed community.

Another small poetic hymnic section serves to demonstrate that the church of the Pastorals, albeit somewhat deeschatologized, retains the "mystery" in God's household, the church—*i.e.,* the gospel and creed alive in the liturgy in the mystery of piety and worship.

> Great indeed, we confess, is the mystery of our religion:
> He who was manifested in the flesh,
> vindicated in the Spirit,
> seen by angels;
> who was proclaimed among the nations,
> believed in throughout the world,
> glorified in high heaven
>
> (I Tim. 3:16)

Here in miniature are creed and gospel somewhat reminiscent of the Gospel According to Matthew.

Paul's views of Christian brotherhood transcending slavery

The Letter of Paul to Philemon. From Ephesus, where he was imprisoned (*c.* 53–54), Paul wrote his shortest and most personal letter to a Phrygian Christian (probably from Colossae or nearby Laodicea) whose slave Onesimus had run away, after possibly having stolen money from his master. The slave apparently had met Paul in prison, was converted, and was being returned to his master with a letter from Paul appealing not on the basis of his apostolic authority but according to the accepted practices within the system of slavery and the right of an owner over a slave. He requested that Onesimus be accepted "as a beloved brother" and that he be released voluntarily by his master to return and serve Paul and help in Christian work. Paul appealed to the owner that Onesimus (whose name in Greek means "useful") is no longer useless because of his conversion and claimed that the owner owed Paul a debt (as he probably was also instrumental in his conversion) and that any debt or penalty incurred by the slave would be paid by Paul. Such manumission is part of Paul's concept of being an ambassador to further the mission of Christianity, rather than a judgment on the social framework of slavery, because in the Lord such social order is transcended.

Philemon, however, is not a purely personal letter, because it is addressed to a house church (a small Christian community that usually met in a room of a person's home), and it ends with salutations and a benediction in the plural form of address. The body of the letter, however, uses "you" (singular) and is addressed to the slave's owner, a man whom Paul himself has not met. Philemon, the first name in the address, is called a "beloved fellow worker," which implies that he knew Paul, and it has been convincingly argued that the slave's owner was Archippus (see above *Colossians*), perhaps Philemon's son, who was called a "fellow soldier," a term usual in business accounts and suitable for a document on the manumission of a slave. The thanksgiving contains the main theme of the whole letter: sharing of faith for the work of promoting knowledge of Christ.

The letter was written from prison, and Paul apparently expected a release in the near future, because he requested a guest room, a suggestion that he was not very far from Colossae or Laodicea, which would be true of Ephesus. Colossae would be reached from Ephesus via Laodicea, and the letter could be addressed to a house church there.

The role of Onesimus in the early 2nd century

In a letter to the Ephesians (*c.* 112) by Ignatius, bishop of Antioch, the language is very reminiscent of Philemon, and the name of the bishop of Ephesus (*c.* 107–117) was Onesimus. It has been suggested that the slave was released to help Paul, that in his later years he might have become bishop of Ephesus, and that his "ministry" or "service" was the collection of the Pauline corpus. This is based not simply on the identity of name, but on similarities to Philemon found in Ignatius' letter to the Ephesians, as well as two possible plays on words in chapter 2, verse 2 (*cf.* Philemon, verse 20), and chapter 4, verse 2 (*cf.* Philemon 11), relating to the bishop and unity of the church. Such a prominent position and role for one of Paul's followers might shed further light on why Philemon, apparently a very personal plea, became a part of the canon and Pauline corpus. Even if this suggestion cannot be proved, Philemon still shows Paul in his apostolic ministry, furthering the message of Christ and seeing beyond the limitations of the social order of his day, in which both slaves and freemen are servants of God.

THE LETTER TO THE HEBREWS

The question of authorship and peculiarities of style and content

The writing called the Letter to the Hebrews, which was known and accepted in the Eastern church by the 2nd century, was included also by the Western church as the 14th Pauline epistle when the canon of East and West was assimilated and fixed in 367. Hebrews has no salutation giving the name of either the writer or the addressees, although it does have a doxology and greeting at the end, which suggest that at some point the writing was sent as a letter to a community known to the author. There are also numerous admonitions in the text that appear to be directed to a definite circle of addressees and some admonitions to the church at large. In chapter 6, verses 4–8, is a severe warning against the sin of apostasy, for which there is no second repentance. Even so, Hebrews is essentially more a theological treatise than a letter. It is homiletical in style and calls itself a *paraklēsis,* which has many meanings: consolation, exhortation, sermon, advocacy, and even intercession.

The thoughts, metaphors, and ideas of Hebrews are distinct from the rest of the New Testament, with closest affinities to Stephen's speech in Acts, chapter 7. It attempts to prove the superiority and ultimacy of the revelation in Christ and the perfection of his offering of himself once and for all supersedes and makes obsolete any other revelation. Hebrews gives strength to its readers through the example of Christ and the hope and promise of free access to God and to eternal rest, an access in which Christ is High Priest and mediator forever. Such promise, on the basis of Christological developments and new covenant hopes, enables endurance in persecution, but its vocabulary is that of the sacrificial language of the Old Testament. Another theme is a typological analogy with the wilderness wanderings of Israel in which, despite their murmurings of unbelief and the hardening of their hearts in their trials, they persevered. Thus, the church, as the pilgrim people of God, travels toward the future place of Sabbath rest with Christ as their pioneer and perfector of faith.

A "word of consolation" is needed to strengthen faith in time of trouble. Actual persecution leading to martyrdom is seen as not yet come, but the church is sharply warned against apostasy, the sin of all sins. Hope during persecution and trial is expressed in the image of Christ as the perfect everlasting high priest, one of whose functions is to stand as intercessor and protector.

Suggested authors of Hebrews

Hebrews was considered a Pauline letter in the early Eastern church. Clement of Alexandria, a theologian of the late 2nd and early 3rd centuries, held that Paul had written it in Hebrew for the Hebrews and that Luke had translated it into Greek. Origen, Clement's successor as leader in the catechetical school at Alexandria, commented that its thoughts reflected Paul but that it was written at a later time with a totally different style and phraseology, and he stated "who wrote the epistle, God knows." Paul, for example, uses the term mediator only once and in a negative sense, in Galatians, chapter 3, verse 19, but Hebrews uses it several times of Christ as mediator

of the new covenant. In the West, Tertullian, a North African theologian of the late 2nd and early 3rd centuries, suggested Barnabas as the author, because Hebrews, called a "word of consolation," might have been written by Barnabas, whose name is translated by Luke as "son of consolation" in Acts, chapter 4, verse 36. After Hebrews' acceptance into the canon in the mid-4th century, it was considered Pauline, but doubts persisted; and because of basically different content and style in contradiction to Paul, various authors have been suggested for Hebrews—*e.g.,* Apollos (a Jewish Christian Alexandrian), or a follower of Stephen and the Hellenists, who had come into conflict with those not sharing his universalistic ideas. Hebrews, however, remains anonymous. The title "To the Hebrews" is secondary and may reflect either an idea as to its addressees or that it was influenced by its extensive Old Testament material.

According to internal evidence, Hebrews was written in a second or later generation of Christians. Persecution references suggest a time after Nero's persecution and about the time of the emperor Domitian but early enough to be quoted or alluded to in the First Letter of Clement (*c.* 96), thus suggesting a date of *c.* 80–90.

The place of the addressees may be Italy, because 13:24 is understood as a greeting sent home from one writing from abroad, but this is not certain. The addressees were probably Gentile Christians who needed instruction in "the elementary doctrines of Christ" and concerning faith in God.

Allegorical or typological interpretive techniques

Hebrews constitutes the first Christian example of a thoroughly allegorical, typological exegesis (critical interpretation) of the Old Testament. There were precursors of such a methodology in Jewish Alexandrian biblical exegesis (*e.g.,* Philo), and Platonic tendencies found in Hebrews can also be found in Jewish-Alexandrian methods of interpretation of the Old Testament. The language of Hebrews is extremely polished, elegant, and cultured Greek, the best in the New Testament. Linguistically and stylistically, it shows only a slight influence of the Koine (common Greek). The Attic style is broken only in passages in which Hebrews quotes the Septuagint. Plays on words and synonyms with similar beginnings for emphasis show the author's literary craftsmanship.

There are more Old Testament citations in Hebrews than in any other New Testament book. They are drawn mainly from the Pentateuch and some psalms.

The church is viewed as being in danger of discouragement in the face of persecution and possible apostasy. If faithless, church members risk total loss, for no second repentance is possible. Through his special Christology, the author seeks to help the readers by showing that Christ is the saviour superior to any other and that as Saviour, Son of God, High Priest, pioneer, guide, and forerunner, he who has already suffered and been glorified will lead the wandering people of God to their eternal Sabbath rest, an eschatological future state of peace and renewal.

Christological and eschatological motifs

This high type of Christology is combined with much stress on Jesus' humanity. He partook of man's nature and overcame death to destroy the power of the devil in order to deliver man. Thus, having been made like his brethren he has become a faithful High Priest to make expiation for the sins of the people. Because he himself suffered and was tested, he can help those who are tested and tempted. Through suffering, tears, and obedience Jesus was made perfect and thus the source of help and salvation, being designated by God a High Priest after the order of Melchizedek, king of Salem and priest of God Most High in Abraham's time.

Christ and his once for all (*ephapax*) sacrifice has superseded and made all Old Testament sacrifices and cultic practices obsolete. Christ is superior to the prophets because he is a son, superior to the angels because they worship him, and (in the light of his cosmic role as apostle and High Priest) superior to Moses, who brought God's Law to Israel, because Moses was a servant in God's house and Christ a son. Christ is also superior to Moses' successor Joshua, because Joshua did not bring the wandering people into a perfect rest; superior to the Old Testament priesthood of Aaron, because Christ, the true High Priest, has sacrificed himself once for all and is without sin; and superior to the patriarch Abraham, because Abraham paid tithes to the priest of Salem, Melchizedek, who as the prototype of Christ had no human antecedents. Christ, High Priest forever by obedient suffering and perfection in that he lives up to the demand, has become the source of salvation. He is High Priest in the heavenly tabernacle and mediator for the new covenant. On the basis of this Christology and ecclesiology, the rest of Hebrews is composed of injunctions to faithful life in all situations, spiritual or temporal. In chapter 11, verse 1, Hebrews gives a programmatic statement that should be translated: "Faith is the Reality [rather than "assurance," as in the usual translation] of what is hoped for and the Proof concerning what is invisible." In Hebrews, Jesus is that Reality and that Proof, and everything else is unreal or at best an earthly copy or a shadow. The heroes and martyrs of old were looking toward his coming (chapter 11) and those now under persecution look toward him and find strength (chapter 12) as they leave the ultimately unreal structures of this world, seeking the "coming city" and going out to him who was executed outside the walls of the city made with hands. Thus, the message of Hebrews is: Reality versus sham and shadow, Christ's sacrifice (priest and victim in one) versus the cult of temples, and the real heavenly rest and heavenly city versus the sabbath and Jerusalem.

THE CATHOLIC LETTERS

As the history of the New Testament canon shows, the seven so-called Catholic Letters (*i.e.,* James, I and II Peter, I, II, and III John, and Jude) were among the last of the literature to be settled on before the agreement of East and West in 367. During the 2nd and 3rd centuries, only I John and I Peter were universally recognized and, even after acceptance of all seven, their varying positions in Greek manuscripts and early versions revealed some conflict concerning their inclusion. The designation Catholic Letters was already known and used by the church historian Eusebius in the 4th century for a group of seven letters, among which he especially mentions James and Jude. The word catholic meant general—*i.e.,* addressed to the whole, universal church as distinguished, for example, from Pauline letters addressed to particular communities or individuals. The earliest known occurrence of the adjective "catholic" referring to a letter is in the account of an anti-Montanist, Apollonius (*c.* 197) in his rebuke of a Montanist writer who "dared, in imitation of the Apostle [probably John] to compose a catholic epistle" for general instruction. In the time of Origen (*c.* 230), the term catholic was also applied to the *Letter of Barnabas* as well as to I John, I Peter, and Jude.

The meaning of "Catholic Epistles"

In the West, however, "catholic" took on the meaning in Christian usage as implying a value judgment as to orthodoxy or general acceptance. Thus, the West used it for all the New Testament letters that were in the canon along with the four gospels and Acts. All letters considered authoritative and of equal standing with those of Paul were therefore termed canonical in the West. Not until the Middle Ages did both East and West designate the seven as "catholic epistles" in the sense of being addressed to the whole Christian Church, in order to distinguish them from letters with more particular addresses. Had not the main tradition placed Hebrews in the Pauline corpus, it would perhaps rather have been counted among the Catholic Letters. Hebrews, however, looked "Pauline" rather than "Catholic" in that it presented an extensive theological argument to which the parenesis (advice or counsel) was applied at the end.

These seven letters are grouped together despite their disparate authorship and dates because of a number of characteristics common to all of them. Though the three Johannine letters, and especially I John, are distinctly Johannine in character, the four other Catholic Letters are of special interest precisely because they lack strong personal or peculiar traits both in their theological and in their ethical statements. This characteristic makes them a good source for understanding the piety and life-style of the majority of early Christians. These letters differ from the Pauline letters in that they seem to have been written for

general circulation throughout the church, rather than for specific congregations. Though Paul wrote as a missionary responsible for his recent Gentile converts, these letters address established congregations in more general terms. It is interesting to note, for example, that in I Pet. 2:12 the word Gentiles refers to "non-Christians" without any awareness of its older and Pauline meaning of "non-Jews."

The purpose of the Catholic Letters

The purpose of the Catholic Letters is to meet ordinary problems encountered by the whole church: refuting false docrines, strengthening the ethical implications of the Gospel message, sharing in the common catechetical and moral materials, and giving encouragement in the face of the delay of the Parousia and strength in the face of possible martyrdom under Roman persecution. They guide the ordinary Christian in his day-to-day life in the church.

The Catholic Letters preserve a considerable common legacy of ethical themes and quotations. Such themes and quotations (from the Old Testament) were handed down traditionally, though the writers interpreted them independently for their situations. For example, Proverbs, chapter 3, verse 34, showing God's scorn to scorners and favour to the humble, is used in James, chapter 4, verse 6, as a warning against involvement in the world and an exhortation to submission and humility, but in I Peter, chapter 5, verse 5, it exhorts Christians to humility and submission in relation to one another in the church and brotherhood. Because the Catholic Letters represent a common pool of Christian teaching, there are overlapping points, but these come from shared tradition rather than literary dependency. The virtues extolled in the early church are not particularly Christian but often coincide with those cultivated in Hellenistic culture, sometimes with a Jewish Hellenistic emphasis. An act of mercy and virtue valued in both Jewish and Hellenistic tradition is epitomized in hospitality (*e.g.,* I Peter 4:9). Similarly, Hellenistic lists of virtues and vices occur as needed from the general body of early Gentile Hellenistic tradition applied to the Christian communities. In these epistles, theological and credal statements are woven in and used for immediate ethical application. Thus, they differ from the Pauline style of extensive theological sections coupled with ethical applications that follow at the end of the epistle.

In the Catholic Letters, to be a Christian was to be in opposition to the world, a member of a minority church and thus at any time liable to be called as witness to the faith and perhaps to suffer and die for it. Eschatological trials are coming (*e.g.,* I Pet. 1:6f., 4:12–19; II Pet. 3:2–10; I John 2:18 ff., 4:1–4; Jude 17 ff.), and the Christian views false prophecy and heresy as well as hostile encounter with the world as part of the trials. The theme of joy in persecution, suffering, and the final trial or ultimate "testing" is based on Christ's victory over these events and the sense of being a member of his community. Thus, the Christian should show submission, nonretaliation, humility and patience, good conduct, and obedience to authorities, because his witness must be blameless when his faith is tested in the world, in the courtroom, and in martyrdom.

The Letter of James. The Letter of James, though often criticized as having nothing specifically Christian in its content apart from its use of the phrase the "Lord Jesus Christ" and its salutation to a general audience depicted as the twelve tribes in the dispersion (the Diaspora), is actually a letter most representative of early Christian piety. It depicts the teachings of the early church not in a missionary vein but to a church living dispersed in the world knowing the essentials of the faith but needing instruction in everyday ethical and communal matters with traditional critiques on wealth and status. In matters of church discipline and the practice of healing, there is stress on prayer, anointing, and confession of sin in order that the healing of the sick may be effected. Steadfastness, even joy, in persecution is based on pure religion with strong ethical demands, as noted in chapter 1, verses 2–4 and 19–27.

A debate as to how James' statement that "faith apart from works is dead" compares with Paul's "justification by faith without works" in Romans has a long history. The debate, central to the history of Christianity, has usually overlooked the simple fact that Paul speaks about "works of the Law" and does so with reference to those "works" that divide Jews and Gentiles—*e.g.,* circumcision and food laws. James, on the other hand, refers to works of mercy. Thus, the two statements are not only reconcilable but address themselves to quite distinct and different issues. Even Paul referred to mutual support of the brethren by the glorious phrase "the law of Christ" (Gal. 6:2) and this is the same as James' "royal law" (James 2:8). The Pauline language presumably was not in James' mind. In James, chapter 2, the example of Abraham's faith is used to show justification by works. It is to be noted that Paul also used Abraham as the paradigm of righteousness to demonstrate justification by faith in Romans, chapter 4, again showing the difference in purpose and setting of the two epistles.

In view of the post-apostolic situation depicted, James, the son of Zebedee, who died as a martyr before AD 44, could not have been the author. From the content, neither could James, a brother of the Lord and the leader of the Jerusalem church; his martyrdom is reported as *c.* AD 62. Thus, James is pseudepigraphical, with the purpose of gaining apostolic authority for its needed message. The date of writing is probably at the turn of the 1st century, and its addressees are the whole church.

James' stress on ethical imperatives

Of James' 108 verses, 54 contain imperatives—an obvious proof that advice is stressed. Such admonitions are expressed in the form of general ethical wisdom sayings, Hellenistic Jewish lists of virtues and vices, and Christian as well as pagan aphorisms sometimes related to popular preaching of the Stoic Cynic style.

In chapter 5 the community is enjoined to patience, steadfastness, and good behaviour. The Old Testament prophets, who spoke in the name of the Lord, are used as examples of suffering and endurance as they awaited the Judge. Thus, reference to the Parousia of Christ may have been conflated by the Christian writer to the coming of the Lord in judgment, an interpretation with "the day of the Lord" in mind. "Behold, the Judge is standing at the doors" is accompanied by the admonition, "You also be patient. Establish your hearts, for the coming of the Lord is at hand," (chapter 5, verses 8 and 9).

The purpose of I Peter

The First Letter of Peter. The purpose of the First Letter of Peter is exhortation directed to "the exiles of the Dispersion" in Asia Minor in order that they "stand fast" in God's grace in the face of persecution. On the one hand, such persecution is viewed as part of the trials of the end-time that the community must undergo before the coming of the new age. On the other, persecution is viewed as a simple fact of Christian community life in the world. In imitation of Christ, tribulations and testing can be a basis for joy.

In the address, the author calls himself "Peter, an apostle of Jesus Christ," and in chapter 5, verse 1, a "fellow-elder and witness of the suffering of Christ." Any Christian, not just a fellow eyewitness, however, might be such a witness and hope to partake in the future "glory that is to be revealed." The writer or the redactor of I Peter used Pauline and gospel theology and terminology both in quotations and in allusions and, if literary dependency cannot always be demonstrated, there is dependence on the catechetical traditions known in the post-apostolic church.

The milieu of the letter seems to reflect the time and temper of the correspondence of the emperor Trajan with Pliny the Younger, governor of Bithynia (*c.* 117). Pliny requested clarification as to the punishment of Christians "for the name itself" or for crimes supposedly associated with being a Christian. I Peter, chapter 4, verse 15, appears to reflect this situation: that a Christian be blameless of all crime and, if punished, be persecuted only "as a Christian." Pliny continued that denounced Christians are executed if they persevere in their belief but that whatever their creed "contumacy and inflexible obstinacy deserved punishment"; Trajan's response was that those denounced as Christians be punished. The warning in I Peter, chapter 3, on a Christian's manner of defense and submissiveness to authorities points to a date in the first quarter of the 2nd century. Such a date does not preclude reflection on earlier persecutions, such as those under Domitian.

The Greek style is hardly in keeping with a Galilean Pe-

ter—described as illiterate or uneducated in Acts, chapter 4, verse 13. The Greek is fluid, and the Old Testament citations are from the Septuagint. The addressees appear to be Gentile Christians portrayed as the new Israel dispersed among the (heathen) Gentiles, based on the analogy of the old Israel, a diaspora among the nations.

The work is thus pseudonymous, attributed to Peter through Silvanus, whose name constitutes a part of the pseudepigraphic device that strengthens the authority of the epistle. I Peter is an excellent example of the testament form modelled on the traditions of an Apostle and the message of his martyrdom. Peter, whose death and traditions concerning him were known to the readers of the time of I Peter, gives weight and authority to the letter that is formed in many ways as a farewell and admonition to those who follow, in order that they may stand firm.

The letter in the form of a testament

Warnings are given from the Apostle's own example along with counter-virtues for vices. Such testament forms have a mixture of wisdom material, advice, exhortation, hymns for ethical admonition, and apocalyptic elements with accounts of trials to come. This mixture is found in strange arrangements, but is perhaps solved if read as a testament form. Peter had denied that Christ must suffer and in I Peter suffering is the way of discipleship and even of joy. In Luke, chapter 22, Peter's denial was prophesied, and Jesus interceded for him in order that he might repent and strengthen his brethren (*cf.* I Peter, chapter 5, verses 10 and 12). In Mark and Matthew the defection of the Apostles was foretold in terms of the scattering of the sheep when the shepherd was stricken, and Peter does deny his Lord. In John, chapter 21, the risen Lord paralleled Peter's threefold denial with a threefold question as to Peter's love. At each affirmation the Lord responds with the forgiving command to feed the sheep—to care for the community. This is a central motif in I Peter. Immediately following the charge to Peter in John is the prediction of his own martyr death, and in I Peter the church is urgently admonished to accept trials as nothing strange, because they are a sharing in the sufferings of Christ. In the Garden of Gethsemane, Peter in particular was rebuked because he did not watch, and in I Peter the church is admonished to watch and be vigilant against the Devil. Prayer against temptation is also stressed.

In the Matthean account, Peter is delegated to build the church, and in I Peter it is the chief Apostle (Peter) who points to Christ as Shepherd and Bishop, who through his suffering collected the wandering sheep to himself. In like manner—on the model of Christ or perhaps Peter—the elders are exhorted to feed their flocks humbly and faithfully. Thus, there is a typical testament form: Peter has failed and repented; and the church is warned, admonished, and strengthened as by the Apostle, who, on the analogy of Jesus' Passion and death in innocence, exhorts the church to share in the vocation of innocent suffering and to do good in innocence. Finally, I Peter, viewed as a "testament," is in itself an apocalyptic "witness," and with its admixture of advice, example, and general address to the faithful living in the Diaspora as sojourners, with the authority of its martyred "author," it constitutes authority and strength for the church that faces the persecution of the world. References in chapter 5 to Rome (called Babylon) and to Mark are then also part of the pseudepigraphic testament form, as they presuppose the common tradition of Peter's martyrdom in Rome and his connection with Mark.

Christological elements

There are three Christological hymnic fragments in I Peter: 1:18–21, ransom by Christ; 2:21–25, with reference to the Book of Isaiah, chapter 53, used as ethical admonition; and 3:18–20, Christ's descent into hell. The last is in the context of Christ's going and preaching to the spirits in prison (a reference to the apocryphal *First Book of Enoch* with Satan chained under the earth but his descendants at work in the world until the end-time) in order to show that Christ, through his descent, has overcome the powers that underlie and engender persecution of the Christians. This is reaffirmed in chapter 5 by encouraging Christians in their fight against the Devil, for, though suffering will be a part of this resistance, there will be victory at the end. Imitation of Christ is a basis for joy even in suffering. The end is viewed as near, and final salvation can thus be anticipated.

The Second Letter of Peter. The Second Letter of Peter was written as a letter to the whole church purporting to be similar in testament form to that of I Peter. It deals with the problems of the delay of the Parousia and accounts for it in terms of God's time being different from that of man and God's patience in waiting for all men to be better ethically. This letter, the latest of the New Testament, shows how Christendom dealt with the delay of the Parousia, discarded older Jewish apocalyptic ideas by substituting those with Hellenistic emphases, and is clearly in its content and exposition a methodically worked out artistic product, fictionalizing the older beliefs, in order to bring them into some agreement with traditional Christian terminology.

Problems dealt with in II Peter

II Peter names Simon Peter as its author and declares his position by setting down rules for true faith as he sees it. His work is different in meaning and interpretation from the earlier tradition and understanding of the church. He regards the Transfiguration of Jesus on the mountain as the first Parousia and urges patient waiting for the final coming of the Lord. Although he refers to his letter as a second letter of Peter, his Hellenistic concepts and rhetoric could hardly be attributed even to the author of I Peter. II Peter speaks of "partakers of divine nature," a term from the mystery religions, and mixes proverbs with familiar quotations from Hellenistic tradition. Thus, not only is this letter pseudepigraphic, but it is an even later fiction, probably nearer to AD 150 than the end of the 1st century.

Almost all of Jude is used in II Peter, but II Peter drops out a quotation from *I Enoch* in Jude 14 ff., possibly demonstrating some fear of using apocryphal writings. Heresies are attacked by criticism of their interpretation of scripture and misuse of set tradition, another evidence of the late date of II Peter. Reference is made to "all the epistles of Paul which contain things hard to understand" and to "other scriptures," evidence of a New Testament canon well on its way to being delineated over against the Old Testament. Though skillfully composed, II Peter cannot hide the Gnosticism included in its view and much misinterpretation of the traditional body of faith of the early church. Thus, II Peter is an example of the church at a relatively late period, de-eschatologized for the most part and brought near to early institutionalized religion with a ministry but depending on ideas and a theology so changed that it is almost unrecognizable.

Attacks on heresies and eschatological views

The eschatology of II Peter awaits a new heaven and a new earth after the dissolution by fire of the old, evil earth with its unrepentant people. The Parousia no longer is Christological in nature but anthropologically oriented, with a vindication of the good and a punishment of the wicked. II Peter presents a picture of the church at the latest point in the canon and illustrates the necessity to reevaluate and recall more normative Christian traditions.

The Johannine Letters: I, II, and III John. The three epistles gathered under the name of John were written to guide and strengthen the post-apostolic church as it faced both attacks from heresies and an ever increasing need for community solidarity—along with the concomitant love and ethics necessary to such unity.

The purpose of the Johannine Letters

I John, though lacking any formal epistolary salutation or ending, directs itself to a circle of readers with whom the writer is acquainted. Taking the form of an anonymous "homily" for admonition against heresy and instruction in faith and love, it was directed to a wide audience or was to be circulated beyond a particular congregation. II and III John are brief letters from an author described only as "the elder," implying a position of some authority. II John, chapter 1, is addressed to an "elect lady and her children," probably a designation of a church with difficulties similar to those found in I John. III John is the most personal, being addressed by the elder "to the beloved Gaius," who has been praised particularly for his hospitality (probably to missionaries) and his brotherly love. The presbyter (elder), probably the author of II and III John, apparently was a man who was authoritative enough to influence and direct mission activities. All three letters, despite their differences of address, appear to have

been accepted among the Catholic Letters as having been circulated for the church at large.

I, II, and III John share much common terminology, style, and general situation. They are all called Johannine because they are loosely related to the Gospel According to John in style and terminology and could be the outcome of its theology.

The early church attributed I, II, and III John to John, the Apostle, the son of Zebedee. Although II and III John may possibly have been written by the same presbyter, this "elder" is not necessarily the author of I John, although it is commonly accepted that the three Johannine letters came from a "Johannine" inner circle. The earliest reference to the Johannine letters is in the *Letter to the Philippians* by Polycarp of Smyrna (7:1). Papias, who was a 2nd-century bishop of Hierapolis, mentions I John and quotes it several times, but he distinguishes between John, the Apostle, and John, the presbyter. Polycarp, Papias, and internal evidence point to the region of Asia Minor as the probable sources of the Johannine literature. These references and the organization of the churches indicated in the letters, as well as the lack of signs of persecution, suggest a date for the letters at around the beginning of the 2nd century.

Apologetics against Docetic Gnosticism

The First Letter of John. I John assumes a knowledge of the Johannine Gospel (the author of I John may be the ecclesiastical redactor of the Gospel According to John) and adds ethical admonition and instruction regarding the well-being of the church as it confronts heresy and stresses the lack of moral concern that springs from it. There is strong defense against the threat of a type of Gnosticism called Docetism that denied the reality of Jesus' earthly life and thus the meaning of the cross. Possessing special spiritual knowledge, the Docetic Gnostics had no need of the earthly Jesus and the humanity of Christ. This Docetic heresy led them to reject the Lord's Supper, but not Baptism. Their special possession of the Spirit had led them erroneously to consider themselves sinless and to deny the fellowship that has the cleansing of sins. Because the heresy may have led to libertinism, the ethics of Christians must accord with their faith and find expression in the love of the brethren in the church. "He who hears my word and . . . believes has passed from death to life" (John 5:24) is continued in I John 3:14, "We have passed out of death into life, because we love the brethren." The Gnostics separated themselves from the church in schism and have thereby committed the "sin unto death." They are false prophets and deceivers described by the term Antichrist. The true Christians, the "children of God," hold the true faith evidenced by their loyalty to the church and their charity toward its members.

The emphasis on love in I John

A constant theme in I John is that of God's love, which makes Christians the children of God. As children of God they keep the new commandment of love, which is of light—that of brotherly love—and resist the world, evil, and false teaching. Because Christ gave his life for man, the Christian's response is also to be self-giving. Through obedience and faith, God forgives even when man's heart condemns him, "for God is greater than his heart." It is of interest to note that in I John 2:1–2, Jesus is referred to as paraclete (advocate), but in the Gospel According to John, such references are to the Spirit. John 14:16, however, refers to "another Counselor." This discrepancy can be resolved by interpreting Jesus with his disciples as their advocate with another to come (the Spirit), and, in I John 2:1–2, the risen Lord becomes the advocate for the expiation of all sin. Righteousness and faith are emphasized in chapters 4–5, and again these characteristics are those of the children of God, who will finally in the end-time be like him who gave the promise, the commandment, and the joy of love.

The Second Letter of John. II John warns a specific church (or perhaps churches), designated as "the elect lady and her children," against the influence of the Docetic heresy combatted in I John, whose proponents lured Christians from "following the truth, just as we have been commanded by the Father." In II John, as in the Gospel According to John and I John, the light–darkness images are similar to those of the Dead Sea Scrolls. To "walk in the truth" in II John is to reject heresy and follow the doctrine of Christ.

The Third Letter of John. III John, addressed to Gaius, shows that the writer is concerned about and has responsibility as presbyter for the missionaries of the church. It is somewhat of a short note concerned with church discipline, encouraging hospitality to true missionaries, and thus not unconnected with true doctrine and the command of love.

The purpose and authorship of Jude

The Letter of Jude. The Letter of Jude, after a salutation that attributes it to Jude, the brother of James, and addresses itself to the church as a whole, develops the theme of the short letter—a polemic against heretics who have abandoned the transmitted traditional faith and who will thus be judged by the Lord. They deny Christ, and punishment similar to that of Sodom and Gomorrah in the Old Testament for such a denial is threatened. Heretical beliefs led to various sins and libertinism, and the judgment that will come upon them is cited from *Enoch* 1:9, demonstrating that this short letter reflects the post-biblical Jewish apocalyptic train of thought in the early Christian era.

"Jude, a servant of Jesus Christ and brother of James" is probably meant pseudepigraphically to relate this Jude to James the brother of the Lord so that this Jude is also a brother of the Lord. This, however, is impossible because the letter reflects a later time. Verse 17 refers to "the predictions of the apostles of our Lord Jesus Christ" concerning mockers and sinners. Thus, the author is recalling a former time that was prophesied regarding the heresies and trials of the end-time. Such a bearer of apostolic tradition is violently attacking heresy in the interest of transmitted traditional faith. Again, it would appear that the letter is pseudepigraphic and may have originated in Syria or Asia Minor.

The author struggles forcefully against heretics who deny God and Christ and attempts to strengthen his readers in their fight against such heresy that leads to wickedness and disorder. Libertinism is a characteristic of such heresy and the punishment of the heretics will be similar to that which befell the unfaithful in the Old Testament patriarchal times. Only steadfastness in faith, true doctrine, and prayer can lead to mercy, forgiveness, restoration, and final salvation. An attempt to bring the erring to repentance may save them. The letter concludes with a typical doxology.

The form is less a catholic letter than a declared position that lays down general rules. The date is probably near the end of the 1st century and before II Peter, which draws upon it.

THE REVELATION TO JOHN

The Revelation (*i.e.,* Apocalypse) to John is an answer in apocalyptic terms to the needs of the church in time of persecution, as it awaits the end-time expected in the near future. The purpose of the book is to encourage and admonish the church to be steadfast and endure. The form of an apocalypse shows affinities with contemporary Jewish, Oriental, and Hellenistic writings in which problems of the end of the world and of history are linked both with prophecy of an eschatological nature and with "sealed" secret mysteries. Such revelations are traditionally received in trances, characterized by strange symbols, numbers, images, and parables or allegories that represent people and historical situations. Apocalypticism is essentially dualistic, presenting the present eon as evil and the future as good, with an ultimate battle between the divine and the demonic to be won only after one or more cosmic catastrophes. The aim of apocalyptic literature is to depict in the age of present tribulation a knowledge of a future glorious victory and vindication, thus giving hope and assurance.

Apocalyptic themes

In Revelation it is God who gives the revelation to Jesus Christ to be shown by Christ through an angel to his servant John, in exile on the island of Patmos, in order that John become his seer and prophet to the church. John is to write down what he has seen, what is, and what is to come. In contradistinction to most Jewish apocalyptic works, Revelation is not pseudonymous and John is to

give finally unsealed, clear prophecy related to the present and to the end-time.

As in the rest of the New Testament, the starting point of eschatological hope is the saving act of God in Jesus, a historical centre pointing toward historical developments that will bring about the establishment of God's kingdom and vindication of his people, ransomed by the blood of Christ, the Lamb who was slain. It provides certainty and encouragement with the example of the faithfulness of those who have already witnessed unto death (martyrs) and their reward—special inheritance in the eternal kingdom.

The content of Revelation

After the introduction, Revelation continues first as a series of seven letters to seven churches in the province of Asia, thence to the whole church with an epistolary introduction and, after the apocalypse proper, an epistolary blessing as the last verse. The letters sent from the heavenly Christ through John (chapters 2 and 3) exhort, comfort, or censure the churches according to their condition under persecution or danger of heresy. From chapters 4–22 there are series of visions in three main cycles, each recapitulating but expanding the former in greater and clearer detail with groups of seven symbols predominating in each (seals, chapters 6–7; trumpets, chapters 8–10; and bowls, chapters 15–16). This material is interspersed with visions of God in His heavenly council, various visions of catastrophe and of Satan, the destroyer, the appearance of two witnesses and other martyr examples to spur the church to endurance, the victory of the archangel Michael over the dragon (Satan) by the blood of the Lamb (Christ), and the representation of the powers of emperor cult and false prophecy as beasts who bring destruction to the unfaithful in God's judgment. A heavenly woman who bears a messianic son is threatened by a dragon. Her child is carried up to heaven by God, and she escapes by hiding in a place prepared for her by God. The beasts who appear persecute the Christians and the "number" signifying the second beast is that of a man, "666" (or, in a variant reading, "616") probably indicating the emperor Nero. God's triumph in history is depicted in his judgment on the harlot Babylon (Rome), and the final consummation portrays the victory of Christ over the Antichrist and his followers. In chapter 20 the thousand-year reign of Christ with those who witnessed unto death is depicted. Satan, again loosed, is vanquished by fire from heaven with the beasts (empire power and false prophet), and the last judgment leads to a new heaven and a new earth, the new Jerusalem. This writing is, thus, a prophetic-apocalyptic work.

In summary, the seer reminds the reader that the words, because they are of God, are trustworthy and true. The motif that the Lord is coming soon is again repeated. This reflection of the early Christian watchword suggests a sacred liturgical style. The last verse is the closing benediction—perhaps not only of the letters in the beginning of Revelation but of the whole of Revelation, which was to be read aloud in a worship setting.

Authorship and style

After AD 70 (the fall of Jerusalem), apocalypticism was introduced into Asia Minor and *c.* 80–90 a prophetic circle was formed near Ephesus. Its leader was John, a prophet, who might well have been the author of Revelation, which is deeply steeped in apocalyptic traditions. The "Johannine circle" bearing the tradition of John, the Apostle of the Lord, and from which emerged the Gospel and letters bearing his name, might have been a continuation of the prophetic conventicle of Ephesus in which John was prominent. The various writings do not have to be consistent except in their basic faith in Jesus Christ; and, as the situations to which they addressed themselves were different, different styles and content were required. The seer was probably involved in an actual historical situation in the late 80s under Domitian, a time when there was open conflict between the church and the Roman state. There is a tradition supported by Irenaeus, a 2nd-century bishop of Lyons, that in this persecution punishment was death or banishment. John's prominence might have led to banishment to Patmos, an isle off the coast of Asia Minor, from his homeland in or around Ephesus. From Patmos he wrote a circular letter to the churches in Asia.

Though the style of Revelation is certainly eclectic in form and content, containing elements of a heavenly epistle and with more than three-fourths of the rest made up of prophetic-apocalyptic forms from varied sources, it reflects a systematic and careful plan. Even the apocalyptic, however, is "anti-apocalyptic" in that the seer's message is open and the mysteries serve not to conceal but to heighten what is seen and to be expected. Apocalyptic schemata and motifs are, however, used toward this purpose, and allegorical incorporation of sources is more a demonstration of the true, ultimate message than a literary device. Blurred images (*e.g.*, God, Christ, and angels; chiliastic [1,000-year] eras and temporal duplications; as well as interpretations) are part of the apocalyptic style, but a current concrete historical situation is the foundation. Revelation is written in fantastic imagery, blending Jewish apocalyptic, Babylonian mythology, and astrological speculation. It is pictorial, dramatic, and poetic.

Revelation contains long sections characterized by Greek that is grammatically and stylistically crude, strangely Hebraized to give a unique, almost Oriental, colour. This may have been deliberate. Although Revelation is replete with Old Testament allusions, there are no direct quotations, and this may reflect the seer's conviction that the work is a direct revelation from God. In other sections the poetry of Revelation might stem from the seer's experience in the heavenly throne room of God, from hearing the hymns of the angelic host, or from his recollection on Patmos of the liturgical practice of the church. The image of the Bride and wedding feast together with the "Come, Lord Jesus!" have associations with the eucharistic liturgy of the early church.

The recapitulation of images and the use of numbers

The recapitulations of the seven seals, trumpets, and bowls may be deliberate schematization. The purpose of such repetition and increasing revelation can be a way of heightening enthusiasm to encourage the church.

Mysterious numbers and divisions (such as 7, 3, 12) recur and are part of the theme of assurance, because God has numbers in their order as a sign of his plan of salvation, turning chaos to orderly cosmos. The mysterious name of the second beast, 666, in 13:18, can be calculated by "gematria," assigning their numerical values to letters of the word and summing them up. The most adequate solution is Nero (the numerical value of the Hebrew letters for *Caesar Neron* equals 666), a demonic Nero *redivivus* (revived), who returns from the dead as Antichrist. Astronomy and astrology have also been applied to Revelation in terms of the signs of the zodiac or a calendar of feasts and seasons as keys to understanding its structure, because it is God who orders the times and seasons.

Martyrological themes

Two witnesses described in chapter 11 have been assumed to be Elijah and Moses, Peter and Paul, or simply two examples of martyrs through whom God shows His punishment of the wicked and vindication of the righteous to his glory. There are strong martyrological themes throughout Revelation, and it seems to stand on the border line of the point at which the word witness (*martys*) became a technical term for a witness unto death, or martyr. The cosmic battle in heaven is fought by those willing to give their lives, who mix their blood with the blood of the Lamb, whose blood "ransomed men for God." The writer of Revelation based his hope for the church on perseverance, on endurance even to death, and on what the future will bring when the church will live with the glorified Christ, slain as a lamb. The harlot of Babylon will be destroyed and the church will endure; Babylon falls and the new Jerusalem, the city of God that is to come, is depicted in all its glory. These are the hopes to strengthen the persecuted church, assurance that God will soon triumph. With trumpet call and heavenly voices there is the joyful promise that "The kingdom of the world has become the kingdom of our Lord and of his Christ, and he shall reign for ever and ever." (K.St./E.T.Sa.)

New Testament Apocrypha

NATURE AND SIGNIFICANCE

The title New Testament Apocrypha may suggest that the books thus classified have or had a status comparable to that of the Old Testament Apocrypha and have been recognized as canonical. In a few instances such has been the

case, but generally these books were accepted only by individual Christian writers or by minority heretical groups. The word apocryphal (secret) is applied to Gnostic traditions and writings both by Gnostics and by their critics; from the 2nd century, for example, comes the *Apocryphon* (secret book) *of John.* In the 4th century the word referred to books not publicly read in churches. It meant apocryphal in the modern sense (*i.e.,* fictitious) only by implication, as when the church historian Eusebius speaks of some of "the so-called secret books" as forgeries composed by heretics.

Pseudepigraphical gospels, acts, letters and apocalypses

Like the New Testament books themselves, the New Testament apocryphal books consist of gospels, acts, letters, and apocalypses. The apocryphal writings, however, are almost exclusively pseudepigraphical—*i.e.,* written in the name of the apostles or disciples or concerning individual apostles. In general, they were created after and in imitation of the New Testament books but before the time when a relatively restricted canon, or list, of approved books was being formulated. They arose chiefly during the 2nd century, when the lines between orthodoxy and heresy were not absolutely fixed and when popular piety seems to have been rather freely expressed. What these works tell about Jesus and his disciples resembles the imaginative Midrashic (didactic commentarial) retelling of Old Testament stories among Jewish teachers.

As the New Testament canon was gradually given definite shape, these apocryphal books came to be excluded, first from public reading in churches, then from private reading as well. With the development of creeds and of systematic theologies based on the nascent canon, the apocryphal books were neglected and suppressed. Most of them have survived only in fragments, although a few have been found in Greek and Coptic papyri from Egypt. They are valuable to the historian primarily because of the light they cast on popular semi-orthodox beliefs and on Gnostic revisions of Christianity; occasionally, they may contain fairly early traditions about Jesus and his disciples. In the 3rd century, Neoplatonists (followers of the philosopher Plotinus, who advocated a system of levels of reality) joined Christians in attacking such books as "spurious," "modern," and "forged."

The difficulties the New Testament apocryphal books caused at the end of the 2nd century are well illustrated in a letter by Serapion, bishop of Antioch. He stated that he accepts Peter and the other apostles "as Christ" but rejects what is falsely written in their name. When some Christians showed him the *Gospel of Peter,* he allowed them to read it, but after further investigation he discovered that its teaching about Christ was false, and he had to withdraw his permission.

In the early 4th century Eusebius himself found it difficult to create categories for the various books then in circulation or used by earlier authors. He seems to have concluded that the books could be called "acknowledged," "disputed," "spurious," and absolutely rejected. Thus, the *Acts of Paul,* the *Apocalypse of Peter,* and the *Gospel According to the Hebrews* were rather well attested, and he called them spurious but disputed. He definitely rejected books used by heretics but not by church writers: the gospels ascribed to Peter, Thomas, and Matthias, and the *Acts of Andrew,* John, and other apostles. About a century earlier, the North African theologian Tertullian had written about how a presbyter who wrote the *Acts of Paul* had been deposed.

Categories of authenticity and spuriousness

Without reference to the standards of canonicity and orthodoxy gradually being worked out by the churches of the 2nd through 4th centuries, it is evident that many of these books reflect the kinds of rather incoherent Christian thought that church leaders were trying to prune and shape from the 1st century onward. Often such works represented what was later viewed as inadequate orthodoxy because the views presented had become obsolete. All the apocrypha taken together show the variety of expression from which the canon was a critical selection.

THE NEW TESTAMENT APOCRYPHAL WRITINGS

This section will classify these documents in relation to their literary forms: gospels, acts, letters, and apocalypses.

Gospels. A few papyrus fragments come from gospels not known by name (*e.g.,* Egerton Papyrus 2, Oxyrhynchus Papyrus 840, Strasbourg Papyrus 5–6). There are also the *Gospel* produced in the 2nd century by Marcion (a "semi-Gnostic" heretic from Asia Minor), who removed what he regarded as interpolations from the Gospel According to Luke; the lost Gnostic *Gospel of Perfection;* and the *Gospel of Truth,* published in 1956 and perhaps identical with the book that Irenaeus (*c.* 185), bishop of Lyon, said was used by the followers of Valentinus, a mid-2nd-century Gnostic teacher. The *Gospel of Truth* is a mystical–homiletical treatise that is Jewish–Christian and, possibly, Gnostic in origin. In addition, there were gospels ascribed to the Twelve (Apostles) and to individual apostles, including the *Protevangelium of James,* with legends about the birth and infancy of Jesus; the lost Gnostic *Gospel of Judas* (Iscariot); the *Gospel of Peter,* with a legendary account of the resurrection; the *Gospel of Philip,* a Valentinian Gnostic treatise; the *Gospel of Thomas,* published in 1959 and containing "the secret sayings of Jesus" (Greek fragments in Oxyrhynchus papyri 1, 654, and 655); and an "infancy gospel" also ascribed to Thomas. Beyond these lie gospels ascribed to famous women, namely Eve and Mary (Magdalene), or named after the groups that used them: Ebionites (a Jewish Christian sect), Egyptians, Hebrews, and Nazarenes (an Ebionite sect).

Acts. The various acts, close in form and content to the contemporary Hellenistic romances, turned the apostolic drama into melodrama and satisfied the popular taste for stories of travel and adventure, as well as for a kind of asceticism that was generally rejected by Christian leaders: Andrew (including the *Acts of Andrew and Matthias Among the Cannibals*), Barnabas (a companion of St. Paul), Bartholomew, John (with semi-Gnostic traits), Paul (including the *Acts of Paul and Thecla,* with a Christian version of the story of Androcles and the lion), Peter—with the apostle's question to the risen Lord, "Lord, where are you going?" ("Domine, quo vadis?") and Peter's crucifixion upside down, Philip, Thaddaeus (his conversion of a king of Edessa), and Thomas (with the Gnostic "Hymn of the Pearl").

Popular stories of travel and adventure

Letters. Among the apocryphal letters are: a 2nd-century *Epistula Apostolorum* ("Epistle of the Apostles"; actually apocalyptic and antiheretical), the *Letter of Barnabas,* a lost *Letter of Paul to the Alexandrians* (said to have been forged by followers of Marcion), the late-2nd-century letter called "III Corinthians" (part of the *Acts of Paul* and composed largely out of the genuine letters of Paul), along with a letter from the Corinthians to Paul, and a Coptic version of a letter from Peter to Philip. There is also a famous forgery purporting to have been written by Jesus to Abgar, king of Edessa (noted in Eusebius, *Church History* I. 13).

Apocalypses. Other than the Revelation to John, which some early Christian writers rejected, there are apocalypses ascribed to two Jameses, the Virgin Mary, Paul, Peter, Philip, Stephen, and Thomas. Only the *Apocalypse of Peter* won any significant acceptance and is important for its vivid description of the punishment of the wicked.

In addition, it should be noted that there were apocryphal books with titles not so closely related to the New Testament. Among these are: the *Didachē,* or *Teaching of the Twelve Apostles* (and its later revisions, such as the *Didascalia Apostolorum,* or the "Teaching of the Apostles," and the *Apostolic Constitutions*), and the *Kerygma of Peter,* a favourite at Alexandria, as well as various Gnostic works, such as *The Dialogue of the Redeemer, Pistis Sophia* ("Faith-Wisdom"), and the *Sophia Jesu Christi* ("Wisdom of Jesus Christ"). From the 5th century there is even a *Testamentum Domini* ("Testament of the Lord"), an expansion of the 2nd–3rd-century Roman Church leader and theologian Hippolytus' *Apostolic Tradition.*

(R.M.G.)

Biblical literature in liturgy

BIBLICAL LITERATURE IN THE LITURGY OF JUDAISM

The liturgy of Judaism is that of the synagogue, which arose during and after the Babylonian Exile of 586–538

BCE and gradually replaced the Temple cult as the spiritual centre of Jewish life. The Hebrew biblical canon and the liturgy of the synagogue, to a great extent, grew up together.

The synagogue liturgy

Because the synagogue arose in a land separated from the Jerusalem Temple with its sacrificial emphasis and its priestly class, worship in the synagogue differed from what went before it in several respects. A local congregation worshipped together on a certain day of the week in a place set apart for that purpose, rather than primarily on special festival days and periods. The people worshipped without priest or cultic sacrifice, yet consciously as a community within a larger covenant fellowship and in response to a divine word that was written down in a holy scripture. Bible reading and interpretation, the singing of psalms, and prayers, both corporate and individual, were the staple content of the liturgy. The ancient synagogue liturgy has come down to the present in two books: the *Siddur,* or daily prayer book, and the *Mahzor,* or festival prayer book.

The biblically prescribed rhythm of days, weeks, months, and years gave order to the lives of the people. The Bible became familiar to old and young by being read aloud in the synagogue, and no part of worship was esteemed more highly than the reading of scripture. The Torah, the first five books of the Bible, is handwritten on a scroll. Viewed as the holiest object in the synagogue, it is kept in a sacred cabinet called the ark. Special prayers and ceremonies accompany its being taken out and replaced in the ark, and during the course of the year it is read in its entirety at the sabbath services. Torah portions are also read on the religious holidays.

A reading from the Prophets, called the Haftarah, follows each Torah reading. One of the five Megillot (Scrolls) is read on certain holidays: the Song of Solomon at Pesah (Passover), the Book of Ruth at Shavuot (Weeks), Lamentations of Jeremiah at Tisha be-Av (Av 9), Ecclesiastes at Sukkot (Tabernacles), and the Book of Esther at Purim (Lots). The Book of Jonah is read on the afternoon of Yom Kippur (Day of Atonement). Psalms are said or sung in every service. From the chanting of biblical texts, especially the Psalms, the music of the synagogue's cantor has developed into an incomparable art form (see also JUDAISM).

BIBLICAL LITERATURE IN THE LITURGY OF CHRISTIANITY

Eastern Orthodoxy. The first Christians were Jews, and they worshipped along with other Jews in the synagogue. The earliest Gentile converts also attended the synagogue. When Christians met outside the synagogue, they still used its liturgy, read its Bible, and preserved the main characteristics of synagogue worship. Every historic liturgy is divided into (1) a Christian revision of the sabbath service in the synagogue and (2) a celebration of Jesus' Last Supper with his disciples as a fulfillment of the Passover and a new covenant with a newly redeemed people of God. Thus, the church was never without traditional forms of worship.

The use of the Old and New Testament texts

For more than 100 years Christians had no authorized New Testament, the Old Testament being read, as had been done previously, in the worship service. By the middle of the 2nd century, however, Christian writings also were in the Sunday service. The Old Testament, the version used most generally in its Greek translation (the Septuagint), was the Bible from which the Gospel was preached. Its reading preceded that of the Christian writings, and the reading was far more extensive than it is in modern Christian churches.

As the liturgies grew longer and more elaborate, the biblical readings were reduced, and the New Testament gradually displaced the Old Testament. No Old Testament lesson remained in the Greek or Russian liturgy or in the Roman mass, though it has been reintroduced in the 20th century in most liturgies. All liturgies have at least two readings from the New Testament: one from a letter or other (non-Gospel) New Testament writing, and one from a Gospel, in that order. The Eastern liturgies all honour the Gospel with a procession called the Little Entrance. This action is accompanied by hymns and prayers that interpret the Gospel as the coming of Christ to redeem the world.

The Eastern liturgies, especially after the great theological controversies of the first four centuries, have favoured composed texts of prayers, hymns, and choral anthems that summarize the thought of many biblical passages, thus becoming short sermons or confessions of faith. The Nicene Creed (4th century) itself is one such text, in contrast with the Shema ("Hear, O Israel"—a type of creed) in Judaism, which consists of verbatim passages from Deuteronomy and Numbers.

The Divine Liturgy of the Eastern Orthodox churches contains many such composed texts, such as prayers that proclaim Orthodox theology (*e.g.,* the "Only begotten Son and Word of God" following the second antiphon). Isaiah, chapter 6, verse 3 ("Holy, holy, holy is the Lord of hosts; the whole earth is full of his glory"), used in the Jewish Kedusha (Glorification of God), generates two separate texts in the Eastern liturgy: the Trisagion (a solemn threefold acclamation to God) at the Little Entrance and the Greek original of the "Holy, holy, holy" in the eucharistic liturgy.

Psalms are sung extensively at the daily hours of prayer in the East as in the West. At the beginning of the Sunday service, entire psalms or more than one psalm are sometimes sung. More often, however, a psalm verse or two are combined with other material into a composite text of a hymn or anthem. A mosaic of selected psalm verses may be used either as a text for music or a spoken prayer. Most characteristic of all, especially in the Greek Church's tradition, however, is the freely composed and imaginative hymn text, based on a biblical incident or person, or an extended paraphrase of a passage of scripture. In addition to such biblically based psalms and other hymns, there are the famous Cherubic Hymn of the Greek and Russian liturgies and the original texts of hymns that have become well known in the Western churches—*e.g.,* "O gladsome light of the Father immortal," and "Let all mortal flesh keep silent."

Roman Catholicism. Liturgical worship in both Judaism and Christianity is an action that moves within the framework of biblical ideas and explains itself in biblical language. Preoccupied with really different views from opposite windows, Jews and Christians have often overlooked the common heritage that they share. This has likewise been true of the differences between Eastern and Western Christians.

Development of the Latin rite

At Rome, the liturgy was sung and said in Greek until the 4th century and was probably more like the liturgy of Syria at that time than that of Rome after the 16th century. The Latin rite developed many distinctive features, but what happened in Rome happened also to some extent in the East. The biblical readings at mass were reduced to two: the first reading, formally called the Epistle, was usually from an apostolic letter but sometimes from the Acts of the Apostles or even the Old Testament, and the second was a Gospel passage selected as appropriate for that particular day in the Church Year. The West, like the East, retained the Jewish week and developed a yearly cycle of Easter–Pentecost and Christmas–Epiphany celebrations with appropriate biblical selections. The development of the Church Year became so elaborate in the West, however, that the Roman calendar provided for every day in the year.

In the West as in the East, monastic and other religious communities observed the daily hours of prayer, in which there was little Bible reading as such but a great deal of corporate praying as well as the reading or singing of psalms. The Roman canonical hours were further enriched with homilies and legends from many sources, with Latin metrical hymns, and with biblical canticles, including a daily singing of the early Christian songs that are quoted in the Gospel According to Luke: the "Benedictus" ("Song of Zechariah") in chapter 1, verses 68–79, at Lauds (morning prayer), the "Magnificat" ("Song of Mary") in chapter 1, verses 46–55, at Vespers (evening prayer), and the "Nunc Dimittis" ("Song of Simeon") in chapter 2, verses 29–32, at Compline (prayer at the end of the day). The great anonymous canticle called the "Te Deum," a vast array of

biblical images ascribing praise and glory to God, is sung every day at Matins (an early morning prayer).

The mass is an abbreviation of a much longer liturgy. Many items are mere vestiges of more elaborate actions or texts. The psalms once sung at the entrance, for example, have been reduced to a traditional form of a sung text: an antiphon of one or two verses from a psalm, the first verse of the psalm, the "Glory be to the Father," and the antiphon repeated. The same has occurred in other parts of the mass. Psalms were once interspersed among the readings of scripture. The traditional gradual was a formalized text sung between the Epistle and Gospel, but in the reformed mass it becomes a responsorial psalm between the first and second readings. The short texts at the Offertory (offering of the bread and wine) and Communion are fragments in biblical language, but they are also masterpieces of the Latin genius for brevity, clarity, and order—as are the inimitable Latin collects (prayers), each basing its definite petition on an equally definite biblical revelation.

For centuries the mass was heard only in Latin and repeated the same readings on the same days every year, with the result that only a limited number of unconnected passages were heard in church. The second Vatican Council (1962–65) approved the plan of having a three-year cycle of biblical readings, providing an Old Testament lesson for every mass, a more nearly continuous reading from one of the Gospels each year, and a reading from one of the letters or other New Testament books over a period of weeks.

Protestantism. The term Protestant covers so wide a variety of theological views and religious and cultural groups and so many different ways of worshipping and using the Bible in worship that it is virtually impossible to say anything about the liturgy or the Bible's place in worship that would be true of all Protestants. Among Anglicans, what was said of the Bible in the Roman Catholic liturgy would generally apply. It would also apply to most Lutherans in the 20th century, but not to all Lutherans. On the other hand, there have been and are Protestants who claim or tacitly assume that nothing but the Bible should be used in worship. The use of the Bible in Protestant liturgy lies between these extremes.

Variations in Protestant liturgies

In the 16th century, the New Testament was appealed to as a guide for reforming the worship as well as the doctrine of the time. Because the worship reflected in the New Testament is synagogue worship, Protestant worship of the less liturgical kind became, in many respects, a return to synagogue worship. Protestants separated the two services (instructional and Eucharistic) that had been joined together in the historic liturgy of Christendom. The Protestant Sunday service is the Liturgy of the Learners, a new revision of the synagogue liturgy. It centres in the biblical word read and preached. The congregation worships in anticipation of and response to the scriptural word. Praise becomes corporate only in hymns sung by the congregation, and prayer voices human need and misery as revealed in the Bible and claims the promises heard there.

The absence of a developed liturgy generally limits the amount and variety of scripture read in the course of a year, as well as the forms of congregational participation. On the one hand, it limits worship to the resources and skill of local ministers, but, on the other hand, it also leaves a freedom to choose what is useful from any source—this has become an increasing practice in almost every Protestant church in the 20th century. Such freedom has been welcomed by many in the latter part of the 20th century—when all Protestant and Catholic liturgies seem likely to change without much advance notice (see also CHRISTIANITY). (H.G.D.)

The critical study of biblical literature: exegesis and hermeneutics

Exegesis, or critical interpretation, and hermeneutics, or the science of interpretive principles, of the Bible have been used by both Jews and Christians throughout their histories for various purposes. The most common purpose has been that of discovering the truths and values of the Old and New Testaments by means of various techniques and principles, though very often, due to the exigencies of certain historical conditions, polemical or apologetical situations anticipate the truth or value to be discovered and thus dictate the type of exegesis or hermeneutic to be used. The primary goal, however, is to arrive at biblical truths and values by an unbiassed use of exegesis and hermeneutics.

NATURE AND SIGNIFICANCE

Biblical exegesis is the actual interpretation of the sacred book, the bringing out of its meaning; hermeneutics is the study and establishment of the principles by which it is to be interpreted. Where the biblical writings are interpreted on a historical perspective, just as with philological and other ancient documents, there is little call for a special discipline of biblical hermeneutics. But it has been widely held that the factors of divine revelation and inspiration in the Bible, which, according to Jewish and Christian belief, set it apart from other literature, impose their appropriate hermeneutical principles, although there has been divergence of opinion on what these principles are. Again, because of the place that the biblical writings have occupied in synagogue and church, their exploitation for apologetical or polemical ends, their employment as a source for dogma or as a means of grace, fostering individual and community devotion, and the use of certain parts (especially the psalms) in the congregational liturgy, the science of hermeneutics has been studiously cultivated as a theological discipline. To treat the Bible like any other book (even in order to discover that it is not like any other book) has been condemned by believers as an unworthy, not to say impious, attitude.

Varying standards and presuppositions

At times the languages in which the biblical texts were originally composed have for that reason been treated as sacred languages. Hebrew may be to the philologist a Canaanite dialect, not substantially different from Phoenician, or Moabite, or other Semitic languages, but for some people even today this language is invested with an aura of sacredness. As for the language of the New Testament, in the days before its place within the general development of Hellenistic Greek was properly appreciated, it could be called a "language of the Holy Ghost," as it was by the German Lutheran theologian Richard Rothe (1799–1867). And even scholars who know very well the true character of the biblical languages are tempted at times to make the Old and New Testament vocabularies, down to the very prepositions, bear a greater weight of theological significance than sound linguistic practice permits. Where in other Greek literature the context would be allowed to determine the precise force of this or that synonym, there is a tendency to approach the New Testament with definitions ready made and to impose them on the text: to give one example, of two common Greek words meaning "new," it is sometimes laid down in advance that *kainos* denotes new in character and *neos* new in time ("young"). Often such distinctions are valid, but their validity must be established by the context; where the context discourages such precise differentiations, they must not be forced upon it.

Again, it is a truism in linguistic study that the meaning of a word depends on its usage, not on its derivation. It may be of interest to know that the Hebrew word for "burnt offering" (*'ola*) etymologically means "ascending" (*cf.* the verb *'ala,* "ascend"), and to trace the stages by which it attained its biblical meaning, but this knowledge is almost wholly irrelevant to the understanding of the word in the Old Testament ritual vocabulary, and any attempt to link it, say, with the ascension of Jesus in the New Testament, as has been done, can lead only to confusion.

Similarly there has been a tendency to place the history contained in the biblical writings on a different level from "ordinary" history. Here the increasing knowledge of the historical setting of the biblical narrative, especially in the Old Testament, has helped to remove the impression that the persons and peoples portrayed in this narrative are not quite "real"; it has integrated them with contemporary life and promoted a better understanding of what they had in

common with their neighbours and what their distinctive qualities were.

BIBLICAL CRITICISM

A prerequisite for the exegetical study of the biblical writings, and even for the establishment of hermeneutical principles, is their critical examination. Most forms of biblical criticism are relevant to many other bodies of literature.

Textual criticism. Textual criticism is concerned with the basic task of establishing, as far as possible, the original text of the documents on the basis of the available materials. For the Old Testament, until 1947, these materials consisted principally of: (1) Hebrew manuscripts dated from the 9th century AD onward, the Masoretic text, the traditional Jewish text with its vocalization and punctuation marks as recorded by the editors called Masoretes (Hebrew *masora,* "tradition") from the 6th century to the end of the 10th; (2) Hebrew manuscripts of medieval date preserving the Samaritan edition of the Pentateuch (first five books of the Bible); (3) Greek manuscripts, mainly from the 3rd and 4th centuries AD onward, preserving the text of the pre-Christian Greek version of the Hebrew Bible together with most of the apocryphal books (the Septuagint); (4) manuscripts of the Syriac (Peshitta) and Latin (Vulgate) versions, both of which were based directly on the Hebrew. Since 1947 the discovery of Hebrew biblical texts at Qumrān (then Jordan) and other places west of the Dead Sea has made it possible to trace the history of the Hebrew Bible back to the 2nd century BC and to recognize, among the manuscripts circulating in the closing generations of the Second Jewish Commonwealth (*c.* 450 BC–*c.* AD 135), at least three types of Hebrew text: (1) the ancestor of the Masoretic text, (2) the Hebrew basis of the Septuagint version, and (3) a popular text of the Pentateuch akin to the Samaritan edition. A comparative examination of these three indicates that the ancestor of the Masoretic text is in the main the most reliable; the translators of the Revised Standard Version (1952) and New English Bible (1970) have continued to use the Masoretic text as their Old Testament basis.

Biblical manuscript texts and editions

For the New Testament the chief text-critical materials are (1) manuscripts of the Greek text, from the 2nd to the 15th centuries, of which some 5,000 are known, exhibiting the New Testament text in whole or in part; (2) ancient versions in Syriac, Coptic, Latin, Armenian, Georgian, Ethiopic, and other languages; and (3) citations in early Christian writers. A comparative study of this material enables scholars to get behind the Byzantine type of text (the type that first diffused from Constantinople from the 4th century onward, gained currency throughout Greek-speaking Christendom, and formed the basis of the earliest printed editions of the Greek Testament) to a variety of types current in various localities in the generations immediately preceding; but the more recent discovery of manuscripts (mainly on papyrus) of the 3rd and even 2nd centuries, which cannot be neatly assigned to one or another of these types, makes the earlier history of the text more problematic, and the Revised Standard Version and New English Bible are both based on an eclectic text (in which, where the witnesses show variant readings, the reading preferred is that which best suits the context and the author's known style).

New Testament textual problems

Philological criticism. Philological criticism consists mainly in the study of the biblical languages in their widest scope, so that the vocabulary, grammar, and style of the biblical writings can be understood as accurately as possible with the aid not only of other biblical writings but of other writings in the same or cognate languages. New Testament Greek, for example, is a representative of Hellenistic Greek written in the 1st century AD, ranging from the literary Hellenistic of Hebrews, I Peter, and portions of Luke–Acts, to the colloquial or vernacular idiom of some other books (*e.g.,* the conversations in the Gospels). Some Aramaic influences have been discerned in parts of the New Testament that have a Palestinian setting, but not to a point where scholars are obliged to conclude that some books, or parts of books, were originally composed in Aramaic. Moreover, the Septuagint version exercised on some New Testament writers the kind of influence that the King James Version has exercised on many English writers, especially in the provision of a theological vocabulary in areas such as law, ethics, atonement, and sacrifice. The study of Old Testament Hebrew has been enriched by the study of other Semitic languages—Akkadian and Ugaritic among the ancient languages, and Arabic, which preserves many archaic features. Such comparative study has led to the suggestion of new meanings for a considerable number of biblical Hebrew words—a tendency that is amply illustrated by the New English Bible—but this department of philological criticism requires much more carefully defined guiding lines than have hitherto been laid down.

Literary criticism. Literary criticism endeavours to establish the literary genres (types or categories) of the various documents and to reach conclusions about their structure, date, and authorship. These conclusions are based as far as possible on internal evidence, but external evidence is also very helpful, especially where date is concerned. If the document under consideration is unmistakably quoted in another composition, for example, that quotation forms a *terminus ante quem* (later limiting point in time) for dating purposes. If, on the other hand, the document is clearly dependent on another document that can be dated on independent grounds, the date of the earlier document provides a *terminus post quem* (earlier limiting point in time).

Importance of literary genres

Proved dependence on such an earlier document may also throw light on the structure of the work being studied. But much of the evidence for the history of its structure is internal. The evaluation of such evidence is the province of what used to be called the higher criticism, a term first employed with a biblical reference by the German biblical scholar and orientalist Johann Gottfried Eichhorn (1752–1827):

> I have been obliged to bestow the greatest amount of labour on a hitherto entirely unworked field, the investigation of the inner constitution of the separate books of the Old Testament by the aid of the higher criticism (a new name to no humanist).

Eichhorn paid special attention to the Pentateuch; his work marks an important step forward in Pentateuchal criticism. The chronological arrangement of the successive law codes contained in the Pentateuch, or of the successive editions of one fundamental law code, has been related to the history of Israelite culture and religion recorded in the other Old Testament books—histories, prophecies, and psalms—with the mounting aid supplied by contemporary non-Israelite documents. The development of some Old Testament books is indicated expressly in their contents: one can note the composition of the first and second editions of the Book of Jeremiah in Jer. 36:4, 32; and scholars can reach some conclusions about later editions by a comparison of the longer edition in the Masoretic text with the shorter edition in the Septuagint (now also attested in a fragmentary Hebrew text from Qumrān). In the absence of such explicit evidence, conclusions about the structure of other prophetic books, such as Isaiah and Ezekiel, must be more tentative.

In the New Testament, literary criticism has centred principally on the Gospels. In the Synoptic Gospels (that is, those having a common source; *i.e.,* Matthew, Mark, and Luke) indicators as to source and composition are provided by the presence of so much material common to two or to all three of them. The majority opinion for well over a century has been that Mark served as a source for Matthew and Luke, and that the two latter had a further common source, generally labelled Q (for *Quelle,* the German term for "source"), comprising mainly sayings of Jesus. Aspects of the Gospel problem that literary criticism leaves unsolved are more likely to be illuminated by other critical approaches. The Fourth Gospel (John), having much less in common with the Synoptic Gospels than the latter three have among themselves, presents an independent line of transmission, and a comparative study of those areas where the Johannine and Synoptic traditions touch each other yields valuable conclusions for the beginnings of the gospel story.

Tradition criticism. Tradition criticism takes up where

Tracing the oral tradition

literary criticism leaves off; it goes behind the written sources to trace the development of oral tradition, where there is reason to believe that this preceded the earliest documentary stages, and attempts to trace the development of the tradition, phase by phase, from its primary life setting to its literary presentation. The development of the tradition might cover a lengthy period, as in the Old Testament narratives of the patriarchs—Abraham, Isaac, and Jacob—and the judges, such as Deborah and Samuel, many of which were originally attached to particular sanctuaries. The recognition of the life setting of each successive phase is necessary to the interpretation of the material received and delivered by one generation after another.

In the New Testament, too, special attention has been paid to the oral stage of the Gospel tradition, though here the preliterary period is measured in decades, not (as in the Old Testament) in generations and centuries. Not only the record of the ministry of Jesus but the development of Christian theology in the short preliterary stage has formed the subject matter of this study.

Form criticism. Form criticism has become one of the most valuable tools for the reconstruction of the preliterary tradition. This discipline classifies the literary material according to the principal "forms"—such as legal, poetic, and other forms—represented in its contents, and examines these in order to discover how they were handed down and what their successive life settings were until they assumed their present shape and position. In their various ways laws, narratives, psalms, and prophecies are amenable to this approach. By this means some scholars have undertaken to recover the *ipsissima verba* ("very own words") of Jesus by removing the accretions attached to them in the course of transmission. The exegetical task assumes a threefold shape as scholars work back from (1) interpretation of the present Gospels through (2) interpretation of the tradition lying behind them to (3) reconstruction of the proclamation of Jesus.

Scholars are not left completely to speculation as they attempt to reconstruct the stages by which the Gospel tradition attained its final form: here and there in the New Testament letters, and in some of the speeches included in Acts (which convey the general sense of what was said and should not be regarded as the author's free creations), there are fragments and outlines of the story of Jesus and of his teaching. Sometimes the characteristic terminology of tradition ("I received . . . I delivered") is used when such fragments are introduced, a decade or so before the composition of the earliest Gospel (*cf.* I Cor. 11:23; 15:3).

Other types of exegetical critical techniques. *Redaction criticism.* Redaction criticism concentrates on the end product, studying the way in which the final authors or editors used the traditional material that they received and the special purpose that each had in view in incorporating this material into his literary composition. It has led of late to important conclusions about the respective outlooks and aims of the four evangelists, Matthew, Mark, Luke, and John.

Biblical texts in relation to their historical milieu

Historical criticism. Historical criticism places the documents in their historical setting and promotes their interpretation in the light of their contemporary environment. This is necessary for their understanding, whether they are historical in character or belong to another literary genre. If they are historical in character it is important to establish how faithfully they reflect their dramatic date—the date of the events they record (as distinct from the date of final composition). This test has been applied with singularly positive results to Luke–Acts, especially in relation to Roman law and institutions; and in general the biblical outline of events from the middle Bronze Age (*c.* 21st–*c.* mid-16th centuries BC) to the 1st century AD fits remarkably well into its Near Eastern context as recovered by archaeological research.

"History of religions" criticism. "History of religions" criticism, to use an ungainly expression, relates Old and New Testament religion to the religious situation of the contemporary world of the writings and tries to explain biblical religion as far as possible in terms of current religious attitudes and practices. This is helpful to a point, insofar as it throws into relief those features of Hebrew and Christian faith that are distinctive; it is carried to excess when it attempts to deprive those features of their unique qualities and to account completely for them in religious–historical terms. When the cult of Israel was practically indistinguishable from that of the Canaanites, the protests of the 8th-century-BC Hebrew prophets Amos or Hosea stand out over against popular Yahweh worship (Hebrew) and Baal worship (Canaanite) alike. Another attempt has been made by historians of religion to recreate for the 1st century AD a pre-Christian Gnostic myth—referring to an esoteric dualism in which matter is viewed as evil and spirit good—of the primal or heavenly man who comes from the realm of light to liberate particles of a heavenly essence that are imprisoned on earth in material bodies and to impart the true knowledge. By men's acceptance of this secret salvatory knowledge (gnosis), the heavenly essence within man is released from its thraldom and reascends to its native abode. Fragments of this myth have been recognized in several books of the New Testament. But the attempt has not been successful: according to many recent (latter half of the 20th century) New Testament scholars and historians of the early church, it is probable that the concepts of primal man and redeemer-revealer were not brought together in Gnosticism *except* under the influence of the Christian apostolic teaching, in which Jesus fills the role of Son of man (or Second Adam) together with that of Saviour and Revealer.

On the other hand, the Iranian religious influence, primarily that of Zoroastrianism, on the angelology and eschatology (concepts of the last times) of Judaism in the last two centuries BC is unmistakable, especially among the Pharisees (a liberal Jewish sect emphasizing piety) and the Qumrān community (presumably the Essenes) near the Dead Sea. In the latter, indeed, Zoroastrian dualism finds clear expression, such as in the concept of a war between the sons of light and the sons of darkness, although it is subordinated to the sovereignty of the one God of Israel.

The value of these critical methods of Bible study lies in their enabling the reader to interpret the writings as accurately as possible. By their aid he can ascertain better what the writers meant by the language they used at the time they wrote and how their first readers would have understood their language. If the understanding of readers today is to have any validity, it must bear a close relation to what the original readers were intended to understand.

For additional information about the various forms of biblical criticism, see above: *Old Testament canon, texts, and versions*; and *New Testament canon, texts, and versions.*

TYPES OF BIBLICAL HERMENEUTICS

As has been said, the importance of biblical hermeneutics has lain in the Bible's status as a sacred book in Judaism and Christianity, recording a divine revelation or reproducing divine oracles. The "oracles" are primarily prophetic utterances, but often their narrative setting has also come to acquire oracular status. Quite different hermeneutical principles, however, have been inferred from this axiom of biblical inspiration: whereas some have argued that the interpretation must always be literal, or as literal as possible (since "God always means what he says"), others have treated it as self-evident that words of divine origin must always have some profounder "spiritual" meaning than that which lies on the surface, and this meaning will yield itself up only to those who apply the appropriate rules of figurative exegesis. Or again, it may be insisted that certain parts must be treated literally and others figuratively; thus some expositors who regard the allegorical (symbolic) interpretation of the Old Testament histories as the only interpretation that has any religious value maintain that in the apocalyptic writings that interpretation which is most literal is most reliable.

Interpretation of biblical inspiration

Literal interpretation. Literal interpretation is often, but not necessarily, associated with the belief in verbal or plenary inspiration, according to which not only the biblical message but also the individual words in which that message was delivered or written down were divinely chosen. In an extreme form this would imply that God dictated the

message to the speakers or writers word by word, but most proponents of verbal inspiration repudiate such a view on the reasonable ground that this would leave no room for the evident individuality of style and vocabulary found in the various authors. Verbal inspiration received classic expression by the 19th-century English biblical scholar John William Burgon:

> The Bible is none other than *the voice of Him that sitteth upon the Throne!* Every Book of it, every Chapter of it, every Verse of it, every word of it, every syllable of it, (*where* are we to *stop?*) every letter of it, is the direct utterance of the Most High! (From *Inspiration and Interpretation,* 1861).

This explains Burgon's severe judgment that the revisers of the English New Testament (1881), in excluding what they believed to be scribal or editorial additions to the original text, "stand convicted of having deliberately rejected the words of Inspiration in every page" (*The Revision Revised,* p. vii, London, 1883). Such a high view of inspiration has commonly been based on the statement in II Tim. 3:16 that "all [Old Testament] scripture is God-breathed" (Greek *theopneustos,* which means "inspired by God") or Paul's claim in I Cor. 2:13 to impart the gospel "in words not taught by human wisdom but taught by the Spirit, interpreting spiritual truths in spiritual language." On this latter passage the English bishop and biblical scholar Joseph Barber Lightfoot (1828–89) remarked:

> The notion of a verbal inspiration in a certain sense is involved in the very conception of an inspiration at all, because words are at once the instruments of carrying on and the means of expressing ideas, so that the words must both lead and follow the thought. But the passage gives no countenance to the popular doctrine of verbal inspiration, whether right or wrong (From *Notes on Epistles of St. Paul from Unpublished Commentaries,* 1895).

The detailed attention that Lightfoot and his Cambridge University colleagues, Brooke Foss Westcott (1825–1901), successor of Lightfoot as bishop of Durham, and Fenton John Anthony Hort (1828–92), paid in their exegesis to the vocabulary and grammatical construction of the biblical documents, together with their concern for the historical context, sprang from no dogmatic attachment to any theory of inspiration but represented the literal method of interpretation at its best. Such grammatico-historical exegesis can be practiced by anyone with the necessary linguistic tools and accuracy of mind, irrespective of confessional commitment, and is likely to have more permanent value than exegesis that reflects passing fashions of philosophical thought. Biblical theology itself is more securely based when it rests upon such exegesis than when it forms a hermeneutical presupposition.

The Bible as a guide to conduct

Moral interpretation. Moral interpretation is necessitated by the belief that the Bible is the rule not only of faith but also of conduct. The Jewish teachers of the late pre-Christian and early Christian Era, who found "in the law the embodiment of knowledge and truth" (Rom. 2:20), were faced with the necessity of adapting the requirements of the Pentateuchal codes to the changed social conditions of the Hellenistic Age (3rd century BC–3rd century AD). This they did by means of a body of oral interpretation, which enabled the conscientious Jew to know his duty in the manifold circumstances of daily life. If, for example, he wished to know whether this or that activity constituted "work" that was forbidden on the sabbath, the influential school of legal interpretation headed by the rabbi Hillel (late 1st century BC to early 1st century AD) supplied a list of 39 categories of activity that fell under the ban.

The Christian Church rejected the Jewish "tradition of the elders" but for the most part continued to regard the Ten Commandments as ethically binding and devised new codes of practice, largely forgetting Paul's appeal to the liberty of the Spirit, or viewing it as an invitation to indulge in allegory. In order to deduce moral lessons from the Bible, allegorization was resorted to, as when the *Letter of Barnabas* (*c.* AD 100) interprets the Levitical food laws prescribed in the book of Leviticus as forbidding not the flesh of certain animals but the vices imaginatively associated with the animals. To set up principles of exegesis by which ethical lessons may be drawn from all parts of the Bible is not easy, since many of the commandments enjoined upon the Israelites in the Pentateuch no longer have any obvious relevance, such as the ban on boiling a kid in its mother's milk (Ex. 23:19b, etc.), or on wearing a mixed woollen and linen garment (Deut. 22:11); and much of the teaching of Jesus in the Sermon on the Mount is widely regarded as a counsel of perfection, impracticable for the average man, even when he professes the Christian faith. Even summaries of the biblical ethic, such as the golden rule (Matt. 7:12; *cf.* Tob. 4:15) or the twofold law of love to God and love to one's neighbour (Deut. 6:5; Lev. 19:18), in which the Decalogue (Ten Commandments) is comprehended (Mark 12:29–31; *cf.* Rom. 13:8–10), involve casuistic interpretation (fitting general principles to particular cases) when they are applied to the complicated relations of present-day life. The difficulties of applying biblical ethics to modern situations do not mean that the task of application should be abandoned but that it should not be undertaken as though it provided an easy shortcut to moral solutions.

Allegorical interpretation. Allegorical interpretation places on biblical literature a meaning that, with rare exceptions, it was never intended to convey. Yet at times this interpretation seemed imperative. If the literal sense, on which heretics, such as the 2nd-century biblical critic Marcion, and anti-Christian polemicists, such as the 2nd-century philosopher Celsus, insisted, was unacceptable, then allegorization was the only procedure compatible with a belief in the Bible as a divine oracle. Law, history, prophecy, poetry, and even Jesus' parables yielded new meanings when allegorized. The surface sensuous meaning of the Canticles (the Song of Solomon) was gladly forgotten when its mutual endearments were understood to express the communion between God and the soul, or between Christ and the church. There are still readers who can reconcile themselves to the presence of a book such as Joshua in the canon only if its battles can be understood as pointing to the warfare of Christians "against the spiritual hosts of wickedness in the heavenly places" (Eph. 6:12). As for the Gospel parables, when in the story of the good Samaritan (Luke 10:30–37) an allegorical meaning is sought for the thieves, the Samaritan's beast, the inn, the innkeeper, and the two pence, the result too often is that the explicit point of the story, "Go and do likewise," is blunted.

Typological interpretation

Closely allied to allegorical interpretation, if not indeed a species of it, is typological interpretation, in which certain persons, objects, or events in the Old Testament are seen to set forth at a deeper level persons, objects, or events in the New. In such interpretations, Noah's ark (Gen. 6:14–22) is interpreted to typify the church, outside which there is no salvation; Isaac carrying the wood for the sacrifice (Gen. 22:6) typifies Jesus carrying the cross; Rahab's scarlet cord in the window (Jos. 2:18–21) prefigures the blood of Christ; and so on. These are not merely sermon illustrations but rather aspects of a hermeneutical theory that maintains that this further significance was designed (by God) from the beginning. Traces of typology appear in the New Testament, as when Paul in Rom. 5:14 calls Adam a "type" of the coming Christ (as the head of the old creation involved its members in the results of his disobedience, so the head of the new creation shares with its members the fruit of his obedience), or when in I Cor. 10:11 he says that the Israelites' experiences in the wilderness wanderings befell them "typically," so as to warn his own converts of the peril of rebelling against God. The fourth evangelist stresses the analogy between the sacrificial Passover lamb of the Hebrews and Christ in his death (John 19). The writer of the Hebrews treats the priest-king of Salem, Melchizedek, who was involved with Abraham as a type of Christ (Heb. 7)—without using the word "type"—and the Levitical ritual of the Day of Atonement as a model (though an imperfect one) of Christ's sacrificial ministry (Heb. 9).

Other hermeneutical principles. *Anagogical interpretation.* Anagogical (mystical or spiritual) interpretation seeks to explain biblical events or matters of this world so that they relate to the life to come. Jordan is thus interpreted as the river of death; by crossing it one enters into the heavenly Canaan, the better land, the "rest that remains

for the people of God." "The Jerusalem that now is" points to the new Jerusalem that is above. In Judaism of the closing centuries BC, the Eden of Genesis, the earthly paradise, lent its name to the heavenly paradise mentioned occasionally in the New Testament (Luke 23:43; II Cor. 12:3; Rev. 2:7).

Another form of mystical interpretation is the Mariological (referring to Mary, the mother of Jesus) application of scriptures that have another contextual sense. Thus Mary is the second Eve, whose offspring bruises the serpent's head (Gen. 3:15); Mary is the star-crowned woman of Rev. 12, whose son is caught up to the throne of God, and in more popular piety the dark-faced Madonna of the monastery at Montserrat, near Barcelona, Spain, can be identified with the "black but comely" bride of the Song of Solomon.

Parallelism. Parallelism, the interpretation of Scripture by means of Scripture, is a corollary of the belief in the unity of Scripture. But as a hermeneutical principle it must be employed sparingly, since the unity of Scripture should be based on comprehensive exegetical study, rather than itself provide a basis. Where one or two biblical documents (*e.g.,* the letters to the Romans and to the Galatians) are treated as the norm of biblical doctrine, there is a danger that other parts of the volume (*e.g.,* the Letter to the Hebrews) will be forced to yield the same sense as the "normative" documents; the distinctiveness of certain biblical authors will then be blurred. One naive form of parallelism is the "concordant" method, in which it is axiomatic that a Hebrew or Greek word will always (or nearly always) have the same force wherever it occurs in the Bible, no matter who uses it. There is, again, a harmonistic tradition that smooths out disparities in the biblical text (*e.g.,* as between the gospel narratives or the parallel records of Kings and Chronicles) in a manner that imposes a greater strain on faith than do the disparities themselves.

Concordant and harmonistic methods

One exegetical device of the Jewish rabbis (teachers, biblical commentators, and religious leaders) was that of *gezera shawa,* "equal category," according to which an obscure passage might be illuminated by reference to another containing the same key term. There are several examples in Paul's Old Testament exegesis, one of the best known being in Gal. 3:10–14, where the mystery of Christ's dying the death that incurred the divine curse (Deut. 21:23) is explained by his bearing vicariously the curse incurred by the lawbreaker (Deut. 27:26). One may compare the explanation in Heb. 4:3–9 of God's "rest" mentioned in Ps. 95:11 by reference to his resting on the seventh day after creation's work (Gen. 2:3)—an explanation dependent on the Septuagint, not the Hebrew.

Analogical interpretation. Analogical interpretation traditionally includes not only interpretation according to the analogy of Scripture (parallelism, in other words) but also interpretation according to the "analogy of faith"—an expression that misapplies the language of Rom. 12:6 in the King James Version of 1611. It has at times been pressed to mean that no biblical interpretation is valid unless it conforms to the established teaching of a religious community, to the verdict of tradition, or to the "unanimous consensus of the fathers." Where the established teaching is based, in intention, on Scripture, then an interpretation of Scripture that conflicts with it naturally calls for further scrutiny, but such conflict does not rule out the interpretation beforehand; if the conflict is confirmed, it is the established teaching that requires revision.

Other types. There is an unconscious tendency to conform hermeneutical principles to the climate of opinion in and around the community concerned, and to change the hermeneutic pattern as the climate of opinion changes. It is not surprising that in the circles where Pseudo-Dionysius (early-6th-century writings attributed to Dionysius, a convert of St. Paul) was revered as a teacher, Scripture was interpreted in Neoplatonic (idealistic and mystical) categories, and if in the latter half of the 20th century there is an influential and persuasive school of existential hermeneutics, this may be as much due to a widespread contemporary outlook on life as was the liberal hermeneutic of the preceding generations.

Existential interpretations

At a far different level contemporary movements continue to influence biblical interpretation. The interpretation of prophecy and apocalyptic in terms of events of the interpreter's day, which has ancient precedent, is still avidly pursued. Just as in the 16th century the apocalyptic beast of Revelation was interpreted to be the papacy or Martin Luther (in accordance with the interpreter's viewpoint), so also today in some nonacademic circles the ten kings denoted by the beast's horns in Revelation are identified with the European Economic Community in its ultimate development, or the threat to "destroy the tongue of the sea of Egypt" (Isa. 11:15) is believed to be fulfilled in the condition of the Suez Canal in the years following 1967. Whatever critical exegetes think of such aberrations, historians of exegesis will take note of them and recognize the doctrine of Scripture that underlies them.

THE DEVELOPMENT OF BIBLICAL EXEGESIS AND HERMENEUTICS IN JUDAISM

Early stages. The beginnings of biblical exegesis are found in the Old Testament itself, where earlier documents are interpreted in later documents, as in the recasting of earlier laws in later codes, or the Chronicler's reworking of material in Samuel and Kings. In addition, even before the Babylonian Exile (586 BC) there is evidence of the kind of midrashic exposition (nonliteral interpretations) familiar in the rabbinical period (*c.* 300 BC–*c.* AD 500) and after.

In Isa. 40 and following, the restoration of Israel after the return from exile is portrayed as a new creation: the characteristic verbs of the Genesis creation narrative—"create" (*bara*), "make" (*'asa*) and "form" (*yatzar*)—are used of this new act of God (*e.g.,* Isa. 43:7). Even more clearly are the same events portrayed as a new Exodus: on their journey back from Babylon, as earlier through the wilderness, the God of Israel makes a way for his people; he protects them before and behind; he champions them "with a mighty hand and an outstretched arm," he brings water from the rock for their sustenance (Isa. 43:2, 16, 19; 48:21; 52:12; Ezek. 20:33).

A pattern of divine action in mercy and judgment is discernible as one moves from the earlier prophets to the later prophets and apocalyptists (those concerned with the intervention of God in history). Yahweh's "strange work" in bringing the Assyrians against Israel in the 8th century BC (Isa. 28:21; 29:14) is repeated a century later when he raises up the Chaldaeans (Babylonians) to execute his judgment (Hab. 1:5 fol.). Ezekiel's visionary figure Gog is the invader whose aggression was foretold in earlier days by Yahweh through his "servants the prophets" (Ezek. 38:17), and one may recognize in him a revival not only of Isaiah's Assyrian (Isa. 10:4 fol.) but also of Jeremiah's destroyer from the north (Jer. 1:14 fol.; 4:6 fol.). The same figure reappears in the last "king of the north" in Dan. 11:40 fol.; he too is diverted from his path by "tidings from the east and the north" (*cf.* Isa. 37:7) and "shall come to his end, with none to help him" (*cf.* Isa. 31:8).

Later events as recapitulations of earlier events

In some degree these later predictions are interpretations, or reinterpretations, of the earlier ones, as when the non-Israelite prophet Balaam's "ships . . . from Kittim" (Num. 24:24) are interpreted in Dan. 11:30 as the Roman vessels off Alexandria in 168 BC that frustrated the Syrian king Antiochus IV Epiphanes (*c.* 215–164/163 BC) in his attempt to annex Egypt.

Ezra (*c.* 400 BC), whose role as the archetypal "scribe" is magnified by tradition, is said in the canonical literature to have brought the law of God from Babylonia to Jerusalem (Ezra 7:14), where it was read aloud to a large assembly by relays of readers "with interpretation"—and "they gave the sense, so that the people understood the reading" (Neh. 8:8). This may be the first recorded use of an Aramaic Targum—a paraphrase of the Hebrew that included interpretation as well as translation.

In the scribal and rabbinic tradition, two forms of exposition were early distinguished—*peshaṭ,* "plain meaning," and *derash,* "interpretation," by which religious or social morals were derived, often artificially, from the text. There was, however, no sense of conflict between the two.

The Hellenistic period. The translation of the Hebrew Bible into Greek by Alexandrian Jews in the 2nd and 3rd

centuries BC provided opportunities for recording interpretations that were probably current in Hellenistic Judaism. Literal translations might be misleading to Greek readers; metaphors natural in Hebrew were rendered into less figurative Greek. "Walking with God" or "walking before God" was rendered as "pleasing God." Such renderings are scarcely to be called anti-anthropomorphisms (that is, against depicting God in human terms or forms). In certain books there are some renderings that might be so described: in Ex. 24:10, for example, "they saw the God of Israel" becomes "they saw the place where the God of Israel stood"; but an examination of the Hebrew context suggests that this is precisely what was seen.

Metaphorical and philosophical interpretations

There was a tendency to universalize certain particularist statements of the Hebrew: in Amos 9:11 fol. the prophecy that David's dynasty will repossess the residue of Edom becomes a promise that the residue of men (the Gentiles) will seek the true God—a promise that is quoted in the New Testament as a "testimony" to the Christian Gentile mission.

The other main contribution to biblical exegesis in Alexandria was made by the Jewish philosopher Philo (*c.* 30/*c.* 20 BC–after AD 40), whose interpretation of the Pentateuch in terms of Platonic idealism and Stoic ethics had more influence on Christian than on Jewish hermeneutics.

In Palestinian Judaism the most distinctive exegetical work in the Hellenistic period was that of the Qumrān community (*c.* 130 BC–AD 70). The community, believing itself raised up to prepare for the new age of everlasting righteousness, interpreted Scripture so as to find there the divine purpose about on the point of fulfillment, together with its own duty in the impending crisis. Biblical prophecies in the Qumrān commentaries refer to persons and events of the recent past, the present, or the imminent future. The time of their fulfillment was concealed from the prophets; only when this was revealed to the Teacher of Righteousness, the organizer of the community, could their intent be grasped.

Rabbinic exegesis was present in all the varieties of rabbinic literature but is found especially in the Targumim and Midrashim (plural of Targum and Midrash). Among the former, special interest attaches to the early Palestinian Pentateuch Targum; it preserves, for example, messianic (referring to the expected anointed deliverer) exegesis of certain passages to which later rabbis gave a different interpretation because of the Christians' appeal to them. The earlier Midrashim—those whose contents are not later than AD 200—expound Exodus, Leviticus, Numbers, and Deuteronomy and are almost entirely Halakhic—*i.e.,* recording legal interpretations from various schools. The later Midrashim are more homiletic and include a considerable element of Haggada; *i.e.,* illustrative material drawn from all sources.

Rabbinic exegesis was not haphazard; it observed certain rules, which were variously formulated in the schools. The name of the famous interpreter Hillel is linked with seven *middot*, or norms; (1) inference from less important to more important and vice versa, (2) inference by analogy, (3) the grouping of related passages under an interpretative principle that primarily applies to one of them, (4) similar grouping where the principle primarily applies to two passages, (5) inference from particular to general and vice versa, (6) exposition by means of a similar passage, (7) inference from the context. By the time of Rabbi Ishmael (*c.* AD 100) these rules were expanded to 13, and Eliezer ben Yose the Galilaean (*c.* AD 150) formulated 32 rules, reflecting rational principles of exegesis, which remained normative into the Middle Ages.

Norms of interpretation

The medieval period. By the beginning of the Middle Ages the Masoretes of Babylonia and Palestine (6th–10th century) had fixed in writing, by points and annotation, the traditional pronunciation, punctuation, and (to some extent) interpretation of the biblical text. The rise of the Karaites, who rejected rabbinic tradition and appealed to Scripture alone (8th century onward) stimulated exegetical study in their own sect and in Judaism generally: in reaction against them Sa'adia ben Joseph (882–942), who was the *gaon*, or head, of the Sura academy in Babylonia, did some of his most important work. He adopted as one basic principle that biblical interpretation must not contradict reason. He translated most of the Bible into Arabic and composed an Arabic commentary on the text.

The French Jewish biblical and Talmudic scholar Rashi (Rabbi Shlomo Yitzhaqi of Troyes, 1040–1105), the most popular of all Jewish commentators, paid careful heed to the language and rejected those midrashic traditions that were inconsistent with the plain meaning of the text. Abraham ibn Ezra, of Spanish birth (1092/93–1167), in some respects anticipated the Pentateuchal literary criticism of later centuries. Other important names are Joseph Qimḥi of Narbonne and his sons Moses and David, the last of whom (*c.* 1160–1235) commented on the prophets and psalms; his psalms commentary took issue especially with Christian exegesis.

The great philosopher and codifier Maimonides (Moses ben Maimon, 1135–1204) composed, among many other works, his *Guide of the Perplexed* to help readers who were bewildered by apparent contradictions between the biblical text and the findings of reason. Like his younger contemporary David Qimḥi, he classified some biblical narratives as visionary accounts.

Far removed from the rational exegesis of these scholars was the mystical tradition, or Kabbala, which combined with an earlier mysticism—involving reflection on Ezekiel's inaugural chariot vision—the Neoplatonic doctrine of emanations. Adherents of this mystical exegesis found encouragement in the Pentateuch commentary of the Spanish Talmudist, Kabbalist, and biblical commentator Moses ben Naḥman (*c.* 1195–1270). The tracing of mystical significance in the numerical values of Hebrew letters and words (*gematria*) made a distinctive contribution to mystical exegesis. The chief monument of mystical exegesis is the 13th-century Spanish *Sefer ha-zohar* ("Book of Splendour"), in form a midrashic commentary on the Pentateuch. In the *Zohar* the *peshaṭ* (literal) and *derash* (nonliteral meanings) types of interpretation are accompanied by those called *remez* ("allusion"), including typology and allegory, and *sod* ("secret"), the mystical sense. The initials of the four were so arranged as to yield the word PaRDeS ("Paradise"), a designation for the fourfold meaning. The highest meaning led by knowledge through love to ecstasy and the beatific vision.

Mystical interpretation

The modern period. Following a line marked out earlier by the Spanish philosopher and poet Moses ibn Ezra (1060–1139), Benedict de Spinoza (1632–77) put forward a thoroughgoing reappraisal of the traditional account of the origin of the Pentateuch in his *Tractatus Theologico-Politicus* (1679). In the following century the Jewish Enlightenment (Haskala) brought a fresh appreciation of the Bible as literature. The pioneer of the Enlightenment, Moses Mendelssohn (1729–86), prepared a German translation of the Pentateuch, which he furnished (along with Solomon Dubno and others) with a commentary; he also translated the psalms and the Song of Solomon.

The tradition of orthodox Jewish exegesis has been maintained to the present day. In the 19th century the Russian rabbi Meir ben Yehiel Michael, "Malbin," (1809–79) wrote commentaries on the prophets and the writings, making a special point of explaining differences between synonyms. In the 20th century the traditional values of Judaism were popularly expounded in Joseph Herman Hertz's commentary on *The Pentateuch and Haftorahs* (1929–36) and in the Soncino *Books of the Bible* (1946–51). Martin Buber (1878–1965), the great modern Jewish philosopher, imparted to his many studies in biblical literature and religion—including his revolutionary German translation of the Bible (1926 and following), partly executed in association with the religious philosopher Franz Rosenzweig (1886–1926)—the qualities of his personal genius that was influenced by Ḥasidic (18th-century mystical) piety and an existential interpretation of life.

20th-century commentators

In recent decades the most valuable Jewish exegesis has been in association with the wider world of biblical scholarship. Journals such as the *Jewish Quarterly Review* and the *Hebrew Union College Annual* welcome contributions from non-Jewish scholars; in interconfessional projects such as the Anchor Bible, Jewish scholars cooperate in the Old and New Testament alike.

The whole field of biblical study, including exegesis, is cultivated most intensively in Israel. Yehezkel Kaufmann (1890–1963) produced the encyclopaedic *History of Israelite Religion from Its Beginnings to the End of the Second Temple* (8 vol., 1937–56) in Hebrew that pursues a path involving a radical revision of current biblical criticism and interpretation. Mosheh Zevi Hirsh Segal (died 1968) dealt with a wide area of biblical and related literature, maintaining the essential Mosaic authorship of the Pentateuch (supplemented by later editors who worked in Moses' spirit). The most ambitious enterprise in this field is the "Bible Project" of the Hebrew University of Jerusalem, which aims to produce a critical edition of the Hebrew Bible but also fosters a number of ancillary studies in biblical text and interpretation, mostly published in its annual report *Textus,* in which non-Jewish as well as Jewish scholars participate.

THE DEVELOPMENT OF BIBLICAL EXEGESIS AND HERMENEUTICS IN CHRISTIANITY

Early stages. The earliest Christian exegesis of the Old Testament is found in the New Testament, not in the written texts only but in the oral tradition lying behind them. Some lines of exegesis are present in so many separate strands of primitive Christian teaching that they are most reasonably assigned to Jesus, who began his Galilaean ministry with the announcement that the time appointed for the fulfillment of prophecy, and the Kingdom of God that was its main theme, had arrived. If the accomplishment of his ministry involved his death, that was accepted in the same spirit; he submitted to his captors with the words: ". . . Let the scriptures be fulfilled" (Mark 14:49). The church began with the conviction that Jesus, crucified and risen, was the one of whom the prophets spoke. He was the prophet like Moses, prince of the house of David, priest of the order of Melchizedek, servant of the Lord, Son of man, and exalted Lord. If the prophets themselves were uncertain about the person or time indicated by their oracles, the early Christians were certain: the person was Jesus, the time was now. The New Testament writers shared a creative and flexible principle of exegesis that has regard for the literary and historical context and traces a consistent pattern of divine action in judgment and mercy, reproduced repeatedly in the history of Israel and manifested definitively in Christ. This exegesis is elaborated at times by means of typology and allegory, as when Paul illustrates the relationship between law and gospel by the story of Hagar and Sarah, the concubine and wife of Abraham, respectively (Gal. 4:21–31), or when Israel's tabernacle in the wilderness becomes the material counterpart to the heavenly sanctuary in which believers of the new age offer spiritual worship to God (Heb. 8:2 fol.). The writer to the Hebrews, indeed, occasionally relates the old order to the new order platonically in terms of the earthly copy of an eternal archetype.

At an early date Christians developed a line of Old Testament exegesis designed to show that they, not the Jews, stand in the true succession of the original people of God. This line is seen in the *Letter of Barnabas,* the apologist Justin's (*c.* 100–*c.* 165) *Dialogue with Trypho,* and the 3rd-century *Against the Jews* ascribed to the North African bishop Cyprian (*c.* 200–258).

Alexandrian allegorization

The patristic period. Alexandria had long boasted a school of classical study that practiced the allegorical interpretation of the Homeric epics and the Greek myths. This method of exegesis was taken over by Philo and from him by Christian scholars of Alexandria in the 2nd and 3rd centuries. Clement of Alexandria (*c.* 150–*c.* 215) and Origen (*c.* 185–*c.* 254) did not completely rule out the literal sense of Scripture—Origen's *Hexapla,* a six column edition of various biblical versions, was a monument to his painstaking study of the text—but claimed that the most meaningful aspects of divine revelation could be extracted only by allegorization. Clement stated that the Fourth Gospel was a "spiritual gospel" because it unfolds the deeper truth concealed in the matter-of-fact narratives of the other three. Origen treated literal statements as "earthen vessels" preserving divine treasure; their literal sense is the body as compared with the moral sense (the soul) and the spiritual sense (the spirit). The true exegete, he claimed, pursues the threefold sense and recognizes the spiritual (allegorical) as the highest.

Later, the Antiochene fathers, represented especially by Theodore of Mopsuestia (*c.* 350–428/429) and John Chrysostom (*c.* 347–407), patriarch of Constantinople, developed an exegesis that took more account of literal meaning and historical context. But the allegorizers could claim that their method yielded lessons that (while arbitrary) were more relevant and interesting to ordinary Christians.

In the West, the Alexandrian methods were adopted by Ambrose (*c.* 339–397), bishop of Milan, and Augustine (354–430), bishop of Hippo, especially as formulated in the seven "rules" of Tyconius (*c.* 380), a Donatist heretic (one who denied the efficacy of sacraments administered by an allegedly unworthy priest), which classified allegorical interpretation in relation to: (1) the Lord and his church, (2) true and false believers, (3) promise and law, (4) genus and species, (5) numerical significance, (6) "recapitulation," and (7) the devil and his followers. There were other Latin exegetes, like Ambrosiaster (commentaries ascribed to Ambrose) and, supremely, Jerome (*c.* 347–419/420), the learned Latin Father, who paid close attention to the grammatical sense. In the Old Testament Jerome appealed from the Greek version to the "Hebraic verity" and in such a work as his commentary on Daniel provided some fine examples of historical exegesis. Augustine, though not primarily an exegete, composed both literal and allegorical commentaries and expository homilies on many parts of Scripture, and his grasp of divine love as the essential element in revelation supplied a unifying hermeneutical principle that compensates for technical deficiencies.

The medieval period. As the patristic age gave way to the scholastic age, the English monk Bede of Jarrow (died 735) wrote commentaries designed to perpetuate patristic exegesis, mainly allegorical: thus Elkanah with his two wives (1 Sam. 1:2) is interpreted as referring to Christ with the synagogue and the church.

The fourfold sense of Scripture

In the early Middle Ages the fourfold sense of Scripture—developed from Origen's threefold sense by subdividing the spiritual sense into the allegorical (setting forth the doctrine) and the anagogical (relating to the coming world)—was increasingly expounded and received its final authority from Thomas Aquinas (1225/26–74). For Thomas, the literal sense, expressing the author's intention, was a fit object of scientific study; the figurative senses unfolded the divine intention.

Medieval exegesis was greatly influenced by the *Glossa Ordinaria,* a digest of the views of the leading fathers and early medieval doctors (teachers) on biblical interpretation. This compilation owed much in its initial stages to Anselm of Laon (died 1117); it had reached its definitive form by the middle of the 12th century and provided the exegetical norm of the *Summa theologiae* ("Summation of Theology") of Thomas Aquinas and others.

For all the interest in allegory, literal interpretation was cultivated in many centres in the West, often with the aid of Hebrew, knowledge of which was obtainable from Jewish rabbis. One such centre was the Abbey of Saint-Victor at Paris, where Hugh (died 1141) compiled biblical commentaries that fill three volumes of J.-P. Migne's (1800–75) *Patrologiae Cursus Completus* (Series Latina) and indicate the commentator's dependence on Rashi as well as on his Christian predecessors. Of Hugh's disciples, Andrew, abbot of Wigmore (died 1175), carried on his master's tradition of literal scholarship, and Richard, the Scottish-born prior of Saint-Victor (died 1173) pursued a line more congenial to his mystical temperament. Herbert of Bosham (*c.* 1180) produced a commentary on Jerome's Hebrew Psalter. Robert Grosseteste, bishop of Lincoln (died 1253), wrote commentaries on the days of creation and the Psalter that both drew on the Greek fathers and profited by his direct study of the Hebrew text. Nicholas of Lyra (*c.* 1265–*c.* 1349), the greatest Christian Hebraist and expositor of the later Middle Ages, compiled *postillae,* or commentaries, both literal and figurative, on the whole Bible; he insisted that only the literal sense could establish proof. Luther ranked him among the best exegetes: "a fine soul, a good Hebraist and a true Christian."

The Reformation period. The English theologian John Colet (*c.* 1466–1519) broke with medieval scholasticism when he returned from the Continent to Oxford in 1496 and lectured on the Pauline letters, expounding the text in terms of its plain meaning as seen in its historical context. The humanist Erasmus (*c.* 1466–1536) owed to him much of his insight into biblical exegesis. By the successive printed editions of his Greek New Testament (1516 and following), Erasmus made his principal, but not his only, contribution to biblical studies.

Reformation principles

Martin Luther (1483–1546) was a voluminous expositor, insisting on the primacy of the literal sense and dismissing allegory as so much rubbish—although he indulged in it himself on occasion. The core of Scripture was to him its proclamation of Christ as the one in whom alone lay man's justification before God. John Calvin (1509–64), a more systematic expositor, served his apprenticeship by writing a youthful commentary on the Roman statesman and philosopher Seneca the Younger's (*c.* 4 BC–AD 65) *De clementia* ("Concerning Mercy"); systematic theologian though he was, he did not allow his theological system to distort the plain meaning of Scripture, and his philological–historical interpretation is consulted with profit even today.

Scientific exegesis was pursued on the Catholic side by scholars such as F. de Ribera (1591) and L. Alcasar (1614), who showed the way to a more satisfactory understanding of the Revelation. On the Reformed side, the *Annotationes in Libros Evangeliorum* (1641–50) by the jurist Hugo Grotius (1583–1645) were so objective that some criticized them for rationalism.

The modern period. The modern period is marked by advances in textual criticism and in the study of biblical languages and history, all of which contribute to the interpretation of the Bible. The German theologian J.A. Bengel's (1687–1752) edition of the Greek text of the New Testament with critical apparatus (1734), in which he framed the canon that "the more difficult reading is to be preferred," was followed by his exegetical *Gnomon Novi Testamenti* ("Introduction to the New Testament," 1742): "apply thyself wholly to the text," he directed; "apply the text wholly to thyself." The English bishop Robert Lowth's (1710–87) Oxford lectures on *The Sacred Poetry of the Hebrews,* published in Latin in 1753, greatly promoted the understanding of the poetry of the Old Testament by expounding the laws of its parallelistic structure. The German philologist Karl Lachmann (1793–1851) applied his expertise in classical criticism to editing the text of the New Testament; to him also belongs the credit of arguing that Mark was the earliest of the Gospels and a main source of Matthew and Luke (1835).

Source analysis and historical interpretations

The problem of the source analysis of the Pentateuch was given what for long appeared to be its final solution by Julius Wellhausen (1844–1918), who related the successive law codes to the development of the Israelite cultus. For the period preceding the 9th century BC, however, he operated in a historical vacuum that Near Eastern archaeology was in his day only beginning to fill; its subsequent findings have dictated radical modifications in his reconstruction of Israel's religious history. In the middle half of the 19th century, New Testament exegesis was overshadowed by the school of Ferdinand Christian Baur (1792–1860), which envisaged a sharply opposed Petrine (Peter) and Pauline (Paul) antithesis in the primitive church, followed in the 2nd century by a synthesis that is reflected in most of the New Testament writings. In France, Ernest Renan's (1823–92) works on early Christianity were helpful philological and historical studies; the most popular volume, his *Vie de Jésus* (1863), was the least valuable. In England, where the poet and educator Matthew Arnold (1822–88) endeavoured to find an impregnable moral foundation for biblical authority, New Testament exegesis received contributions of unsurpassed worth between 1865 and the end of the century from J.B. Lightfoot, B.F. Westcott, and F.J.A. Hort.

At the beginning of the 20th century a new direction was given to Gospel interpretation by the German scholar William Wrede (*Das Messiasgeheimnis in den Evangelien,* 1901) and the medical missionary theologian Albert Schweitzer (*The Quest of the Historical Jesus,* Eng. trans., 1910), who so emphasized the eschatological orientation of Jesus' mind and message that New Testament scholarship can never be the same again. The writings of the biblical scholar C.H. Dodd (*The Parables of the Kingdom,* 1935; *The Apostolic Preaching and Its Developments,* 1936) stressed realized eschatology—that the standards of the last times were realized by Jesus and his disciples—in the preaching of Jesus and of the primitive church; he has been a leading pioneer of the "biblical theology" movement. Karl Barth's (1886–1968) commentary on Romans (1919) launched an existential interpretation of the New Testament, which has been pursued more radically by Rudolf Bultmann (1884–1976), under the influence of Wilhelm Dilthey (1833–1911), according to whom the interpreter must project himself into the author's experience so as to relive it, and of Martin Heidegger (1889–1976), whose conception of the truly authentic man as capable of freedom because he has faced reality provides the "pre-understanding" for Bultmann's existential theology. Bultmann's disciple Ernst Fuchs considers the hermeneutical task to be the creation of a "language event" in which the authentic language of Scripture encounters one now, challenging decision, awakening faith, and accomplishing salvation. The chief rival to existential exegesis is the "salvation-history" hermeneutic espoused by Oscar Cullmann.

Existential and form-critical exegesis

Rudolf Bultmann and Martin Dibelius (1883–1947) pioneered the modern form-critical study of the Gospels. The form-critical method was fruitfully applied to the Old Testament by Hermann Gunkel (1862–1932) and Sigmund Mowinckel (1884–1965). Among Catholic scholars, exegetical studies are vigorously promoted by Jean Daniélou (with his researches into early Jewish Christianity), the Dominicans of the École Biblique et Archéologique (The School of the Bible and Archeology) in Jerusalem (to whom one must credit the Jerusalem Bible), and the Jesuits of the Pontifical Biblical Institute and others.

The encouragement given by the second Vatican Council (1962–65) of the Roman Catholic Church to biblical scholarship, to be cultivated in association with "separated brethren" and with consideration for the requirements of non-Christians, is one indication of a new direction in biblical exegesis, in which this study will no longer be pursued as a vindication of sectional traditions but rather as a cooperative enterprise aiming at making widely available the permanent value of the Bible. (F.F.B.)

BIBLIOGRAPHY

Biblical literature. *Nature and significance.* General articles and notes in *The Oxford Annotated Bible* (1962), *The Jerusalem Bible* (1966), and the *Genesis* volume of *The Anchor Bible,* by E.A. SPEISER (1964); E. H. GOMBRICH, *The Story of Art,* 12th rev. ed. (1972); ABRAHAM J. HESCHEL, *Man Is Not Alone* (1951), a classic statement of modern Judaism; ERICH AUERBACH, *Mimesis: Dargestellte Wirklichkeit in der abendländischen Literatur* (1946; Eng. trans., *Mimesis: The Representation of Reality in Western Literature,* 1953), a classic work; WILLIAM R. MUELLER, *The Prophetic Voice in Modern Fiction* (1959), religious themes interpreting Joyce, Camus, Kafka, Faulkner, Greene, and Silone; NATHAN A. SCOTT, JR. (ed.), *The Tragic Vision and the Christian Faith* (1957), essays by 12 writers on faith and the tragic dimension of existence; JAMES BARR, *The Scope and Authority of the Bible* (1981), questions the divine inspiration of biblical texts.

Old Testament canon, texts, and versions: OTTO EISSFELDT, *Einleitung in das Alte Testament,* 3rd ed. (1964; Eng. trans., *The Old Testament: An Introduction,* 1965); *The Cambridge History of the Bible* (CHB), 3 vol. (1963–70). (*The Canon*): FRANTS BUHL, *Kanon und Text des Alten Testaments* (1891; Eng. trans., *Canon and Text of the Old Testament,* 1892); MAX L. MARGOLIS, *The Hebrew Scriptures in the Making* (1922); HERBERT E. RYLE, *The Canon of the Old Testament,* 2nd ed. (1895); SOLOMON ZEITLIN, "An Historical Study of the Canonization of the Hebrew Scriptures," *Proceedings of the American Academy for Jewish Research,* pp. 121–158 (1932). (*Textual criticism, texts and manuscripts, and early versions*): FRANK MOORE CROSS, *The Ancient Library of Qumrân and Modern Biblical Studies,* 2nd ed. (1961); "The History of the Biblical Text in the Light of Discoveries in the Judaean Desert," *Harvard Theological Review,* 57:281–299 (1964); and "The Contribution of the Qumrân Discoveries to the Study of the Biblical Text," *Israel Exploration Journal,* 16:81–95 (1966);

CHRISTIAN D. GINSBURG, *Introduction to the Massoretico: Critical Edition of the Hebrew Bible* (1897, reprinted 1966); MOSHE H. GOSHEN-GOTTSTEIN, *Linguistic Structure and Tradition in the Qumran Documents* (1958); "Theory and Practice of Textual Criticism," *Textus,* 3:130–158 (1963); and *The Book of Isaiah: Sample Edition with Introduction* (1965); MOSHE GREENBERG, "The Stabilization of the Text of the Hebrew Bible," *Journal of the American Oriental Society,* 76:157–167 (1956). PAUL KAHLE, *The Cairo Genizah,* 2nd ed. (1959); FREDERICK G. KENYON, *The Bible and the Ancient Manuscripts,* 5th ed. rev. (1958); HARRY M. ORLINSKY, "The Textual Criticism of the Old Testament," in GEORGE E. WRIGHT (ed.), *The Bible and the Ancient Near East,* pp. 113–132 (1961); BLEDDYN J. ROBERTS, *The Old Testament Text and Versions* (1951); and "The Old Testament: Manuscripts, Text and Versions," *CHB,* vol. 2, pp. 1–26 (1969); P.W. SKEHAN, "Qumran and the Present State of Old Testament Text Studies," *Journal of Biblical Literature,* 78:21–25 (1959); S. TALMON, "Aspects of the Textual Transmission of the Bible in the Light of Qumran Manuscripts," *Textus,* 4:95–132 (1964); ERNST WURTHWEIN, *Der Text des Alten Testaments* (1952; Eng. trans., *The Text of the Old Testament,* 1957). (*Later and modern versions–English versions*): DAVID DAICHES, *The King James Version of the English Bible* (1941, reprinted 1968); MARGARET DEANESLY, *The Lollard Bible and Other Medieval Biblical Versions* (1920, reprinted 1966); HERMAN HAILPERIN, *Rashi and the Christian Scholars* (1963); WILLIAM F. MOULTON, *The History of the English Bible,* 5th ed. (1911); ALFRED W. POLLARD, *Records of the English Bible* (1911); and, with G.R. REDGRAVE, *A Short-Title Catalogue of Books Printed in England, Scotland, and Ireland and of English Books Printed Abroad 1475–1640* (1926, reprinted 1969); B.F. WESTCOTT, *A General View of the History of the English Bible,* 3rd ed. rev. by W.A. WRIGHT (1905). (*Continental versions and non-European versions*): THOMAS H. DARLOW and HORACE F. MOULE, *Historical Catalogue of the Printed Editions of the Holy Scripture in the Library of the British and Foreign Bible Society,* 2 vol. (1903–11); JOSEF SCHMID (ed.), "Moderne Bibelübersetzungen," *Zeitschrift für katholische Theologie,* 82:290–332 (1960).

Old Testament history: Two current histories of Israel exhibit the full range of historiographical problems and methods relating to the subject: JOHN BRIGHT, *A History of Israel* (1959); and MARTIN NOTH, *Geschichte Israels,* 3rd ed. (1956; Eng. trans., *The History of Israel,* 1958). They differ mainly in where they begin; Bright begins with Abraham, Noth with the federation of tribes that calls itself Israel in the land of Canaan. They disagree about the demonstrability of such a community in the pre-Canaanite times because of their respective assessment of the character of the Pentateuch. Bright assumes that it was intended as a history concerned to record the early past, while Noth assumes that its thematic traditions were intended to define and celebrate the identity of the later Israel and hence do not constitute a usable historical resource about its earliest beginnings. This whole methodological problem in Israelite historiography is lucidly discussed and illustrated in a little book by JOHN BRIGHT—*Early Israel in Recent History Writing: A Study in Method* (1956). For the use of archaeology, geography, and history of religion in the study of the history of Israel, see GEORGE ERNEST WRIGHT. *Biblical Archaeology,* rev. ed. (1962); LUC H. GROLLENBERG, *Atlas van de Bijbel,* 3rd ed. (1954; Eng. trans., *Atlas of the Bible,* 1956); YEHEZKEL KAUFMANN, *The Religion of Israel, from Its Beginnings to the Babylonian Exile* (1960); and HELMER RINGGREN, *Israelitische Religion* (1963; Eng. trans., 1966).

Old Testament literature: For various modern critical methods of studying the formation of the Old Testament, see the "Old Testament Series" of *Guides to Biblical Scholarship:* NORMAN C. HABEL, *Literary Criticism of the Old Testament,* GENE M. TUCKER, *Form Criticism of the Old Testament,* and WALTER E. RAST, *Tradition History and the Old Testament* (1971–72). Among general introductions, the most exhaustive is OTTO EISSFELDT (*op. cit.*), based mainly on literary criticism. The other methods are reflected to a somewhat greater extent in AAGE BENTZEN, *Introduction to the Old Testament,* 3rd ed. (1957); and in the briefer, less original but very readable work of ARTUR WEISER, *Einleitung in das Alte Testament,* 4th ed. (1957; Eng. trans., *The Old Testament: Its Formation and Development,* 1961). For pioneering research in tradition analysis of the Pentateuch and the Former Prophets, see MARTIN NOTH, *Überlieferungsgeschichte des Pentateuch,* 3rd ed. (1966; Eng. trans., *A History of Pentateuchal Traditions,* 1972), and *Überlieferungsgeschichtliche Studien* (1957); the latter deals with what its author calls "The Deuteronomic History," an envisioned work containing the books of Deuteronomy, Joshua, Judges, Samuel, and Kings. The contribution of form criticism to the understanding of the history of the Book of Psalms may best be approached through HERMANN GUNKEL, *The Psalms: A Form-Critical Introduction* (1967), a translation of his article in *Die Religion in Geschichte und Gegenwart* (2nd ed.) summarizing his seminal work in *Die Psalmen* (1926) and *Einleitung in die Psalmen* (1928). ELMER A. LESLIE, *The Psalms, Translated and Interpreted in the Light of Hebrew Life and Worship* (1949), is heavily dependent on Gunkel and illustrates his use of form criticism. The celebrated work of SIGMUND MOWINCKEL on the Psalter, culminating in his masterful *Offersang ob Sangoffer* (1951; Eng. trans., *The Psalms in Israel's Worship,* 2 vol., 1962), combines the methods of Gunkel with those of the comparative historian of religion and locates the setting for the production of most of the psalms in the cult of the Solomonic temple. The application of the newer methods to the study of the Latter Prophets is evident in the essays in HAROLD H. ROWLEY (ed.), *Studies in Old Testament Prophecy* (1950). The new approaches were deeply under the impact of HENRIK S. NYBERG, *Studien zum Hoseabuche* (1935). Other books that amplify the implications of his assumptions include: JOHANNES LINDBLOM, *Prophecy in Ancient Israel* (1962); CURT KUHL, *Israels Propheten* (1956; Eng. trans., *The Prophets of Israel,* 1960); and SIGMUND MOWINCKEL, *Prophecy and Tradition: The Prophetic Books in the Light of the Study of the Growth and History of the Tradition* (1946). ABRAHAM J. HESCHEL, *The Prophets* (1962), though of independent origin, belongs with those new interpretations of the prophetic materials. An old classic in a new edition, OLIVER S. RANKIN, *Israel's Wisdom Literature: Its Bearing on Theology and the History of Religion* (1936, reprinted 1969), presents Israel's wisdom literature in relation both to its extra-Israelite cultural connections and to the rest of Israel's heritage in the Old Testament. Two new approaches to the legacy of wisdom literature—through literary form and through theology—are presented, respectively, in R.B.Y. SCOTT, *The Way of Wisdom in the Old Testament* (1971); and GERHARD VON RAD, *Weisheit in Israel* (1970). See also NORTHROP FRYE, *The Great Code: The Bible and Literature* (1982), and ELSA TAMEZ, *Bible of the Oppressed* (1982), an interpretation from a Latin, female theologian's perspective.

Intertestamental literature: Standard translations of the Jewish intertestamental literature are ROBERT H. CHARLES (ed.), *The Apocrypha and Pseudepigrapha of the Old Testament in English* (1913); and EMIL KAUTZSCH (ed.), *Die Apocryphen und Pseudepigraphen des Alten Testaments* (1900). PAUL RIESSLER, *Altjüdisches Schrifttum ausserhalb der Bibel* (1928), is indispensable because it contains translations of the fullest number of writings. The best translations of the Dead Sea Scrolls are GEZA VERMES, *The Dead Sea Scrolls in English* (1962); JOHANN MAIER, *Die Texte vom Toten Meer* (1960); and ANDRE DUPONT-SOMMER, *Les Écrits esséniens découverts près de la Mer Morte,* 3rd ed. (1964). ALBERT-MARIE DENIS, *Introduction aux Pseudépigraphes grecs d'Ancien Testament* (1970), does not treat the Apocrypha and is important mainly for its bibliography. Basic books dealing with intertestamental literature are R.H. PFEIFFER, *History of New Testament Times, with an Introduction to the Apocrypha* (1949); EMIL SCHURER, *Geschichte des jüdischen Volkes im Zeitalter Jesu Christi,* 3rd–4th ed., 3 vol. (1898–1901; Eng. trans., *A History of the Jewish People in the Time of Jesus Christ,* 2nd and rev. ed., 5 vol., 1885–91); and ROBERT H. CHARLES, *Religious Development Between the Old and the New Testaments* (1914). Still interesting is ROBERT TRAVERS HERFORD, *Talmud and Apocrypha* (1933, reprinted 1971). Information about the library of the Dead Sea Scrolls is in two books: JOZEF T. MILIK, *Dix Ans de découvertes dans le désert de Juda* (1957; Eng. trans., *Ten Years of Discovery in the Wilderness of Judaea,* 1959); and FRANK MOORE CROSS, *The Ancient Library of Qumrân and Modern Biblical Studies,* 2nd ed. (1961). A fragment of Ben Sira from antiquity was published by YIGAEL YADIN, *The Ben Sira Scroll from Masada, with Introduction, Emendations and Commentary* (1965). The best book about Jewish eschatology is PAUL VOLZ, *Die Eschatologie der jüdischen Gemeinde im neutestamentlichen Zeitalter* (1934). On Apocalyptic and Messianism, see HAROLD H. ROWLEY, *The Relevance of Apocalyptic,* 3rd ed. (1963); DAVID S. RUSSELL, *The Method and Message of Jewish Apocalyptic, 200 BC–AD 100* (1964); SIGMUND MOWINCKEL, *Han som kommer* (1951; Eng. trans., *He That Cometh,* 1954); ERIK SJOBERG, *Der Menschensohn im äthiopischen Henochbuch* (1946); and A.S. VAN DER WOUDE, *Die messianischen Vorstellungen der Gemeinde von Qumrân* (1957).

New Testament canon, texts, and versions: (*Canon*): For the relevant primary texts on the history of the canon, see DANIEL J. THERON (ed.), *Evidence of Tradition* (1957), with selected source material in Greek or Latin with English translation; and JAMES STEVENSON (ed.), *A New Eusebius* (1957). For introductions, see ALEXANDER SOUTER and C.S.C. WILLIAMS, *The Text and Canon of the New Testament,* 2nd ed. rev. (1954); and ROBERT M. GRANT, *The Formation of the New Testament* (1965). For a phenomenological approach, see GERARDUS VAN DER LEEUW, *Phänomenologie der Religion,* 2nd ed., 2 vol. (1956; Eng. trans., *Religion in Essence and Manifestation,* 2nd

ed., 2 vol., 1963), ch. 64. (*Texts*): The major text for further study is BRUCE H. METZGER, *The Text of the New Testament* (1964). (*Translations*): On translation in general, see REUBEN A. BROWER (ed.), *On Translation* (1959). For translation of the Bible into English, see FREDERICK F. BRUCE, *The English Bible: A History of Translations from the Earliest English Versions to the New English Bible,* 2nd ed. (1970).

New Testament history: (*Jewish culture and history*): Standard works are R.H. PFEIFFER (*op. cit.*); and GEORGE F. MOORE, *Judaism in the First Centuries of the Christian Era,* 3 vol. (1927–30). (*Qumrān, Dead Sea Scrolls*): FRANK MOORE CROSS, JR. (*op. cit.*); on Qumrān and New Testament problems, see KRISTER STENDAHL (ed.), *The Scrolls and the New Testament* (1958). (*Greco-Roman culture and history*): WILLIAM W. TARN, *Hellenistic Civilisation,* 3rd ed. rev. (1952). For a broad cultural comparison, see ERIC R. DODDS, *Pagan and Christian in an Age of Anxiety* (1965). (*Pauline chronology*): The debate can be best assessed by comparing JOHN KNOX, *Chapters in a Life of Paul* (1950), with DIETER GEORGI, *Die Geschichte der Kollekte des Paulus für Jerusalem* (1965).

New Testament literature: The following works are useful for commentary, survey articles, and bibliographic material: GEORGE A. BUTTRICK (ed.), *The Interpreter's Bible,* especially vol. 1, 7, and 12 (1952–57); MATTHEW BLACK (ed.), *Peake's Commentary on the Bible,* 2nd ed. (1962); and RAYMOND E. BROWN, JOSEPH A. FITZMYER, and ROLAND E. MURPHY (eds.), *The Jerome Biblical Commentary* (1968). WERNER G. KUEMMEL, *The New Testament: The History of the Investigations of Its Problems* (1972), covers the whole history of New Testament studies with ample excerpts from the major scholars since the 18th century. For a rich introduction to the 27 books of the New Testament with full and balanced reporting on all major issues of contemporary discussion and extensive bibliographies, see PAUL FEINE, JOHANNES BEHM, and WERNER G. KUEMMEL, *Einleitung in das Neue Testament,* 14th rev. ed. (1965; Eng. trans., *Introduction to the New Testament,* 1966). For a general dictionary to the Bible, see GEORGE A. BUTTRICK (ed.), *The Interpreter's Dictionary of the Bible,* 4 vol. (1962). The most extensive tool for the study of New Testament theological terms is GERHARD KITTEL (ed.), *Theological Dictionary of the New Testament,* vol. 1–8 (1964–72, in progress). For New Testament theologies, see RUDOLF BULTMANN, *Theologie des Neuen Testaments,* 3rd ed. (1958; Eng. trans., *Theology of the New Testament,* 2 vol., 1951–55); HANS CONZELMANN, *Grundriss der Theologie des Neuen Testaments,* 2nd ed. (1967; Eng. trans., *An Outline of the Theology of the New Testament,* 1969). For general commentary, see *The International Critical Commentary on the Holy Scriptures of the Old and New Testaments,* 41 vol. (1895–1920); for the major German commentary, see *Kritisch exegetischer Kommentar über das Neuen Testament* ("Meyer Series," frequently updated); *Handbuch zum Neuen Testament* (Lietzmann-Bornkamm); and *Das Neue Testament Deutsch (Göttinger Bibelwerk).* For a major French Protestant commentary, see *Commentaire du Nouveau Testament* and for major French and German Roman Catholic commentaries, see *Etudes bibliques* and *Das Neue Testament übersetzt und erklärt* (the *Regensburger New Testament*). (*Gospels—texts*): KURT ALAND (ed.), *Synopsis Quattuor Evangeliorum* (1964), a Greek synopsis, includes the Gospel of John and translations (Eng. trans. 1972) of the Coptic *Gospel of Thomas.* For a synopsis, see BURTON H. THROCKMORTON, JR. (ed.), *Gospel Parallels: A Synopsis of the First Three Gospels,* 3rd ed. (1967). For a general study of the Gospels and the Synoptic problem, see FREDERICK C. GRANT, *The Gospels: Their Origin and Their Growth* (1957). For arguments against the priority of Mark, see WILLIAM R. FARMER, *The Synoptic Problem* (1964). Significant new approaches to gospel study are found in JAMES M. ROBINSON and HELMUT KOESTER, *Trajectories Through Early Christianity* (1971). For form criticism, see RUDOLF BULTMANN, *Die Geschichte der synoptischen Tradition,* 3rd ed. (1958; Eng. trans., *The History of the Synoptic Tradition,* 1963). AMOS N. WILDER, *Early Christian Rhetoric* (1971), goes beyond form criticism by fuller attention to modern literary criticism. (*Mark*): ROBERT H. LIGHTFOOT, *The Gospel Message of St. Mark* (1950); and WILLI MARXSEN, *Der Evangelist Markus* (1959; Eng. trans., *Mark the Evangelist,* 1969), are two outstanding works representing different periods and methods of scholarship. (*Matthew*): For discussion of the arrangement, Old Testament citations, and theology of Matthew, see GUENTHER BORNKAMM, GERHARD BARTH, and HEINZ J. HELD, *Auslegung im Mattäusevangelium* (1960; Eng. trans., *Tradition and Interpretation in Matthew,* 1963). DAVID HILL, *New Testament Prophesy* (1980), a discussion of prophesy both in the Bible and in the church today. KRISTER STENDAHL, "Prayer and Forgiveness," in *Svensk Exegetisk Årsbok,* 22–23:75–86 (1957–58), in English; and *The School of St. Matthew and Its Use of the Old Testament,* 2nd ed. (1968). (*Luke*): HENRY J. CADBURY, *The Making of Luke-Acts,* 2nd ed. (1958); and HANS CONZELMANN, *Die Mitte der Zeit: Studien zur Theologie des Lukas,* 3rd ed. (1960; Eng. trans., *The Theology of St. Luke,* 1960), represent a classic treatment of Luke-Acts. (*John*): Among the most important recent studies on John are CHARLES H. DODD, *Historical Tradition in the Fourth Gospel* (1963), and *The Interpretation of the Fourth Gospel* (1953); ERNST KAESEMANN, *Jesu letzter Wille nach Johannes 17.* (1966; Eng. trans., *The Testament of Jesus: A Study of the Gospel of John in the Light of Chapter 17,* 1968); and JAMES L. MARTYN, *History and Theology in the Fourth Gospel* (1968). (*Acts*): See also *Luke* above. For Acts viewed in its own time, see HENRY J. CADBURY, *The Book of Acts in History* (1955). Literary style and methods of composition are discussed in MARTIN DIBELIUS, *Aufsätze zur Apostelgeschichte* (1951; Eng. trans., *Studies in the Acts of the Apostles,* 1956). The scope and purpose of Acts are treated in P.M. MENOUD, "Le Plan des Actes des Apôtres," *New Testament Studies,* 1:44–50 (1954–55); and W.C. VAN UNNIK, "The 'Book of Acts' the Confirmation of the Gospel," *Novum Testamentum,* 4:26–59 (1960). (*Paul*): For general works on Paul and the epistles, see GUENTHER BORNKAMM, *Early Christian Experience* (1970), and *Paulus* (1969; Eng. trans., 1971); WILLIAM D. DAVIES, *Paul and Rabbinic Judaism,* 2nd ed. (1955); MARTIN DIBELIUS and WERNER G. KUEMMEL, *Paulus* (1951; Eng. trans., 1953); JOHANNES MUNCK, *Paulus und die Heilsgeschichte* (1954; Eng. trans., *Paul and the Salvation of Mankind,* 1959); ARTHUR D. NOCK, *St. Paul* (1938); and HANS J. SCHOEPS, *Paulus: Die Theologie des Apostels...* (1959; Eng. trans., *Paul: The Theology of the Apostle...,* 1961). See also KRISTER STENDAHL, "The Apostle Paul and the Introspective Conscience of the West," *Harvard Theological Review,* 51: 199–215 (1963). For a survey of Pauline studies, see EDWARD E. ELLIS, *Paul and His Recent Interpreters* (1961); WAYNE A. MEEKS (ed.), *The Writings of St. Paul* (1972); and ERNST KAESEMANN, *Paulinische Perspektiven* (1969; Eng. trans., *Perspectives on Paul,* 1971). (*Romans*): JOHN KNOX, "A Note on the Text of Romans," *New Testament Studies,* 2: 191–192 (1955–56); KRISTER STENDAHL, "Hate, Non-Retaliation, and Love: 1QS x, 17–20 and Romans 12:19–21," *Harvard Theological Review,* 50:343–355 (1962). (*I Corinthians*): For a discussion of the heresies met in I Corinthians, see WALTER SCHMITHALS, *Die Gnosis in Korinth,* 3rd ed. (1969; Eng. trans., *Gnosticism in Corinth,* 1971). (*II Corinthians*): For the arrangement of the fragments of II Corinthians and their redaction, see GUENTHER BORNKAMM, "The History of the Origin of the So-Called 2nd Letter to the Corinthians," *New Testament Studies,* 8:258–264 (1961–62). For a discussion of Paul's opponents in II Corinthians, see DIETER GEORGI, *Die Gegner des Paulus im 2. Korintherbrief: Studien zur religiösen Propaganda in der Spätantike* (1964); and his shorter article on this subject, "Forms of Religious Propaganda," in HANS J. SCHULTZ (ed.), *Die Zeit Jesu* (1966; Eng. trans., *Jesus in His Time,* 1971). (*Galatians*): For a discussion of the heretics in Galatia, see WALTER SCHMITHALS, "Die Häretiker in Galatien," *Zeitschrift für die Neutestamentliche Wissenschaft und die Kunde der Aelteren Kirche* (ZNW), pp. 25–67 (1956). (*Ephesians*): For the meaning and goal of Ephesians, see EDGAR J. GOODSPEED, *The Meaning of Ephesians* (1933), and *The Key to Ephesians* (1956). See also C. LESLIE MITTON, *The Epistle to the Ephesians* (1951). (*Philippians*): For the place of Philippians in the Pauline collection and the meaning of its various sections, see HELMUT KOESTER, "The Purpose of the Polemic of a Pauline Fragment (Philippians III)," *New Testament Studies,* 8:317–332 (1961–62). For the concept of Philippians as a testament, see DIETER GEORGI, "Ein Testament des Paulus (Phil. 3, 2ff.)," *ZNW* (1972). (*Philemon*): JOHN KNOX, *Philemon Among the Letters of Paul,* 2nd ed. (1959). (*Pastoral Epistles*): For evidence against Pauline authorship, see PERCY N. HARRISON, *The Problem of the Pastoral Epistles* (1921). See also EDUARD SCHWEIZER, *Church Order in the New Testament* (1961). (*Hebrews*): Concerning the Christology of Hebrews and the idea of the "wandering people of God," see ERNST KAESEMANN, *Das wandernde Gottesvolk,* 3rd ed. (1959). An approach to the eschatology of Hebrews and an origin connected with followers of Stephen is found in WILLIAM MANSON, *The Epistle to the Hebrews* (1951). (*Catholic Epistles*): For the typical admixture of parenesis, apocalyptic, and the general address of the Catholic Epistles, see CARL ANDRESEN, "Zum Formular frühchristlicher Gemeindebriefe," *ZNW,* 56:233–259 (1965). The similarity of style of the Catholic Epistles to later Christian Greek literature is treated in A. WIFSTRAND, "Stylistic Problems in the Epistles of James and Peter," *Studia Theologica,* 11:35–60 (1948). (*James*): For a solution to the apparent contradiction of Paul and James concerning "works," see JOACHIM JEREMIAS, "Paul and James," *Expository Times,* 66:368–371 (1954–55); for clarification of special passages with a modern technique similar to rabbinic methodology, see ROY B. WARD, "The Works of Abraham: James 2:14–26," *Harvard Theological Review,* 61:283–290 (1968), and "Partiality in the Assembly: James 2:2–4," *ibid.,* 62:87–97 (1969). (*I Peter*): For a date in Trajan's time, see JOHN KNOX,

"Pliny and I Peter: A Note on I Pet. 4:14–16 and 3:15," *Journal of Biblical Literature,* 72:187–189 (1953); an interpretation of the Descent into Hell is found in B. REICKE, *The Disobedient Spirits and Christian Baptism: A Study of I Peter iii, 19 and Its Context* (1946). (*II Peter and Jude*): For motivation for the writing of II Peter, see ERNST KAESEMANN, "An Apologia for Primitive Christian Eschatology," in *Essays on New Testament Themes* (1964). (*Johannine Epistles*): For speculations as to authorship, date, and nature of the situation of the Johannine Epistles, see W.F. HOWARD, "The Common Authorship of the Johannine Gospel and Epistles," *Journal of Theological Studies* (1947). (*Revelation*): Concerning liturgical style and content in Revelations, see GUENTHER BORNKAMM, "On the Understanding of Worship; B," in *Early Christian Experience* (1969). For a study of Revelation as a creative revelatory poem with unity throughout, drawing upon apocalyptic imagery of its time, see AUSTIN M. FARRER, *A Rebirth of Images* (1949, reprinted 1963). A general survey of apocalypticism and apocalypses from 200 BC into the early Christian era is found in DAVID S. RUSSELL (*op. cit.*).

Apocrypha: EDGAR HENNECKE, *Neutestamentliche Apokryphen in deutscher Übersetzung* (1959; Eng. trans., *New Testament Apocrypha,* 2 vol., 1963–65), a standard work; MONTAGUE R. JAMES, *The Apocryphal New Testament* (1924, reprinted 1955), convenient but obsolete; R.M. GRANT, D.N. FREEDMAN, and W.R. SCHOEDEL, *The Secret Sayings of Jesus* (1960); B. PICK, *The Apocryphal Acts of Paul, Peter, John, Andrew and Thomas* (1909); for Greek texts, see R.A. LIPSIUS and M. BONNET, *Acta Apostolorum Apocryphe.* A Greek papyrus (late 3rd century) of the Acts of Paul was edited by C. SCHMIDT in *Praxeis Paulou* (1936); he notes other papyrus fragments. The Seneca letters were edited by C.W. BARLOW, *Epistolae Seneca ad Paulum et Pauli ad Senecam* (*quae vocantur*) (1938).

Biblical literature in liturgy: ABRAHAM Z. IDELSOHN, *The Jewish Liturgy and Its Development* (1932, reprinted 1967); JOSEPH H. HERTZ, *The Authorized Daily Prayer Book,* rev. ed. (1948), Hebrew and English with historical notes and commentary; FAN S. NOLI, *Three Liturgies of the Eastern Orthodox Church* (1955); DONALD ATTWATER, *Eastern Catholic Worship* (1945), eight Uniate liturgies in English; JOSEF A. JUNGMANN, *Missarum Sollemnia: Eine Genetische Erklärung der römischen Messe,* 2 vol. (1958; Eng. trans., *The Mass of The Roman Rite: Its Origins and Development,* abridged ed., 1959); CLEMENT J. MCNASPY, *Our Changing Liturgy* (1966), reforms following Vatican II; GREGORY DIX, *The Shape of the Liturgy* (1945); BARD THOMPSON, *Liturgies of the Western Church* (1961), includes the main Protestant traditions.

Biblical exegesis and hermeneutics. *The Cambridge History of the Bible,* 3 vol. (1963–70), includes contributions by specialists on biblical interpretation from pre-Christian times to the present day. J. BARR, *Old and New in Interpretation* (1966), discusses the relation between the Old and New Testaments and examines critically some of the interpretative principles favoured by exegetes and theologians; another work on this subject is E.C. BLACKMAN, *Biblical Interpretation* (1957). C.E. BRAATEN, *History and Hermeneutics* (1966), discusses the relevance of the historical-critical method to theological study and the idea of revelation through history; F.F. BRUCE, *Biblical Exegesis in the Qumran Texts* (1959), examines the interpretative principles followed by biblical commentaries and other documents among the Dead Sea Scrolls. The major work on the theme of salvation-history in the Bible is O. CULLMANN, *Salvation in History* (1967). C.H. DODD, *According to the Scriptures* (1952), shows the various ways in which the Christian interpretation of important areas of the Old Testament provided the substructure of New Testament theology. F.W. FARRAR, *History of Interpretation* (1886, reprinted 1961), provides a classical survey of biblical exegesis from the early rabbinical period to the 19th century; R.M. GRANT, *A Short History of the Interpretation of the Bible,* rev. ed. (1963), is probably the best work of its kind. B. LINDARS, *New Testament Apologetic* (1962), studies the Old Testament quotations in the New Testament as evidence, in their text and interpretation, for the developing life and thought of the primitive church. J.M. ROBINSON and J.B. COBB (eds.), *The New Hermeneutic* (1964), expounds modern hermeneutical concerns. B. SMALLEY, *The Study of the Bible in the Middle Ages,* 2nd rev. ed. (1952), remains the standard work on early medieval exegesis. G. VERMES, *Scripture and Tradition in Judaism* (1961), gives an account of the interaction of the written text and oral tradition in Jewish exegesis of the pre-Christian and early rabbinical age. An outline of the history of biblical interpretation and of the main exegetical trends of the mid-20th century is presented in J.D. WOOD, *The Interpretation of the Bible* (1958); A. RICHARDSON and W. SCHWEITZER (eds.), *Biblical Authority for Today* (1951), discusses the difficulties of applying biblical ethics to some of the most urgent concerns of the modern world.

Biochemical Components of Organisms

Every living system contains, besides water and minerals, a large number of organic compounds. In general, the majority of these compounds may be classified as proteins, carbohydrates, and lipids, or fats. Nucleic acids and certain other organic derivatives are also important constituents. Various substances that cannot be classified in the above categories occur as well, though usually not in appreciable amounts. Such substances include vitamins and hormones of the nonprotein variety, which are biologically effective in relatively small quantities.

Proteins are fundamental to life. Some serve as structural material, comprising a major constituent of cellular membranes and the principal component of skin, hair, horn, and feathers. Other proteins, such as antibodies, provide a defense against invading destructive forces. Still others, the enzymes, are essential biocatalysts that accelerate thousands of complex chemical reactions necessary for sustaining life. Carbohydrates, which include simple sugars, starch, and cellulose, provide a major energy source for organisms as well as vital structural components. Most of the lipids produced by cells serve the same functions. Moreover, the function of some enzymes is dependent on their attachment to lecithin and certain other lipids. The two nucleic acids, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), play an integral part in the synthesis of proteins and in the transmission of hereditary information from one generation to the next.

In most organisms all water-soluble vitamins, with the exception of vitamin C (ascorbic acid), are converted to coenzymes of enzymes that function in energy transfer or in the metabolism of proteins, carbohydrates, and lipids. Certain kinds of fat-soluble vitamins appear to contribute substantially to the structure of membranes or at least aid in maintaining their integrity. Some of them may also control the synthesis of various enzymes. Hormones, produced and secreted by endrocrine glands, help to regulate the activities of other tissues and maintain homeostasis—*i.e.*, a relatively stable internal environment.

This article provides a summary of the structure, properties, and significance of each of the major classes of biochemical substances. It also discusses in brief methods of laboratory synthesis and analysis. Additional information pertaining to the nature and characteristics of many such organic compounds can be found in the article CHEMICAL COMPOUNDS. For details on specialized subjects in which these substances play an important role, see CELLS; TISSUES AND FLUIDS; METABOLISM; GENETICS AND HEREDITY: *The gene.* (Ed.)

This article is divided into the following sections:

PROTEINS

Proteins are highly complex substances that are present in all living organisms. They are of great nutritional value and are directly involved in the chemical processes essential for life. The importance of proteins was recognized by the chemists in the early 19th century who coined the name for these substances from the Greek *proteios*, meaning "holding first place." Proteins are both species-specific and organ-specific; for instance, muscle proteins differ from those of the brain and liver.

A protein molecule is very large compared to molecules of sugar or salt and consists of many amino acids joined together to form long chains, much as beads are arranged on a string. There are about 20 different amino acids that occur naturally in proteins. Proteins of similar function have similar amino acid composition and sequence. Although it is not yet possible to explain all of the functions of a protein from its amino acid sequence, established correlations between structure and function can be attributed to the properties of the amino acids that compose proteins.

Amino acid production and requirements by plants and animals

Plants can synthesize all of the amino acids; animals cannot, even though all of them are essential for life. Plants can grow in a medium containing inorganic nutrients that provide nitrogen, potassium, and other substances essential for growth. They utilize the carbon dioxide in the air during the process of photosynthesis to form organic compounds such as carbohydrates. Animals, however, must obtain organic nutrients from outside sources. Because the protein content of most plants is low, very large amounts of plant material are required by animals, such as ruminants (*e.g.*, cows), that eat only plant material to meet their amino acid requirements. Nonruminant animals, including man, obtain proteins principally from animals and their products—*e.g.*, meat, milk, and eggs. The seeds of legumes are increasingly being used to prepare inexpensive protein-rich food (see NUTRITION: *Human nutrition and diet*).

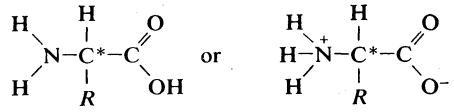
The protein content of animal organs is usually much higher than that of the blood plasma. Muscles, for example, contain about 30 percent protein, the liver 20 to 30 percent, and red blood cells 30 percent. Higher percentages of protein are found in hair, bones, and other organs and tissues with a low water content. The quantity of free amino acids and peptides in animals is much smaller than the amount of protein. Evidently, protein molecules are produced in cells by the stepwise alignment of amino acids and are released into the body fluids only after synthesis is complete.

The high protein content of some organs does not mean that the importance of proteins is related to their amount in an organism or tissue; some of the most important proteins, such as enzymes and hormones, occur in extremely small amounts. The importance of proteins is related principally to their function. All enzymes identified thus far are proteins. Enzymes, which are the catalysts of all metabolic reactions, enable an organism to build up the chemical substances necessary for life—proteins, nucleic acids, carbohydrates, and lipids—to convert them into other substances, and to degrade them. Life without enzymes is not possible. There are several protein hormones with important regulatory functions. In all vertebrates, the respiratory protein hemoglobin acts as oxygen carrier in the blood, transporting oxygen from the lung to body organs and tissues. A large group of structural proteins maintains and protects the structure of the animal body.

General structure and properties of proteins

THE AMINO ACID COMPOSITION OF PROTEINS

The common property of all proteins is that they consist of long chains of α-amino (alpha amino) acids. The general structure of α-amino acids is shown in Formula 1.



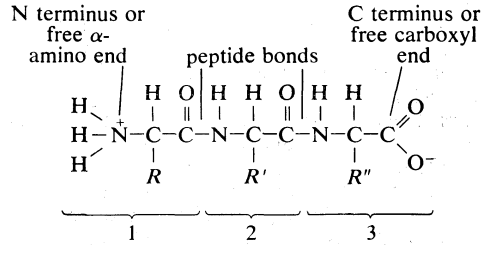
Formula 1: Generalized structure of all α-amino acids. C stands for a carbon atom; C* stands for the α-carbon. H is hydrogen, O is oxygen, and N is nitrogen. *R* is a general term for any of several different chemical structures that range from one hydrogen atom to large and complex molecular units containing many different atoms. The + and − signs represent electrical charges that exist when the molecule takes the configuration shown at the right.

The α-amino acids are so called because the α-carbon atom in the molecule (shown by an asterisk [*] in Formula 1) carries an amino group ($-NH_2$); the α-carbon atom also carries a carboxyl group (−COOH). In acidic solutions, when the pH is less than 4, the −COO groups combine with hydrogen ions (H^+) and are thus converted into the uncharged form (−COOH). In alkaline solutions, at pH above 9, the ammonium groups ($-NH^+_3$) lose a hydrogen ion and are converted into amino groups ($-NH_2$). In the pH range between 4 and 8, the amino acids exist almost exclusively in the structure shown at the right side of Formula 1. Because in this form they carry both a positive and a negative charge, they do not migrate in an electrical field. Such structures have been designated as dipolar ions, or zwitterions (*i.e.*, hybrid ions).

Although more than 100 amino acids occur in nature, particularly in plants, only 20 types are commonly found in most proteins (see Figure 1). In protein molecules the α-amino acids are linked to each other by peptide bonds between the amino group of one amino acid and the carboxyl group of its neighbour; the structure of the peptide bond is given in Formula 2. The condensation

Formula 2: The peptide bond.

(joining) of three amino acids yields the tripeptide shown in Formula 3.



Formula 3: A tripeptide. *R'* and *R''* represent the possibility that the three *R* groups (side chains) could be different.

Peptide structure

It is customary to write the structure of peptides in such a way that the free α-amino group (also called the N terminus of the peptide) is at the left side and the free carboxyl group (the C terminus) at the right side. Proteins are macromolecular polypeptides—*i.e.*, very large molecules composed of many peptide-bonded amino acids. Most of the common ones contain more than 100 amino acids linked to each other in a long peptide chain. The average molecular weight (based on the weight of a hydrogen atom as 1) of each amino acid is approximately 100 to 125; thus, the molecular weights of proteins are usually in the range of 10,000 to 100,000 daltons (one dalton is the weight of one hydrogen atom). The species-specificity and organ-specificity of proteins result from differences in the number and sequences of amino acids. Twenty different amino acids in a chain 100 amino acids long can be arranged in far more than 10^{100} ways (10^{100} is the number one followed by 100 zeroes).

Structures of common amino acids. The amino acids present in proteins differ from each other in the structure of their side (*R*) chains. The simplest amino acid is glycine, in which *R* is a hydrogen atom (see Figure 1). In a number of amino acids, *R* represents straight or branched carbon chains. One of these amino acids is alanine, in which *R* is the methyl group ($-CH_3$). Valine, leucine, and isoleucine, with longer *R* groups, complete the alkyl side-chain series. The alkyl side chains (*R* groups) of these amino acids are nonpolar; this means that they have no affinity for water but some affinity for each other. Although plants can form all of the alkyl amino acids, animals can synthesize only alanine and glycine; thus valine, leucine, and isoleucine must be supplied in the diet.

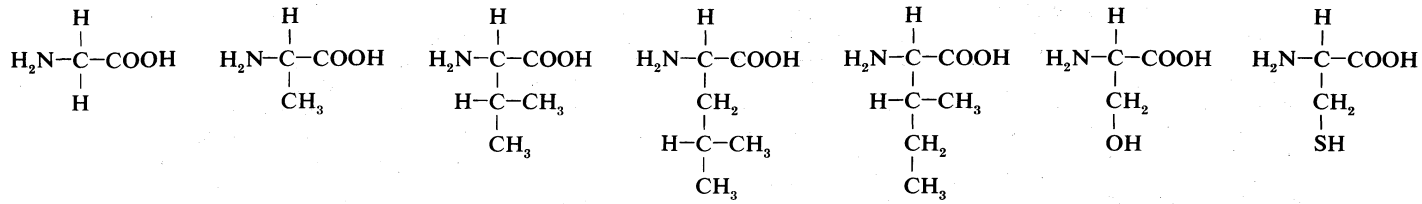
Two amino acids, each containing three carbon atoms, are derived from alanine; they are serine and cysteine. Serine contains an alcohol group ($-CH_2OH$) instead of the methyl group of alanine, and cysteine contains a mercapto group ($-CH_2SH$). Animals can synthesize serine but not cysteine or cystine. Cysteine occurs in proteins predominantly in its oxidized form (oxidation in this sense meaning the removal of hydrogen atoms), called cystine. Cystine consists of two cysteine molecules linked by the disulfide bond (−S−S−) that results when a hydrogen atom is removed from the mercapto group of each of the cysteines (see Figure 1). Disulfide bonds are important in protein structure because they allow the linkage of two different parts of a protein molecule to—and thus the formation of loops in—the otherwise straight chains. Some proteins contain small amounts of cysteine with free sulfhydryl (−SH) groups.

Four amino acids, each consisting of four carbon atoms, occur in proteins; they are aspartic acid, asparagine, threonine, and methionine. Aspartic acid and asparagine, which occur in large amounts, can be synthesized by animals. Threonine and methionine cannot be synthesized and thus are essential amino acids—*i.e.*, they must be supplied in the diet. Most proteins contain only small amounts of methionine.

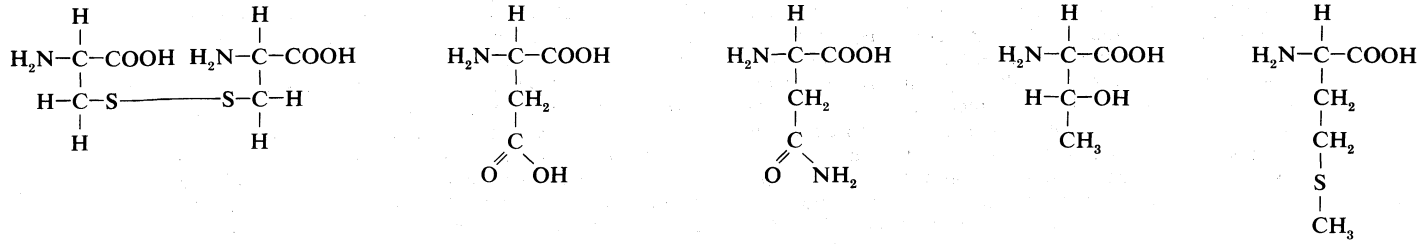
Proteins also contain an amino acid with five carbon atoms (glutamic acid) and an imino acid (proline), which is a structure with the amino group ($-NH_2$) bonded to the alkyl side chain, forming a ring. Glutamic acid and aspartic acid are dicarboxylic acids—that is, they have two carboxyl groups (−COOH). Glutamine is similar to asparagine in that both are the amides of their corresponding dicarboxylic acid forms; *i.e.*, they have an amide group ($-CONH_2$) in place of the carboxyl (−COOH) of the side chain (see Figure 1). Glutamic acid and glutamine are abundant in most proteins; *e.g.*, in plant proteins they sometimes comprise more than one third of the amino acids present. Both glutamic acid and glutamine can be synthesized by animals. The imino acids proline and hydroxyproline occur in large amounts in collagen, the protein of the connective tissue of animals (see Table 1). Proline and hydroxyproline lack free amino ($-NH_2$) groups because the amino group is enclosed in a ring structure with the side chain; they thus cannot exist in a zwitterion form. Although the imino group (>NH) of these amino acids can form a peptide bond with the carboxyl group of another amino acid, the bond so formed gives rise to a kink in the peptide chain—*i.e.*, the imino ring structure alters the regular bond angle of normal peptide bonds.

Most abundant amino acids

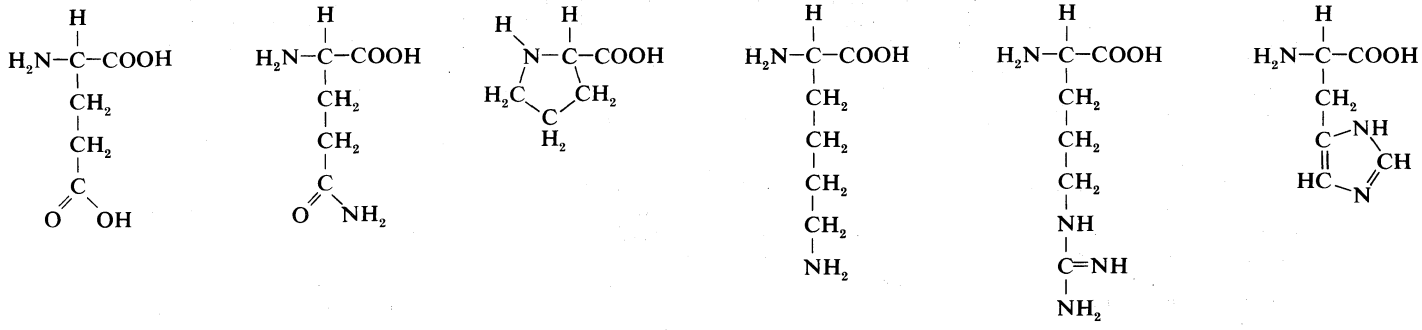
Proteins usually are almost neutral molecules; that is, they have neither acidic nor basic properties. This means that the acidic carboxyl ($-COO^-$) groups of aspartic and glutamic acid are about equal in number to the amino acids with basic side chains. Three such basic amino acids, each containing six carbon atoms, occur in proteins. The one with the simplest structure, lysine, is synthesized by plants but not by animals. Even some plants have a low lysine content. Arginine is found in all proteins; it occurs in particularly high amounts in the strongly basic protamines (simple proteins composed of relatively few amino acids) of fish sperm. The third basic amino acid is



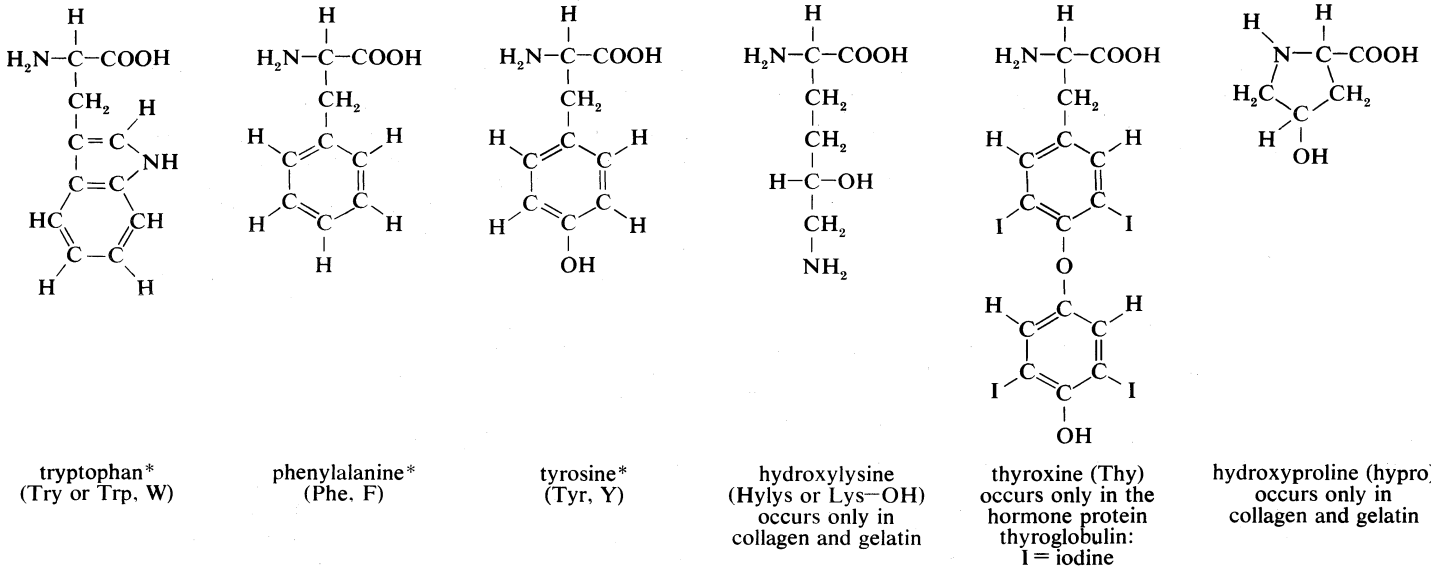
glycine (Gly, G) | alanine (Ala, A) | valine* (Val, V) | leucine* (Leu, L) | isoleucine* (Ile, I) | serine (Ser, S) | cysteine (CysH, C)



cystine (Cys-S-S-Cys, C-C) | aspartic acid (Asp, D; Asx or B) | asparagine ($AspNH_2$ or Asn, N; Asx or B) | threonine* (Thr, T) | methionine* (Met, M)



glutamic acid (Glu, E; Glx or Z) | glutamine ($GluNH_2$, GluN, or Gln, Q; Glx or Z) | proline (Pro, P) an imino acid | lysine* (Lys, K) | arginine (Arg, R) | histidine (His, H)



tryptophan* (Try or Trp, W) | phenylalanine* (Phe, F) | tyrosine* (Tyr, Y) | hydroxylysine (Hylys or Lys—OH) occurs only in collagen and gelatin | thyroxine (Thy) occurs only in the hormone protein thyroglobulin: I = iodine | hydroxyproline (hypro) occurs only in collagen and gelatin

Figure 1: Structures of amino acids found in proteins. Those amino acids marked with an asterisk (*) must be supplied in the diet of animals, which cannot synthesize them. The abbreviations in parentheses represent the shorthand notations (in three-letter codes and one-letter codes) used when indicating protein structures. The one-letter symbol for an unknown amino acid is *X*.

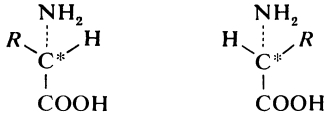
histidine. Both arginine and histidine can be synthesized by animals. Histidine is a weaker base than either lysine or arginine. The imidazole ring, a five-membered ring structure containing two nitrogen atoms in the side chain of histidine (see Figure 1), acts as a buffer (*i.e.*, a stabilizer of hydrogen ion concentration) by binding hydrogen ions (H^+) to the nitrogen atoms of the imidazole ring.

The remaining amino acids—phenylalanine, tyrosine, and tryptophan—have in common an aromatic structure; *i.e.*, a benzene ring is present (see Figure 1). Animals cannot synthesize the benzene ring, and these three amino acids are essential ones; but animals can convert phenylalanine to tyrosine. Because these amino acids contain benzene rings, they can absorb ultraviolet light at wavelengths between 270 and 290 nanometres (nm; one nanometre = 10^{-9} metre = 10 angstrom units). Phenylalanine absorbs very little ultraviolet light; tyrosine and tryptophan, however, absorb it strongly and are responsible for the absorption band most proteins exhibit at 280–290 nanometres. This absorption is often used to determine the quantity of protein present in protein samples.

Most proteins contain only the amino acids described above; however, other amino acids occur in proteins in small amounts. Thyroglobulin, the hormone of the thyroid gland, for example, contains thyroxine, which is an iodine-containing compound derived from tyrosine. The collagen found in connective tissue contains, in addition to hydroxyproline, small amounts of hydroxylysine. Other proteins contain some monomethyl-, dimethyl-, or trimethyllysine—*i.e.*, lysine derivatives containing one, two, or three methyl groups ($-CH_3$). The amount of these unusual amino acids in proteins, however, rarely exceeds 1 or 2 percent of the total amino acids.

Physicochemical properties of the amino acids. The physicochemical properties of a protein are determined by the analogous properties of the amino acids in it.

The α-carbon atom of all amino acids, with the exception of glycine, is asymmetric; this means that four different chemical entities (atoms or groups of atoms) are attached to it. As a result, each of the amino acids, except glycine, can exist in two different spatial, or geometric, arrangements (*i.e.*, isomers), which are mirror images akin to right and left hands (see Formula 4). These isomers exhibit the property of optical rotation.



L-amino acid D-amino acid

Formula 4: The tetrahedral (four-faced) arrangement of the bonds around the α-carbon (C*). The solid lines represent bonds that slant upward from the plane of the drawing (*i.e.*, toward the reader). The broken lines represent bonds that recede from the plane of the drawing (*i.e.*, away from the reader).

Optical rotation is the rotation of the plane of polarized light, which is composed of light waves that vibrate in one plane, or direction, only. Solutions of substances that rotate the plane of polarization are said to be optically active, and the degree of rotation is called the optical rotation of the solution. The direction in which the light is rotated is generally designed as plus, or *d*, for dextrorotatory (to the right), or as minus, or *l*, for levorotatory (to the left). Some amino acids are dextrorotatory; others are levorotatory.

Configuration of amino acids

With the exception of a few small proteins (peptides) that occur in bacteria, the amino acids that occur in proteins have the configuration shown on the left of Formula 4. For this reason all the amino acids found in proteins are designed as L-amino acids.

In bacteria, D-alanine and some other D-amino acids have been found as components of gramicidin and bacitracin. These peptides are toxic to other bacteria and are used in medicine as antibiotics. The D-alanine has also been found in some peptides of bacterial membranes.

In contrast to most organic acids and amines, the amino acids are insoluble in organic solvents. In aqueous solutions they are dipolar ions (zwitterions, or hybrid ions) that react with strong acids or bases in a way that leads to the neutralization of the negatively or positively charged ends, respectively. Because of their reactions with strong acids and strong bases, the amino acids act as buffers—stabilizers of hydrogen ion (H^+) or hydroxide ion (OH^-) concentrations. In fact, glycine is frequently used as a buffer in the pH range from 1 to 3 (acid solutions) and from 9 to 12 (basic solutions). In acid solutions, glycine has a positive charge and therefore migrates to the cathode (negative electrode of a direct-current electrical circuit with terminals in the solution). Its charge, however, is negative in alkaline solutions, in which it migrates to the anode (positive electrode). At pH 6.1 glycine does not migrate, because each molecule has one positive and one negative charge. The pH at which an amino acid does not migrate in an electrical field is called the isoelectric point. Most of the monoamino acids (*i.e.*, those with only one amino group) have isoelectric points similar to that of glycine. The isoelectric points of aspartic and glutamic acids, however, are close to pH 3; and those of histidine, lysine, and arginine are at pH 7.6, 9.7, and 10.8, respectively.

Amino acid sequence in protein molecules. Since each protein molecule consists of a long chain of amino acid residues, linked to each other by peptide bonds, the hydrolytic cleavage of all peptide bonds is a prerequisite for the quantitative determination of the amino acid residues. Hydrolysis is most frequently accomplished by boiling the protein with concentrated hydrochloric acid. The quantitative determination of the amino acids is based on the discovery that amino acids can be separated from each other by chromatography on filter paper and made visible by spraying the paper with ninhydrin. The amino acids of the protein hydrolysate are separated from each other by passing the hydrolysate through a column of adsorbents which adsorb the amino acids with different affinities and, on washing the column with buffer solutions, release them in a definite order. The amount of each of the amino acids can be determined by the intensity of the colour reaction with ninhydrin.

To obtain information about the sequence of the amino acid residues in the protein, the protein is degraded stepwise, one amino acid being split off in each step. This is accomplished by coupling the free α-amino group ($-NH_2$) of the N-terminal amino acid with phenyl isothiocyanate; subsequent mild hydrolysis does not affect the peptide bonds; the procedure, called the Edman degradation, can be applied repeatedly; it thus reveals the sequence of the amino acids in the peptide chain.

Unavoidable small losses that occur during each step make it impossible to determine the sequence of more than about 30 to 50 amino acids by this procedure. For this reason the protein is usually first hydrolyzed by exposure to the enzyme trypsin (see below *Enzymes*), which cleaves only peptide bonds formed by the carboxyl groups of lysine and arginine. The Edman degradation is then applied to each of the few resulting peptides produced by the action of trypsin. Further information can be gained by hydrolyzing another portion of the protein with another enzyme, for instance with chymotrypsin, which splits predominantly peptide bonds formed by the amino acids tyrosine, phenylalanine, and tryptophan. The combination of results obtained with two or more different proteolytic (protein degrading) enzymes was first applied by the English biochemist Frederick Sanger, and it enabled him to elucidate the amino acid sequence of insulin. The amino acid sequences shown in formulas 7 to 11 and those of many other proteins have been determined in this manner.

LEVELS OF STRUCTURAL ORGANIZATION IN PROTEINS

Primary structure. Analytical and synthetic procedures reveal only the primary structure of the proteins—that is, the amino acid sequence of the peptide chains. They do not reveal information about the conformation (arrangement in space) of the peptide chain—that is, whether the peptide chain is present as a long straight thread or is irregularly coiled and folded into a globule. The configuration, or conformation, of a protein is determined by mutual attraction or repulsion of polar or nonpolar groups in the side chains (*R* groups) of the amino acids. The former have positive or negative charges in their side chains; the

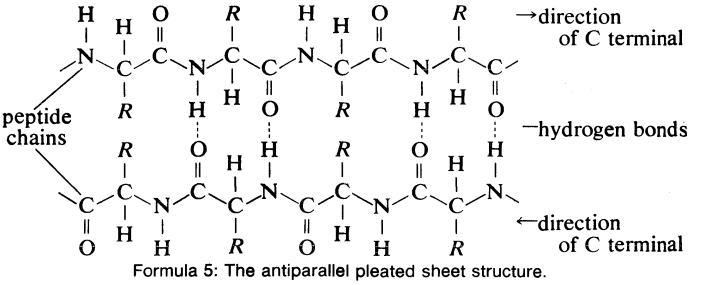
latter repel water but attract each other. Some parts of a peptide chain containing 100 to 200 amino acids may form a loop, or helix; others may be straight or form irregular coils.

Definitions of protein structural terms

The terms secondary, tertiary, and quaternary structure are frequently applied to the configuration of the peptide chain of a protein. A nomenclature committee of the International Union of Biochemistry (IUB) has defined these terms as follows: The primary structure of a protein is determined by its amino acid sequence without any regard for the arrangement of the peptide chain in space. The secondary structure is determined by the spatial arrangement of the main peptide chain without any regard for the conformation of side chains or other segments of the main chain. The tertiary structure is determined by both the side chains and other adjacent segments of the main chain, without regard for neighbouring peptide chains. Finally, the term quaternary structure is used for the arrangement of identical or different subunits of a large protein in which each subunit is a separate peptide chain.

Secondary structure. The nitrogen and carbon atoms of a peptide chain cannot lie on a straight line because of the magnitude of the bond angles between adjacent atoms of the chain; the bond angle is about 110°. Each of the nitrogen and carbon atoms can rotate to a certain extent, however, so that the chain has a limited flexibility. Because all of the amino acids, except glycine, are asymmetric L-amino acids, the peptide chain tends to assume an asymmetric helical shape; some of the fibrous proteins consist of elongated helices around a straight screw axis. Such structural features result from properties common to all peptide chains. The product of their effects is the secondary structure of the protein.

Tertiary structure. The tertiary structure is the product of the interaction between the side chains (*R*) of the amino acids composing the protein. Some of them contain positively or negatively charged groups, others are polar, and still others are nonpolar. The number of carbon atoms in the side chain varies from zero in glycine to nine in tryptophan (see Figure 1). Positively and negatively charged side chains have the tendency to attract each other; side chains with identical charges repel each other. The bonds formed by the forces between the negatively charged side chains of aspartic or glutamic acid on the one hand, and the positively charged side chains of lysine or arginine on the other hand, are called salt bridges. Mutual attraction of adjacent peptide chains also results from the formation of numerous hydrogen bonds. They are shown by dotted lines in the diagram of an antiparallel pleated sheet protein structure (see Formula 5). Hydrogen bonds form

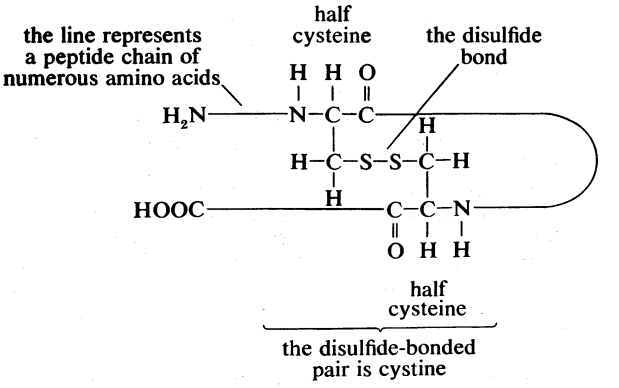


Formula 5: The antiparallel pleated sheet structure.

as a result of the attraction between the nitrogen-bound hydrogen atom (the imide hydrogen) and the unshared pair of electrons of the oxygen atom in the double bonded carbon–oxygen group (the carbonyl group) (>C=O). The result is a slight displacement of the imide hydrogen toward the oxygen atom of the carbonyl group. Although the hydrogen bond is much weaker than a covalent bond (*i.e.*, the type of bond between two carbon atoms, which equally share the pair of bonding electrons between them), the large number of imide and carbonyl groups in peptide chains results in the formation of numerous hydrogen bonds. Another type of attraction is that between nonpolar side chains of valine, leucine, isoleucine, and phenylalanine; the attraction results in the displacement of water molecules and is called hydrophobic interaction.

Hydrophobic interaction defined

In proteins rich in cystine, the conformation of the peptide chain is determined to a considerable extent by the disulfide bonds (—S—S—) of cystine. The halves of cystine may be located in different parts of the peptide chain and thus may form a loop closed by the disulfide bond, as shown in Formula 6. If the disulfide bond is reduced (*i.e.*, hydrogen is added) to two sulfhydryl (—SH) groups, the tertiary structure of the protein undergoes a drastic change—closed loops are broken and adjacent disulfide-bonded peptide chains separate.



Formula 6: The disulfide bridge between two cystine halves in an amino acid chain showing how loops in the chain are formed by this amino acid.

Quaternary structure. The nature of the quaternary structure is demonstrated by the structure of hemoglobin. Each molecule of human hemoglobin consists of four peptide chains, two α-chains and two β-chains; *i.e.*, it is a tetramer. The four subunits are linked to each other by hydrogen bonds and hydrophobic interaction. Because the four subunits are so closely linked, the hemoglobin tetramer is called a molecule, even though no covalent bonds occur between the peptide chains of the four subunits. In other proteins, the subunits are bound to each other by covalent bonds (disulfide bridges; see below the structure of insulin in Formula 8).

THE ISOLATION AND DETERMINATION OF PROTEINS

Animal material usually contains large amounts of protein and lipids and small amounts of carbohydrate; in plants, the bulk of the dry matter is usually carbohydrate. No general method exists for the isolation of proteins from organs or tissues. If it is necessary to determine the amount of protein in a mixture of animal foodstuffs, a sample is converted to ammonium salts by boiling with sulfuric acid and a suitable inorganic catalyst, such as copper sulfate (Kjeldahl method). The method is based on the assumption that proteins contain 16 percent nitrogen, and that nonprotein nitrogen is present in very small amounts. The assumption is justified for most tissues from higher animals but not for insects and crustaceans, in which a considerable portion of the body nitrogen is present in the form of chitin, a carbohydrate. Large amounts of nonprotein nitrogen are also found in the sap of many plants. In such cases, the precise quantitative analyses are made after the proteins have been separated from other biological compounds.

Concentration of protein molecules by dialysis

Proteins are sensitive to heat, acids, bases, organic solvents, and radiation exposure; for this reason, the chemical methods employed to purify organic compounds cannot be applied to proteins. Salts and molecules of small size are removed from protein solutions by dialysis; *i.e.*, by placing the solution into a sac of semipermeable material, such as cellulose or acetylcellulose, which will allow small molecules to pass through but not large protein molecules, and immersing the sac in water or a salt solution. Small molecules can also be removed either by passing the protein solution through a column of resin that adsorbs only the protein or by gel filtration. In gel filtration, the large protein molecules pass through the column, and the small molecules are adsorbed to the gel.

Groups of proteins are separated from each other by salting out—*i.e.*, the stepwise addition of sodium sulfate or ammonium sulfate to a protein solution. Some proteins,

called globulins, become insoluble and precipitate when the solution is half-saturated with ammonium sulfate or when its sodium sulfate content exceeds about 12 percent. Other proteins, the albumins, can be precipitated from the supernatant solution (*i.e.,* the solution remaining after a precipitation has taken place) by saturation with ammonium sulfate. Water-soluble proteins can be obtained in a dry state by freeze-drying (lyophilization), in which the protein solution is deep-frozen by lowering the temperature below −15° C (5° F) and removing the water; the protein is obtained as a dry powder.

Most proteins are insoluble in boiling water and are denatured by it—*i.e.,* irreversibly converted into an insoluble material. Heat denaturation cannot be used with connective tissue because the principal structural protein, collagen, is converted by boiling water into water-soluble gelatin.

Fractionation (separation into components) of a mixture of proteins of different molecular weight can be accomplished by gel filtration. The size of the proteins retained by the gel depends upon the properties of the gel. The proteins retained in the gel are removed from the column by solutions of a suitable concentration of salts and hydrogen ions.

Criteria of purity

Many proteins were originally obtained in crystalline form, but crystallinity is not proof of purity; many crystalline protein preparations contain other substances. Various tests are used to determine whether a protein preparation contains only one protein. The purity of a protein solution can be determined by such techniques as chromatography and gel filtration. In addition, a solution of pure protein will yield one peak when spun in a centrifuge at very high speeds (ultracentrifugation) and will migrate as a single band in electrophoresis (migration of the protein in an electrical field). After these methods and others (such as amino acid analysis) indicate that the protein solution is pure, it can be considered so. Because chromatography, ultracentrifugation, and electrophoresis cannot be applied to insoluble proteins, little is known about them; they may be mixtures of many similar proteins.

Very small (microheterogeneous) differences in some of the apparently pure proteins are known to occur; they are differences in the amino acid composition of otherwise identical proteins and are transmitted from generation to generation; *i.e.,* they are genetically determined; for example, some humans have two hemoglobins, hemoglobin A and hemoglobin S, which differ in one amino acid at a specific site in the molecule. In hemoglobin A the site is occupied by glutamic acid, and in hemoglobin S by valine. Refinement of the techniques of protein analysis has resulted in the discovery of other instances of "microheterogeneity."

The quantity of a pure protein can be determined by weighing or by measuring the ultraviolet absorbancy at 280 nanometres. The absorbency at 280 nanometres depends on the content of tyrosine and tryptophan in the protein (see above *The amino acid composition of proteins*). Sometimes the slightly less sensitive biuret reaction, a purple colour given by alkaline protein solutions upon the addition of copper sulfate, is used; its intensity depends only on the number of peptide bonds per gram, which is similar in all proteins.

PHYSICOCHEMICAL PROPERTIES OF PROTEINS

The molecular weight of proteins. The molecular weight of proteins cannot be determined by the methods of classical chemistry (*e.g.,* freezing-point depression) because they require solutions of a higher concentration of protein than can be prepared.

If a protein contains only one molecule of one of the amino acids or one atom of iron, copper, or another element, the minimum molecular weight of the protein or a subunit can be calculated; for example, the protein myoglobin contains 0.34 gram of iron in 100 grams of protein. The atomic weight of iron is 56; thus the minimum molecular weight of myoglobin is $(56 \times 100)/0.34 =$ about 16,500. Direct measurements of the molecular weight of myoglobin yield the same value. The molecular weight of hemoglobin, however, which also contains 0.34 percent iron, has been found to be 66,000 or $4 \times 16{,}500$; thus hemoglobin contains four atoms of iron.

Determination of molecular weight by ultracentrifugation

The method most frequently used to determine the molecular weight of proteins is ultracentrifugation; *i.e.,* spinning in a centrifuge at velocities up to about 60,000 revolutions per minute. Centrifugal forces of more than 200,000 times the gravitational force on the surface of the Earth are achieved at such velocities. The first ultracentrifuges, built in 1920, were used to determine the molecular weight of proteins. The molecular weights of a large number of proteins have been determined. Most consist of several subunits, the molecular weight of which is usually less than 100,000 and frequently ranges from 20,000 to 30,000. Proteins of very high molecular weights are found among hemocyanins, the copper-containing respiratory proteins of invertebrates; some range as high as several million. Although there is no definite lower limit for the molecular weight of proteins, short amino acid sequences are usually called peptides.

The shape of protein molecules. In the technique of X-ray diffraction the X-rays are allowed to strike a protein crystal; the X-rays, diffracted (bent) by the crystal, impinge on a photographic plate, forming a pattern of spots. This method reveals that peptide chains can assume very complicated, apparently irregular shapes. Two extremes in shape include the closely folded structure of the globular proteins and the elongated, unidimensional structure of the threadlike fibrous proteins; both were recognized many years before the technique of X-ray diffraction was developed. Solutions of fibrous proteins are extremely viscous (*i.e.,* sticky); those of the globular proteins have low viscosity (*i.e.,* they flow easily). A 5 percent solution of a globular protein—ovalbumin, for example—easily flows through a narrow glass tube; a 5 percent solution of gelatin, a fibrous protein, however, does not flow through the tube because it is liquid only at high temperatures and solidifies at room temperature. Even solutions containing only 1 or 2 percent of gelatin are highly viscous and flow through a narrow tube either very slowly or only under pressure. The elongated peptide chains of the fibrous proteins can be imagined to become entangled not only mechanically but also by mutual attraction of their side chains; in this way they incorporate large amounts of water. Most of the hydrophilic (water-attracting) groups of the globular proteins, however, lie on the surface of the molecules; as a result, globular proteins incorporate only a few water molecules. If a solution of a fibrous protein flows through a narrow tube, the elongated molecules become oriented parallel to the direction of the flow (see Figure 2), and the solution thus becomes birefringent like a crystal; *i.e.,* it splits a light ray into two components that travel at different velocities and are polarized at right angles to each other. Globular proteins do not show this phenomenon, which is called flow birefringence. Solutions of myosin, the contractile protein of muscles, show very high flow birefringence; other proteins with very high flow birefringence include solutions of fibrinogen, the clotting material of blood plasma, and solutions of tobacco mosaic virus. The gamma-globulins of the blood plasma show low flow birefringence; and none can be observed in solutions of serum albumin and ovalbumin.

Globular and fibrous proteins

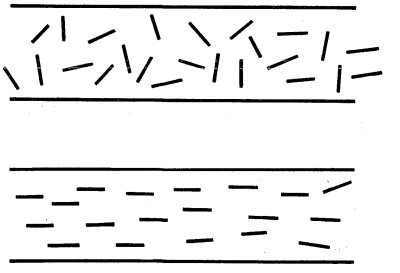


Figure 2: *Flow birefringence.*
The upper diagram shows a solution containing elongated, rodlike macromolecules that, in the resting solution, are randomly oriented. The lower diagram shows the same solution during flow through a horizontal tube.

Hydration of proteins. When dry proteins are exposed to air of high water content, they rapidly bind water up to a maximum quantity, which differs for different proteins; usually it is 10 to 20 percent of the weight of the protein. The hydrophilic groups of a protein are chiefly the positively charged groups in the side chains of lysine and arginine and the negatively charged groups of aspartic and glutamic acid. Hydration (*i.e.*, the binding of water) may also occur at the hydroxyl (−OH) groups of serine and threonine or at the amide ($-CONH_2$) groups of asparagine and glutamine.

The binding of water molecules to either charged or polar (partly charged) groups is explained by the dipolar structure of the water molecule; that is, the two positively charged hydrogen atoms form an angle of about 105°, with the negatively charged oxygen atom at the apex. The centre of the positive charges is located between the two hydrogen atoms; the centre of the negative charge of the oxygen atom is at the apex of the angle. The negative pole of the dipolar water molecule binds to positively charged groups; the positive pole binds negatively charged ones. The negative pole of the water molecule also binds to the hydroxyl and amino groups of the protein.

The water of hydration is essential to the structure of protein crystals; when they are completely dehydrated, the crystalline structure disintegrates. In some proteins this process is accompanied by denaturation and loss of the biological function.

In aqueous solutions, proteins bind some of the water molecules very firmly; others are either very loosely bound or form islands of water molecules between loops of folded peptide chains. Because the water molecules in such an island are thought to be oriented as in ice, which is crystalline water, the islands of water in proteins are called icebergs. Water molecules may also form bridges between the carbonyl (>C=O) and imino (>NH) groups of adjacent peptide chains, resulting in structures similar to those of the pleated sheet (see Formula 5) but with a water molecule in the position of the hydrogen bonds of that configuration. The extent of hydration of protein molecules in aqueous solutions is important, because some of the methods used to determine the molecular weight of proteins yield the molecular weight of the hydrated protein. The amount of water bound to one gram of a globular protein in solution varies from 0.2 to 0.5 gram. Much larger amounts of water are mechanically immobilized between the elongated peptide chains of fibrous proteins; for example, one gram of gelatin can immobilize at room temperature 25 to 30 grams of water.

The salting-out process

Hydration of proteins is necessary for their solubility in water. If the water of hydration of a protein dissolved in water is reduced by the addition of a salt such as ammonium sulfate, the protein is no longer soluble and is salted out, or precipitated. The salting-out process is reversible because the protein is not denatured (*i.e.*, irreversibly converted to an insoluble material) by the addition of such salts as sodium chloride, sodium sulfate, or ammonium sulfate. Some globulins, called euglobulins, are insoluble in water in the absence of salts; their insolubility is attributed to the mutual interaction of polar groups on the surface of adjacent molecules, a process that results in the formation of large aggregates of molecules. Addition of small amounts of salt causes the euglobulins to become soluble. This process, called salting in, results from a combination between anions (negatively charged ions) and cations (positively charged ions) of the salt and positively and negatively charged side chains of the euglobulins. The combination prevents the aggregation of euglobulin molecules by preventing the formation of salt bridges between them. The addition of more sodium or ammonium sulfate causes the euglobulins to salt out again and to precipitate.

Electrochemistry of proteins. Because the α-amino group and α-carboxyl group of amino acids are converted into peptide bonds (see Formula 2) in the protein molecule, there is only one α-amino group (at the N terminus) and one α-carboxyl group (at the C terminus). The electrochemical character of a protein is affected very little by these two groups. Of importance, however, are the numerous positively charged ammonium groups ($-NH_3^+$) of lysine and arginine and the negatively charged carboxyl groups ($-COO^-$) of aspartic acid and glutamic acid. In most proteins, the number of positively and negatively charged groups varies from 10 to 20 per 100 amino acids.

Electrometric titration. When measured volumes of hydrochloric acid are added to a solution of protein in salt-free water, the pH decreases in proportion to the amount of hydrogen ions added until it is about 4. Further addition of acid causes much less decrease in pH because the protein acts as a buffer at pH values of 3 to 4. The reaction that takes place in this pH range is the protonation of the carboxyl group—*i.e.*, the conversion of $-COO^-$ into −COOH. Electrometric titration of an isoelectric protein with potassium hydroxide causes a very slow increase in pH and a weak buffering action of the protein at pH 7; a very strong buffering action occurs in the pH range from 9 to 10 (see Figure 3). The buffering action at pH 7, which is caused by loss of protons (positively charged hydrogen) from the imidazolium groups (*i.e.*, the five-member ring structure in the side chain; see Figure 1) of histidine, is weak because the histidine content of proteins is usually low. The much stronger buffering action at pH values from 9 to 10 is caused by the loss of protons from the hydroxyl group of tyrosine and from the ammonium groups of lysine. Finally, protons are lost from the guanidinium groups (*i.e.*, the nitrogen-containing terminal portion of the arginine side chains; see Figure 1) of arginine at pH 12. A curve of the electrometric titration of glycine is shown in Figure 3. Electrometric titrations of proteins

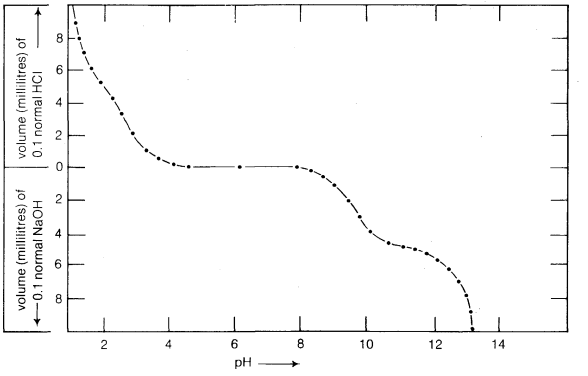

Figure 3: Electrometric titration of glycine. Addition of measured quantities of known-concentration hydrochloric acid (HCl) to glycine is shown in the upper half of the diagram; sodium hydroxide (NaOH) in the lower half. The dots indicate the experimental results. The addition of a trace of acid or base to pure glycine, the isoelectric point of which is close to pH 6.1, causes a strong change in pH. Glycine acts as a buffer, however, in the acidic pH range below 3 and in the alkaline pH range above 8.

yield similar curves. Electrometric titration makes possible the determination of the approximate number of carboxyl groups, ammonium groups, histidines, and tyrosines per molecule of protein.

Electrophoresis. The positively and negatively charged side chains of proteins cause them to behave like amino acids in an electrical field; that is, they migrate during electrophoresis at low pH values to the cathode (negative terminal) and at high pH values to the anode (positive terminal). The isoelectric point, the pH value at which the protein molecule does not migrate, is in the range of pH 5 to 7 for many proteins. Proteins such as lysozyme, cytochrome *c*, histone, and others rich in lysine and arginine (see Table 2), however, have isoelectric points in the pH range between 8 and 10. The isoelectric point of pepsin, which contains very few basic amino acids, is close to 1.

Zone electrophoresis

Free-boundary electrophoresis, the original method of determining electrophoretic migration, has been replaced in many instances by zone electrophoresis, in which the protein is placed in either a gel of starch, agar, or polyacrylamide or in a porous medium such as paper or cellulose acetate. The migration of hemoglobin and other coloured proteins can be followed visually. Colourless proteins are made visible after the completion of electrophoresis by staining them with a suitable dye.

CONFORMATION OF GLOBULAR PROTEINS

Results of X-ray diffraction studies. Most knowledge concerning secondary and tertiary structure of globular proteins has been obtained by the examination of their crystals using X-ray diffraction. In this technique X-rays are allowed to strike the crystal; the X-rays are diffracted by the crystal and impinge on a photographic plate, forming a pattern of spots. The measured intensity of the diffraction pattern, as recorded on a photographic film, depends particularly on the electron density of the atoms in the protein crystal. This density is lowest in hydrogen atoms, and they do not give a visible diffraction pattern. Although carbon, oxygen, and nitrogen atoms yield visible diffraction patterns, they are present in such great number—about 700 or 800 per 100 amino acids—that the resolution of the structure of a protein containing more than 100 amino acids is almost impossible. Resolution is considerably improved by substituting into the side chains of certain amino acids very heavy atoms, particularly those of heavy metals. Mercury ions, for example, bind to the sulfhydryl (−SH) groups of cysteine. Platinum chloride has been used in other proteins. In the iron-containing proteins, the iron atom already in the molecule is adequate.

Although the X-ray diffraction technique cannot resolve the complete three-dimensional conformation (that is, the secondary and tertiary structure of the peptide chain), complete resolution has been obtained by combination of the results of X-ray diffraction with those of amino acid sequence analysis. In this way the complete conformation of such proteins as myoglobin, chymotrypsinogen, lysozyme, and ribonuclease has been resolved.

The X-ray diffraction method has revealed regular structural arrangements in proteins; one is an extended form of antiparallel peptide chains that are linked to each other by hydrogen bonds between the carbonyl (≥C=O) and imino (≥NH) groups (shown in Formula 5). This conformation, called the pleated sheet, or β-structure, is found in some fibrous proteins. Short strands of the β-structure have also been detected in some globular proteins.

The α-helix

A second important structural arrangement is the α-helix (see Figure 4); it is formed by a sequence of amino acids wound around a straight axis in either a right-handed or a left-handed spiral. Each turn of the helix corresponds to a distance of 5.4 angstroms (= 0.54 nanometre) in the direction of the screw axis and contains 3.7 amino acids. Hence, the length of the α-helix per amino acid residue is 5.4 divided by 3.7, or 1.5 angstroms (one angstrom = 0.1 nanometre). The stability of the α-helix is maintained by hydrogen bonds between the carbonyl and imino groups of neighbouring turns of the helix. It was once thought, based on data from analyses of the myoglobin molecule, more than half of which consists of α-helices, that the α-helix is the predominant structural element of the globular proteins; it is now known that myoglobin is exceptional in this respect. The other globular proteins for which the structures have been resolved by X-ray diffraction contain only small regions of α-helix. In most of them the peptide chains are folded in an apparently random fashion (see Figure 5), for which the term random coil has been used. The term is misleading, however, because the folding is not random; rather, it is dictated by the primary structure and modified by the secondary and tertiary structures.

The first proteins for which the internal structures were completely resolved are the iron-containing proteins myoglobin and hemoglobin. The investigation of the hydrated crystals of these proteins at Cambridge by Max Perutz and J.C. Kendrew, who won a Nobel Prize for their work, revealed that the folding of the peptide chains is so tight that most of the water is displaced from the centre of the globular molecules. The amino acids that carry the ammonium ($-NH_3^+$) and carboxyl ($-COO^-$) groups were found to be shifted to the surface of the globular molecules, and the nonpolar amino acids were found to be concentrated in the interior.

Other approaches to the determination of protein structure. None of the several other physical methods that have been used to obtain information on the secondary and tertiary structure of proteins provides as much direct information as the X-ray diffraction technique. Most of the techniques, however, are much more simple than X-ray diffraction, which requires, for the resolution of the structure of one protein, many years of work and equipment such as electronic computers. Some of the simpler techniques are based on the optical properties of proteins—refractivity, absorption of light of different wavelengths, rotation of the plane polarized light at different wavelengths, and luminescence.

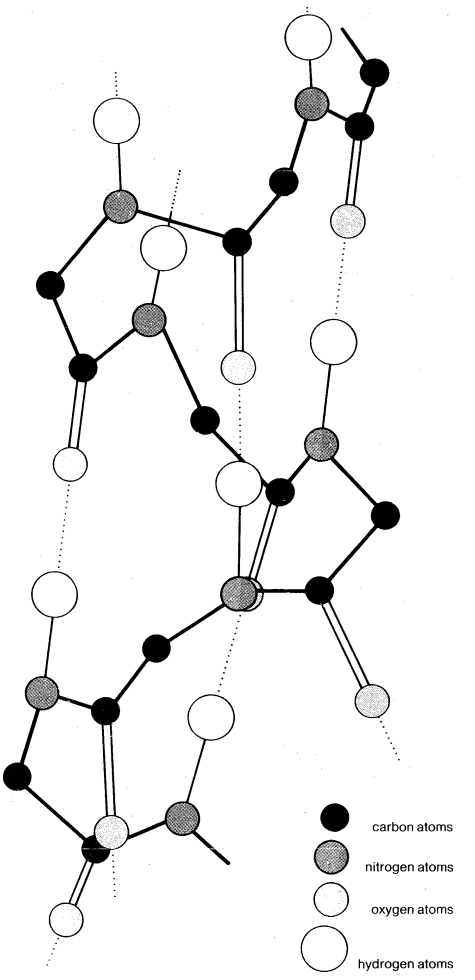

Figure 4: The α-helix (see text).

Spectrophotometric behaviour. Spectrophotometry of protein solutions (the measurement of the degree of absorbance of light by a protein within a specified wavelength) is useful within the range of visible light only with proteins that contain coloured prosthetic groups (the nonprotein components). Examples of such proteins include the red heme proteins of the blood, the purple pigments of the retina of the eye, green and yellow proteins that contain bile pigments, blue copper-containing proteins, and dark brown proteins called melanins. Peptide bonds, because of their carbonyl groups, absorb light energy at very short wavelengths (185–200 nanometres). The aromatic rings of phenylalanine, tyrosine, and tryptophan (see Figure 1), however, absorb ultraviolet light between wavelengths of 280 and 290 nanometres. The absorbance of ultraviolet light by tryptophan is greatest, that of tyrosine is less, and that of phenylalanine is least. If the tyrosine or tryptophan content of the protein is known, therefore, the concentration of the protein solution can be determined by measuring its absorbance between 280 and 290 nanometres.

Polarized light rotation ranges among proteins

Optical activity. It will be recalled that the amino acids, with the exception of glycine, exhibit optical activity (rotation of the plane of polarized light; see above, *Physicochemical properties of the amino acids*). It is not surprising, therefore, that proteins also are optically active. They are usually levorotatory (*i.e.*, they rotate the

plane of polarization to the left) when polarized light of wavelengths in the visible range is used. Although the specific rotation (a function of the concentration of a protein solution and the distance the light travels in it) of most L-amino acids varies from −30° to +30°, the amino acid cystine has a specific rotation of approximately −300°. Although the optical rotation of a protein depends on all of the amino acids, the most important ones are cystine and the aromatic amino acids phenylalanine, tyrosine, and tryptophan. The contribution of the other amino acids to the optical activity of a protein is negligibly small.

Chemical reactivity of proteins. Information on the internal structure of proteins can be obtained with chemical methods that reveal whether certain groups are present on the surface of the protein molecule and thus able to react or whether they are buried inside the closely folded peptide chains and thus are unable to react. The chemical reagents used in such investigations must be mild ones that do not affect the structure of the protein.

The reactivity of tyrosine is of special interest. It has been found, for example, that only three of the six tyrosines found in the naturally occurring enzyme ribonuclease can be iodinated (*i.e.,* reacted to accept an iodine atom). Enzyme-catalyzed breakdown of iodinated ribonuclease is used to identify the peptides in which the iodinated tyrosines are present. The three tyrosines that can be iodinated lie on the surface of ribonuclease; the others, assumed to be inaccessible, are said to be buried in the molecule. Tyrosine can also be identified by using other techniques; *e.g.,* treatment with diazonium compounds or tetranitromethane. Because the compounds formed are coloured, they can easily be detected when the protein is broken down with enzymes.

Cysteine can be detected by coupling with compounds such as iodoacetic acid or iodoacetamide; the reaction results in the formation of carboxymethylcysteine or carbamidomethylcysteine, which can be detected by amino acid determination of the peptides containing them. The imidazole groups of certain histidines can also be located by coupling with the same reagents under different conditions. Unfortunately, few other amino acids can be labelled without changes in the secondary and tertiary structure of the protein.

Association of protein subunits. Many proteins with molecular weights of more than 50,000 occur in aqueous solutions as complexes: dimers, tetramers, and higher polymers—*i.e.,* as chains of two, four, or more repeating basic structural units. The subunits, which are called monomers or protomers, usually are present as an even number. Less than 10 percent of the polymers have been found to have an odd number of monomers. The arrangement of the subunits is thought to be regular and may be cyclic, cubic, or tetrahedral. Some of the small proteins also contain subunits. Insulin, for example, with a molecular weight of about 6,000, consists of two peptide chains linked to each other by disulfide bridges (—S—S—). Similar interchain disulfide bonds have been found in the immunoglobulins. In other proteins, hydrogen bonds and hydrophobic bonds (resulting from the interaction between the amino acid side chains of valine, leucine, isoleucine, and phenylalanine) cause the formation of aggregates of the subunits. The subunits of some proteins are identical; those of others differ. Hemoglobin is a tetramer consisting of two α-chains and two β-chains.

Protein denaturation. When a solution of a protein is boiled, the protein frequently becomes insoluble—*i.e.,* it is denatured—and remains insoluble even when the solution is cooled. The denaturation of the proteins of egg white by heat—as when boiling an egg—is an example of irreversible denaturation. The denatured protein has the same primary structure as the original, or native, protein. The weak forces between charged groups and the weaker forces of mutual attraction of nonpolar groups are disrupted at elevated temperatures, however; as a result, the tertiary structure of the protein is lost. In some instances the original structure of the protein can be regenerated; the process is called renaturation.

Methods of denaturation

Denaturation can be brought about in various ways. Proteins are denatured by treatment with alkaline or acid, oxidizing or reducing agents, and certain organic solvents. Interesting among denaturing agents are those that affect the secondary and tertiary structure without affecting the primary structure. The agents most frequently used for this purpose are urea and guanidinium chloride. These molecules, because of their high affinity for peptide bonds, break the hydrogen bonds and the salt bridges between positive and negative side chains, thereby abolishing the tertiary structure of the peptide chain. When denaturing agents are removed from a protein solution, the native protein re-forms in many cases. Denaturation can also be accomplished by reduction of the disulfide bonds of cystine—*i.e.,* conversion of the disulfide bond (—S—S—) to two sulfhydryl groups (—SH). This, of course, results in the formation of two cysteines. Reoxidation of the cysteines by exposure to air sometimes regenerates the native protein. In other cases, however, the wrong cysteines become bound to each other, resulting in a different protein. Finally, denaturation can also be accomplished by exposing proteins to organic solvents such as ethanol or acetone. It is believed that the organic solvents interfere with the mutual attraction of nonpolar groups.

Some of the smaller proteins, however, are extremely stable, even against heat; for example, solutions of ribonuclease can be exposed for short periods of time to temperatures of 90° C (194° F) without undergoing significant denaturation. Denaturation does not involve identical changes in protein molecules; a common property of denatured proteins, however, is the loss of biological activity—*e.g.,* the ability to act as enzymes or hormones.

Although denaturation had long been considered an all-or-none reaction, it is now thought that many intermediary states exist between native and denatured protein. In some instances, however, the breaking of a key bond could be followed by the complete breakdown of the conformation of the native protein.

Although many native proteins are resistant to the action of the enzyme trypsin, which breaks down proteins during digestion, they are hydrolyzed by the same enzyme after denaturation. Evidently, the peptide bonds that can be split by trypsin are inaccessible in the native proteins but become accessible during denaturation. Similarly, denatured proteins give more intense colour reactions for tyrosine, histidine, and arginine than do the same proteins in the native state. The increased accessibility of reactive groups of denatured proteins is attributed to an unfolding of the peptide chains.

Unfolded peptide chains in denatured proteins

If denaturation can be brought about easily and if renaturation is difficult, how is the native conformation of globular proteins maintained in living organisms, in which they are produced stepwise, by incorporation of one amino acid at a time? Experiments on the biosynthesis of proteins from amino acids containing radioactive carbon or heavy hydrogen reveal that the protein molecule grows stepwise from the N terminus to the C terminus; in each step a single amino acid residue is incorporated. As soon as the growing peptide chain contains six or seven amino acid residues, the side chains interact with each other and thus cause deviations from the straight or β-chain configuration shown in Formula 3. Depending on the nature of the side chains, this may result in the formation of an α-helix (Figure 4) or of loops closed by hydrogen bonds (Formula 5) or disulfide bridges (Formula 6). The final conformation is probably frozen when the peptide chain attains a length of 50 or more amino acid residues.

Conformation of proteins in interfaces. Like many other substances with both hydrophilic and hydrophobic groups, soluble proteins tend to migrate into the interface between air and water or oil and water; the term oil here means a hydrophobic liquid such as benzene or xylene. Within the interface, proteins spread, forming thin films. Measurements of the surface tension, or interfacial tension, of such films indicate that tension is reduced by the protein film. Proteins, when forming an interfacial film, are present as a monomolecular layer; *i.e.,* a layer one molecule in height. Although it was once thought that globular protein molecules unfold completely in the interface, it has now been established that many proteins can be recovered from films in the native state. The application of

lateral pressure on a protein film causes it to increase in thickness and finally to form a layer with a height corresponding to the diameter of the native protein molecule. Protein molecules in an interface, because of Brownian motions (molecular vibrations), occupy much more space than do those in the film after the application of pressure. The Brownian motion of compressed molecules is limited to the two dimensions of the interface, since the protein molecules cannot move upward or downward.

The motion of protein molecules at the air–water interface has been used to determine the molecular weight of proteins. The technique involves measuring the force exerted by the protein layer on a barrier.

When a protein solution is vigorously shaken in air, it forms a foam, because the soluble proteins migrate into the air–water interface and persist there, preventing or slowing the reconversion of the foam into a homogeneous solution. Some of the unstable, easily modified proteins are denatured when spread in the air–water interface. The formation of a permanent foam when egg white is vigorously stirred is an example of irreversible denaturation by spreading in a surface.

Classification of proteins

CLASSIFICATION BY SOLUBILITY

Methods of classification

After two German chemists, Emil Fischer and Franz Hofmeister, independently stated in 1902 that proteins are essentially polypeptides consisting of many amino acids, an attempt was made to classify proteins according to their chemical and physical properties, because the biological function of proteins had not yet been established. (The protein character of enzymes was not proved until the 1920s.) Proteins were classified primarily according to their solubility in a number of solvents. This classification is no longer satisfactory, however, because proteins of quite different structure and function sometimes have similar solubilities; conversely, proteins of the same function and similar structure sometimes have different solubilities. The terms associated with the old classification, however, are still widely used. They are defined below.

Albumins are proteins that are soluble in water and in water half-saturated with ammonium sulfate. On the other hand, globulins are salted out (*i.e.*, precipitated) by half-saturation with ammonium sulfate. Globulins that are soluble in salt-free water are called pseudoglobulins; those insoluble in salt-free water are euglobulins. Both prolamins and glutelins, which are plant proteins, are insoluble in water; the prolamins dissolve in 50 to 80 percent ethanol, the glutelins in acidified or alkaline solution. The term protamine is used for a number of proteins in fish sperm that consist of approximately 80 percent arginine and therefore are strongly alkaline. Histones, which are less alkaline, apparently occur only in cell nuclei, where they are bound to nucleic acids. The term scleroproteins has been used for the insoluble proteins of animal organs. They include keratin, the insoluble protein of certain epithelial tissues such as the skin or hair, and collagen, the protein of the connective tissue. A large group of proteins has been called conjugated proteins, because they are complex molecules of protein consisting of protein and nonprotein moieties. The nonprotein portion is called the prosthetic group. Conjugated proteins can be subdivided into mucoproteins, which, in addition to protein, contain carbohydrate; lipoproteins, which contain lipids; phosphoproteins, which are rich in phosphate; chromoproteins, which contain pigments such as iron-porphyrins, carotenoids, bile pigments, and melanin; and finally, nucleoproteins, which contain nucleic acid.

The weakness of the above classification lies in the fact that many, if not all, globulins contain small amounts of carbohydrate; thus there is no sharp borderline between globulins and mucoproteins. Moreover, the phosphoproteins do not have a prosthetic group that can be isolated; they are merely proteins in which some of the hydroxyl groups of serine are phosphorylated (*i.e.*, contain phosphate). Finally, the globulins include proteins with quite different roles—enzymes, antibodies, fibrous proteins, and contractile proteins.

CLASSIFICATION BY BIOLOGICAL FUNCTIONS

In view of the unsatisfactory state of the old classification, it is preferable to classify the proteins according to their biological function. Such a classification is far from ideal, however, because one protein can have more than one function. The contractile protein myosin, for example, also acts as an ATPase (adenosine triphosphatase), an enzyme that hydrolyzes adenosine triphosphate (removes a phosphate group from ATP by introducing a water molecule). In addition, the definite function of a protein frequently is not known. A protein cannot be called an enzyme as long as its substrate (the specific compound upon which it acts) is not known. It cannot even be tested for its enzymatic action when its substrate is not known.

Special structure and function of proteins

Despite its weaknesses, a functional classification is used here in order to demonstrate, whenever possible, the correlation between the structure and function of a protein. The structural, fibrous proteins are presented first, because their structure is simpler than that of the globular proteins and more clearly related to their function, which is the maintenance of either a rigid or a flexible structure.

STRUCTURAL PROTEINS

Scleroproteins. *Collagen.* Collagen is the structural protein of bones, tendons, ligaments, and skin. For many years collagen was considered to be insoluble in water. Part of the collagen of calf skin, however, can be extracted with citrate buffer at pH 3.7. A precursor of collagen called procollagen is converted in the body into collagen. Procollagen has a molecular weight of 120,000. Cleavage of one or a few peptide bonds of procollagen yields collagen, which has three subunits, each with a molecular weight of 95,000; therefore, the molecular weight of collagen is 285,000 ($3 \times 95{,}000$). The three subunits are wound as spirals around an elongated straight axis. The length of each subunit is 2,900 angstroms, and its diameter is approximately 15 angstroms. The three chains are staggered, so that the trimer has no definite terminal limits.

Structure of collagen

The amino acid composition of collagen is shown in Table 1. It differs from all other proteins in its high content of proline and hydroxyproline. Hydroxyproline does not occur in significant amounts in any other protein except elastin. Most of the proline in collagen is present in the sequence glycine–proline-*X*, in which *X* is frequently alanine or hydroxyproline. Collagen does not contain cystine or tryptophan and therefore cannot substitute for other proteins in the diet. The presence of proline causes kinks

Table 1: Amino Acid Content of Some Proteins

amino acid*	protein

*Number of amino acids is given per 100,000 daltons of protein—*i.e.*, the number of gram molecules of amino acid per 100,000 grams of protein.
†The values for aspartic and glutamic acid include asparagine and glutamine, respectively. ‡Isoleucine plus leucine.

in the peptide chain and thus reduces the length of the amino acid unit from 3.7 angstroms in the extended chain of the β-structure to 2.86 angstroms in the collagen chain. In the intertwined triple helix, the lycines are inside, close to the axis; the prolines are outside.

Native collagen resists the action of trypsin but is hydrolyzed by the bacterial enzyme collagenase. When collagen is boiled with water, the triple helix is destroyed, and the subunits are partially hydrolyzed; the product is gelatin. The unfolded peptide chains of gelatin trap large amounts of water, resulting in a hydrated molecule.

When collagen is treated with tannic acid or with chromium salts, cross links form between the collagen fibres, and it becomes insoluble; the conversion of hide into leather is based on this tanning process. The tanned material is insoluble in hot water and cannot be converted to gelatin. On exposure to water at 62° to 63° C (144° to 145° F), however, the cross links formed by the tanning agents collapse, and the leather contracts irreversibly to about one-third its original volume.

Collagen seems to undergo an aging process in living organisms that may be caused by the formation of cross links between collagen fibres. They are formed by the conversion of some lysine side chains to aldehydes (compounds with the general structure *R*CHO), and the combination of the aldehydes with the ε-amino groups of intact lysine side chains. The protein elastin, which occurs in the elastic fibres of connective tissue, contains similar cross links and may result from the combination of collagen fibres with other proteins. When cross-linked collagen or elastin is degraded, products of the cross-linked lysine fragments, called desmosins and isodesmosins, are formed.

Keratin. Keratin, the structural protein of epithelial cells in the outermost layers of the skin, has been isolated from hair, nails, hoofs, and feathers. Keratin is completely insoluble in cold or hot water; it is not attacked by proteolytic enzymes (*i.e.,* enzymes that break apart, or lyse, protein molecules), and therefore cannot replace proteins in the diet. The great stability of keratin results from the numerous disulfide bonds of cystine. The amino acid composition of keratin differs from that of collagen (see Table 1). Cystine may account for 24 percent of the total amino acids. The peptide chains of keratin are arranged in approximately equal amounts of antiparallel and parallel pleated sheets, in which the peptide chains are linked to each other by hydrogen bonds between the carbonyl (>C=O) and imino (>NH) groups.

Pleated-sheet structure of keratin

Reduction of the disulfide bonds to sulfhydryl groups results in dissociation of the peptide chains, the molecular weight of which is 25,000 to 28,000 each. The formation of permanent waves in the beauty treatment of hair is based on partial reduction of the disulfide bonds of hair keratin by thioglycol, or some other mild reducing agent, and subsequent oxidation of the sulfhydryl groups (−SH) in the reoriented hair to disulfide bonds (−S−S−) by exposure to the oxygen of the air.

The length of keratin fibres depends on their water content. They can bind approximately 16 percent of water; this hydration is accompanied by an increase in the length of the fibres of 10 to 12 percent.

The most thoroughly investigated keratin is hair keratin, particularly that of wool. It consists of a mixture of peptides with high and low cystine content. When wool is heated in water to about 90° C (190° F), it shrinks irreversibly. This is attributed to the breakage of hydrogen bonds and other noncovalent bonds; disulfide bonds do not seem to be affected.

Others. The most thoroughly investigated scleroprotein has been fibroin, the insoluble material of silk. The raw silk comprising the cocoon of the silkworm consists of two proteins. One, sericin, is soluble in hot water; the other, fibroin, is not. The amino acid composition of the latter differs from that of all other proteins. It contains large amounts of glycine, alanine, tyrosine, and serine; small amounts of the other amino acids; and no sulfur-containing ones. The peptide chains are arranged in antiparallel β-structures. Fibroin is partly soluble in concentrated solutions of lithium thiocyanate or in mixtures of cupric salts and ethylene diamine. Such solutions contain a protein of molecular weight 170,000, which is a dimer of two subunits.

Little is known about either the scleroproteins of the marine sponges or the insoluble proteins of the cellular membranes of animal cells. Some of the membranes are soluble in detergents; the membrane of the red blood cells contains an insoluble membrane protein that consists of a single peptide chain of molecular weight 200,000.

The muscle proteins. The total amount of muscle proteins in mammals, including man, exceeds that of any other protein. About 40 percent of the body weight of a healthy human adult weighing about 70 kilograms (150 pounds) is muscle, which is composed of about 20 percent muscle protein. Thus, the human body contains about five to six kilograms (11 to 13 pounds) of muscle protein. An albumin-like fraction of these proteins, originally called myogen, contains various enzymes—phosphorylase, aldolase, glyceraldehyde phosphate dehydrogenase, and others; it does not seem to be involved in contraction. The globulin fraction contains myosin, the contractile protein, which also occurs in blood platelets, small bodies found in blood. Similar contractile substances occur in other contractile structures; for example, in the cilia or flagella (whiplike organs of locomotion) of bacteria and protozoans. In contrast to the scleroproteins, the contractile proteins are soluble in salt solutions and susceptible to enzymatic digestion.

Occurrence of contractile proteins

The energy required for muscle contraction is provided by the oxidation of carbohydrates or lipids. The term mechano-chemical reaction has been used for this conversion of chemical into mechanical energy. Although the molecular process underlying the reaction is not yet completely understood, it is known to involve the fibrous muscle proteins, the peptide chains of which undergo a change in conformation during contraction.

Myosin, which can be removed from fresh muscle by adding it to a chilled solution of dilute potassium chloride and sodium bicarbonate, is insoluble in water. Myosin, solutions of which are highly viscous, consists of an elongated—probably double-stranded—peptide chain, which is coiled at both ends in such a way that a terminal globule is formed. The length of the molecule is approximately 160 nanometres and its average diameter 2.6 nanometres. The equivalent weight of each of the two terminal globules is approximately 30,000; the molecular weight of myosin is close to 500,000. Trypsin splits myosin into large fragments called meromyosin. Myosin contains many amino acids with positively and negatively charged side chains (see Table 1); they form 18 and 16 percent, respectively, of the total number of amino acids. Myosin catalyzes the hydrolytic cleavage of ATP (adenosine triphosphate). A smaller protein with properties similar to those of myosin is tropomyosin. It has a molecular weight of 70,000 and dimensions of 45 by 2 nanometres. More than 90 percent of its peptide chains are present in the α-helix form.

Myosin combines easily with another muscle protein called actin, the molecular weight of which is about 50,000; it forms 12 to 15 percent of the muscle proteins. Actin can exist in two forms—one, G-actin, is globular; the other, F-actin, is fibrous. Actomyosin is a complex molecule formed by one molecule of myosin and one or two molecules of actin. In muscle, actin and myosin filaments are oriented parallel to each other and to the long axis of the muscle. The actin filaments are linked to each other lengthwise by fine threads called S filaments. During contraction the S filaments shorten, so that the actin filaments slide toward each other, past the myosin filaments, thus causing a shortening of the muscle (for a detailed description of the process see MUSCLES AND MUSCLE SYSTEMS: *Muscle contraction*).

Fibrinogen and fibrin. Fibrinogen, the protein of the blood plasma, is converted into the insoluble protein fibrin during the clotting process. The fibrinogen-free fluid obtained after removal of the clot, called blood serum, is blood plasma minus fibrinogen. The fibrinogen content of the blood plasma is 0.2 to 0.4 percent.

Fibrinogen can be precipitated from the blood plasma by half-saturation with sodium chloride. Fibrinogen solutions are highly viscous and show strong flow birefringence. In

electron micrographs the molecules appear as rods with a length of 47.5 nanometres and a diameter of 1.5 nanometres; in addition, two terminal and a central nodule are visible. The molecular weight is 340,000. An unusually high percentage, about 36 percent, of the amino acid side chains are positively or negatively charged.

The clotting process

The clotting process is initiated by the enzyme thrombin, which catalyzes the breakage of a few peptide bonds of fibrinogen; as a result, two small fibrinopeptides with molecular weights of 1,900 and 2,400 are released. The remainder of the fibrinogen molecule, a monomer, is soluble and stable at pH values less than 6 (*i.e.,* in acid solutions). In neutral solution (pH 7) the monomer is converted into a larger molecule, insoluble fibrin; this results from the formation of new peptide bonds. The newly formed peptide bonds form intermolecular and intramolecular cross links, thus giving rise to a large clot, in which all molecules are linked to each other. Clotting, which takes place only in the presence of calcium ions, can be prevented by compounds such as oxalate or citrate, which have a high affinity for calcium ions.

ALBUMINS, GLOBULINS, AND OTHER SOLUBLE PROTEINS

The blood plasma, the lymph, and other animal fluids usually contain one to seven grams of protein per 100 millilitres of fluid, which includes small amounts of hundreds of enzymes and a large number of protein hormones. The discussion below is limited largely to the proteins that occur in large amounts and can be easily isolated from the body fluids. For further information on enzymes and hormones, see below *Enzymes* and *Hormones.*

Proteins of the blood serum. Human blood serum contains about 7 percent protein, two-thirds of which is in the albumin fraction; the other third is in the globulin fraction. Electrophoresis of serum reveals a large albumin peak and three smaller globulin peaks, the alpha-, beta-, and gamma-globulins. The amounts of alpha-, beta-, and gamma-globulin in normal human serum are approximately 1.5, 1.9, and 1.1 percent, respectively. Each globulin fraction is a mixture of many different proteins, as has been demonstrated by immuno-electrophoresis. In this method, the serum of a rabbit injected with human serum is allowed to diffuse into the four protein bands—albumin, alpha-, beta-, and gamma-globulin—obtained from the electrophoresis of human serum. Because the rabbit has previously been injected with human serum, its blood contains antibodies (substances formed in response to a foreign substance introduced into the body) against each of the human serum proteins; each antibody combines with the serum protein (antigen) that caused its formation in the rabbit. The result is the formation of about 20 regions of insoluble antigen-antibody precipitate, which appear as white arcs in the transparent gel of the electrophoresis medium. Each region corresponds to a different human serum protein.

Globulin fractions of serum

Serum albumin is much less heterogeneous (*i.e.,* contains fewer distinct proteins) than are the globulins; in fact, it is one of the few serum proteins that can be obtained in a crystalline form. Serum albumin combines easily with many acidic dyes (*e.g.,* Congo red and methyl orange); with bilirubin, the yellow bile pigment; and with fatty acids. It seems to act, in living organisms, as a carrier for certain biological substances. Present in blood serum in relatively high concentration, serum albumin also acts as a protective colloid, a protein that stabilizes other proteins. Albumin (molecular weight of 68,000) has a single free sulfhydryl (−SH) group, which on oxidation forms a disulfide bond with the sulfhydryl group of another serum albumin molecule, thus forming a dimer. The isoelectric point of serum albumin is pH 4.7.

The alpha-globulin fraction of blood serum is a mixture of several conjugated proteins. The best known are an α-lipoprotein (combination of lipid and protein) and two mucoproteins (combinations of carbohydrate and protein). One mucoprotein is called orosomucoid, or α_1-acid glycoprotein; the other is called haptoglobin because it combines specifically with globin, the protein component of hemoglobin. Haptoglobin contains about 20 percent carbohydrate.

The beta-globulin fraction of serum contains, in addition to lipoproteins and mucoproteins, two metal-binding proteins, transferrin and ceruloplasmin, which bind iron and copper, respectively. They are the principal iron and copper carriers of the blood.

The gamma-globulins are the most heterogeneous globulins. Although most have a molecular weight of approximately 150,000, that of some, called macroglobulins, is as high as 800,000. Because typical antibodies are of the same size and exhibit the same electrophoretic behaviour as γ-globulins, they are called immunoglobulins. The designation IgM or gamma M (γM) is used for the macroglobulins; the designation IgG or gamma G (γG) is used for γ-globulins of molecular weight 150,000.

Milk proteins. Milk contains the following: an albumin, α-lactalbumin; a globulin, beta-lactoglobulin; and a phosphoprotein, casein. If acid is added to milk, casein precipitates. The remaining watery liquid (the supernatant solution), or whey, contains lactalbumin and lactoglobulin. Both have been obtained in crystalline form; their molecular weights are 16,000 and 18,500, respectively. Lactoglobulin also occurs as a dimer of molecular weight 37,000. Small variations known to occur in the amino acid composition of lactoglobulin result from genetic variations. The amino acid composition and the tertiary structure of lactalbumin resemble that of lysozyme, an egg protein (see below).

Casein is precipitated not only by the addition of acid but also by the action of the enzyme rennin, which is found in gastric juice. Rennin from calf stomachs is used to precipitate casein, from which cheese is made. Milk fat precipitates with casein; milk sugar, however, remains in the supernatant (whey). Casein is a mixture of several similar phosphoproteins, called α-, β-, γ-, and κ-casein, all of which contain some serine side chains combined with phosphoric acid. Approximately 75 percent of casein is α-casein (see Table 1). Cystine has been found only in κ-casein. In milk, casein seems to form polymeric globules (micelles) with radially arranged monomers, each with a molecular weight of 24,000; the acidic side chains occur predominantly on the surface of the micelle, rather than inside.

Composition of casein

Egg proteins. About 50 percent of the proteins of egg white are composed of ovalbumin, which is easily obtained in crystals. Its molecular weight is 46,000 and its amino acid composition differs from that of serum albumin. Other proteins of egg white are conalbumin, lysozyme, ovoglobulin, ovomucoid, and avidin. Lysozyme is an enzyme that hydrolyzes the carbohydrates found in the capsules certain bacteria secrete around themselves; it causes lysis (disintegration) of the bacteria. The molecular weight of lysozyme is 14,100; its amino acid composition is shown in Table 2. Its three-dimensional structure, shown in Figure 5, is similar to that of α-lactalbumin, which stimulates the formation of lactose by the enzyme lactose synthetase. Lysozyme has also been found in the urine of patients suffering from leukemia.

Avidin is a glycoprotein that combines specifically with biotin, a vitamin. In animals fed large amounts of raw egg white, the action of avidin results in "egg-white injury." The molecular weight of avidin, which forms a tetramer, is 16,200. Its amino acid sequence is known.

Egg-yolk proteins contain a mixture of lipoproteins and livetins. The latter are similar to serum albumin, α-globulin, and β-globulin. The yolk also contains a phosphoprotein, phosvitin. Phosvitin, which has also been found in fish sperm, has a molecular weight of 40,000 and an unusual amino acid composition; one third of its amino acids are phosphoserine.

Protamines and histones. Protamines are found in the sperm cells of fish. The most thoroughly investigated protamines are salmine from salmon sperm and clupeine from herring sperm. The protamines are bound to deoxyribonucleic acid (DNA), forming nucleoprotamines. The amino acid composition of the protamines is simple; they contain, in addition to large amounts of arginine, small amounts of five or six other amino acids. The composition of the salmine molecule, for example, is: Arg_{51}, Ala_4, Val_4, Ile_1, Pro_7, and Ser_6, in which the subscript numbers indicate

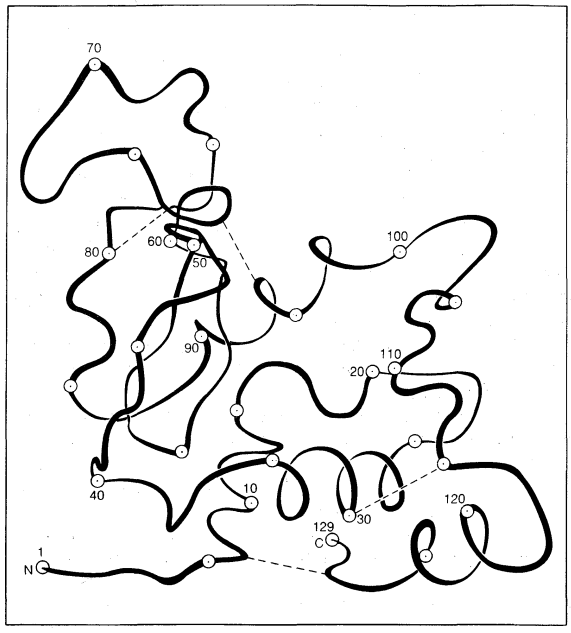

Figure 5: Conformation of lysozyme. Lysozyme from hen's egg white has a single peptide chain of 129 amino acids. The diagram shows the structure in simplified form. The amino acid residues are numbered from the terminal α amino group (N) to the terminal carboxyl group (C). Every fifth residue is shown by a circle, and every tenth residue is numbered. The four disulfide bridges are shown by broken lines. Alpha-helices are visible in the ranges 25 to 35, 90 to 100, and 120 to 125.

Protamine composition

the number of each amino acid in the molecule. Because of the high arginine content, the isoelectric points of the protamines are at pH values of 11 to 12; *i.e.*, the protamines are alkaline. The molecular weights of salmine and clupeine are close to 6,000. All of the protamines investigated thus far are mixtures of several similar proteins.

The histones are less basic than the protamines. They contain high amounts of either lysine or arginine and small amounts of aspartic acid and glutamic acid. Histones occur in combination with DNA as nucleohistones in the nuclei of the body cells of animals and plants, but not in animal sperm. The molecular weights of histones vary from 10,000 to 22,000. In contrast to the protamines, the histones contain most of the 20 amino acids, with the exception of tryptophan and the sulfur-containing ones. Like the protamines, histone preparations are heterogeneous mixtures. The amino acid sequence of some of the histones has been determined.

Plant proteins. Plant proteins, mostly globulins, have been obtained chiefly from the protein-rich seeds of cereals and legumes. Small amounts of albumins are found in seeds. The best known globulins, insoluble in water, can be extracted from seeds by treatment with 2 to 10 percent solutions of sodium chloride. Many plant globulins have been obtained in crystalline form; they include edestin from hemp, molecular weight 310,000; amandin from almonds, 330,000; concanavalin A (42,000) and B (96,000); and canavalin (113,000) from jack beans. They are polymers of smaller subunits; edestin, for example, is a hexamer of a subunit with a molecular weight of 50,000, and concanavalin B a trimer of a subunit with a molecular weight of 30,000. After extraction of lipids from cereal seeds by ether and alcohol, further extraction with water containing 50 to 80 percent of alcohol yields proteins that are insoluble in water but soluble in water–ethanol mixtures and have been called prolamins. Their solubility in aqueous ethanol may result from their high proline and glutamine content (see Table 1). Gliadin, the prolamin from wheat, contains 14 grams of proline and 46 grams of glutamic acid in 100 grams of protein; most of the glutamic acid is in the form of glutamine. The total amounts of the basic amino acids (arginine, lysine, and histidine) in gliadin are only 5 percent of the weight of gliadin. None of the prolamins has yet been obtained in a pure crystalline state. Because the lysine content is either low or nonexistent, human populations dependent on grain as a sole protein source suffer from lysine deficiency.

CONJUGATED PROTEINS

Chemical bonding in conjugated proteins

Combination of proteins with prosthetic groups. The link between a protein molecule and its prosthetic group is a covalent (electron-sharing) bond in the glycoproteins, the biliproteins, and some of the heme proteins. In lipoproteins, nucleoproteins, and some heme proteins, the two components are linked by noncovalent bonds; the bonding results from the same forces that are responsible for the tertiary structure of proteins: hydrogen bonds, salt bridges between positively and negatively charged groups, disulfide bonds, and mutual interaction of hydrophobic groups. In the metalloproteins (proteins with a metal element as a prosthetic group), the metal ion usually forms a centre to which various groups are bound.

Some of the conjugated proteins have been mentioned in preceding sections because they occur in the blood serum, in milk, and in eggs; others are discussed below in sections dealing with respiratory proteins and enzymes.

Mucoproteins and glycoproteins. The prosthetic groups in mucoproteins and glycoproteins are oligosaccharides (carbohydrates consisting of a small number of simple sugar molecules) usually containing from four to 12 sugar molecules; the most common sugars are galactose, mannose, glucosamine, and galactosamine. Xylose, fucose, glucuronic acid, sialic acid, and other simple sugars sometimes also occur. Some mucoproteins contain 20 percent or more of carbohydrate, usually in several oligosaccharides attached to different parts of the peptide chain. The designation mucoprotein is used for proteins with more than 3 to 4 percent carbohydrate; if the carbohydrate content is less than 3 percent, the protein is sometimes called a glycoprotein or simply a protein.

Mucoproteins, highly viscous proteins originally called mucins, are found in saliva, in gastric juice, and in other animal secretions. Mucoproteins occur in large amounts in cartilage, synovial fluid (the lubricating fluid of joints and tendons), and egg white. The mucoprotein of cartilage is formed by the combination of collagen with chondroitinsulfuric acid, which is a polymer of either glucuronic or iduronic acid and acetylhexosamine or acetylgalactosamine. It is not yet clear whether or not chondroitinsulfate is bound to collagen by covalent bonds.

Lipoproteins and proteolipids. The bond between the protein and the lipid portion of lipoproteins and proteolipids is a noncovalent one. It is believed that some of the lipid is enclosed in a meshlike arrangement of peptide chains and becomes accessible for reaction only after the unfolding of the chains by denaturing agents. Although

Table 2: Number of Amino Acids per Protein Molecule

amino acid	protein*						
	Cyto	Hb α	Hb β	RNase	Lys	Chgen	Fdox

Total	104	141	146	124	129	245	97

*Cyto = human cytochrome *c*; Hb α = human hemoglobin A, α-chain; Hb β = human hemoglobin A, β-chain; RNase = bovine ribonuclease; Lys = chicken lysozyme; Chgen = bovine chymotrypsinogen; Fdox = spinach ferredoxin. †The values recorded for aspartic and glutamic acid include asparagine and glutamine.

lipoproteins in the α- and β-globulin fraction of blood serum are soluble in water (but insoluble in organic solvents), some of the brain lipoproteins, because they have a high lipid content, are soluble in organic solvents; they are called proteolipids. The β-lipoprotein of human blood serum is a macroglobulin with a molecular weight of about 1,300,000, 70 percent of which is lipid; of the lipid, about 30 percent is phospholipid and 40 percent cholesterol and compounds derived from it. Because of their lipid content, the lipoproteins have the lowest density (mass per unit volume) of all proteins and are usually classified as low- and high-density lipoproteins (LDL and HDL).

Coloured lipoproteins are formed by the combination of protein with carotenoids. Crustacyanin, the pigment of lobsters, crayfish, and other crustaceans, contains astaxanthin, which is a compound derived from carotene.

Pigments of the eye

Among the most interesting of the coloured lipoproteins are the pigments of the retina of the eye. They contain retinal, which is a compound derived from carotene and which is formed by the oxidation of vitamin A. In rhodopsin, the red pigment of the retina, the aldehyde group (−CHO) of retinal forms a covalent bond with an amino ($-NH_2$) group of opsin, the protein carrier. Colour vision is mediated by the presence of several visual pigments in the retina that differ from rhodopsin either in the structure of retinal or in that of the protein carrier.

Metalloproteins. Proteins in which heavy metal ions are bound directly to some of the side chains of histidine, cysteine, or some other amino acid are called metalloproteins. Two metalloproteins, transferrin and ceruloplasmin, occur in the globulin fractions of blood serum; they act as carriers of iron and copper, respectively. Transferrin has a molecular weight of 84,000 and consists of two identical subunits, each of which contains one ferric ion (Fe^{3+}) that seems to be bound to tyrosine. Several genetic variants of transferrin are known to occur in man. Another iron protein, ferritin, which contains 20 to 22 percent iron, is the form in which iron is stored in animals; it has been obtained in crystalline form from liver and spleen. A molecule consisting of 20 subunits, its molecular weight is approximately 480,000. The iron can be removed by reduction from the ferric (Fe^{3+}) to the ferrous (Fe^{2+}) state. The iron-free protein, apoferritin, is synthesized in the body before the iron is incorporated.

Green plants and some photosynthetic and nitrogen-fixing bacteria (*i.e.*, bacteria that convert atmospheric nitrogen, N_2, into amino acids and proteins in their own bodies) contain various ferredoxins. They are small proteins containing 50 to 100 amino acids (see Table 2) and a chain of iron and disulfide units (FeS_2), in which some of the sulfur atoms are contributed by cysteine; others are sulfide ions (S^{2-}). The number of FeS_2 units per ferredoxin molecule varies from five in the ferredoxin of spinach to 10 in the ferredoxin of certain bacteria. Ferredoxins act as electron carriers in photosynthesis and in nitrogen fixation.

Function of ceruloplasmin

Ceruloplasmin is a copper-containing globulin with a molecular weight of 151,000; the molecule consists of eight subunits, each containing one copper ion. Ceruloplasmin is the principal carrier of copper in organisms, although copper can also be transported by the iron-containing globulin transferrin. Another copper-containing protein, erythrocuprein (molecular weight 64,000), has been isolated from red blood cells; it has also been found in the liver and the brain. The molecule, which consists of four subunits with a molecular weight of 16,000 each, contains four copper and four zinc ions. Because of their copper content, ceruloplasmin and erythrocuprein may have some catalytic activity in oxidation-reduction reactions. Another copper-containing protein, hemocyanin, is described below (see *Respiratory proteins*).

Many animal enzymes contain zinc ions, which are usually bound to the sulfur of cysteine. Horse kidneys contain the protein metallothionein, which contain zinc and cadmium; both are bound to sulfur. A vanadium-protein complex (homovanadin) has been found in surprisingly high amounts in yellowish-green cells (vanadocytes) of tunicates, which are marine invertebrates.

Heme proteins and other chromoproteins. Although the heme proteins contain iron, they are usually not classified as metalloproteins, because their prosthetic group is an iron-porphyrin complex in which the iron is bound very firmly. The intense red or brown colour of the heme proteins is not caused by iron but by porphyrin, a complex cyclic structure. All porphyrin compounds absorb light intensely at or close to 410 nanometres. Porphyrin consists of four pyrrole rings (five-membered closed structures containing one nitrogen and four carbon atoms) linked to each other by methine groups (−CH=). The iron atom is kept in the centre of the porphyrin ring by interaction with the four nitrogen atoms. The iron atom can combine with two other substituents; in oxyhemoglobin, one substituent is a histidine of the protein carrier, the other is an oxygen molecule. In some heme proteins, the protein is also bound covalently to the side chains of porphyrin. Heme proteins are described below (see *Respiratory proteins* and *Oxidoreductases*).

Little is known about the structure of the chromoprotein melanin, a pigment found in dark skin, dark hair, and melanotic tumours. It is probably formed by the oxidation of tyrosine, which results in the formation of red, brown, or dark-coloured derivatives.

Green chromoproteins called biliproteins are found in many insects, such as grasshoppers, and also in the eggshells of many birds. The biliproteins are derived from the bile pigment biliverdin, which in turn is formed from porphyrin; biliverdin contains four pyrrole rings and three of the four methine groups of porphyrin. Large amounts of biliproteins, the molecular weights of which are about 270,000, have been found in red and blue-green algae; the red protein is called phycoerythrin, the blue one phycocyanobilin. Phycocyanobilin consists of eight subunits with a molecular weight of 28,000 each; about 89 percent of the molecule is protein with a large amount of carbohydrate.

Nucleoproteins. When a protein solution is mixed with a solution of a nucleic acid, the phosphoric acid component of the nucleic acid combines with the positively charged ammonium groups ($-NH_3^+$) of the protein to form a protein–nucleic acid complex. The nucleus of a cell contains predominantly deoxyribonucleic acid (DNA) and the cytoplasm predominantly ribonucleic acid (RNA); both parts of the cell also contain protein. Protein–nucleic acid complexes, therefore, form in living cells. It has not yet been definitely established whether the protein–nucleic acid complexes isolated from biological material are indeed formed during the life of the organism or whether they are artifacts produced during the isolation procedure.

The only nucleoproteins for which some evidence for specificity exists are nucleoprotamines, nucleohistones, and some RNA and DNA viruses. The nucleoprotamines are the form in which protamines occur in the sperm cells of fish; the histones of the thymus and of pea seedlings and other plant material apparently occur predominantly as nucleohistones. Both nucleoprotamines and nucleohistones contain only DNA.

Proteins of the tobacco mosaic virus

Some of the simplest viruses consist of a specific RNA, which is coated by protein. One of the best known RNA viruses, tobacco mosaic virus (TMV), has the shape of a rod. RNA comprises only 5.1 percent of the mass of the virus. The complete sequence of the virus protein, which consists of about 2,130 identical peptide chains, each containing 158 amino acids, has been determined. The protein is arranged in a spiral around the RNA core.

DNA has been found in most bacterial viruses (bacteriophages) and in some animal viruses. As in TMV, the core of DNA is surrounded by protein. Phage protein is a mixture of enzymes and therefore cannot be considered as the protein portion of only one nucleoprotein.

Respiratory proteins. *Hemoglobin.* Hemoglobin is the oxygen carrier in all vertebrates and some invertebrates. In oxyhemoglobin (HbO_2), which is bright red, the ferrous ion (Fe^{2+}) is bound to the four nitrogen atoms of porphyrin; the other two substituents are an oxygen molecule and the histidine of globin, the protein component of hemoglobin. Deoxyhemoglobin (deoxy-Hb), as its name implies, is oxyhemoglobin minus oxygen (*i.e.*, reduced hemoglobin); it is purple in colour. Oxidation of the ferrous ion of hemoglobin yields a ferric compound, methemoglobin, sometimes called hemiglobin or ferrihemoglobin. The oxy-

C.S.N.L.S.T.C.V.L.S.A.Y.W.K.D.L.N.N.Y.H.R.F.S.G.M.G.F.G.P.E.T.P($CONH_2$)

Formula 7: The amino acid sequence of human calcitonin. At the left end the line represents the disulfide bond. At the right end ($CONH_2$) indicates that the C terminal proline is present as prolinamide.

gen of oxyhemoglobin can be displaced by carbon monoxide, for which hemoglobin has a much greater affinity, preventing oxygen from reaching the body tissues.

The hemoglobins of all mammals, birds, and many other vertebrates are tetramers of two α- and two β-chains (see Table 2). The molecular weight of the tetramer is 64,500; the molecular weight of the α- and β-chains is approximately 16,100 each, and the four subunits are linked to each other by noncovalent interactions. If hemin (the ferric porphyrin component) is removed from globin (the protein component), two molecules of globin, each consisting of one α- and one β-chain, are obtained; the molecular weight of globin is 32,200. In contrast to hemoglobin, globin is an unstable protein that is easily denatured. If native globin is incubated with a solution of hemin at pH values of 8 to 9, native hemoglobin is reconstituted. Both the hemoglobin of the lamprey and the myoglobin, the red pigment of mammalian muscles, are monomers with a molecular weight of 16,000.

Mammalian hemoglobins

The mammalian hemoglobins differ from each other in their amino acid composition and therefore in their secondary and tertiary structure. Rat and horse hemoglobin crystallize very easily, but those of man, cattle, and sheep, because they are more soluble, are difficult to crystallize. The shape of hemoglobin crystals varies in different species; moreover, decomposition and denaturation occur at different rates in different species. It was also found that the blood of newborn children contains two different hemoglobins, about 20 percent of an adult hemoglobin (hemoglobin A) and 80 percent of a fetal hemoglobin (hemoglobin F). Hemoglobin F persists in the child for the first seven months of life. The same hemoglobin F has also been found in the blood of patients suffering from thalassemia, an anemia that occurs in the countries of southern Europe. Hemoglobin F contains, as does hemoglobin A, two α-chains; the two β-chains, however, have been replaced by two quite different γ-chains. When the technique of electrophoresis was first applied to the hemoglobin of blacks suffering from sickle cell anemia in 1949, a new hemoglobin (hemoglobin S) was discovered. More than 100 different human hemoglobins now are known. They differ from normal hemoglobin A in the amino acid composition of either the α- or the β-chain.

The hemoglobins of some of the lowest fishes are monomers containing one iron atom per molecule. Hemoglobin-like respiratory proteins have been found in some invertebrates. The red hemoglobin of insects, mollusks, and protozoans is called erythrocruorin. It differs from vertebrate hemoglobin by its high molecular weight.

Although green plants contain no hemoglobin, a red protein, called leg-hemoglobin, has been discovered in the root nodules of leguminous plants. It seems to be produced by the nitrogen-fixing bacteria of the root nodules and may be involved in the reduction of atmospheric nitrogen to ammonia and amino acids.

Other respiratory proteins. A green respiratory protein, chlorocruorin, has been found in the blood of the marine worm *Spirographis*. It has the same high molecular weight as erythrocruorin, but differs from hemoglobin in its prosthetic group. A red metalloprotein, hemerythrin, acts as a respiratory protein in marine worms of the phylum Sipuncula. The molecule consists of eight subunits with a molecular weight of 13,500 each. Hemerythrin contains no porphyrins and therefore is not a heme protein.

A metalloprotein containing copper is the respiratory protein of crustaceans (shrimps, crabs, etc.) and of some gastropods (snails). The protein, called hemocyanin, is pale yellow when not combined with oxygen, and blue when combined with oxygen. The molecular weights of hemocyanins vary from 300,000 to 9,000,000. Each animal investigated thus far apparently has a species-specific hemocyanin.

Hemocyanin

PROTEIN HORMONES

Some hormones that are products of endocrine glands are proteins or peptides; others are steroids. (The origin of hormones, their physiological role, and their mode of action are dealt with below in the section *Hormones*.) None of the hormones has any enzymatic activity. Each has a target organ in which it elicits some biological action; *e.g.*, secretion of gastric or pancreatic juice, production of milk, production of steroid hormones. The mechanism by which the hormones exert their effects is not fully understood. Cyclic adenosine monophosphate is involved in the transmittance of the hormonal stimulus to the cells whose activity is specifically increased by the hormone.

Functional aspects of hormones

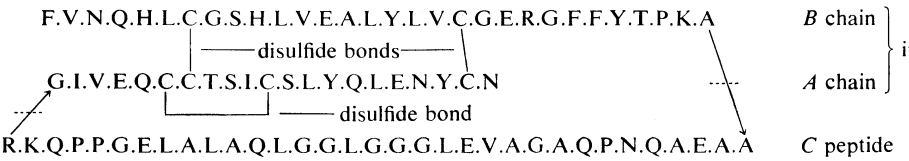
Hormones of the thyroid gland. Thyroglobulin, the active groups of which are two molecules of the iodine-containing compound thyroxine (see Figure 1), has a molecular weight of 670,000.

Thyroglobulin also contains thyroxine with two and three iodine atoms instead of the four shown in Figure 1, and trosine, with one and two iodine atoms. Injection of the hormone causes an increase in metabolism; lack of it results in a slowdown. Another hormone, calcitonin, which lowers the calcium level of the blood, occurs in the thyroid gland. The structure of human calcitonin is given in Formula 7 (see Figure 1 for structures of amino acids corresponding to the one-letter codes).

The amino acid sequences of calcitonin from pig, beef, and salmon differ from human calcitonin in some amino acids. All of them, however, have the half-cystines and the prolinamide in the same position. Porcine calcitonin has been synthesized in the laboratory.

The parathyroid hormone (parathormone), produced in small glands that are embedded in or lie behind the thyroid gland, is essential for maintaining the calcium level of the blood. Its lack results in the disease hypocalcemia. Bovine parathormone has a molecular weight of 8,500; it contains no cystine or cysteine and is rich in aspartic acid, glutamic acid, or their amides.

Hormones of the pancreas. Although the structure of insulin has been known since 1949, repeated attempts to synthesize it gave very poor yields because of the failure of the two peptide chains to combine forming the correct disulfide bridge. The ease of the biosynthesis of insulin is explained by the discovery in the pancreas of proinsulin, from which insulin is formed. The single peptide chain of proinsulin loses a peptide consisting of 33 amino acids and called the connecting peptide, or C peptide, during its conversion to insulin. The structure of porcine proinsulin is shown in Formula 8.



Formula 8: The amino acid sequence of porcine proinsulin. The arrows indicate the direction from the N terminus of the *B* chain to the C terminus of the *A* chain. In the *C* peptide the N terminus is at the right (A=alanine) end and the C terminus is at the left end in order to show the connection with the *A* and *B* chains. Insulin is released when the two peptide bonds at the ends of the *C* peptide (broken lines) are hydrolyzed (broken by the introduction of a water molecule).

In aqueous solutions insulin exists predominantly as a complex of six subunits, each of which contains an *A*- and a *B*-chain. The insulins of several species have been isolated and analyzed; their amino acid sequences differ somewhat, but all apparently contain the same disulfide bridges between the two chains.

Opposite functions of insulin and glucagon

Although the injection of insulin lowers the blood sugar, administration of glucagon, another pancreas hormone, raises the blood sugar level. Glucagon consists of a straight peptide chain of 29 amino acids. Its structure, which is free of cystine and isoleucine, is given in Formula 9. It has been synthesized; the synthetic product has the full biological activity of natural glucagon.

Pituitary hormones. The pituitary gland has an anterior lobe, a posterior lobe, and an intermediate portion; they differ in cellular structure and in the structure and action of the hormones they form. The posterior lobe produces

Formula 9: Amino acid sequence of the pancreas hormone glucagon.

two similar hormones, oxytocin and vasopressin. The former causes contraction of the pregnant uterus; the latter raises the blood pressure. Both are octapeptides formed by a ring of five amino acids (the two cystine halves count as one amino acid) and a side chain of three amino acids. The structure of oxytocin is given in Formula 10. The two cystine halves are linked to each other by a disulfide bond, and the C terminal amino acid is glycinamide. The structure has been established and confirmed. Human vasopressin (Formula 10) differs from oxytocin in that isoleucine is replaced by phenylalanine and leucine by arginine. Porcine vasopressin contains lysine instead of arginine.

A Cys.Tyr.Ile.GluN.Asn.Cys.Pro.Leu.Gly($CONH_2$)

B Cys.Tyr.Phe.GluN.Asn.Cys.Pro.Arg.Gly($CONH_2$)

Formula 10: Amino acid sequence of the two similar hormones of the posterior lobe of the pituitary gland. (A) Oxytocin. (B) Human vasopressin. The solid line represents the disulfide bond between the two halves of cystine.

The intermediate part of the pituitary gland produces the melanocyte-stimulating hormone (MSH), which causes expansion of the pigmented melanophores (cells) in the skin of frogs and other batrachians. Two hormones, called α-MSH and β-MSH, have been prepared from hog pituitary glands. α-MSH consists of 13 amino acids (see Formula 11); its N terminal serine is acetylated (*i.e.*, the acetyl group, CH_3CO, of acetic acid is attached), and its C terminal valine residue is present as valinamide. β-MSH contains in its 18 amino acids many of those occurring in α-MSH (see Formula 11).

The anterior pituitary lobe produces several protein hormones—a thyroid-stimulating hormone, molecular weight 28,000; a lactogenic hormone, molecular weight 22,500; a growth hormone, molecular weight 21,500; a luteinizing hormone, molecular weight 30,000; and a follicle-stimulating hormone, molecular weight 29,000. The thyroid-stimulating hormone (TSH, thyrotropin) consists of α and β subunits with a composition similar to the subunits of luteinizing hormone. When separated, neither of the two subunits has hormonal activity; when combined, however, they regain about 50 percent of the original activity. The lactogenic hormone (prolactin) from sheep pituitary glands contains 190 amino acids. Their sequence has been elucidated; a similar peptide chain of 188 amino acids that has been synthesized not only has 10 percent of the biological activity of the natural hormone but also some activity of the growth hormone. The amino acid sequence of the growth hormone (somatotropic hormone) is also known; it seems to stimulate the synthesis of RNA and in this way to accelerate growth. The luteinizing hormone (LH) consists of two subunits, each with a molecular weight of approximately 15,000; when separated, the subunits recombine spontaneously. LH is a mucoprotein containing about 12 percent carbohydrate. The urine of pregnant women contains chorionic gonadotropin, the presence of which makes possible early diagnosis of pregnancy. The amino acid sequence is known. The sequence of 160 of its 190 amino acids is identical with those of the growth hormone; 100 of these also occur in the same sequence as in lactogenic hormone. The different pituitary hormones and the chorionic gonadotropin thus may have been derived from a common substance that, during evolution, underwent differentiation.

Derivation of pituitary hormones

Peptides with hormonelike activity. Small peptides have been discovered that, like hormones, act on certain target organs. One peptide, angiotensin (angiotonin or hypertensin), is formed in the blood from angiotensinogen by the action of renin, an enzyme of the kidney. It is an octapeptide and increases blood pressure. Similar peptides include bradykinin, which stimulates smooth muscles; gastrin, which stimulates secretion of hydrochloric acid and pepsin in the stomach; secretin, which stimulates the flow of pancreatic juice; and kallikreine, the activity of which is similar to bradykinin.

IMMUNOGLOBULINS AND ANTIBODIES

Antibodies, proteins that combat foreign substances in the body, are associated with the globulin fraction of the immune serum (see IMMUNITY). As stated previously, when the serum globulins are separated into α-, β-, and γ- fractions, antibodies are associated with the γ-globulins. Antibodies can be purified by precipitation with the antigen (*i.e.*, the foreign substance) that caused their formation, followed by separation of the antigen-antibody complex. Antibodies prepared in this way consist of a mixture of many similar antibody molecules, which differ in molecular weight, amino acid composition, and other properties. The same differences are found in the γ-globulins of normal blood serums. It is believed that the γ-globulin of normal blood serum is a mixture of thousands of different γ-globulins, each of which occurs in amounts too small for isolation. Because the physical and chemical properties of normal γ-globulins are the same as those of antibodies, the γ-globulins are frequently called immunoglobulins. They may be considered to be antibodies against unknown antigens. If solutions of γ-globulin are resolved by gel filtration through dextran, the first fraction has a molecular weight of 800,000. This fraction is called IgM or γM; Ig is an abbreviation for immunoglobulin and M for macroglobulin. The next two fractions are IgA (γA) and IgG (γG), with molecular weights of about 300,000 and 150,000 respectively. Two other immunoglobulins, known as IgD and IgE, have also been detected in much smaller amounts in some immune sera.

γ-globulins of blood serums

The bulk of the immunoglobulins is found in the IgG fraction, which also contains most of the antibodies. The IgM molecules are apparently pentamers—aggregates of five of the IgG molecules. Electron microscopy shows their five subunits to be linked to each other by disulfide bonds in the form of a pentagon. The IgA molecules are found principally in milk and in secretions of the intestinal mucosa. Some of them contain, in addition to a dimer of IgG, a "secretory piece," the structure of which

Formula 11: The amino acid sequence of hormones produced by the intermediate part of the pituitary gland. The amino acid sequence M.E.H.F.R.W.G. occurs in all melanocyte-stimulating hormones and in adrenocorticotropic hormones (corticotropins).

is not yet known. The IgM and IgA immunoglobulins and antibodies contain 10 to 15 percent carbohydrate; the carbohydrate content of the IgG molecules is 2 to 3 percent.

IgG molecules treated with the enzyme papain split into three fragments of almost identical molecular weight of 50,000. Two of these, called Fab fragments, are identical; the third is abbreviated Fc. Reduction to sulfhydryl groups of some of the disulfide bonds of IgG results in the formation of two heavy, or *H*, chains (molecular weight 55,000) and two light, or *L*, chains (molecular weight 22,000). They are linked by disulfide bonds in the order *L*—*H*—*H*—*L*. Each *H* chain contains four intrachain disulfide bonds, each *L* chain contains two. The structure of antibodies and normal immunoglobulins of the IgG type is shown in Figure 6.

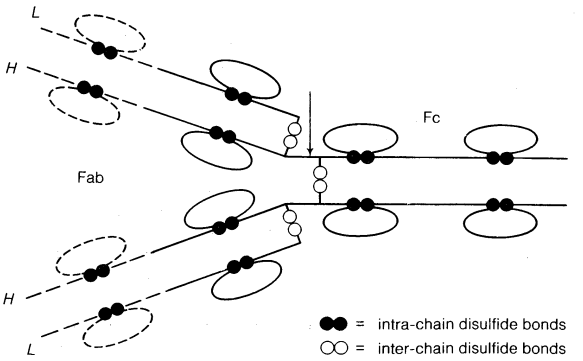

Figure 6: Diagram of an IgG immunoglobulin. Two heavy chains (*H*) and two light chains (*L*) are linked to each other by inter-chain disulfide bonds. Intra-chain disulfide bonds cause loops to form in the 12 peptide portions, each of which contains about 110 amino acid residues. The 12 peptide regions have cystine residues at similar positions and other similarities in their amino acid sequences. The broken lines represent variable portions and the solid lines represent constant portions of the chains. Specific sites that bind antigens are formed by the variable portions. The vertical arrow indicates cleavage of the IgG molecule into two Fab fragments and one Fc fragment by the action of the enzyme papain.

Antibody preparations of the IgG type, even after removal of IgM and IgA antibodies, are heterogeneous. The *H* and *L* chains consist of a large number of different *L* chains and a variety of *H* chains. Pure IgG, IgM, and IgA immunoglobulins, however, occur in the blood serum of patients suffering from myelomas, which are malignant tumours of the bone marrow. The tumours produce either an IgG, an IgM, or an IgA protein, but rarely more than one class. A protein called the Bence-Jones protein, which is found in the urine of patients suffering from myeloma tumours, is identical with the *L* chains of the myeloma protein. Each patient has a different Bence-Jones protein; no two of the more than 100 Bence-Jones proteins that have been analyzed thus far are identical. It is thought that one lymphoid cell among hundreds of thousands becomes malignant and multiplies rapidly, forming the mass of a myeloma tumour that produces one γ-globulin.

Bence-Jones proteins

Analyses of the Bence-Jones proteins have revealed that the *L* chains of man and other mammals are of two quite different types, kappa (κ) and lambda (λ). Both consist of approximately 220 amino acids. The N–terminal halves of κ- and λ-chains are variable, differing in each Bence-Jones protein. The C–terminal halves of these same *L* chains have a constant amino acid sequence of either the κ- or the λ-type. The fact that one half of a peptide chain is variable and the other half invariant is contradictory to the view that the amino acid sequence of each peptide chain is determined by one gene (see GENETICS AND HEREDITY: *The gene*). Evidently, two genes, one of them variable, the other invariant, fuse to form the gene for the single peptide chain of the *L* chains. Whereas the normal human *L* chains are always mixtures of the κ- and λ-types, the *H* chains of IgG, IgM, and IgA are different. They have been designated as gamma (γ), mu (μ), and alpha (α) chains, respectively. The N-terminal quarter of the *H* chains has a variable amino acid sequence; the C-terminal three-quarters of the *H* chains have a constant amino acid sequence, as indicated in Figure 6.

Some of the amino acid sequences in the *L* and *H* chains are transmitted from generation to generation. As a result, the constant portion of the human *L* chains of the κ-type has in position 191 either valine or leucine. They correspond to two alleles (character-determining portions) of a gene; the two types are called allotypes. The valine-containing genetic type has been designated as $InV(a^+)$, the leucine-containing type as $InV(b^+)$. Many more allotypes, called Gm allotypes, have been found in the gamma chains of the human IgG immunoglobulins; more than 20 Gm allotypes are now known. Certain combinations of Gm types occur; the combination of Gm types 5, 6, and 11 has been found in Caucasians and Negroes but not in Chinese; the combination of 1, 2, and 17 has not been found in Negroes; and the combination of 1, 4, and 17 has not been found in Caucasians. Allotypes have also been discovered to occur in a number of other animals, including rabbits and mice.

It is understandable from the occurrence of a large number of allotypes that antibodies, even if produced in response to a single antigen, are mixtures of different allotypes. The existence of several classes of antibodies, of different allotypes, and of adaptation of the variable portions of antibodies to different regions of an antigen molecule results in a multiplicity of antibody molecules even if only a single antigen is administered. For this reason it has not yet been possible to unravel the amino acid sequence in the variable portion of antibody molecules. Much of the amino acid sequence in the constant regions of the *L* and *H* chains of man and rabbit immunoglobulins, however, has been resolved.

(F.Ha./Ed.)

ENZYMES

Practically all of the numerous and complex biochemical reactions that take place in animals, plants, and microorganisms are regulated by enzymes. These catalytic proteins are efficient and specific—that is, they accelerate the rate of one kind of chemical reaction of one type of compound, and they do so in a far more efficient manner than man-made catalysts. They are controlled by activators and inhibitors that initiate or block reactions. All cells contain enzymes, which usually vary in number and composition, depending on the cell type; an average mammalian cell, for example, is approximately one one-billionth (10^{-9}) the size of a drop of water and generally contains about 3,000 enzymes.

The existence of enzymes was established in the middle of the 19th century by scientists studying the process of fermentation. Their role as catalysts of all living things followed rapidly. Developments before 1850 included (in 1833) the separation from malt of the enzyme amylase, which converts starch into sugar, and (in 1836) the isolation from the stomach wall of animals of a component of gastric juice that could partially digest food in a test tube, the enzyme pepsin.

Enzymes were known for many years as ferments, a term derived from the Latin word for yeast. In 1878 the name enzyme, from the Greek words meaning "in yeast," was introduced; since the late 19th century it has been universally used.

Role of enzymes in metabolism. Some enzymes help to break down large nutrient molecules, such as proteins, fats, and carbohydrates, into smaller molecules. This process occurs during the digestion of foodstuffs in the stomach and intestines of animals. Other enzymes guide the smaller, broken-down molecules through the intestinal wall into the bloodstream. Still other enzymes promote the formation of large, complex molecules from the small, simple ones to produce cellular constituents. Enzymes are also responsible for numerous other functions, which include the storage and release of energy, the course of reproduction, the processes of respiration, and vision. They are indispensable to life.

Each enzyme is able to promote only one type of chemical reaction. The compounds on which the enzyme acts are called substrates. Enzymes operate in tightly organized metabolic systems called pathways. A seemingly simple

Metabolic pathways

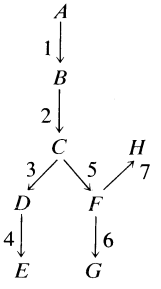
biological phenomenon—the contraction of a muscle, for example, or the transmission of a nerve impulse—actually involves a large number of chemical steps in which one or more chemical compounds (substrates) are converted to substances called products; the product of one step in a metabolic pathway serves as the substrate for the succeeding step in the pathway.

The role of enzymes in metabolic pathways can be illustrated diagrammatically. The chemical compound represented by *A* (see diagram) is converted to product *E* in a series of enzyme-catalyzed steps, in which intermediate compounds represented by *B, C,* and *D* are formed in succession. They act as substrates for enzymes represented by 2, 3, and 4. Compound *A* may also be converted by another series of steps, some of which are the same as those in the pathway for the formation of *E,* to products represented by *G* and *H.*

The letters represent chemical compounds; numbers represent enzymes that catalyze individual reactions. The relative heights represent the thermodynamic energy of the compounds; *e.g.,* compound *A* is more energy-rich than *B, B* more energy-rich than *C.* Compounds *A, B,* etc., change very slowly in the absence of a catalyst but do so rapidly in the presence of catalysts 1, 2, 3, etc.

The regulatory role of enzymes in metabolic pathways can be clarified by using a simple analogy: that between the compounds, represented by letters in the diagram, and a series of connected water reservoirs on a slope. Similarly, the enzymes represented by the numbers are analogous to the valves of the reservoir system. The valves control the flow of water in the reservoir; that is, if only valves 1, 2, 3, and 4 are open, the water in *A* flows only to *E,* but, if valves 1, 2, 5, and 6 are open, the water in *A* flows to *G.* In a similar manner, if enzymes 1, 2, 3, and 4 in the metabolic pathway are active, product *E* is formed, and, if enzymes 1, 2, 5, and 6 are active, product *G* is formed. The activity or lack of activity of the enzymes in the pathway therefore determines the fate of compound *A; i.e.,* it either remains unchanged or is converted to one or more products. In addition, if products are formed, the activity of enzymes 3 and 4 relative to that of enzymes 5 and 6 determines the quantity of product *E* formed compared with product *G.*

Both the flow of water and the activity of enzymes obey the laws of thermodynamics; hence, water in reservoir *F*



cannot flow freely to *H* by opening valve 7, because water cannot flow uphill. If, however, valves 1, 2, 5, and 7 are open, water flows from *F* to *H,* because the energy conserved during the downhill flow of water through valves 1, 2, and 5 is sufficient to allow it to force the water up through valve 7. In a similar way, enzymes in the metabolic pathway cannot convert compound *F* directly to *H* unless energy is available; enzymes are able to utilize energy from energy-conserving reactions in order to catalyze reactions that require energy. During the enzyme-catalyzed oxidation of carbohydrates to carbon dioxide and water, energy is conserved in the form of an energy-rich compound, adenosine triphosphate (ATP). The energy in ATP is utilized during an energy-consuming process such as the enzyme-catalyzed contraction of muscle.

Because the needs of cells and organisms vary, not only the activity but also the synthesis of enzymes must be regulated; *e.g.,* the enzymes responsible for muscular activity in a leg muscle must be activated and inhibited at appropriate times. Some cells do not need certain enzymes; a liver cell, for example, does not need a muscle enzyme. A bacterium does not need enzymes to metabolize substances that are not present in its growth medium. Some enzymes, therefore, are not formed in certain cells, others are synthesized only when required, and still others are found in all cells. The formation and activity of enzymes are regulated not only by genetic mechanisms but also by organic secretions (hormones) from endocrine glands and by nerve impulses. Small molecules also play an important role (see below *Enzyme flexibility and allosteric control*).

The significance of enzymes in disease

If an enzyme is defective in some respect, disease may occur. The enzymes represented by the numbers 1 to 4 in the diagram must function during the conversion of the starting substance *A* to the product *E.* If one step is blocked because an enzyme is unable to function, product *E* may not be formed; if *E* is necessary for some vital function, disease results. Many inherited diseases of man result from a deficiency of one enzyme. Some of these are listed in Table 3. The disease called albinism, for example, results from an inherited lack of ability to synthesize the enzyme tyrosinase, which catalyzes one step in the pathway by which the pigment for hair and eye colour is formed (see also METABOLISM).

Other functions. Enzymes play an increasingly important role in medicine. The enzyme thrombin is used to promote the healing of wounds. Other enzymes are used to diagnose certain kinds of disease, to cause the remission of some forms of leukemia—a disease of the blood-forming organs—and to counteract unfavourable reactions in people who are allergic to penicillin. The enzyme lysozyme, which destroys cell walls, is used to kill bacteria. Research concerning medical applications of enzymes may lead to their use as preventives of tooth decay and as anticoagulants in the treatment of thrombosis, a disease characterized by the formation of a clot, or plug, in a blood vessel. Enzymes may eventually be used to control enzyme deficiencies and abnormalities resulting from diseases.

Table 3: Enzymes Identified with Hereditary Diseases

disease name	defective enzyme
Albinism	tyrosinase
Phenylketonuria	phenylalanine hydroxylase
Fructosuria	fructokinase
Methemoglobinemia	methemoglobin reductase
Galactosemia	galactose-1-phosphate uridyl transferase

It might also be noted in passing that enzymes are used in industrial processes involving the preparation of certain chemical compounds and the tanning of leather; they are valuable in analytical procedures involving the detection of very small quantities of specific substances. Enzymes are necessary in such food-related industries as cheese making, the brewing of beer, the aging of wine, and the baking of bread. Enzymes also may be used to clean clothes. For industrial use of enzymes, see FOOD PROCESSING: *Baking and bakery products* and BEVERAGE PRODUCTION: *Brewing; Wine making.*

General properties. *Classification and nomenclature.* The first enzyme name, proposed in 1833, was diastase. Sixty-five years later, it was suggested that all enzymes be named by adding "-ase" to a root indicative of the nature of the substrate of the enzyme. Although enzymes are no longer named in such a simple manner, with the exception of a few—*e.g.,* pepsin, trypsin, chymotrypsin, papain—most enzyme names do end in "-ase."

Any systematic classification of enzymes should be based on a common property or quality that varies sufficiently to be useful as a distinguishing feature. In this regard, three properties of enzymes could serve as a basis for enzyme classification—the exact chemical nature of the enzyme, the chemical nature of the substrate, and the nature of the reaction catalyzed. Adequate information about the detailed chemical structures of more than a few enzymes does not yet exist. In addition, although, as indicated above, early attempts at enzyme classification were based on the nature of broad groups of substrates (*e.g.,* enzymes called carbohydrases act on carbohydrates), close functional similarities among enzymes in different groups were often obscured. By general agreement, enzymes now

Table 4: Classification of Some Enzymes

systematic name*		trivial name	reaction catalyzed	biological role
code number†	name‡			
1.1.1.1	alcohol: NAD oxidoreductase	alcohol dehydrogenase	alcohol + NAD → acetaldehyde NADH	alcoholic fermentation
1.1.1.27	L-lactate: NAD oxidoreductase	lactic dehydrogenase	lactate + NAD → pyruvate + NADH	carbohydrate metabolism
2.7.1.40	ATP: pyruvate phospho transferase	pyruvate kinase	pyruvic acid + ATP → phosphoenol-pyruvic acid + ADP	carbohydrate metabolism
3.1.1.7	acetylcholine: acetyl hydrolase	acetylcholinesterase	acetylcholine + H_2O → acetate + choline	nerve-impulse conduction
3.4.4.13	peptide peptido hydrolase	thrombin	peptide bond + $H_2O \rightarrow -\overset{O}{\overset{\|}{C}}-OH + H_3^+N-$	blood-clotting mechanism

*Based on recommendations (1964) of the International Union of Biochemistry. †The numbering system is as follows: the first number places the enzyme in one of six general groups—1, oxidoreductases; 2, transferases; 3, hydrolases; 4, lyases; 5, isomerases and 6, ligases. The second number places the enzyme in a subclass based on substrate type or reaction type; *e.g.*, the enzyme may act on molecules with —CHOH groups. The third number places the enzyme in a subsubclass, which specifies the reaction type more fully; *e.g.*, NAD coenzyme required. The fourth number is the serial number of the enzyme in its subsubclass. ‡NAD and NADH represent the oxidized and reduced forms of nicotinamide adenine dinucleotide (NAD), respectively; ATP and ADP represent adenosine triphosphate and adenosine diphosphate, respectively.

are classified according to their substrates and the nature of the reaction they catalyze.

Systematic and trivial names

In an attempt to devise a rational system of enzyme nomenclature, two names are given to an enzyme. One, known as the systematic name, is based on logical principles but is often long and awkward; the other, "trivial" name is short and generally used but not usually exact or systematic (see Table 4). In the scheme of systematic nomenclature, six main groups of enzymatic reactions are recognized; each catalyzes one reaction type and is subdivided on the basis of detailed definitions of the reaction catalyzed and of the substrate involved in the reaction. Enzymes that catalyze reactions in which hydrogen is transferred belong to the group known as oxidoreductases; those that catalyze the introduction of the elements of water at a specific site in a molecule are called hydrolases. The other four groups of reactions are the transferases—which catalyze reactions in which substances other than hydrogen are transferred—the lyases, the isomerases, and the ligases. Oxidoreductases and transferases account for about 50 percent of the approximately 1,000 enzymes recognized thus far. Table 4 lists a few enzymes, their trivial names, their systematic names, and their biological roles.

Chemical nature. Little was known about the chemical nature of enzymes until the beginning of the 20th century, although scientists were almost convinced that they were proteins. In 1926, the enzyme urease was the first to be crystallized and clearly identified as a protein. Within the next few years, the digestive enzymes pepsin, trypsin, and chymotrypsin were shown to be proteins. Since that time, hundreds of enzymes, all of them proteins, have been prepared and characterized by chemical methods. Much of the knowledge of protein chemistry has, in fact, resulted from studies involving enzymes and from attempts to understand their nature and mode of action.

Although some enzymes consist of a single chain of the amino acids (*i.e.*, simple organic molecules containing nitrogen), most enzymes are composed of more than one chain. Each chain is called a subunit. Many enzymes have two, four, or six subunits, and some consist of as many as 12 to 60 subunits. In many cases, the subunits have identical structures; in others, however, several different types of subunit chains are involved.

With the exception of proteins that act as structural elements, most of the proteins in physiologically active tissues such as kidney and liver are enzymes. Regardless of the exact amount of enzymatic protein in an organism, it is clear that hundreds of different enzymes must be present in each tissue to account for the myriad reactions comprising metabolism.

Cofactors. Although some enzymes consist only of protein, many are complex proteins; *i.e.*, they have a protein component and a so-called cofactor. A complete enzyme is called a holoenzyme; if the cofactor is removed, the protein, no longer enzymatically active, is called the apoenzyme. A cofactor may be a metal—such as iron, copper, or magnesium—a moderately sized organic molecule called a prosthetic group, or a special type of substrate molecule known as a coenzyme. The cofactor may aid in the catalytic function of an enzyme, as do metals and prosthetic groups, or take part in the enzymatic reaction, as do coenzymes.

Holoenzyme

Coenzymes

A coenzyme serves as a type of substrate in certain enzymatic reactions and thus reacts in the exact proportions (*i.e.*, stoichiometrically) required for reaction, rather than in catalytic quantities. A coenzyme may, for example, assume the role of a hydrogen acceptor, as does nicotinamide adenine dinucleotide (NAD), which accepts hydrogen from the substrate, or a chemical-group donor, as does adenosine triphosphate (ATP), which donates phosphoric acid to the substrate. After ATP has donated a phosphoric acid molecule to the substrate, the phosphoric acid can be reacquired in a second stoichiometric reaction catalyzed by a second enzyme. The catalytic nature of a coenzyme is apparent only when it couples the activities of two enzymes in this way. Coenzymes thus are the links, or shuttles, in metabolic pathways that enable substances—*e.g.*, hydrogen, phosphoric acid—to be exchanged.

The nature of enzyme-catalyzed reactions. *The nature of catalysis.* In a chemical reaction—for example, one in which substance *A* is converted into product *B*—a point of equilibrium eventually is reached at which no further chemical change occurs; *i.e.*, the rate of conversion of *A* to *B* equals the rate of conversion of *B* to *A*. The so-called thermodynamic-equilibrium constant expresses this chemical equilibrium. A catalyst may be defined as a substance that accelerates a chemical reaction but is not consumed in the process. The amount of catalyst has no relationship to the quantity of substance altered; very small amounts of enzymes are very efficient catalysts. Because the presence of an enzyme accelerates the rate of conversion of a compound to a product, it accelerates the approach to equilibrium; it does not, however, influence the equilibrium point attained.

The molecules in the watery medium of the cell are in constant thermal motion but, because they are more or less stable compounds, they would react only occasionally to form products in the absence of enzymes. There exists an energy barrier to the reaction of a molecule. The energy required to overcome the barrier to reaction is called the energy of activation. A reaction proceeds to equilibrium only if the molecules have sufficient energy of activation to form an activated complex, from which products can be derived. Enzymes greatly increase the chances for reactions by their ability to make large numbers of specific molecules more reactive (*i.e.*, unstable) by forming intermediate compounds with them. The unstable intermediates quickly break down to form stable products, and the enzymes, unchanged by the reaction, are able to catalyze the formation of additional products.

The role of the active site. That the compound on which an enzyme acts (substrate) must combine in some

way with it before catalysis can proceed is an old idea, now supported by much experimental evidence. The combination of substrate molecules with enzymes involves collisions between the two. Enzymes are large molecules, the molecular weights of which (based on the weight of a hydrogen atom as 1) range from several thousand to several million. The substrates on which enzymes act usually have molecular weights of several hundred. Because of the difference in size between the two, only a fraction of the enzyme is in contact with the substrate; the region of contact is called the active site. Usually, each subunit of an enzyme has one active site capable of binding substrate.

The characteristics of an enzyme derive from the sequence of amino acids, which determine the shape of the enzyme (*i.e.*, the structure of the active site) and hence the specificity of the enzyme.

Figure 7A shows the way in which the substrate fits into the active site of an enzyme. A small portion of the structure of the enzyme is represented by the various dark lines and symbols. The triangles labeled *A* and *B* represent the amino acids at the active site that actually catalyze the reaction in which the bond (indicated by the indentation) in the substrate molecule is broken as a product forms. The circles in the enzyme structure represent amino acids that function in attracting certain regions of the substrate, so that it is held in the proper position to allow the reaction at the active site to proceed.

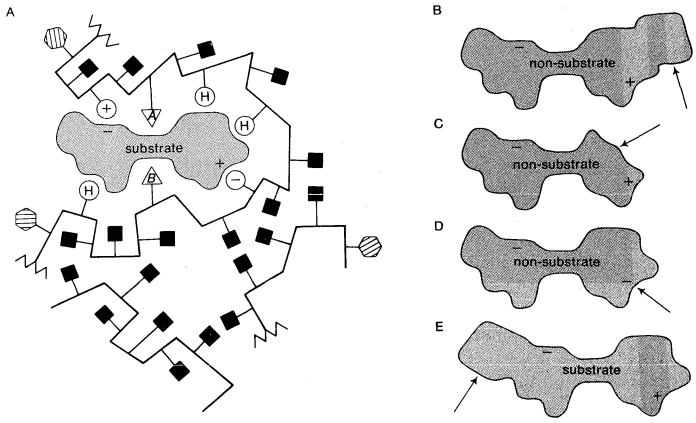


Figure 7: The role of active site in lock and key fit of a substrate—the key—to an enzyme—the lock (see text).

Forces attracting enzyme and substrate

The forces that attract the substrate to the surface of an enzyme may be of a physical or a chemical nature. Electrostatic bonds may occur between oppositely charged groups—the circles containing plus and minus signs on the enzyme are attracted to their opposites in the substrate molecule. Such electrostatic bonds can occur with groups that are completely positively or negatively charged (*i.e.*, ionic groups) or with groups that are partially charged (*i.e.*, dipoles). The attractive forces between substrate and enzyme may also involve so-called hydrophobic bonds, in which the oily, or hydrocarbon, portions of the enzyme (represented by H-labelled circles) and the substrate are forced together in the same way as oil droplets tend to coalesce in water.

Modifications in the structure of the amino acids at or near the active site usually affect the enzyme's activity, because these amino acids are intimately involved in the fit and attraction of the substrate to the enzyme surface. The characteristics of the amino acids near the active site determine whether or not a substrate molecule will fit into the site. A molecule that is too bulky in the wrong places, as indicated by the arrow in Figure 7B, cannot fit into the active site and thus cannot react with the enzyme. In a similar manner, a molecule lacking essential attractive forces (indicated by the arrow in 7C) or the appropriately charged regions (indicated by the arrow in 7D) might not be bound to the enzyme. On the other hand, a molecule with a bulky group (7E) at a position such that it does not interfere with the binding of the molecule to the enzyme or with the function of the active site is able to serve as a substrate for the enzyme. The idea of a fit between substrate and enzyme, called the "key–lock" hypothesis, was proposed by a German chemist, Emil Fischer, in 1899 and explains one of the most important features of enzymes, their specificity. In most of the enzymes studied thus far, a cleft, or indentation, into which the substrate fits (see 7A), is found at the active site.

The specificity of enzymes. Since the substrate must fit into the active site of the enzyme before catalysis can occur, only properly designed molecules can serve as substrates for a specific enzyme; in many cases, an enzyme will react with only one naturally occurring molecule. Two oxidoreductase enzymes from Table 4 will serve to illustrate the principle of enzyme specificity. One (alcohol dehydrogenase) acts on alcohol, the other (lactic dehydrogenase) on lactic acid; the activities of the two, even though both are oxidoreductase enzymes, are not interchangeable—*i.e.*, alcohol dehydrogenase will not catalyze a reaction involving lactic acid or vice versa, because the structure of each substrate differs sufficiently to prevent its fitting into the active site of the alternative enzyme. Enzyme specificity is essential because it keeps separate the many pathways, involving hundreds of enzymes, that function during metabolism.

Figure 7 illustrates enzyme specificity. As mentioned above, the molecules in B, C, and D cannot serve as substrates for the enzyme because they are either too large (B), too small (C), or too repulsive because of charge (D) to bind to the enzyme's active site. Molecules with structural differences that do not affect the active site (see arrow, Figure 7E) are able to react with the enzyme and are substrates.

Not all enzymes are as highly specific as the example in Figure 7; digestive enzymes such as pepsin and chymotrypsin, for example, are able to act on almost any protein, as they must if they are to act upon the varied types of proteins consumed as food. On the other hand, thrombin, which reacts only with the protein fibrinogen, is part of a very delicate blood-clotting mechanism and thus must act only on one compound in order to maintain the proper functioning of the system.

When enzymes were first studied, it was thought that most of them were "absolutely specific"—*i.e.*, that they would react with only one compound. In most cases, however, a molecule other than the natural substrate can be synthesized in the laboratory; it is enough like the natural substrate to react with the enzyme. Use of these synthetic substrates has been valuable in understanding enzymatic action. It must be remembered, however, that, in the living cell, many enzymes are absolutely specific for the compounds found there.

All enzymes isolated thus far are specific for the type of chemical reaction they catalyze—*i.e.*, oxidoreductases do not catalyze hydrolase reactions, and hydrolases do not catalyze reactions involving oxidation and reduction. An enzyme therefore catalyzes a specific chemical reaction but may be able to do so on several similar compounds.

The mechanism of enzymatic action. An enzyme attracts substrates to its active site, catalyzes the chemical reaction by which products are formed, and then allows

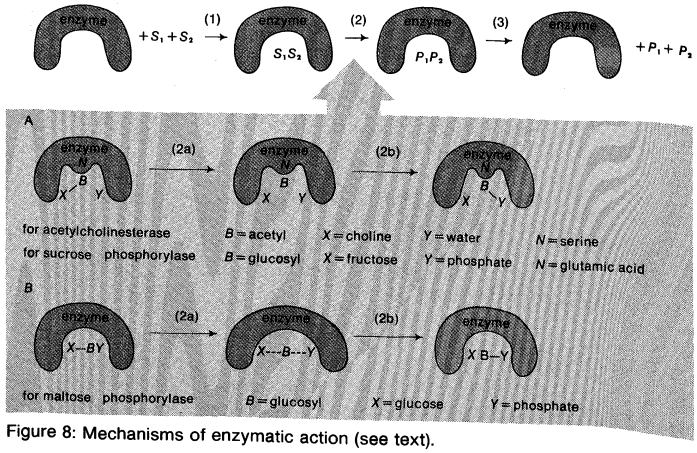

Figure 8: Mechanisms of enzymatic action (see text).

the products to dissociate—*i.e.*, separate from the enzyme surface. This sequence is shown in Figure 8. The combination formed by an enzyme and its substrates is called the enzyme–substrate complex. When two substrates and one enzyme are involved, the complex is called a ternary complex; one substrate and one enzyme are called a binary complex. The substrates are attracted to the active site by electrostatic and hydrophobic forces, which are called noncovalent bonds because they are physical attractions and not chemical bonds (see above *The role of the active site*).

Enzyme–substrate complex

In Figure 8, two substrates (S_1 and S_2) bind to the active site of the enzyme during step (1) and react to form products (P_1 and P_2) during step (2). The products dissociate from the enzyme surface in step (3), releasing the enzyme. The enzyme, unchanged by the reaction, is able to react with additional substrate molecules in this manner many times per second to form products. The step in which the actual chemical transformation occurs is of great interest, and, although much is known about it, it is not yet fully understood. In general there are two types of enzymatic mechanisms, one in which a so-called covalent intermediate forms (see below) and one in which none forms (Figure 8B). Figure 8A and B show the catalytic events that occur during an enzyme-catalyzed reaction.

Figure 8A shows the mechanism by which a covalent intermediate—*i.e.*, an intermediate with a chemical bond between substrate and enzyme—forms. One substrate, $B-X$ (in 8A), reacts with the group N on the enzyme surface to form an enzyme-B intermediate compound. The intermediate compound then reacts with the second substrate, Y, to form the products $B-Y$ and X.

Many enzymes catalyze reactions by this type of mechanism. Acetylcholinesterase (Table 4 and Figure 8A) is used as a specific example in the sequence described below. The two substrates (S_1 and S_2) for acetylcholinesterase are acetylcholine (the $B-X$ of Figure 8A) and water (the Y of Figure 8A). After acetylcholine ($B-X$) binds to the enzyme surface, a chemical bond forms between the acetyl moiety (B) of acetylcholine and the group N (part of the amino acid serine) on the enzyme surface. The result of the formation of this bond, called an acyl–serine bond, is one product, choline (X), and the enzyme-B intermediate compound (an acetyl–enzyme complex). The water molecule (Y) then reacts with the acyl–serine bond to form the second product, acetic acid ($B-Y$), which dissociates from the enzyme. Acetylcholinesterase is regenerated and is again able to react with another molecule of acetylcholine. This kind of reaction, involving the formation of an intermediate compound on the enzyme surface, is generally called a double displacement reaction.

Double displacement reaction

Sucrose phosphorylase (see Figure 8A) acts in a similar way. The substrate for sucrose phosphorylase is sucrose, or glucosyl-fructose ($B-X$), and the group N on the enzyme surface is a chemical group called a carboxyl group (COOH). The enzyme-B intermediate, a glucosyl–carboxyl compound, reacts with phosphate (Y) to form glucosyl-phosphate ($B-Y$). The other product (X) is fructose.

In double displacement reactions, the covalent intermediate between enzyme and substrate apparently influences the reaction to proceed more rapidly. Because the enzyme is unaltered at the end of the reaction, it functions as a true catalyst, even though it is temporarily altered during the enzymatic process.

Although many enzymes form a covalent intermediate, the mechanism is not essential for catalysis; some reactions proceed as illustrated in Figure 8B. One substrate (Y) reacts directly with the second substrate ($X-B$), in a so-called single displacement reaction. The B moiety, which is transformed in the chemical reaction, is involved in only one reaction and does not form a bond with a group on the enzyme surface. In Figure 8B, the enzyme maltose phosphorylase directly affects the bonds of the substrates ($B-X$ and Y), which, in this case, are maltose (glucosyl-glucose) and phosphate, to form the products, glucose (X) and glucosylphosphate ($B-Y$).

Covalent intermediates between part of a substrate and an enzyme occur in many enzymatic reactions, and various amino acids—serine, cysteine, lysine, and glutamic acid—are involved.

The rate of enzymatic reactions. *The Michaelis-Menten hypothesis.* If the velocity of an enzymatic reaction is represented graphically as a function of the substrate concentration (S), the curve obtained in most cases is a hyperbola (see Figure 9). The mathematical expression of this curve, shown in the equation below, was developed in 1913 by two German biochemists, L. Michaelis and M.L. Menten. In the equation, V_M is the maximal velocity of the reaction, and K_M is called the Michaelis constant,

$$\text{velocity} = \frac{V_M(S)}{K_M + (S)} .$$

The shape of the curve is a logical consequence of the active-site concept; *i.e.*, the curve flattens at the maximum velocity (V_M), which occurs when all the active sites of the enzyme are filled with substrate. The fact that the velocity approaches a maximum at high substrate concentrations provides support for the assumption that an intermediate enzyme–substrate complex forms. At the point of half the maximum velocity ($\frac{V_M}{2}$ in Figure 9), the substrate concentration in moles per litre (M) is equal to the Michaelis constant, which is a rough measure of the affinity of the substrate molecule for the surface of the enzyme. K_M values usually vary from about 10^{-8} to 10^{-2} M, and V_M from 10^5 to 10^9 molecules of product formed per molecule of enzyme per second. The value for V_M is referred to as the turnover number when expressed as moles of product formed per mole of enzyme per minute. The binding of molecules that inhibit or activate the protein surface usually results in similar types.

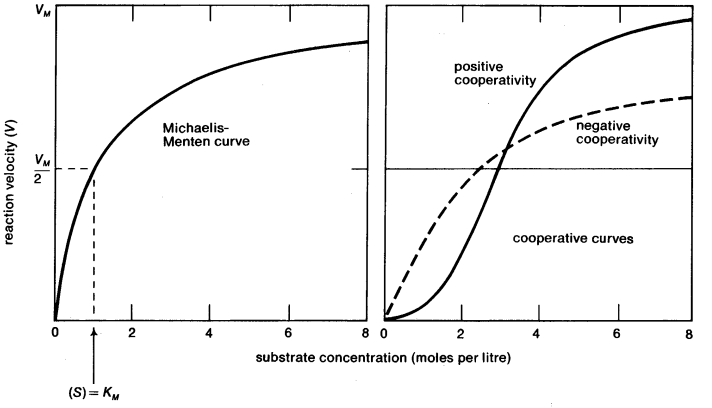

Figure 9: Curves representing enzyme action (see text).

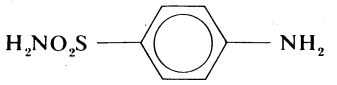
The efficiency of enzymes

Enzymes are more efficient than man-made catalysts operating under the same conditions. Because many enzymes with different specificities occur in a cell, adequate space exists only for a few enzyme molecules catalyzing one specific reaction. Each enzyme, therefore, must be very efficient. One molecule of the enzyme catalase, for example, can produce 10^{12} molecules of oxygen per second. The catalytic groups at the active site of an enzyme act 10^6 to 10^9 times more effectively than do analogous groups in a nonenzymatic reaction.

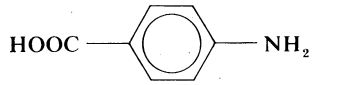
The reason for the great efficiency of enzymes is not completely understood. It results in part from the precise positioning of the substrates and the catalytic groups at the active site, which serves to increase the probability of collision between the reacting atoms. In addition, the environment at the active site may be favourable for reaction—that is, acidic and basic groups may act together more effectively there, or some strain may be induced in the substrate molecules so that their bonds are broken more easily, or the orientation of the reacting substrates may be optimal at the enzyme surface. The theories that have been formulated to account for the high catalytic efficiency of enzymes, although reasonable, still remain to be proved.

Inhibition of enzymes. Some molecules very similar to the substrate for an enzyme may be bound to the active site but be unable to react. Such molecules cover the active site and thus prevent the binding of the actual substrate to the site. This inhibition of enzyme action is of

a competitive nature, because the inhibitor molecule actually competes with the substrate for the active site. The inhibitor sulfanilamide (see below), for example, is similar enough to a substrate (*p*-aminobenzoic acid) of an enzyme involved in the metabolism of folic acid that it binds to the enzyme but cannot react. It covers the active site and prevents the binding of *p*-aminobenzoic acid. This enzyme is essential in certain disease-causing bacteria but is not essential to man; large amounts of sulfanilamide therefore kill the microorganism but do not harm man. Inhibitors such as sulfanilamide are called anti-metabolites. Sulfanilamide and similar compounds that kill a pathogen without harming its host are now widely used in chemotherapy.



sulfanilamide
(inhibitor)



p-aminobenzoic acid
(substrate)

Some inhibitors prevent, or block, enzymatic action by reacting with groups at the active site. The nerve gas diisopropyl fluorophosphate, for example, reacts with the serine at the active site of acetylcholinesterase to form a covalent bond. The nerve-gas molecule involved in bond formation prevents the active site from binding the substrate, acetylcholine, thereby blocking catalysis and nerve action. Iodoacetic acid similarly blocks a key enzyme in muscle action by forming a bulky group on the amino acid cysteine, which is found at the enzyme's active site. This process is called irreversible inhibition.

Some inhibitors modify amino acids other than those at the active site, resulting in loss of enzymatic activity. The inhibitor causes changes in the shape of the active site. Some amino acids other than those at the active site, however, can be modified without affecting the structure of the active site; in these cases, enzymatic action is not affected.

Such chemical changes parallel natural mutations. Inherited diseases frequently result from a change in an amino acid at the active site of an enzyme, thus making the enzyme defective. In some cases, an amino acid change alters the shape of the active site to the extent that it can no longer react; such diseases are usually fatal. In others, however, a partially defective enzyme is formed, and an individual may be very sick but able to live.

Denaturation of enzymes

Effects of temperature. Enzymes function most efficiently within a physiological temperature range. Since enzymes are protein molecules, they can be destroyed by high temperatures. An example of such destruction, called protein denaturation, is the curdling of milk when it is boiled. Increasing temperature has two effects on an enzyme. First, the velocity of the reaction increases somewhat, because the rate of chemical reactions tends to increase with temperature; second, the enzyme is increasingly denatured. Increasing temperature thus increases the metabolic rate only within a limited range. If the temperature becomes too high, enzyme denaturation destroys life. Low temperatures also change the shapes of enzymes. With enzymes that are cold-sensitive, the change causes loss of activity. Both excessive cold and heat are therefore damaging to enzymes.

The degree of acidity or basicity of a solution, which is expressed as pH, also affects enzymes. As the acidity of a solution changes—*i.e.,* the pH is altered—a point of optimum acidity occurs, at which the enzyme acts most efficiently. Although this pH optimum varies with temperature and is influenced by other constituents of the solution containing the enzyme, it is a characteristic property of enzymes. Because enzymes are sensitive to changes in acidity, most living systems are highly buffered; *i.e.,* they have mechanisms that enable them to maintain a constant acidity. This acidity level, or pH, is about 7 in most organisms. Some bacteria function under moderately acidic or basic conditions; and the digestive enzyme pepsin acts in the acid milieu of the stomach. There is no known organism that can survive in either a very acidic or a very basic environment.

Enzyme flexibility and allosteric control. *The induced-fit theory.* The key–lock hypothesis (see above *The nature of enzyme-catalyzed reactions*) does not fully account for enzymatic action; *i.e.,* certain properties of enzymes cannot be accounted for by the simple relationship between enzyme and substrate proposed by the key–lock hypothesis. A theory called the induced-fit theory retains the key–lock idea of a fit of the substrate at the active site but postulates in addition that the substrate must do more than simply fit into the already preformed shape of an active site. Rather, the theory states, the binding of the substrate to the enzyme must cause a change in the shape of the enzyme that results in the proper alignment of the catalytic groups on its surface. This concept has been likened to the fit of a hand in a glove, the hand (substrate) inducing a change in the shape of the glove (enzyme). Although some enzymes appear to function according to the older key–lock hypothesis, most apparently function according to the induced-fit theory.

During step 1 in Figure 10, which illustrates the induced-fit theory, the substrate approaches the enzyme surface and induces a change in its shape that results in the correct alignment of the catalytic groups (indicated by triangles *A* and *B*). In the case of the digestive enzyme carboxypeptidase, the binding of the substrate causes a tyrosine molecule at the active site to move by as much as 15 angstroms. Circles *C* and *D* in the figure represent substrate-binding groups on the enzyme that are essential for catalytic activity. During step 2 the catalytic groups at the active site react with the substrate to form products. The products separate from the enzyme surface during step 3, and the enzyme is able to repeat the sequence.

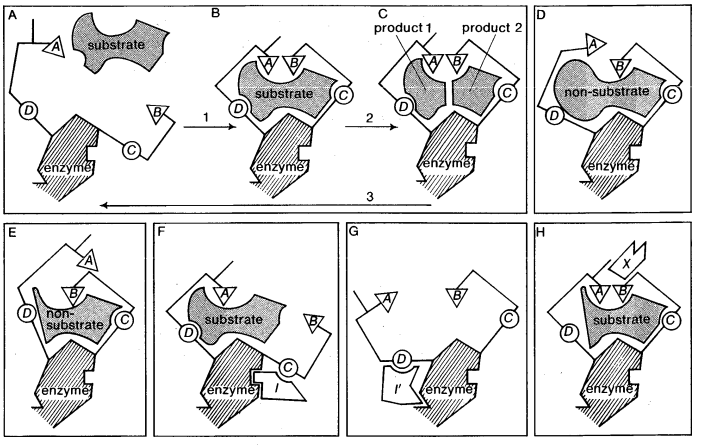


Figure 10: Induced-fit binding of a substrate to an enzyme surface and allosteric effects (see text).

Nonsubstrate molecules that are too bulky (Figure 10D) or too small (Figure 10E) alter the shape of the enzyme so that a misalignment of catalytic groups *A* and *B* occurs; such molecules are not able to react even if they are attracted to the active site.

The induced-fit theory explains a number of anomalous properties of enzymes; for example, "noncompetitive inhibition" (Figure 10F), in which a compound inhibits the reaction of an enzyme but does not prevent the binding of the substrate. In this case, the inhibitor compound *I* attracts the binding group *C* so that the catalytic group *B* is too far away from the substrate to react. The site at which the inhibitor binds to the enzyme is not the active site and is called an allosteric site. The inhibitor changes the shape of the active site to prevent catalysis without preventing binding of the substrate.

Figure 10G shows the effect of an inhibitor (*I'*), which distorts the active site by affecting the essential binding group *D;* as a result, the enzyme can no longer attract the

substrate. In Figure 10H, a so-called activator molecule, *X*, affects the active site so that a nonsubstrate molecule is properly aligned and hence can react with the enzyme; *X* is called an allosteric activator of the reaction. Such activators can affect both binding and catalytic groups at the active site.

The importance of enzyme flexibility

Enzyme flexibility is extremely important because it provides a mechanism for regulating enzymatic activity. As shown in Figure 10F and G, the orientation at the active site can be disrupted by the binding of an inhibitor at a site other than the active site. Moreover, the enzyme can be activated by molecules that induce a proper alignment of the active site for a substrate that alone cannot induce this alignment (Figure 10H).

As mentioned above, the sites that bind inhibitors and activators are called allosteric sites to distinguish them from active sites. Allosteric sites are in fact regulatory sites able to activate or inhibit enzymatic activity by influencing the shape of the enzyme. When the activator or inhibitor dissociates from the enzyme, it returns to its normal shape. Thus, the flexibility of the protein structure allows the operation of a simple, reversible control system similar to a thermostat.

Types of allosteric control. Allosteric control can operate in many ways; two examples serve to illustrate some general effects. A pathway consisting of ten enzymes is involved in the synthesis of the amino acid histidine. When a cell contains enough histidine, synthesis stops—an appropriate economy move by the cell. Synthesis is stopped by the inhibition of the first enzyme in the pathway by the product, histidine; the mechanism is similar to that of Figure 10G. The inhibition of an enzyme by a product is called feedback inhibition; *i.e.,* a product many steps removed from an initial enzyme blocks its action. Feedback inhibition occurs in many pathways in all living things.

Allosteric control can also be achieved by activators. The hormone adrenaline (epinephrine) acts in this way. When energy is needed, adrenaline is released and activates, by allosteric activation, the enzyme adenyl cyclase. This enzyme catalyzes a reaction in which the compound cyclic adenosine monophosphate (cyclic AMP) is formed from ATP. Cyclic AMP in turn acts as an allosteric activator of enzymes that speed the metabolism of carbohydrate to produce energy. This type of allosteric regulation also is widespread in biological systems.

Thus, a combination of allosteric activation and inhibition allows the production of energy or materials when they are needed and shuts off production when the supply is adequate.

Allosteric control is a rapid method of regulating products continuously needed by living things. Yet some cells have no need for certain enzymes, and it would be wasteful for the cell to synthesize them. In this case, certain molecules, called repressors, prevent the synthesis of unneeded enzymes. The repressors are proteins that bind to DNA and prevent the first step in the process resulting in protein synthesis. If certain metabolites are added to cells that need an enzyme, enzyme synthesis occurs—*i.e.,* it is induced. Addition of galactose to a growth medium containing *Escherichia coli* bacteria, for example, induces the synthesis of the enzyme beta galactosidase. The bacteria thus can synthesize this galactose-metabolizing enzyme when it is needed and prevent its synthesis when it is not. The way in which the synthesis of enzymes is induced or repressed in mammalian systems is less understood but is believed to be similar.

Different types of cells in complex organisms have different enzymes, even though they have the same DNA content. The enzymes actually synthesized are the ones needed in a specific cell and vary not only for different types of cells—*e.g.,* nerve, muscle, eye, and skin cells—but also for different species.

In an enzyme consisting of several subunits, or chains, alteration in the shape of one chain as a result of the influence either of a substrate molecule or of allosteric inhibitors or activators may change the shape of a neighbouring chain. As a result, the binding of a second molecule of substrate occurs in a different way from the binding of the first, and the third is different from the second. This phenomenon, called cooperativity, is characteristic of allosteric enzymes.

Cooperativity

Cooperativity (see Figure 9) is reflected by a sigmoid curve, as compared to the hyperbolic curve of Michaelis–Menten. An enzyme of several subunits that exhibits cooperativity is far more sensitive to control mechanisms than is an enzyme of one subunit and hence one active site.

The first example of cooperativity was observed in hemoglobin, which is not an enzyme but behaves like one in many ways. The absorption of oxygen in the lungs and its deposition in the tissues is far more efficient because the subunits of hemoglobin show positive cooperativity, so-called because the first molecule of substrate makes it easier for the next to bind.

Negative cooperativity (also illustrated in Figure 9), in which the binding of one molecule makes it less easy for the next to bind, also occurs in living things. Negative cooperativity makes an enzyme less sensitive to fluctuations in concentrations of metabolites and may be important for enzymes that must be present in the cell at relatively constant levels of activity.

Some enzymes are closely associated aggregates of several enzyme units; the pyruvate dehydrogenase system, for example, contains five different enzymes, has a total molecular weight of 4,000,000, and consists of four different types of chains. Apparently, the enzymes in cells may be organized by forming complex units, by being absorbed on a cell wall, or by being isolated by membranes in special compartments. Since a pathway involves the stepwise modification of chemical compounds, aggregations of the enzymes in a given pathway facilitate their function in a manner similar to an industrial assembly line.

(D.E.K./Ed.)

CARBOHYDRATES

The term carbohydrate, which means watered carbon, represents a class of naturally occurring compounds and derivatives formed from them. In the early part of the 19th century, substances such as wood, starch, and linen were found to be composed mainly of molecules containing atoms of carbon (C), hydrogen (H), and oxygen (O), and to have the general formula $C_6H_{12}O_6$; other organic molecules with similar formulas were found to have a similar ratio of hydrogen to oxygen. The general formula $C_x(H_2O)_x$ is commonly used to represent many carbohydrates.

Carbohydrates are probably the most abundant and widespread organic substances in nature. Essential constituents of all living things, carbohydrates are formed by green plants from carbon dioxide and water during the process of photosynthesis. Carbohydrates serve organisms as energy sources and as essential structural components; in addition, part of the structure of nucleic acids, which contain genetic information, consists of carbohydrate.

General features

CLASSIFICATION AND NOMENCLATURE

Although a number of classification schemes have been devised for carbohydrates, the division into four major groups—monosaccharides, disaccharides, oligosaccharides, and polysaccharides—used here is among the most common. Most monosaccharides, or simple sugars, are found in grapes, other fruits, and honey. Although they can contain from three to nine carbon atoms, the most common representatives consist of five or six joined together to form a chainlike molecule. Three of the most important simple sugars, glucose—also known as dextrose, grape sugar, and corn sugar—fructose (fruit sugar), and galactose, have the same molecular formula, $(C_6H_{12}O_6)$, but, because their atoms have different structural arrangements, the sugars have different characteristics; *i.e.,* they are isomers. Slight changes in structural arrangements are detectable by living

Basic molecular structures

things and influence the biological significance of isomeric compounds. It is known, for example, that the degree of sweetness of various sugars differs according to the arrangement of the hydroxyl groups (—OH) that compose part of the molecular structure; a direct correlation that may exist between taste and any specific structural arrangement, however, has not yet been established—that is, it is not yet possible to predict the taste of a sugar by knowing its specific structural arrangement. The energy in the chemical bonds of glucose indirectly supplies most living things with a major part of the energy that is necessary for them to carry on their activities. Galactose, which is rarely found as a simple sugar, is usually combined with other simple sugars in order to form larger molecules.

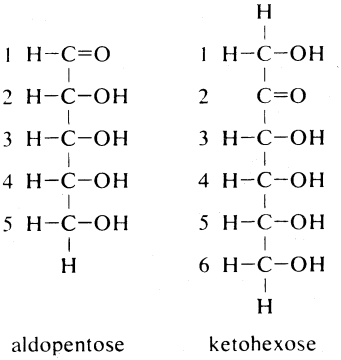
Two molecules of a simple sugar that are linked to each other form a disaccharide, or double sugar. The disaccharide sucrose, or table sugar, consists of one molecule of glucose and one molecule of fructose; the most familiar sources of sucrose are sugar beets and cane sugar. Milk sugar, or lactose, and maltose are also disaccharides. Before the energy in disaccharides can be utilized by living things, the molecules must be broken down into their respective monosaccharides.

Oligosaccharides, which consist of three to six monosaccharide units, are rather infrequently found in natural sources, although a few plant derivatives have been identified.

Polysaccharides (the term means many sugars) represent most of the structural and energy-reserve carbohydrates found in nature. Large molecules that may consist of as many as 10,000 monosaccharide units linked together, polysaccharides vary considerably in size, in structural complexity, and in sugar content; several hundred distinct types have thus far been identified. Cellulose, the principal structural component of plants, is a complex polysaccharide comprising many glucose units linked together; it is the most common polysaccharide. The starch found in plants and the glycogen found in animals also are complex glucose polysaccharides. Starch (from the old English word *stercan* meaning "to stiffen") is found mostly in seeds, roots, and stems, where it is stored as an available energy source for plants. Plant starch may be processed into such foods for man as bread, or it may be consumed directly—as are potatoes. Glycogen, which consists of branching chains of glucose molecules, is formed in the liver and muscles of higher animals and is stored as an energy source.

Names for monosaccharides

The generic nomenclature ending for the monosaccharides is -ose; thus, the term pentose (pent = five) is used for monosaccharides containing five carbon atoms, and hexose (hex = six) is used for those containing six. In addition, because the monosaccharides contain a chemically reactive group that is either an aldehydo group (H–C=O) or a keto group (R–C=O), they are frequently referred to as aldopentoses or ketopentoses or aldohexoses or ketohexoses; in the examples below, the aldehydo group is at position 1 of the aldopentose, the keto group is at position 2 of the ketohexose. Glucose is an aldohexose—*i.e.*, it contains six carbon atoms, and the chemically reactive group is an aldehydo group.



aldopentose ketohexose

BIOLOGICAL SIGNIFICANCE

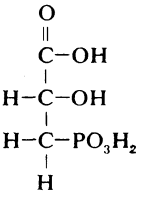
The importance of carbohydrates to living things can hardly be overemphasized. The energy stores of most animals and plants are both carbohydrate and lipid in nature; carbohydrates are generally available as an immediate energy source, whereas lipids act as a long-term energy resource and tend to be utilized at a slower rate. Glucose, the prevalent uncombined, or free, sugar circulating in the blood of higher animals, is essential to cell function. The proper regulation of glucose metabolism is of paramount importance to survival.

The ability of ruminants, such as cattle, sheep, and goats, to convert the polysaccharides present in grass and similar feeds into protein provides a major source of protein for man. A number of medically important antibiotics, such as streptomycin, are carbohydrate derivatives. The cellulose in plants is used to manufacture paper, wood for construction, and fabrics.

Role in the biosphere. The essential process in the biosphere, the portion of the Earth in which life can occur, that has permitted the evolution of life as it now exists is the conversion by green plants of carbon dioxide from the atmosphere into carbohydrates, using light energy from the Sun. This process, called photosynthesis, results in both the release of oxygen gas into the atmosphere and the transformation of light energy into the chemical energy of carbohydrates. The energy stored by plants during the formation of carbohydrates is used by animals to carry out mechanical work and to perform biosynthetic activities.

Photosynthesis

All green plants apparently photosynthesize in the same way, yielding as an immediate product the compound 3-phosphoglyceric acid; the formula, in which P represents phosphorus, is illustrated below.



3-phosphoglyceric acid

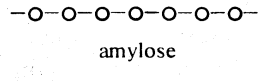
This compound then is transformed into cell-wall components such as cellulose, varying amounts of sucrose, and starch—depending on the plant type—and a wide variety of polysaccharides, other than cellulose and starch, that function as essential structural components. For a detailed discussion of the process of photosynthesis, see PHOTOSYNTHESIS.

Role in human nutrition. The total caloric, or energy, requirement for an individual depends on age, occupation, and other factors but generally ranges between 2,000 and 4,000 calories per 24-hour period (one calorie, as this term is used in nutrition, is the amount of heat necessary to raise the temperature of 1,000 grams of water from 15° to 16° C [59° to 61° F]; in other contexts this amount of heat is called the kilocalorie). Carbohydrate that can be used by man produces four calories per gram as opposed to nine calories per gram of fat and four per gram of protein. In areas of the world where nutrition is marginal, a high proportion (approximately one to two pounds) of an individual's daily energy requirement may be supplied by carbohydrate, with most of the remainder coming from a variety of fat sources.

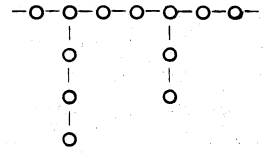
Although carbohydrates may compose as much as 80 percent of the total caloric intake in the human diet, for a given diet, the proportion of starch to total carbohydrate is quite variable, depending upon the prevailing customs. In the Far East and in areas of Africa, for example, where rice or tubers such as manioc provide a major food source, starch may account for as much as 80 percent of the total carbohydrate intake. In a typical Western diet, 33 to 50 percent of the caloric intake is in the form of carbohydrate. Approximately half (*i.e.*, 17 to 25 percent) is represented by starch; another third by table sugar (sucrose) and milk sugar (lactose); and smaller percentages by monosaccharides such as glucose and fructose, which are

common in fruits, honey, syrups, and certain vegetables such as artichokes, onions, and sugar beets. The small remainder consists of bulk, or indigestible carbohydrate, which comprises primarily the cellulosic outer covering of seeds and the stalks and leaves of vegetables. (See also NUTRITION.)

Role in energy storage. Starches, the major plant-energy-reserve polysaccharides used by man, are stored in plants in the form of nearly spherical granules that vary in diameter from about three to 100 micrometres (about .0001 to .004 inch). Most plant starches consist of a mixture of two components, amylose and amylopectin (see diagrams). As the diagrams show, the glucose molecules composing amylose have a straight-chain, or linear, structure; amylopectin has a branched-chain structure and is a somewhat more compact molecule. Several thousand glucose units may be present in a single starch molecule (each small circle represents one glucose molecule).



amylose



amylopectin

Starch content of plants

In addition to granules, many plants have large numbers of specialized cells, called parenchymatous cells, the principal function of which is the storage of starch; examples of plants with these cells include root vegetables and tubers. The starch content of plants varies considerably; the highest concentrations are found in seeds and in cereal grains, which contain up to 80 percent of their total carbohydrate as starch. The amylose and amylopectin components of starch occur in variable proportions; most plant species store approximately 25 percent of their starch as amylose and 75 percent as amylopectin. This proportion can be altered, however, by selective-breeding techniques, and some varieties of corn have been developed that produce up to 70 percent of their starch as amylose, which is more easily digested by man than is amylopectin.

In addition to the starches, some plants (*e.g.*, the Jerusalem artichoke and the leaves of certain grasses, particularly rye grass) form storage polysaccharides composed of fructose units rather than glucose. Although the fructose polysaccharides can be broken down and used to prepare syrups, they cannot be digested by higher animals.

Starches are not formed by animals; instead, they form a closely related polysaccharide, glycogen. Virtually all vertebrate and invertebrate animal cells, as well as those of numerous fungi and protozoans, contain some glycogen; particularly high concentrations of this substance are found in the liver and muscle cells of higher animals. The overall structure of glycogen, which is a highly branched molecule consisting of glucose units, has a superficial resemblance to that of the amylopectin component of starch, although the structural details of glycogen are significantly different. Under conditions of stress or muscular activity in animals, glycogen is rapidly broken down to glucose, which is subsequently used as an energy source. In this manner, glycogen acts as an immediate carbohydrate reserve. Furthermore, the amount of glycogen present at any given time, especially in the liver, directly reflects an animal's nutritional state; *i.e.*, when adequate food supplies are available, both glycogen and fat reserves of the body increase, but when food supplies decrease or when the food intake falls below the minimum energy requirements, the glycogen reserves are depleted quite rapidly, while those of fat are used at a slower rate.

Role in plant and animal structure. Whereas starches and glycogen represent the major reserve polysaccharides of living things, most of the carbohydrate found in nature occurs as structural components in the cell walls of plants. Carbohydrates in plant cell walls generally consist of several distinct layers, one of which contains a higher concentration of cellulose than the others. The physical and chemical properties of cellulose are strikingly different from those of the amylose component of starch.

In most plants, the cell wall is about 0.5 micrometres thick and contains a mixture of cellulose, pentose-containing polysaccharides (pentosans), and an inert (chemically unreactive) plastic-like material called lignin. The amounts of cellulose and pentosan may vary; most plants contain between 40 and 60 percent cellulose, although higher amounts are present in the cotton fibre.

Polysaccharides also function as major structural components in animals. Chitin, which is similar to cellulose, is found in insects and other arthropods. Other complex polysaccharides predominate in the structural tissues of higher animals.

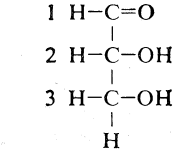
Structural arrangements and properties

STEREOISOMERISM

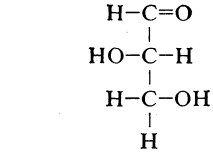
Isomers of glyceraldehyde

Studies by the German chemist Emil Fischer in the late 19th century showed that carbohydrates, such as fructose and glucose, with the same molecular formulas but with different structural arrangements and properties (*i.e.*, isomers) can be formed by relatively simple variations of their spatial, or geometric, arrangements. This type of isomerism, which is called stereoisomerism, exists in all biological systems; and, among carbohydrates, the simplest example is provided by the three-carbon aldose sugar glyceraldehyde. There is no way by which the structures of the two isomers of glyceraldehyde (see the formulas below, which are the so-called Fischer projection formulas that are commonly used to distinguish between such isomers) can be made identical, excluding breaking and reforming the linkages, or bonds, of the hydrogen (—H) and hydroxyl (—OH) groups attached to the carbon at position 2. The isomers are, in fact, mirror images akin to right and left hands; the term enantiomorphism is frequently employed for such isomerism. The chemical and physical properties of enantiomers are identical except for the property of optical rotation.

As explained above, optical rotation is the rotation of the plane of polarized light. Polarized light is light that has been separated into two beams that vibrate at right angles to each other; solutions of substances that rotate the plane of polarization are said to be optically active, and the degree of rotation is called the optical rotation of the solution. In the case of the isomers of glyceraldehyde, the magnitudes of the optical rotation are the same, but the direction in which the light is rotated—generally designated as plus, or *d* for dextrorotatory (to the right), or as minus, or *l* for levorotatory (to the left)—is opposite; *i.e.*, a solution of D-(*d*)-glyceraldehyde causes the plane of polarized light to rotate to the right, and a solution of L-(*l*)-glyceraldehyde rotates the plane of polarized light to the left. Fischer projection formulas for the two isomers of glyceraldehyde are given below (see *Configuration*, below, for explanation of D and L).



D-(*d*)-glyceraldehyde

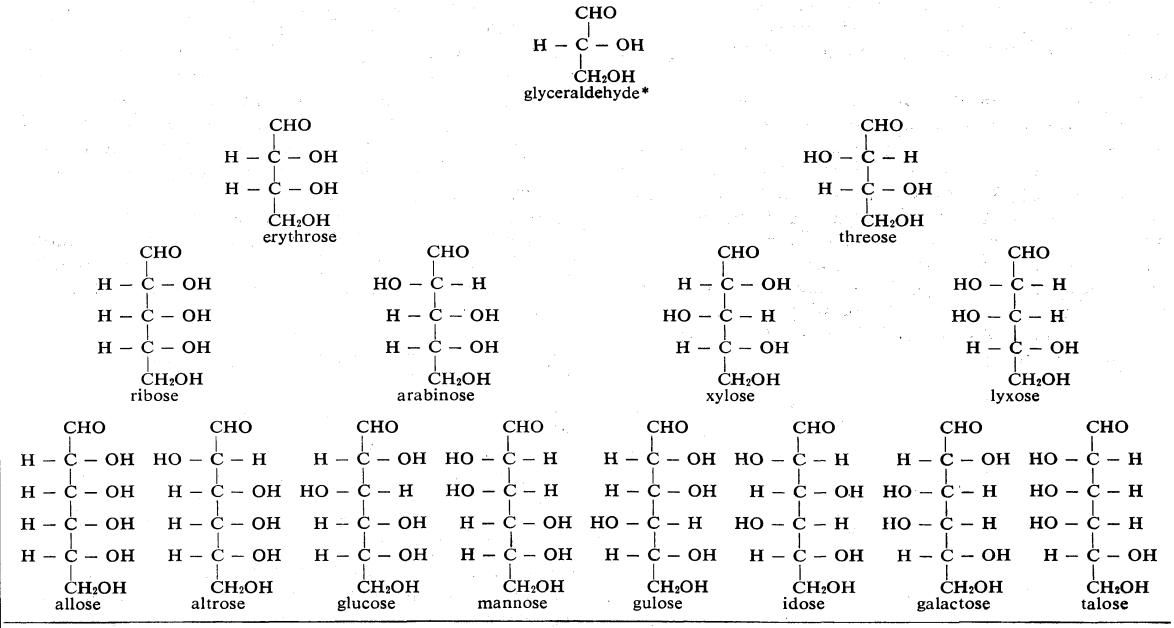


L-(*l*)-glyceraldehyde

CONFIGURATION

Molecules, such as the isomers of glyceraldehyde—the atoms of which can have different structural arrangements—are known as asymmetrical molecules. The number of possible structural arrangements for an asymmetrical molecule depends on the number of centres of asymmetry; *i.e.*, for n (any given number of) centres of asymmetry, 2^n different isomers of a molecule are possible. An asymmetrical centre in the case of carbon is defined as a carbon atom to which four different groups are attached. In the three-carbon aldose sugar, glyceraldehyde, the asymmetri-

Table 5: Aldoses, up to Aldohexoses, of the D-Series



*Aldehydo carbon (—CHO) is carbon atom 1; the remaining carbon atoms are numbered in succession. The hydroxyl groups only are shown for the asymmetrical carbon atoms. The D-configuration is derived from the asymmetrical carbon atom most remote from the aldehydo end of the molecule; *i.e.*, the hydroxyl group at carbon 3 in 4 carbon sugars; 4 in pentoses, and 5 in hexoses projects to the right. The L-series are corresponding mirror images; *i.e.*, the hydroxyl group projects to the left.

cal centre is located at the central carbon atom. The four different groups attached to the atom are:

(1) $H-\overset{|}{C}=O$; (2) $H-$; (3) $-OH$; and (4) $H-\overset{|}{C}-OH$ (H).

The position of the hydroxyl group (—OH) attached to the central carbon atom—*i.e.*, whether —OH projects from the left or the right—determines whether the molecule rotates the plane of polarized light to the left, or to the right. Since glyceraldehyde has one asymmetrical centre, n is one in the relationship 2^n, and there thus are two possible isomers. Sugars containing four carbon atoms have two asymmetrical centres; hence, there are four possible isomers (2^2). Similarly, sugars with five carbon atoms have three asymmetrical centres, and thus have eight isomers (2^3). Keto sugars have one less asymmetrical centre for a given number of carbon atoms than do aldehydo sugars.

A convention of nomenclature, devised in 1906, states that the form of glyceraldehyde whose asymmetrical carbon atom has a hydroxyl group projecting to the right (see Fischer projection formulas) is designated as of the D-configuration; that form, whose asymmetrical carbon atom has a hydroxyl group projecting to the left, is designated as L. All sugars that can be derived from D-glyceraldehyde—*i.e.*, hydroxyl group attached to the asymmetrical carbon atom most remote from the aldehydo or keto end of the molecule projects to the right—are said to be of the D-configuration; those sugars derived from L-glyceraldehyde are said to be of the L-configuration. See Table 5 for aldoses—*i.e.*, sugars containing an aldehydo group ($\diagdown C=O$) —of the D-configuration.

The configurational notation D or L is independent of the sign of the optical rotation of a sugar in solution. It is common, therefore, to designate both, as for example, D-(*l*)-fructose or D-(*d*)-glucose; *i.e.*, both have a D-configuration at the centre of asymmetry most remote from the aldehydo end (in glucose) or keto end (in fructose) of the molecule, but fructose is levorotatory, and glucose is dextrorotatory—hence the latter has been given the alternative name dextrose. Although the initial assignments of configuration for the glyceraldehydes were made on purely arbitrary grounds, studies that were carried out nearly half a century later established them as correct in an absolute spatial sense. In biological systems, only the D or L form may be utilized.

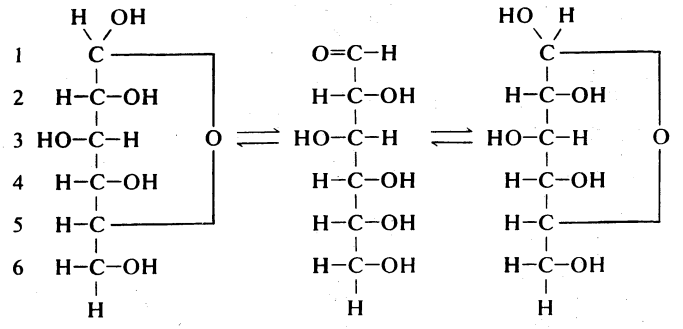
When more than one asymmetrical centre is present in a molecule, as is the case with sugars having four or more carbon atoms, a series of DL pairs exists, and they are functionally, physically, and chemically distinct; thus, although D-xylose and D-lyxose (see Table 5) both have five carbon atoms and are of the D-configuration, the spatial arrangement of the asymmetrical centres (at carbon atoms 2, 3, and 4) is such that they are not mirror images.

DL pairs

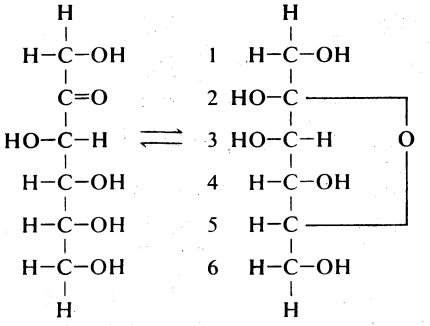
HEMIACETAL AND HEMIKETAL FORMS

Although optical rotation has been one of the most frequently determined characteristics of carbohydrates since its recognition in the late 19th century, the rotational behaviour of freshly prepared solutions of many sugars differs from that of solutions that have been allowed to stand. This phenomenon, termed mutarotation, is demonstrable even with apparently identical sugars and is caused by a type of stereoisomerism involving formation of an asymmetrical centre at the first carbon atom (aldehydo carbon) in aldoses and the second one (keto carbon) in ketoses.

Most pentose and hexose sugars, therefore, do not exist as linear, or open-chain, structures in solution, as indicated for the aldoses in Table 5, but form cyclic, or ring, structures termed hemiacetal or hemiketal forms, respectively. As illustrated for glucose and fructose, the cyclic structures are formed by the addition of the hydroxyl group (—OH) from either the fourth, fifth, or sixth carbon atom (in the diagram, the numbers 1 through 6 represent the positions of the carbon atoms) to the carbonyl group ($\diagdown C=O$) at position 1 in glucose or 2 in fructose. A five-membered ring is illustrated for the ketohexose, fructose; a six-membered ring is illustrated for the aldohexose, glucose. In either case, the cyclic forms are in equilibrium with (*i.e.*, the rate of conversion from one form to another is stable) the open-chain structure—a free aldehyde if the solution contains glucose, a free ketone if it contains fructose; each form has a different optical rotation value. Since the forms are in equilibrium with each other, a constant value of optical rotation is measurable; the two cyclic forms represent more than 99.9 percent of the sugar in the case of a glucose solution.



α-D-glucose (hemiacetal form) | D-glucose (linear, open-chain, or free form) | β-D-glucose (hemiacetal form)



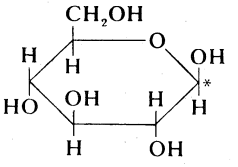
D-fructose (linear, open-chain, or free form) | α-D-fructose (hemiketal form)

By definition, the carbon atom containing the aldehydo () or keto group () is termed the anomeric carbon atom; similarly, carbohydrate stereoisomers that differ in configuration only at this carbon atom are called anomers. When a cyclic hemiacetal or hemiketal structure forms, the structure with the new hydroxyl group projecting on the same side as that of the oxygen involved in forming the ring is termed the alpha anomer (see hemiacetal forms for glucose and diagram); that with the hydroxyl group projecting on the opposite side from that of the oxygen ring is termed the beta anomer (see diagram). The spatial arrangements of the atoms in these

Anomeric carbon atom

alpha isomer | beta isomer

cyclic structures are better shown (glucose is used as an example) in the representation devised by the British organic chemist Walter Norman (later Sir Norman) Haworth about 1930; they are still in widespread use. In the formulation the asterisk indicates the position of the anomeric carbon atom; the carbon atoms, except at position 6, usually are not labelled. The large number of asymmetrical carbon atoms and the consequent number of possible isomers considerably complicates the structural chemistry of carbohydrates.



Haworth formulation of β-D-glucose

Classes of carbohydrates

MONOSACCHARIDES

Sources. The most common naturally occurring monosaccharides are D-glucose, D-mannose, D-fructose, and D-galactose among the hexoses, and D-xylose and L-arabinose among the pentoses. In a special sense, D-ribose and 2-deoxy-D-ribose are ubiquitous because they form the carbohydrate component of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), respectively; these sugars are present in all cells as components of nucleic acids. Sources of some of the naturally occurring monosaccharides are listed in Table 6.

Table 6: Some Naturally Occurring Monosaccharides

sugar	sources
L-arabinose	mesquite gum; wheat bran
D-ribose	all living cells as component of ribonucleic acid
D-xylose	corncobs; seed hulls; straw
D-ribulose	one derivative, is an intermediate in photosynthesis
2-deoxy-D-ribose	as constituent of deoxyribonucleic acid
D-galactose	lactose; agar; gum arabic; brain glycolipids
D-glucose	sucrose; cellulose; starch; glycogen
D-mannose	seeds; ivory nut
D-fructose	sucrose; artichokes; honey
L-fucose	marine algae; seaweed
L-rhamnose	poison-ivy blossom; oak bark
D-mannoheptulose	avocado
D-altroheptulose	numerous plants

D-xylose, found in most plants in the form of a polysaccharide called xylan, is prepared from corncobs, cottonseed hulls, or straw by chemical breakdown of xylan. D-galactose, a common constituent of both oligosaccharides and polysaccharides, also occurs in carbohydrate-containing lipids, called glycolipids, which are found in the brain and other nervous tissues of most animals. Galactose is generally prepared by acid hydrolysis (breakdown involving water) of lactose, which is composed of galactose and glucose. Since the biosynthesis of galactose in animals occurs through intermediate compounds derived directly from glucose, animals do not require galactose in the diet. In fact, in most human populations (Caucasoid peoples being the major exception) the majority of people do not retain the ability to manufacture the enzyme necessary to metabolize galactose after they reach the age of four, and many individuals possess a hereditary defect known as galactosemia and never have the ability to metabolize galactose.

D-glucose

D-glucose (from the Greek word *glykys*, meaning "sweet"), the naturally occurring form, is found in fruits, honey, blood, and, under abnormal conditions, in urine. It is also a constituent of the two most common naturally found disaccharides, sucrose and lactose, as well as the exclusive structural unit of the polysaccharides cellulose, starch, and glycogen. Generally, D-glucose is prepared from either potato starch or cornstarch.

D-fructose, a ketohexose, is one of the constituents of the disaccharide sucrose and is also found in uncombined form in honey, apples, and tomatoes. Fructose, generally considered the sweetest monosaccharide, is prepared by sucrose hydrolysis and is metabolized by man.

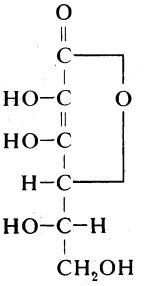
Chemical reactions. The reactions of the monosaccharides can be conveniently subdivided into those associated with the aldehydo or keto group and those associated with the hydroxyl groups.

Reactions involving the aldehydo or keto group

The relative ease with which sugars containing a free or potentially free aldehydo or keto group can be oxidized to form products has been known for a considerable time and once was the basis for the detection of these so-called reducing sugars in a variety of sources. For many years, analyses of blood glucose and urinary glucose were carried out by a procedure involving the use of an alkaline copper compound. Because the reaction has undesirable

features—extensive destruction of carbohydrate structure occurs, and the reaction is not very specific (*i.e.,* sugars other than glucose give similar results) and does not result in the formation of readily identifiable products—blood and urinary glucose now are analyzed by using the enzyme glucose oxidase, which catalyzes the oxidation of glucose to products that include hydrogen peroxide. The hydrogen peroxide then is used to oxidize a dye present in the reaction mixture; the intensity of the colour is directly proportional to the amount of glucose initially present. The enzyme, glucose oxidase, is highly specific for β-D-glucose.

In another reaction, the aldehydo group of glucose (H–C=O) reacts with alkaline iodine to form a class of compounds called aldonic acids. One important aldonic acid is ascorbic acid (vitamin C, see structure), an essential dietary component for man and guinea pigs. The formation of similar acid derivatives does not occur with the keto sugars.



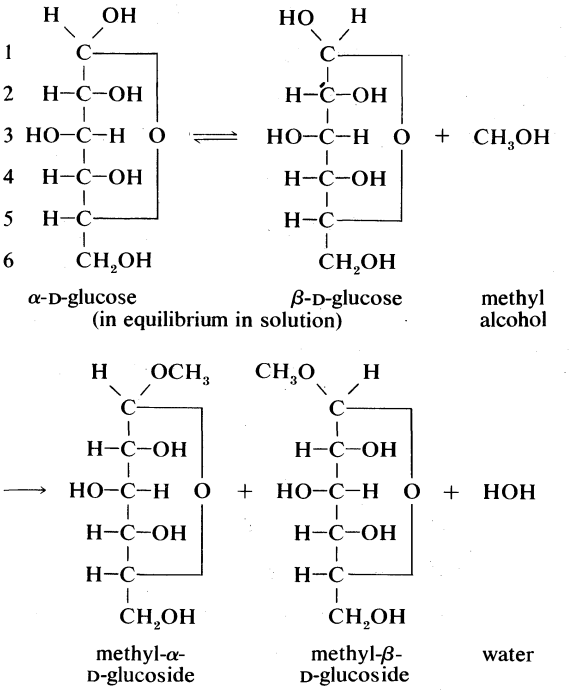
ascorbic acid, vitamin C (L-gulonolactone-2,3-enediol)

Either the aldehydo or the keto group of a sugar may be reduced (*i.e.,* hydrogen added) to form an alcohol; compounds formed in this way are called alditols, or sugar alcohols. The product formed as a result of the reduction of the aldehydo carbon of D-glucose is called sorbitol (D-glucitol). D-glucitol also is formed when L-sorbose is reduced. The reduction of mannose results in mannitol, that of galactose in dulcitol.

Sugar alcohols that are of commercial importance include sorbitol (D-glucitol), which is commonly used as a sweetening agent, and D-mannitol, which is also used as a sweetener, particularly in chewing gums, because it has a limited water solubility and remains powdery and granular on long storage.

Formation of glycosides

The hydroxyl group that is attached to the anomeric carbon atom (*i.e.,* the carbon containing the aldehydo or keto group) of carbohydrates in solution has unusual reactivity, and derivatives, called glycosides, can be formed; glycosides formed from glucose are called glucosides. It is not possible for equilibration between the α- and β-anomers of a glycoside in solution (*i.e.,* mutarotation) to occur. The reaction by which a glycoside is formed (see below) involves the hydroxyl group (—OH) of the anomeric carbon atom (numbered 1) of both α and β forms of D-glucose—α and β forms of D-glucose are shown in equilibrium in the reaction sequence—and the hydroxyl group of an alcohol (methyl alcohol in the reaction sequence); methyl α-D-glucosides and β-D-glucosides are formed as products, as is water.



α-D-glucose (in equilibrium in solution) β-D-glucose methyl alcohol

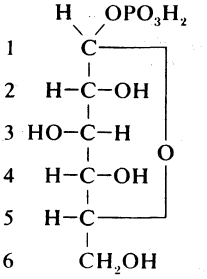
methyl-α-D-glucoside methyl-β-D-glucoside water

Among the wide variety of naturally occurring glycosides are a number of plant pigments, particularly those red, violet, and blue in colour; these pigments are found in flowers and consist of a pigment molecule attached to a sugar molecule, frequently glucose. Plant indican (from *Indigofera* species), composed of glucose and the pigment indoxyl, was important in the preparation of indigo dye before synthetic dyes became prevalent. Of a number of heart-muscle stimulants that occur as glycosides, digitalis is still used. Other naturally occurring glycosides include vanillin, which is found in the vanilla bean, and amygdalin (oil of bitter almonds); a variety of glycosides found in mustard have a sulfur atom at position 1 rather than oxygen.

Important antibiotics

A number of important antibiotics are glycosides; the best known are streptomycin and erythromycin. Glucosides—*i.e.,* glycosides formed from glucose—in which the anomeric carbon atom (at position 1) has phosphoric acid linked to it, are extremely important biological compounds.

For example, α-D-glucose-1-phosphate (see formula), is an intermediate product in the biosynthesis of cellulose, starch, and glycogen; similar glycosidic phosphate derivatives of other monosaccharides participate in the formation of naturally occurring glycosides and polysaccharides.



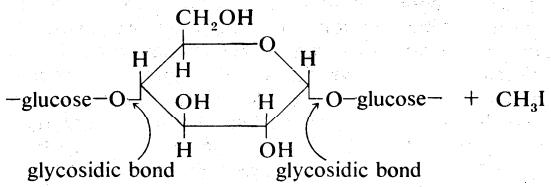
α-D-glucose-1-phosphate

The hydroxyl groups other than the one at the anomeric carbon atom can undergo a variety of reactions, several of which deserve mention. Esterification, which consists of reacting the hydroxyl groups with an appropriate acidic compound, results in the formation of a class of compounds called sugar esters. Among the common ones are the sugar acetates, in which the acid is acetic acid. Esters of phosphoric acid and sulfuric acid are important biological compounds; glucose-6-phosphate, for example, plays a central role in the energy metabolism of most living cells, and D-ribulose 1,5-diphosphate is important in photosynthesis.

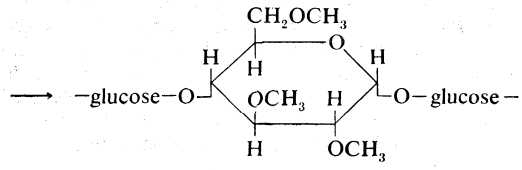
Formation of methyl ethers

Treatment of a carbohydrate with methyl iodide or similar agents under appropriate conditions results in the formation of compounds in which the hydroxyl groups are converted to methyl groups (—CH_3). Called methyl ethers, these compounds are employed in structural studies of oligosaccharides and polysaccharides because their formation does not break the bonds, called glycosidic bonds, that

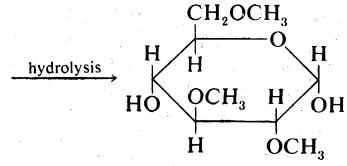
link adjacent monosaccharide units. In the reaction sequence shown, a segment of a starch molecule, consisting of three glucose units, is indicated; the Haworth formulation used to represent one of the glucose units shows the locations of the glycosidic bonds and the —OH groups. When complete etherification of the starch molecule is carried out, using methyl iodide, methyl groups become attached to the glucose molecules at the three positions shown in the methylated segment of the starch molecule; note that the glycosidic bonds have not been broken by the reaction with methyl iodide. When the methylated starch molecule then is broken down (hydrolyzed), hydroxyl groups are located at the positions in the molecule previously involved in linking one sugar molecule to another, and a methylated glucose, in this case named 2,3,6 tri-*O*-methyl-D-glucose, forms. The linkage positions (in the example, at carbon atoms 1 and 4; the carbon atoms are numbered in the structure of the methylated glucose),



segment of a starch molecule — methyl iodide



methylated segment of starch molecule

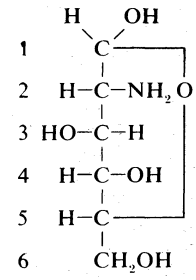


methylated glucose

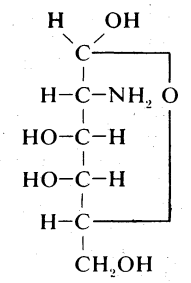
which are not methylated, in a complex carbohydrate can be established by analyzing the locations (in the example, at carbon atoms 2, 3, and 6) of the methyl groups in the monosaccharides. This technique is useful in determining the structural details of polysaccharides, particularly since the various methylated sugars are easily separated by techniques involving gas chromatography, in which a moving gas stream carries a mixture through a column of a stationary liquid or solid, the components thus being resolved.

When the terminal group (CH_2OH) of a monosaccharide is oxidized chemically or biologically, a product called a uronic acid is formed. Glycosides that are derived from D-glucuronic acid (the uronic acid formed from D-glucose) and fatty substances called steroids appear in the urine of animals as normal metabolic products; in addition, foreign toxic substances are frequently converted in the liver to glucuronides before excretion in the urine. D-glucuronic acid also is a major component of connective tissue polysaccharides, and D-galacturonic acid and D-mannuronic acid, formed from D-galactose and D-mannose, respectively, are found in several plant sources.

Other compounds formed from monosaccharides include those in which one hydroxyl group, usually at the carbon at position 2 (see formulas for D-glucosamine and D-galactosamine), is replaced by an amino group ($-NH_2$); these compounds, called amino sugars, are widely distributed in nature. The two most important ones are glucosamine (2-amino-2-deoxy-D-glucose) and galactosamine (2-amino-2-deoxy-D-galactose).



D-glucosamine

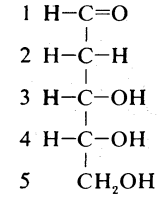


D-galactosamine

Neither amino sugar is found in the uncombined form. Both occur in animals as components of glycolipids or polysaccharides; *e.g.*, the primary structural polysaccharide (chitin) of insect outer skeletons and various blood-group substances.

Deoxy sugars

In a number of naturally occurring sugars, known as deoxy sugars, the hydroxyl group at a particular position is replaced by a hydrogen atom. By far the most important representative is 2-deoxy-D-ribose (see formula), the pentose sugar found in deoxyribonucleic acid (DNA); the hydroxyl group at the carbon atom at position 2 has been replaced by a hydrogen atom.



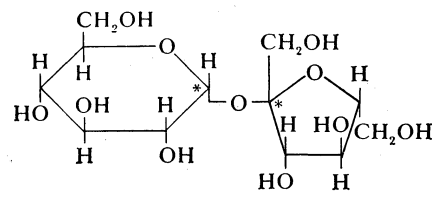
2-deoxy-D-ribose

Other naturally occurring deoxy sugars are hexoses, of which L-rhamnose (6-deoxy-L-mannose) and L-fucose (6-deoxy-L-galactose) are the most common; the latter, for example, is present in the carbohydrate portion of blood-group substances and in red-blood-cell membranes.

DISACCHARIDES AND OLIGOSACCHARIDES

Disaccharides are a specialized type of glycoside in which the anomeric hydroxyl group of one sugar has combined with the hydroxyl group of a second sugar with the elimination of the elements of water. Although an enormous number of disaccharide structures are possible, only a limited number are of commercial or biological significance.

Sucrose and trehalose. Sucrose, or common table sugar, has a world production amounting to well over 10,000,000 tons annually. The unusual type of linkage between the two anomeric hydroxyl groups of glucose and fructose (see formula, in which the asterisk indicates anomeric carbon atom) means that neither a free aldehydo group (on the glucose moiety) nor a free keto group (on the fructose moiety) is available to react unless the linkage between the monosaccharides is destroyed; for this reason, sucrose is known as a nonreducing sugar. Sucrose solutions do



sucrose

not exhibit mutarotation, which involves formation of an asymmetrical centre at the aldehydo or keto group. If the linkage between the monosaccharides composing sucrose is broken, the optical rotation value of sucrose changes from positive to negative; the new value reflects the composite rotation values for D-glucose, which is dextrorotatory (+52°), and D-fructose, which is levorotatory (−92°). The change in the sign of optical rotation from

Invert sugar

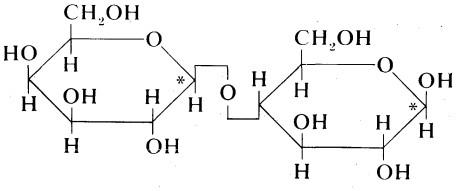
positive to negative is the reason sucrose is sometimes called invert sugar.

The commercial preparation of sucrose takes advantage of the alkaline stability of the sugar, and a variety of impurities are removed from crude sugarcane extracts by treatment with alkali. After this step, syrup preparations are crystallized to form table sugar. Successive "crops" of sucrose crystals are "harvested," and the later ones are known as brown sugar. The residual syrupy material is called either cane final molasses or blackstrap molasses; both are used in the preparation of antibiotics, as sweetening agents, and in the production of alcohol by yeast fermentation.

Sucrose is formed following photosynthesis in plants by a reaction in which sucrose phosphate first is formed.

The disaccharide trehalose is similar in many respects to sucrose but is much less widely distributed. It is composed of two molecules of α-D-glucose and is also a nonreducing sugar. Trehalose is present in young mushrooms and in the resurrection plant (*Selaginella*); it is of considerable biological interest because it is also found in the circulating fluid (hemolymph) of many insects. Since trehalose can be converted to a glucose phosphate compound by an enzyme-catalyzed reaction that does not require energy, its function in hemolymph may be to provide an immediate energy source, a role similar to that of the carbohydrate storage forms (*i.e.*, glycogen) found in higher animals.

Lactose and maltose. Lactose is one of the sugars (sucrose is another) found most commonly in human diets throughout the world; it composes about 5 percent or more of the milk of all mammals. Lactose consists of two aldohexoses—β-D-galactose and glucose—linked so that the aldehydo group at the anomeric carbon of glucose is free to react (see structural formula, in which the asterisk indicates position of anomeric carbon atoms); *i.e.*, lactose is a reducing sugar.



β-lactose

A variety of metabolic disorders related to lactose may occur in infants; in some cases, they are the result of a failure to metabolize properly the galactose portion of the molecule.

Importance of maltose

Although not found in uncombined form in nature, the disaccharide maltose is biologically important because it is a product of the enzymatic breakdown of starches during digestion. Maltose consists of α-D-glucose linked to a second glucose unit in such a way that maltose is a reducing sugar. Maltose, which is readily hydrolyzed to glucose and can be metabolized by animals, is employed as a sweetening agent and as a food for infants whose tolerance for lactose is limited. Table 7 lists the component sugars of, the linkage between, and the occurrence of a number of disaccharides and oligosaccharides.

Table 7: Representative Disaccharides and Oligosaccharides

common name	component sugars	linkages	sources
Cellobiose	glucose, glucose	β 1 → 4†	hydrolysis of cellulose
Gentiobiose	glucose, glucose	β 1 → 6	plant glycosides, amygdalin
Isomaltose	glucose, glucose	α 1 → 6	hydrolysis of glycogen, amylopectin
Raffinose*	galactose, glucose, fructose	α 1 → 6, α 1 → 2	sugarcane, beets, seeds
Stachyose*	galactose, galactose, glucose, fructose	α 1 → 6, α 1 → 6, α 1 → 2	soybeans, jasmine, twigs, lentils

*Note that raffinose and stachyose are galactosyl sucroses. †The linkage joins carbon atom 1 (in the β configuration) of one glucose molecule and carbon atom 4 of the second glucose molecule; the linkage may also be abbreviated β-1, 4.

POLYSACCHARIDES

Polysaccharides, or glycans, may be classified in a number of ways; the following scheme is frequently used. Homopolysaccharides are defined as polysaccharides formed from only one type of monosaccharide. Homopolysaccharides may be further subdivided into straight-chain and branched-chain representatives, depending upon the arrangement of the monosaccharide units. Heteropolysaccharides are defined as polysaccharides containing two or more different types of monosaccharides; they may also occur in both straight-chain and branched-chain forms. In general, extensive variation of linkage types (see Table 8) does not occur within a polysaccharide structure, nor are there many polysaccharides composed of more than three or four different monosaccharides; most contain one or two.

HOMOPOLYSACCHARIDES

In general, homopolysaccharides have a well-defined chemical structure, although the molecular weight of an individual amylose or xylan molecule may vary within a particular range, depending on the source; molecules from a single source also may vary in size, because most polysaccharides are formed biologically by an enzyme-catalyzed process lacking genetic information regarding size. Several naturally occurring homopolysaccharides are listed in Table 8.

Cellulose and xylans

The basic structural component of most plants, cellulose, is widely distributed in nature. It has been estimated that nearly 10,000,000,000 tons of cellulose are synthesized yearly as a result of photosynthesis by higher plants. The proportion of cellulose to total carbohydrate found in plants may vary in various types of woods from 30 to 40 percent, and to more than 98 percent in the seed hair of the cotton plant. Cellulose, a large, linear molecule composed of 3,000 or more β-D-glucose molecules, is insoluble in water.

The chains of glucose units composing cellulose molecules are frequently aligned within the cell-wall structure of a plant to form fibre-like or crystalline arrangements. This alignment permits very tight packing of the chains and promotes their structural stability but also makes structural analysis difficult. The relationships between cellulose and other polysaccharides present in the cell wall are not well established; in addition, the presence of unusual chemical linkages or nonglucose units within the cellulose structure has not yet been established with certainty.

During the preparation of cellulose, raw plant material is treated with hot alkali; this treatment removes most of the lignin, the hemicelluloses, and the mucilaginous components. The cellulose then is processed to produce papers and fibres. The high resistance of cellulose to chemical or enzymatic breakdown is important in the manufacture of paper and cloth. Cellulose also is modified chemically for other purposes; *e.g.*, compounds such as cellulose acetate are used in the plastics industry, in the production of photographic film, and in the rayon-fibre industry. Viscose rayon is produced from an ester of cellulose, and cellulose nitrate is employed in the lacquer and explosives industries.

The noteworthy biological stability of cellulose is dramatically illustrated by trees, the life-span of which may be several thousand years. Enzymes capable of breaking down cellulose are generally found only among several species of bacteria and molds. The apparent ability of termites to utilize cellulose as an energy source depends on the presence in their intestinal tracts of protozoans that can break it down. Similarly, the single-celled organisms present in the rumina of sheep and cattle are responsible for the ability of these animals to utilize the cellulose present in typical grasses and other feeds.

Xylans are almost as ubiquitous as cellulose in plant-cell walls and contain predominantly β-D-xylose units linked as in cellulose (see Table 8). Some xylans contain other sugars, such as L-arabinose, but they form branches and are not part of the main chain. Xylans are of little commercial importance.

Starch

The term starch refers to a group of plant reserve polysaccharides consisting almost exclusively of a linear compo-

Table 8: Representative Homopolysaccharides

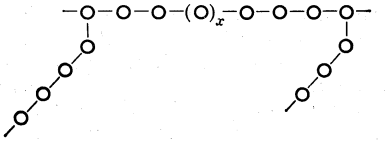
homopolysaccharide	sugar component	linkage	function	sources
Cellulose	glucose	β, 1 → 4	structural	throughout plant kingdom
Amylose	glucose	α, 1 → 4	food storage	starches, especially corn, potatoes, rice
Chitin	N-acetylglucosamine	β, 1 → 4	structural	insect and crustacean skeleton
Inulin	fructose	β, 2 → 1	food storage	artichokes, chicory
Xylan	xylose	β, 1 → 4	structural	all land plants
Glycogen	glucose	α, 1 → 4, 6 ← 1, α	food storage	liver and muscle cells of all animals
Amylopectin	glucose	α, 1 → 4, 6 ← 1, α	food storage	starches, especially corn, potatoes, rice
Dextran	glucose	α, 1 → 6, 4 ← 1, α	unknown	primarily bacterial
Agar*	galactose	α, 1 → 3	structural	seaweeds

*May contain sulfate groups.

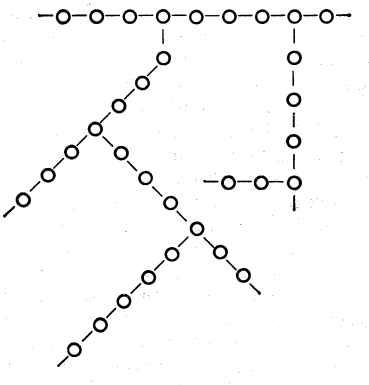
nent (amylose) and a branched component (amylopectin). Man's use of starch as an energy source depends on his ability to convert it completely to individual glucose units; the process is initiated by the action of enzymes called amylases, synthesized by the salivary glands in the mouth, and continues in the intestinal tract. The primary product of amylase action is maltose, which is hydrolyzed to two component glucose units as it is absorbed through the walls of the intestine.

A characteristic reaction of the amylose component of starch is the formation with iodine of a complex compound with a characteristic blue colour. About one iodine molecule is bound for each seven or eight glucose units, and at least five times that many glucose units are needed in an amylose chain to permit the effective development of the colour.

The amylopectin component of starch is structurally similar to glycogen in that both are composed of glucose units linked together in the same way, but the distance between branch points (see schematic diagrams, in which —O— represents one glucose unit) is greater in amylopectin than in glycogen, and the former may be thought of as occupying more space per unit weight.



schematic amylopectin structure



schematic glycogen structure

The applications of starches other than as foods are limited. Starches are employed in adhesive manufacture, and starch nitrate has some utility as an explosive.

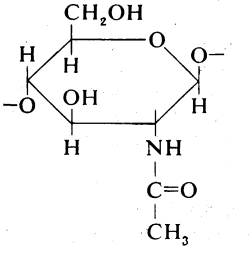
Glycogen

Glycogen, which is found in all animal tissues, is the primary animal storage form of carbohydrate and, indirectly, of rapidly available energy. The distance between branch points in a glycogen molecule is only five or six units (see schematic diagram above), which results in a compact treelike structure. The ability of higher animals to form and break down this extensively branched structure is essential to their well-being; in conditions known as glycogen storage diseases, these activities are abnormal, and the asymmetrical glycogen molecules that are formed have severe, often fatal, consequences. Glycogen synthesis and breakdown are controlled by substances called hormones.

Large molecules—*e.g.*, pectins and agars—composed of galactose or its uronic-acid derivative (galacturonic acid) are important because they can form gels. Pectins, which are predominantly galacturonans, are produced from citrus fruit rinds; they are used commercially in the preparation of jellies and jams. Agar is widely employed in biological laboratories as a solidifying agent for growth media for microorganisms and in the bakery industry as a gelling agent; it forms a part of the diet of people in several areas of the Far East.

Dextrans, a group of polysaccharides composed of glucose, are secreted by certain strains of bacteria as slimes. The structure of an individual dextran varies with the strain of microorganism. Dextrans can be used as plasma expanders (substitutes for whole blood) in cases of severe shock. In addition, a dextran derivative compound is employed medically as an anticoagulant for blood.

Chitin is structurally similar to cellulose, but the repeating sugar is 2-deoxy-2-acetamido-D-glucose (*N*-acetyl-D-glucosamine, see structural formula) rather than glucose.



N-acetyl-D-glucosamine

Sometimes referred to as animal cellulose, chitin is the major component of the outer skeletons of insects, crustaceans, and other arthropods, as well as annelid and nematode worms, mollusks, and coelenterates. The cell walls of most fungi also are predominantly chitin, which comprises nearly 50 percent of the dry weight of some species. Since chitin is nearly as chemically inactive as cellulose and easily obtained, numerous attempts, none of which has thus far been successful, have been made to develop it commercially. The nitrogen content of the biosphere, however, is stabilized by the ability of soil microorganisms to degrade nitrogen-containing compounds such as those found in insect skeletons; these microorganisms convert the nitrogen in complex molecules to a form usable by plants. If such microorganisms did not exist, much of the organic nitrogen present in natural materials would be unavailable to plants.

Heteropolysaccharides. In general, heteropolysaccharides (heteroglycans) contain two or more different monosaccharide units. Although a few representatives contain three or more different monosaccharides, most naturally occurring heteroglycans contain only two different ones and are closely associated with lipid or protein. The complex nature of these substances has made detailed structural studies extremely difficult. The major heteropolysaccharides include the connective-tissue

Table 9: Representative Heteropolysaccharides

heteropolysaccharide	component sugars	functions	distribution
Hyaluronic acid	D-glucuronic acid and *N*-acetyl-D-glucosamine	lubricant, shock absorber, water binding	connective tissue, skin
Chondroitin-4-sulfate*	D-glucuronic acid and *N*-acetyl-D-galactosamine-4-*O*-sulfate	calcium accumulation, cartilage and bone formation	cartilage
Heparin*	D-glucuronic acid, *L*-iduronic acid, *N*-sulfo-D-glucosamine	anticoagulant	mast cells, blood
Gamma globulin*	*N*-acetyl-hexosamine, D-mannose, D-galactose	antibody	blood
Blood group substance*	D-glucosamine, D-galactosamine, *L*-fucose, D-galactose	blood group specificity	cell surfaces, especially red-blood cells

*Covalently linked to protein; the proportion of protein to carbohydrate in such complex molecules varies from about 10% protein in the case of chondroitin-4-sulfate to better than 95% for gamma globulin.

polysaccharides, the blood-group substances, glycoproteins (combinations of carbohydrates and proteins) such as gamma globulin, and glycolipids (combinations of carbohydrates and lipids), particularly those found in the central nervous system of animals and in a wide variety of plant gums (see Table 9).

Connective tissue heteropolysaccharides

The most important heteropolysaccharides are found in the connective tissues of all animals and include a group of large molecules that vary in size, shape, and interaction with other body substances. They have a structural role, and the structures of individual connective-tissue polysaccharides are related to specific animal functions; hyaluronic acid, for example, the major component of joint fluid in animals, functions as a lubricating agent and shock absorber.

The connective-tissue heteropolysaccharides contain acidic groups (uronic acids or sulfate groups) and can bind both water and inorganic metal ions. They can also play a role in other physiological functions; *e.g.*, in the accumulation of calcium before bone formation. Ion-binding ability also appears to be related to the anticoagulant activity of the heteropolysaccharide heparin (see Table 9).

The size of the carbohydrate portion of glycoproteins such as gamma globulin or hen-egg albumin is usually between five and 10 monosaccharide units; several such units occur in some glycoprotein molecules. The function of the carbohydrate component has not yet been established except for glycoproteins associated with cell surfaces; in this case, they appear to act as antigenic determinants—*i.e.*, they are capable of inducing the formation of specific antibodies.

PREPARATION AND ANALYSIS

In general, monosaccharides are prepared by breakdown with acids of the polysaccharides in which they occur. Sugars usually are difficult to obtain in crystalline form, and the crystallization process usually is begun by "seeding" a concentrated solution of the sugar with crystals. The techniques employed for separation of monosaccharides depend to some extent on their physical and chemical properties; chromatographic procedures are often used.

Oligosaccharides and polysaccharides are prepared from natural sources by techniques that take advantage of size, alkaline stability, or some combination of these and other properties of the molecule of interest. It should be noted that preparation of an oligosaccharide or polysaccharide usually results in a range of molecular sizes of the desired molecule. The purity of a carbohydrate preparation, which is frequently based on an analysis of its composition, is more easily established for monosaccharides and disaccharides than for large, insoluble molecules such as cellulose.

Analytical techniques. A variety of organic chemical analytical techniques are generally applicable to studies involving carbohydrates. Optical rotation, for example, once was frequently used to characterize carbohydrates. The ability to measure the rotation of the plane of polarized light transmitted through a solution containing a carbohydrate depends on finding a suitable solvent; water usually is used, with light at a wavelength of 589 mμ (millimicrons). Optical rotation is no longer widely used to characterize monosaccharides. The magnitude and sign of the optical rotation of glycosides, however, is useful in assigning configuration (α or β) to the hydroxyl group at the anomeric centre; glycosides of the α-configuration generally have rotations of higher magnitude than do the same glycosides of the β-configuration. Optical rotation is not a completely additive property; a trisaccharide composed of three glucose residues, for example, does not have a rotation three times that of one glucose molecule. Sugar alcohols cannot form ring structures; their rotation values are extremely small, suggesting a relationship between ring structure and the ability of a carbohydrate to rotate the plane of polarized light. Certain types of reactions (*e.g.*, glycoside hydrolysis) can be monitored by measuring the change in optical rotation as a function of time. This technique is frequently used to examine the breakdown of disaccharides or oligosaccharides to monosaccharide units, especially if a large change in the net optical rotation may be expected, as occurs in the hydrolysis of sucrose.

Optical rotation

Spectroscopic techniques. Several other optical techniques used in chemistry have been applied to the analysis of carbohydrates. Infrared spectroscopy, used to measure vibrational and rotational excitation of molecules, and nuclear magnetic-resonance spectroscopy, which measures the excitation of certain components of molecules in a magnetic field induced by radio-frequency radiation, are valuable, although the similarity of the functional groups (*i.e.*, the hydroxyl groups) limits use of the former technique for most sugars. Proton magnetic-resonance spectroscopy, nuclear magnetic resonance applied to protons (H atoms), is employed to identify the relative spatial arrangements of individual hydrogen atoms in a molecule. When they are precisely placed, the corresponding positions of the hydroxyl groups attached to the same carbon atom can be deduced. An extension of this technique utilizes the resonance spectroscopy of carbon-13, a nonradioactive isotope of carbon, so that ring structures can be established with great accuracy. Both the proton and carbon magnetic resonance methods are best applied to monosaccharides; they are less valuable in studying polysaccharides because an individual hydrogen atom in a large molecule is too small for accurate detection.

Identification of subunits. The study of polysaccharide structure usually focusses on the chemical composition, the linkage between the monosaccharide units, and the size and shape of the molecule. The last two properties can be ascertained by techniques usually applied to large molecules; *e.g.*, the most accurate molecular weight method measures the sedimentation properties of the molecule in an applied gravitational field (*e.g.*, the rate at which a solid material is deposited from a state of suspension or solution in a liquid). Indications of the shape of polysaccharide molecules in solution are obtained from viscosity measurements, in which the resistance of the molecules to flow (viscosity) is equated with the end-to-end length of the molecule; the viscosity of hyaluronic acid, for example, shows a marked dependence on both concentration of the acid and the salt content of the solution, and, under conditions approximating those found in biological systems, the molecule may be thought of as occupying a great deal of space. Alternatively, the compact nature of a glycogen molecule of equal molecular weight results in its accommodation to a much smaller space.

The identification of sugars in a mixture resulting from

the hydrolytic breakdown of a heteropolysaccharide is most often carried out by chromatography of the mixture on paper, silica gel, or cellulose. Ready separations can be achieved between pentoses, hexoses and, for example, deoxy sugars; closely related compounds such as D-glucose and D-galactose also can be separated using chromatographic techniques. The linkage positions in polysaccharides are usually determined using the methylation procedure described previously. The various monosaccharide methyl ethers are separated by gas–liquid chromatography.

Detailed statements about polysaccharide structure and function are limited by the statistical nature of some measurements (*e.g.,* branching frequency), the biological variability of parameters such as size and molecular weight, and incomplete information about associative interactions in living things. (E.A.D.)

LIPIDS

Lipids are a diverse group of organic compounds found in plants, in animals, and in microorganisms. They are greasy to the touch and insoluble in water but soluble in alcohol, ether, and other organic solvents. Lipids comprise one of the three large classes of foods and, with proteins and carbohydrates, are components of all living cells. The proportion of lipids in foodstuffs varies; it is 0.2 percent in white potatoes and 70 percent in some nut kernels. Fats such as olive oil and cod-liver oil contain a mixture of fatty substances, lipids called triglycerides. Triglycerides compose almost 90 percent of the adipose, or fat, tissue of animals. Contrary to popular opinion, adipose tissue is an energy source and can be used when needed. Triglycerides are sometimes called nature's storehouse of energy because, on a weight basis, they contain more than twice as much energy as do carbohydrates and proteins.

As noted previously, lipids made by cells are important not only because they serve as an energy source but also because they form structural components. Lipids such as lecithin and cephalin, which are soluble in both water and fats, serve a vital role in the cell by binding water-soluble compounds such as proteins to lipid-soluble substances. Lecithin is an important structural component of the cell membrane, where it maintains continuity between the water and lipid phases inside and outside the cell. Certain enzymes depend upon their attachment to lipids such as lecithin to perform their function properly.

Variation in lipid structure

The structure of lipids varies from simple chainlike molecules consisting of hydrogen, carbon, and oxygen to complex ring, or cyclic, structures with side chains of varying composition and complexity. Many naturally occurring lipids are associated with proteins, in combinations called lipoproteins. Lipids dealt with in the following section include neutral lipids (or triglycerides; *i.e.,* fatty-acid esters of the alcohol glycerol), phosphoglycerides (or phospholipids; *i.e.,* fatty-acid esters of glycerol and phosphoric acid or one of its derivatives), and sphingolipids (complex lipids containing compounds—sphingosine or phytosphingosine—other than glycerol). The characteristics of fatty acids, which are components of many lipids, also are described. Lipoproteins are dealt with briefly. Sterols and carotenoids, also included here as lipids, are considered in detail in the related article CHEMICAL COMPOUNDS: *Isoprenoids; Steroids.* Other related articles include METABOLISM and CELLS: *Biological membrane.*

General features

FUNCTION AND IDENTIFICATION OF LIPIDS

Lipids as food reserves in cells. The most important role of the fatty-acid components of neutral lipids in plant and animal tissues is to provide a fuel supply for cells; *i.e.,* neutral lipids comprise a reserve supply of potential energy and are broken down, when needed, in such a manner that the energy liberated is employed to make an energy-rich compound called adenosine triphosphate (ATP), which in turn is utilized in energy-requiring cellular processes such as muscle contraction and the synthesis of cell constituents. The energy in a fatty-acid molecule is transformed into ATP by a process known as fatty-acid oxidation (or beta oxidation). For a detailed discussion of the mechanism of fatty-acid oxidation, see METABOLISM.

Triglycerides and fatty acids are formed during digestive processes in animals. After a mammal ingests a fatty meal, the fats are acted upon by digestive secretions containing the enzyme lipase, which breaks down at least part of the triglycerides. The breakdown products and the remaining intact triglycerides then are absorbed through the intestinal cell wall and are recombined, at least in part, to form triglycerides and phospholipids. These lipids, in the form of very small droplets (chylomicrons), are transported in blood and in chyle (a milky fluid from the small intestine) to points of utilization or storage in the body.

One function of bile salts in digestion is to promote the linkage of (*i.e.,* emulsify) lipid-soluble groups with water-soluble ones (such as those in enzymes) and also to increase the solubility of lipids in water. Both emulsification and solubilization are necessary because lipids are completely metabolized only at the lipid-water interface created by bile salts and by the salts of fatty acids (soaps), which are formed during the partial breakdown of lipids (see also DIGESTION AND DIGESTIVE SYSTEMS).

If an animal ingests more energy-rich substances (*e.g.,* fats, carbohydrates) than it can utilize, excess fatty acids combine with glycerol to form neutral lipids, which are stored in the animal; *e.g.,* in adipose tissue in mammals. If the energy requirements of the animal increase, the stored neutral lipids may then be broken down, each molecule forming three molecules of fatty acid and one molecule of glycerol. The three molecules of fatty acid combine with a protein (albumin) in mammalian blood plasma and are carried in the bloodstream to various tissues and organs that require energy. Neutral lipids probably also function as depots of concentrated energy in plant reproductive structures such as pollen grains and seeds; *i.e.,* as food reserves for developing embryos.

Neutral lipids as depot material

The types of neutral lipids in an individual animal may vary according to the animal species and the composition of fats in the food it consumes. Fats used by or stored in animal tissues come from two sources—diet and enzymatic synthesis. The lipids synthesized from carbohydrates or proteins are characteristic of the animal species, whereas those resynthesized from dietary fats are characteristic of the food ingested. Many animals require some lipids containing one or more specific fatty acids, usually linoleic, linolenic, and arachidonic, to prevent the development of an essential fatty-acid deficiency, which is manifested by skin lesions, scaliness, poor hair growth, and low growth rates. These fatty acids cannot be synthesized by the animal and must be supplied in the diet (see also NUTRITION: *Nutritional diseases and disorders*).

Lipids as structural components of cells. *Neutral lipids.* Subcutaneous deposits of neutral lipids insulate animals against cold because of the low rate of heat transfer in fats, a property especially important to animals commonly found in cold waters or cold climates; *e.g.,* whales, walruses, and bears. Neutral lipids also provide structural support or padding for organs.

Phosphoglycerides. Phosphoglycerides, or phospholipids, are important constituents of cell membranes and of the membranes of cell components such as mitochondria; they function in the conduction of nerve impulses, in the insulation of nerve cells, in certain enzyme-catalyzed reactions within cells, and in blood coagulation and the transport of lipids from the liver to other tissues and organs in mammals.

Phosphoglycerides contain acidic (negatively charged) and basic (positively charged) groups as well as fatty-acid groups. Because they have both charged, water-attracting (hydrophilic) groups and lipid-attracting, water-repelling (hydrophobic) groups, phosphoglycerides are moderately soluble in both water and lipids and serve, therefore,

an important role in the cell in binding both types of compounds together; lecithin is a naturally occurring phosphoglyceride of special importance in the cell membrane because its hydrophilic groups maintain continuity between the water outside and that inside the cell, and its hydrophobic groups dissolve lipid materials, allowing them to enter the cell (see CELLS: *Biological membrane*).

Phosphoglycerides in blood bodies called platelets function in the process of blood-clot formation. Blood coagulation in mammals involves the conversion of a soluble protein (fibrinogen) into an insoluble derivative (fibrin clot). This reaction in part is catalyzed by the enzyme thrombin, which is derived from another protein (prothrombin) by the action of the enzyme prothrombinase. Prothrombinase in turn is formed by the interaction of two blood-plasma proteins, a phosphoglyceride, and calcium. The exact role of the phosphoglyceride in this reaction, however, has not yet been established with certainty.

Lipids in nervous tissue

Sphingolipids. Lipids found in nervous tissue (especially the brain) and necessary for its normal function include the sphingolipids, among them sphingomyelins, cerebrosides, sulfatides, and gangliosides. Schwann cells, the source for the membranous sheath surrounding certain nerve fibres, release a lipid material (myelin) that contains sphingomyelins. Myelination of nerve fibres is necessary for the normal development of nerve tissue, and absence or alteration of the myelination process may result in severe mental retardation in man. Sphingolipids have not been studied as exhaustively as some of the other lipids because they are difficult to isolate and separate into homogeneous components.

Sterols and carotenoids. Sterols include cholesterol in vertebrates and saponins and digitaloids in plants; cholesterol, with phospholipids, plays a role in membrane structure and an important role in the synthesis of numerous other biologically active sterols, commonly referred to as steroids—*e.g.*, bile acids, certain hormones, vitamin D. Carotenoids, widely distributed in living things, are pigments (coloured molecules) and function in the photosynthetic process in plants. These substances are discussed in detail in CHEMICAL COMPOUNDS: *Steroids; Isoprenoids.*

PREPARATION AND ANALYSIS

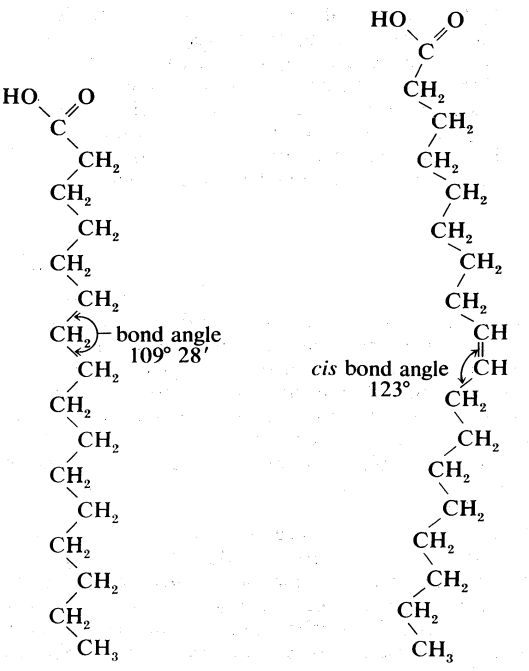
The isolation and identification of lipids is a challenging task. The procedures involve the separation of lipids from other cellular constituents using organic solvents (*e.g.*, chloroform, methanol), in which the lipids dissolve. Two solvents usually are used to separate lipids from other cellular constituents. One solvent, usually methanol, separates the lipoproteins into lipid and protein components; the other, usually chloroform, dissolves the lipids. After this mixture is treated to remove low-molecular-weight compounds, such as inorganic salts, amino acids, and sugars, the lipids are separated by column chromatography into individual components. A typical chromatographic separation of the total lipids, however, does not necessarily result in separation of the components into pure compounds. Additional analytical techniques, such as thin-layer chromatography, mass spectrometry, infrared spectrometry, and optical activity, are needed to establish the identity of each component.

Characteristics and classes of fatty acids

COMPOSITION AND STRUCTURE

The fatty acids of the naturally occurring lipids have an even number of carbon (C) atoms because they are synthesized from acetyl groups, each of which contains two carbon atoms. Fatty acids with 16 (palmitic acid) and 18 (stearic acid) carbon atoms are most commonly found in nature, but the reasons for their abundance have not yet been established. Fatty acids constitute important components of lipids in plants, animals, and microorganisms. In most cases, they are not found in free form but, instead, are bound to other compounds to form fatty-acid-containing lipids; *e.g.*, neutral lipids (triglycerides), sterols, phosphoglycerides such as lecithin, and sphingolipids such as sphingomyelin. Two typical fatty acids are palmitic and oleic.

Fatty-acid-containing lipids



palmitic acid oleic acid

The most stable arrangement of methylene groups ($-CH_2-$ groups), which comprise the hydrocarbon moiety of the molecule, is represented in the formula for palmitic acid; the double bond ($-CH=CH-$) in the oleic acid molecule, whose structure differs from that of palmitic acid only in the double bond between carbon atoms 9 and 10 (the carbon in the carboxyl, or $-COOH$, group is number 1), changes the shape of the molecule from that of palmitic acid. The double bond, which indicates that the acid contains two fewer hydrogen atoms than its counterpart (palmitic acid), makes the oleic acid molecule almost symmetrical because it is located exactly in the middle of the hydrocarbon chain. An additional change in the shape of fatty-acid molecules occurs in those acids that contain two double bonds, such as linoleic acid. Fatty-acid molecules containing one or more double bonds ($-CH=CH-$) are called unsaturated fatty acids; those without double bonds are called saturated fatty acids. Double bonds give rise to a phenomenon called geometrical isomerism; this means that the positions of certain atoms in the acid molecule may lie on the same side of an imaginary plane through the molecule, in which case a bond is said to be *cis*, or on opposite sides of the plane, in which case the bond is said to be *trans*. The unsaturated fatty acids of mammalian tissues usually contain *cis* double bonds (see structural formulas for palmitic and oleic acids); in addition, fatty acids found in mammals usually consist of long, chainlike arrangements of the hydrocarbon portion of the molecule (*e.g.*, as in palmitic acid) rather than branched or cyclic structures. On the other hand, fatty acids with cyclic and branched structures occur in plants and bacteria.

PRINCIPAL CLASSES

Saturated fatty acids. Typical naturally occurring saturated fatty acids are chainlike (nonbranched) compounds with an even number of carbon atoms; *e.g.*, palmitic acid, stearic acid. Names given to fatty acids other than the more commonly used, or trivial, names are called systematic names (*n*-hexadecanoic acid for palmitic and *n*-octadecanoic acid for stearic); they provide information about either the correct geometric form of an unsaturated fatty acid or the exact location of substituted groups in the molecule.

Although palmitic acid and stearic acid are the major saturated fatty acids found in animal and plant tissues, significant amounts of other saturated fatty acids, such as myristic acid and lauric acid, occur in certain tissues, and lignoceric acid and behenic acid are found in high

concentrations in brain sphingolipids. Small amounts of fatty acids with an odd number of carbon atoms also are known; *e.g.*, pentadecanoic acid and heptadecanoic acid. A list of the most common saturated chainlike fatty acids (*i.e.*, those containing 12 or more carbon atoms), including their usual sources, is presented in Table 10. There are several important short-chain fatty acids; these include butyric acid (which has four carbon atoms, or C_4) and caproic acid (C_6), which are important constituents of milk lipids, and octanoic acid (C_8) and decanoic acid (C_{10}), which are present in palm oil.

Table 10: Some Naturally Occurring Saturated Fatty Acids

trivial name	systematic name	chain length*	typical sources
Lauric acid	*n*-dodecanoic acid	12	palm-kernel oil, nutmeg
Myristic acid	*n*-tetradecanoic acid	14	palm-kernel oil, nutmeg
Palmitic acid	*n*-hexadecanoic acid	16	olive oil, animal lipids
Stearic acid	*n*-octadecanoic acid	18	cocoa butter, animal lipids
Behenic acid	*n*-docosanoic acid	22	brain tissue, radish oil
Lignoceric acid	*n*-tetracosanoic acid	24	brain tissue, carnauba wax

*In carbon atoms.

Unsaturated fatty acids. Unsaturated fatty acids have structures similar to those of saturated ones but contain at least one or more olefinic, or double bond. Fatty acids with one double bond are called monounsaturated fatty acids; those with two or more are called polyunsaturated ones. The naturally occuring unsaturated fatty acids may be distinguished solely by the degree of unsaturation and usually contain one or two double bonds; fatty acids containing acetylenic, or triple bonds ($-C\equiv C-$), also have been found in nature.

Mono- and polyunsaturated fatty acids

Monounsaturated fatty acids (also called monoethenoic, monoenoic, ethylenic, olefinic, or alkenoic acids) contain two fewer hydrogen atoms (H) than do corresponding saturated acids and thus have one double bond (*i.e.*, $-CH_2-CH_2$ becomes $-CH{=}CH-$); monounsaturated acids comprise the largest group of unsaturated fatty acids. The major and most representative monounsaturated acids in animal and plant tissues, oleic acid and palmitoleic acid, have the following formulas:

$$CH_3(CH_2)_7CH = CH(CH_2)_7COOH$$

oleic acid

$$CH_3(CH_2)_5CH = CH(CH_2)_7COOH.$$

palmitoleic acid

These two widely distributed fatty acids exist in abundant quantities in nature and have several common features; *i.e.*, a double bond between carbon atoms 9 and 10 (counting from the $-COOH$, or carboxyl, end) and a *cis* configuration at this double bond. Fatty acids with a double bond at other positions are listed in Table 11; *e.g.*, nervonic acid has a double bond between carbon atoms 15 and 16, as indicated by the systematic name, *cis*-15-tetracosenoic acid.

Table 11: Types of Monounsaturated Long-Chain Fatty Acids

trivial name	systematic name	chain length*	typical source(s)
Palmitoleic acid	*cis*-9-hexadecenoic acid	16	marine algae, pine oil
Oleic acid	*cis*-9-octadecenoic acid	18	animal tissues, olive oil
Gadoleic acid	*cis*-9-eicosenoic acid	20	fish oils (cod, sardine)
Erucic acid	*cis*-13-docosenoic acid	22	rapeseed oil
Nervonic acid	*cis*-15-tetracosenoic acid	24	elasmobranch fishes, brain

*In carbon atoms.

Polyunsaturated acids (also called polyethenoic, polyenoic, alkapolyenoic, alkadienoic, or alkatrienoic acids) are found in much smaller amounts in naturally occurring lipids than are monounsaturated ones. The formulas of the three common polyunsaturated fatty acids are given below.

$$CH_3(CH_2)_4CH = CHCH_2CH = CH(CH_2)_7COOH$$

linoleic acid

$$CH_3CH_2CH = CHCH_2CH = CHCH_2CH = CH(CH_2)_7COOH$$

linolenic acid

$$CH_3(CH_2)_4CH = CHCH_2CH = CHCH_2CH = CHCH_2CH = CH(CH_2)_3COOH.$$

arachidonic acid

Linoleic acid and arachidonic acid comprise most of the polyunsaturated fatty acids found in animal tissues. The double bonds usually are located at specific positions, as in linoleic and arachidonic acids. The most important polyunsaturated acids, which contain 18 to 22 carbon atoms, are listed in Table 12.

Table 12: Types of Polyunsaturated Fatty Acids

trivial name	systematic name	chain length*	typical source(s)
Linoleic acid	*cis*-9-, *cis*-12-octadecadienoic acid	18	corn oil, animal tissues, bacteria
Linolenic acid	*cis*-9-, *cis*-12-, *cis*-15-octadecatrienoic acid	18	animal tissues
	5,8,11-eicosatrienoic acid	20	
	8,11,14-eicosatrienoic acid	20	brain tissue
	7,10,13-docosatrienoic acid	22	phospholipids
	8,11,14-docosatrienoic acid	22	
Arachidonic acid	5,8,11,14-eicosatetraenoic acid	20	liver, brain tissue
	4,7,10,13-docosatetraenoic acid	22	brain tissue
	4,7,10,13,16,19-docosahexaenoic acid	22	brain tissue

*In carbon atoms.

Most mammals cannot synthesize linoleic acid, but they are able to convert it to other unsaturated acids; *e.g.*, arachidonic acid and the eicosapolyenoic acids. The polyunsaturated fatty acids in mammals therefore are derived largely from the diet, *i.e.*, they are essential fatty acids.

Alkyl-, hydroxy-, and alicyclic-substituted fatty acids

Fatty acids with substituted groups. Alkyl-substituted, or alkylalkanoic, fatty acids have one alkyl group on the molecule. An alkyl group is a hydrocarbon group with the general formula C_nH_{2n+1}; the methyl group ($-CH_3$) is the alkyl group in the example below. Methyltetradecanoic acid is found in butterfat.

$$CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2(CH_2)_9COOH$$

12-methyltetradecanoic acid (anteiso)

An excellent source of alkyl-substituted fatty acids is the bacterium that causes human tuberculosis; the acid is called tuberculostearic acid, or D-(*l*)-10-methyloctadecanoic acid. Other saturated acids isolated from tubercle bacilli include phytomonic acid (a 10- or 11-methylnonadecanoic acid), phthioic acid (a mixture containing fatty acids with 23 to 31 carbon atoms), mycocerosic acid (a polymethylated fatty acid with 31 carbon atoms), and a number of alkyl branched-chain, unsaturated fatty acids.

Several hydroxy fatty acids (*i.e.*, containing one $-OH$ group) occur in various lipid sources. Ricinoleic acid and cerebronic acid are typical examples.

$$CH_3(CH_2)_5\underset{\displaystyle OH}{\underset{|}{C}}HCH_2CH = CH(CH_2)_7COOH$$

ricinoleic acid
(*d*-12-hydroxy-*cis*-9-octadecanoic acid)

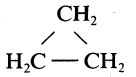
$$CH_3(CH_2)_{21}\underset{\displaystyle OH}{\underset{|}{C}}HCOOH$$

cerebronic acid
(2-hydroxytetracosanoic acid)

Ricinoleic acid occurs in castor oil, and cerebronic acid is present in brain tissue; α-hydroxynervonic acid (an un-

saturated fatty acid with 24 carbon atoms) also occurs in brain tissue. Very small amounts of other hydroxy fatty acids are found in animal and bacterial lipids.

Alicyclic-substituted fatty acids, which contain a cyclopropane group



attached at or near the centre of the molecule, occur in certain bacteria. One such acid, lactobacillic acid, comprises about 30 percent of the total fatty acids of the bacterium *Lactobacillus arabinosus*. Fatty acids containing cyclopropane groups have not yet been found in animal tissues. A series of compounds similar in structure has, however, been found in the chaulmoogra oils.

Several alicyclic acids, called prostaglandins, occur in seminal fluid and in certain glands of sheep and man. Hormone-like substances with widespread physiological effects, prostaglandins lower blood pressure, and stimulate the contraction of smooth muscles.

PHYSICAL AND CHEMICAL PROPERTIES

Solubility. Long-chain fatty acids (10 or more carbon atoms) are insoluble in water; short-chain fatty acids (two to eight carbon atoms) mix easily with water. The reason for the low solubility of long-chain fatty-acid molecules is that the methylene groups ($-CH_2-$) comprising the hydrocarbon chain are not ionized (*i.e.*, lack charge) and thus are nonpolar; they are more important in determining solubility properties of the acids than is the carboxyl ($-COOH$) component, which is ionized and therefore polar. Common table salt is about 1,000 times more soluble in water than is stearic acid; glucose is about 3,300 times more soluble. Fatty acids dissolve in nonpolar solvents or solvents that are less polar than water.

Reactivity of the carboxyl group. The low water solubility of fatty acids, which are members of a large group of organic acids known as carboxylic acids, makes difficult the determination of their properties as acids. Small amounts of fatty acids, which are weak acids compared with mineral acids such as hydrochloric and nitric, do not completely dissociate into ionized (charged) moieties in water. The carboxyl group ($-COOH$) is responsible for the acidic properties of fatty acids (see also CHEMICAL COMPOUNDS: *Carboxylic acids and their derivatives*).

Chlorides, esters, and amides

Most reactions at the carboxyl group of fatty acids involve the hydroxyl moiety ($-OH$) but are influenced by the carbonyl moiety ($-C{=}O$). Several reactions are typical of fatty acids; *e.g.*, formation of chlorides, esters, and amides. Fatty-acid chlorides, called acyl chlorides, are formed by the reaction of a fatty acid with the compound thionyl chloride ($SOCl_2$). Salts of fatty acids are formed in reactions with bases (*e.g.*, sodium hydroxide), in which case the products are called soaps, or with alcohols to form esters. If palmitic acid reacts with the alcohol methanol (CH_3OH), the product, called methyl palmitate, is the methyl ester of palmitic acid; the methyl esters of fatty acids are often used to determine the properties of the acids. The reaction of a fatty acid with ammonia in the presence of heat results in the formation of a product called an amide; the amides of fatty acids also are useful in characterizing them. Amides are found in nature.

Reactivity of the hydrocarbon chain. The most chemically reactive part of a hydrocarbon chain of a fatty acid is the double bond. Halogens (*e.g.*, chlorine, bromine, iodine) and their derivatives, called halides, react with unsaturated fatty acids to remove the double bonds, thereby forming saturated acids; this is known as an addition reaction. Halides such as hydriodic acid (HI) readily attack a double bond to form derivative compounds.

In the presence of a suitable catalyst (*e.g.*, platinum oxide, palladium on charcoal), hydrogen undergoes an addition reaction with unsaturated fatty acids; that is, hydrogen is added to the positions at which double bonds are found. This hydrogenation reaction results in the formation of saturated fatty acids. The double bonds of polyunsaturated fatty acids are hydrogenated in a specific order; linolenic acid (a fatty acid with 18 carbon atoms and three double bonds; Table 12), for example, is hydrogenated first at the bond between carbon atoms 12 and 13 to form a 9,15-octadecadienoic acid, which can then be further hydrogenated to form a saturated acid.

Bond alternation, or any change involving double bonds such as those found in unsaturated fatty acids, also occurs in living cells. The first type, called autoxidation, is a nonenzymatic process; the second, lipoxidation, is an enzyme-catalyzed reaction. Both involve oxygen.

Autoxidation

Autoxidation, or rancidification, which occurs slowly and spontaneously in air, involves the absorption of oxygen by an unsaturated fatty-acid molecule, with the formation of a compound called a hydroperoxide, which decomposes. Autoxidation may occur during the drying or handling of certain oils, under adverse conditions of fat storage, and in certain mammalian deficiencies; *i.e.*, vitamin E deficiency. The acids that undergo autoxidation usually are the polyunsaturated ones; *e.g.*, linoleic acid.

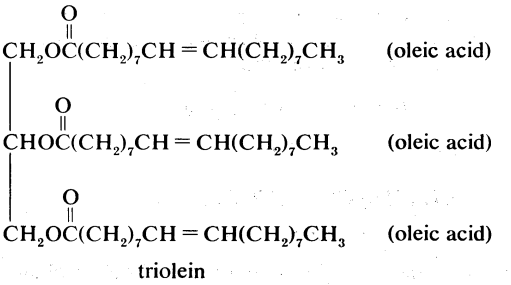
Lipoxidation contrasts with autoxidation in that an enzyme (lipoxidase) catalyzes the addition of oxygen to a double bond in linoleic acid. Lipoxidase is found in legume seeds (for example, soybeans) and in adipose (fat) tissue.

Derivatives of fatty acids and associated compounds

As was previously emphasized, naturally occurring fatty acids are normally found in cells bound to other substances to form triglycerides (neutral lipids), phosphoglycerides (phospholipids), and sphingolipids. Neutral lipids are found almost exclusively in the cytoplasmic compartment of cells, phosphoglycerides and sphingolipids almost exclusively in the membranous structures. For metabolic aspects of these lipids, see METABOLISM.

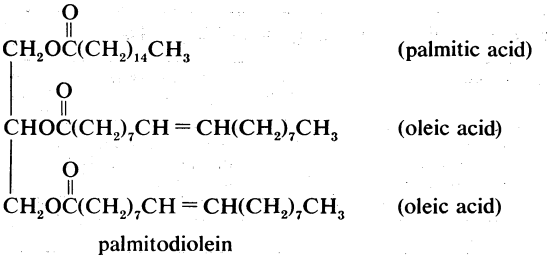
NEUTRAL LIPIDS

General features. Triglycerides, or neutral lipids, are compounds consisting of glycerol and three fatty acids; the structural formula of a typical triglyceride, triolein, is shown below.



triolein

Triolein is called a simple triglyceride since it contains only one type of fatty acid (oleic acid). Naturally occurring triglycerides usually are mixed triglycerides; *i.e.*, they contain more than one type of fatty acid. An example of a mixed triglyceride is palmitodiolein, the fatty-acid composition of which is, as the name indicates, one molecule of palmitic acid and two molecules of oleic acid.

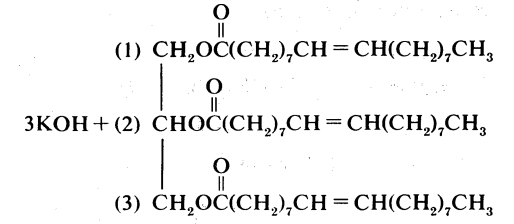


palmitodiolein

This triglyceride may have structural arrangements other than the one shown; *i.e.*, the fatty-acid molecules may be arranged with palmitic acid occupying any of the two possible different positions. (There are only two chemically different positions since the top and the bottom positions in the above formula are undistinguishable.)

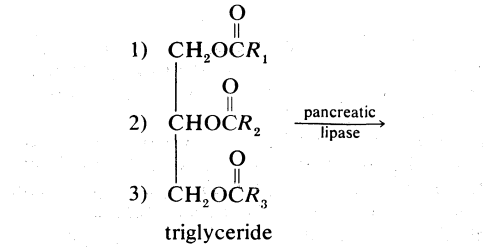
Physical and chemical characteristics. Triglycerides, called neutral lipids because they possess no charged groups, do not migrate in an electrical field and are insoluble in water. Information about the structure of naturally occurring mixed triglycerides containing different fatty acids may be obtained by chemical, enzymatic, and physical methods. Chemical and enzymatic techniques are summarized below.

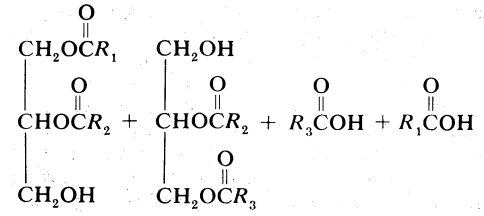
Triglyceride molecules undergo reactions with bases such as potassium hydroxide (KOH). The reaction, shown below, often called a saponification reaction, results in the formation of an alkali soap (potassium oleate) and glycerol.

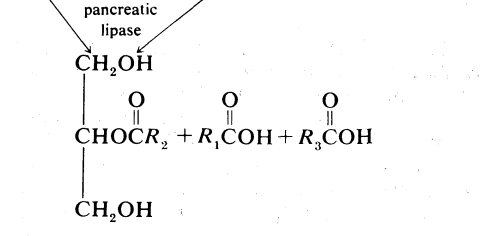


If acid is added to a solution containing the soap, free fatty acids are formed. The saponification reaction helps establish the general nature of the fatty acids associated with a specific triglyceride, but provides no information on their specific locations on the glycerol molecule [positions (1), (2), or (3) in the triolein formula above].

The distribution of fatty acids on the glycerol molecule is determined by using an enzyme (pancreatic lipase) that is found in mammals and plays a role in lipid digestion. Pancreatic lipase acts only at positions (1) and (3) of the triglyceride molecule in the sequence outlined below; the overall reaction occurs in two steps. The first products of the lipase reaction are two molecules of glycerol, each containing two fatty acids (labeled diglycerides I and II) and two molecules of free fatty acids (represented by the general formula *R*COOH) from positions (1) and (3) of the triglyceride. The lipase next reacts with the two diglycerides. A monoglyceride that contains one fatty acid at position (2), and free fatty acids from positions (1) and (3) of the diglycerides are the products of this second reaction. R_1, R_2, and R_3 in the reaction sequence represent hydrocarbon chains of fatty acid ester groups. The various products of the enzyme-catalyzed reactions may be isolated and analyzed to provide information about the chemical nature of the fatty acids at each of the three positions.

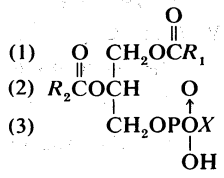






PHOSPHOGLYCERIDES

The most simple phosphoglyceride contains fatty acids combined with glycerophosphate; *i.e.*, glycerol, containing a molecule of phosphoric acid at position (3), as shown below in the general formula. R_1 and R_2 represent hydrocarbon chains of fatty-acid ester groups at positions (1) and (2) of glycerol; *X* at position (3) may be a hydrogen atom or an organic compound (*e.g.*, serine, inositol,

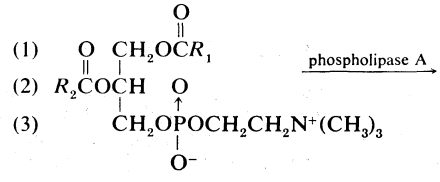


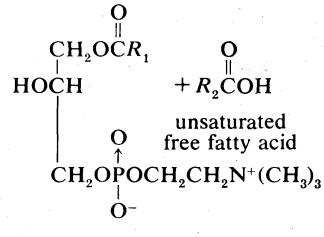
choline, glycerol, glycerophosphoric acid, or a diglyceride). Variations from the general structure occur; phospholipids called plasmalogens, for example, contain an unsaturated ether group in position (1) instead of a fatty-acid ester group, and other phospholipids called glyceryl ether phospholipids contain a saturated ether group in position (1). The properties and characteristics of several phosphoglycerides are summarized in the following sections.

The term phosphatidyl is used to describe the portion of the phosphoglyceride molecule containing the fatty-acid ester groups and glycerophosphate.

Phosphatidyl choline. Phosphatidyl choline, also known as lecithin, is the difatty-acid derivative of glyceryl-3-phosphorylcholine and is perhaps the most representative of all the phosphoglycerides. A lecithin molecule has a nonpolar portion (the two fatty-acid ester groups), which is insoluble in water, and a polar portion (phosphorylcholine), which is soluble in water. Since lecithin molecules contain both polar and nonpolar components, they can orient themselves in a specific way at oil–water or water–air interfaces. The nitrogen-containing component of lecithin (choline) is a strongly basic compound and has a positive charge; since phosphoric acid has a negative charge, lecithin has both acidic and basic groups and behaves as a zwitterion (*i.e.*, a dipolar ion).

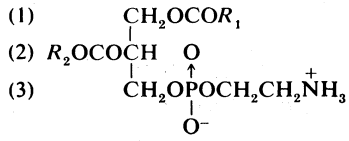
In animal tissues, the fatty-acid ester groups of lecithin are specific with regard to type and position; *e.g.*, reactions (see example below) using the enzyme phospholipase A





(from snake venom) as a catalyst show that lecithins from different sources have saturated fatty acids predominately at position (1) and unsaturated fatty acids at position (2). The action of this enzyme on lecithin results in the liberation of the unsaturated fatty acid at position (2); the remainder of the molecule is called a lysolecithin. R_1 and R_2 represent hydrocarbon chains of fatty-acid ester groups in the equation. The reaction proceeds most efficiently in a diethyl ether solution, which removes liberated fatty acids from the surfaces of the enzyme molecules. The free fatty acid represents the unsaturated fatty-acid ester group at position (2) in lecithin; the lysolecithin has a saturated fatty acid ester group at position (1). The specificity of the fatty-acid positions may act in metabolic utilization.

Phosphatidyl ethanolamine. The structure of phosphatidyl ethanolamine, found in most sources containing phosphatidyl choline, is represented below; R_1 and R_2 represent hydrocarbon chains of fatty-acid ester groups. The fatty acids in phosphatidyl ethanolamine, as in phosphatidyl choline, usually occupy specific positions;



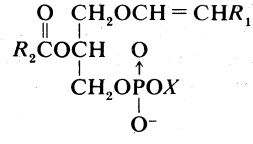
phosphatidyl ethanolamine

saturated fatty acids are located primarily at position (1), unsaturated fatty acids at position (2). Ethanolamine ($\overset{+}{N}H_3CH_2CH_2OH$) is a nitrogen-containing basic compound derived from the amino acid serine. This phosphoglyceride, unlike phosphatidyl choline, is not a zwitterion and exists in various ionic, or charged, forms.

Phosphatidyl serine. Although amino acids other than serine may occur in natural phospholipids, phosphatidyl serine is the most representative one. It is a minor chemical component of cells, compared with phosphatidyl choline and phosphatidyl ethanolamine.

Plasmalogens. Plasmalogens are naturally occurring phosphoglycerides that, under certain conditions, release an organic compound called an aldehyde. The substituent at the (1) position in the general formula below is called a vinyl ether ($-OCH{=}CHR_1$); that on position (2) is a fatty-acid ester, usually of an unsaturated fatty acid. The nitrogen base (*X*) in most plasmalogens is ethanolamine; choline-containing plasmalogens occur in lesser amounts.

Another phospholipid, similar in general structure to plasmalogens, is found in eggs, brain tissue, and red blood cells of cows; it contains a saturated ether ($-OCH_2CH_2R$) substituent instead of a vinyl ether.



general structure of plasmalogens

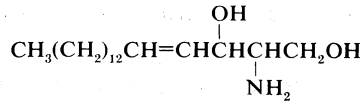
Phosphatidyl inositol. Phosphatidyl inositol, which is not present in large amounts in animals or plants, contains an alcohol (inositol) with a ring structure. Several similar compounds have been isolated from brain tissue, including phosphoglycerides containing inositol polyphosphates; *e.g.*, L-myo-inositol-1,4,5-triphosphate and L-myo-inositol-2,4,-5-triphosphate. More complex inositol-containing phospholipids may contain ethanolamine, tartaric acid, or the sugar galactose.

Minor phosphoglycerides. Not all of the glycerol-containing phospholipids are represented by the structures already described. Minor phosphoglycerides (*e.g.*, phosphatidic acids, phosphatidylglycerol, and bisphosphatidic acid), and usually are present in cells in very small amounts, less than 2 or 3 percent, and often occur in tissues as salts. Phosphatidic acids, which are glycerol phosphate molecules containing two molecules of fatty acid, are important in the biosynthetic pathways that result in the formation of phosphoglycerides and neutral lipids. Small amounts of phosphatidic acids occur in mammals, but they are abundant in plants (*e.g.*, cabbage). Cardiolipin, or diphosphatidylglycerol, which is found in heart muscle, usually contains only unsaturated fatty acids; it has been used in the diagnosis of syphilis. Phosphatidylglycerol, which occurs in a variety of sources, may be involved in both the synthesis and breakdown of phosphatidic acids.

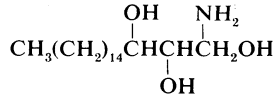
Phosphatidic acids

SPHINGOLIPIDS

The sphingolipids, a group of complex lipids, contain either sphingosine or the closely related compound phytosphingosine instead of glycerol.

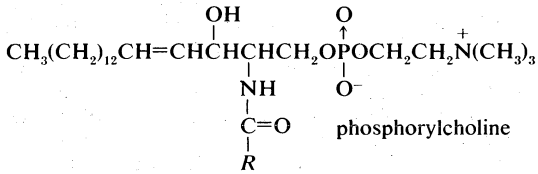


sphingosine



phytosphingosine

Sphingosine is found in the sphingolipids of animals, phytosphingosine in those of plants. Animal sphingolipids occur in high concentration in the brain, in the peripheral nerves, and in the myelin sheaths surrounding nerve fibres; they occur in lower amounts in several other tissues; *e.g.*, liver, blood plasma, kidney. Sphingomyelins are the most frequently encountered sphingolipids in animals; *R* represents the hydrocarbon chain of a fatty-acid ester group in the formula below.



a sphingomyelin

Other sphingolipids include glycosphingolipids, or glycolipids, which contain a sugar instead of the phosphoryl choline unit. A typical glycosphingolipid, present primarily in brain tissue, is the *O*-galactosido derivative of *N*-acyl sphingosine; it is generally called a cerebroside. The sugar component of the molecule is galactose, a hexose sugar (*i.e.*, containing six carbon atoms). The fatty acids found in cerebrosides usually contain 24 carbon atoms and have either a double bond or a hydroxyl group. Some cerebrosides contain sulfuric acid linked to galactose; these molecules are called sulfatides. Other glycosphingolipids are called gangliosides; they differ from the cerebrosides in the more complex chemical nature of the sugar group on the sphingosine molecule. The various ganglioside molecules usually differ in the number of sugar molecules.

Sialic acids

The neuraminic acid component, usually present as *N*-acetyl-*O*-*N*-diacetyl-, or *N*-glycolylneuraminic acid, is commonly known as a sialic acid. Naturally occurring sialic acids, which are found as components of gangliosides and other complex molecules, are widely distributed in animal tissues and in bacteria.

ASSOCIATED COMPOUNDS: STEROLS AND CAROTENOIDS

Widely distributed in nature, sterols and carotenoids usually are closely associated with the fatty-acid-containing lipids in cells. The most commonly occurring natural sterol in vertebrates is cholesterol, which is the starting substance, or precursor, for many other important biologically active sterols (often referred to as steroids). The carotenoids, which are sometimes referred to as tetraterpenes (C_{40}), are widely distributed in plants and microorganisms and to a lesser extent in animals, in which they

probably originate in dietary sources, since animals cannot synthesize them. A frequently encountered carotenoid is β-carotene, a precursor of vitamin A alcohol, which functions in mammalian vision. Other carotenoids function in photosynthesis in plants. These lipids are discussed in detail in CHEMICAL COMPOUNDS: *Isoprenoids; Steroids.*

Lipoproteins

Lipids in living cells normally are associated with proteins. Lipid–protein complexes, or lipoproteins, occur either as soluble components (*e.g.*, those in the blood plasma of mammals or in egg yolk) or as more insoluble types (*e.g.*, those in membranes of cells). The discussion that follows is concerned primarily with composition, structure, and biological behaviour of the soluble lipoproteins in blood plasma, which are relatively easy to isolate and purify and thus have been studied extensively.

One outstanding feature of the association between lipids and proteins is the lack of significant chemical bonds between them. Since lipids can be separated from the protein component, it is assumed that lipoproteins are held together by weak physical forces.

Lipoproteins isolated from various sources usually fall into one of two general groups. In one group are the highly ordered lipoproteins, which are characterized by high protein and low lipid content; the other group consists of disorganized lipoproteins, which are characterized by low protein and high lipid content. A large number of different lipoproteins have been isolated; their molecular weights and lipid contents vary over a wide range. A suitable characterization of a lipoprotein includes several criteria; *e.g.*, solubility characteristics, behaviour when spun in a centrifuge, and chemical composition.

PHYSICAL CHARACTERISTICS

The physical character of lipoproteins resembles that of proteins. Lipoproteins that differ with respect to physical properties can be separated by differences in solubility, in electrophoretic behaviour (migration of a charged particle in an electrical field), and in centrifugal behaviour. A well-established method for separating proteins (salt fractionation) is also useful for separating lipoproteins; it has been replaced to a great extent, however, by a more effective method, centrifugation, mentioned below. Another method now largely replaced by centrifugation involves the separation, using ethanol, or protein components in human blood plasma to obtain two major lipoprotein fractions, designated as α_1-lipoprotein and β-lipoprotein.

Centrifugation

Lipoproteins were first identified in human blood when it was spun in a centrifuge at extremely high speeds (ultracentrifugation). Lipoproteins separate from other serum constitutents after 20 to 24 hours of centrifugation. The lipoproteins gather as a uniform layer at the top of the centrifuge tube. If the density of a solution containing the serum lipoproteins is adjusted by the addition of a soluble material such as a salt, so that the solution at the bottom of the tube has a higher density than that at the top, and if the mixture then is spun in an ultracentrifuge, the lipoproteins become distributed according to the densities of the components. The degree of separation of various lipoproteins depends on the density adjustment of the solution before ultracentrifugation.

The physical characterization of low-density lipoproteins (*i.e.*, high lipid content) is often expressed in S_f values; S_f indicates low density lipoprotein flotation rate in a sodium chloride solution of density 1.063 grams per cubic centimetre at 26° C (79° F) in a unit centrifugal field and is described in Svedberg units (10^{-13} centimetre/second/dyne/gram).

CHEMICAL NATURE

The chemical nature of the three groups of human blood-plasma lipoproteins, the very low density lipoproteins (VLDL), the low-density lipoproteins (LDL_1), and the high-density lipoproteins (HDL_3), which differ from each other in various ways (*e.g.*, types and amounts of both lipids and proteins, immunochemical properties), are summarized in Table 13.

Table 13: Characteristics of Human Blood Plasma Lipoproteins
(a composite picture)

	HDL_3	LDL_1	VLDL
Lipid, in percent	37	48	90
Component lipids, in percent of total lipid			
Phosphatidyl choline	44	24	20
Sphingomyelin	20	16	56
Triglyceride	24	12	8
Cholesterol ester	6	12	8
Cholesterol	6	1	1
Free fatty acid	45	15	10
Protein, in percent	18	37	...
Water, in percent	84	185	500
Diameter, in angstrom units	1.13	1.04	0.91
Density, hydrated (grams per cubic centimetre)	300,000	2×10^6	8×10^6
Molecular weight (approx.)			

Variations in age and sex of individuals are reflected by differences in distribution of low-density lipoproteins (LDL_1) and high-density lipoproteins (HDL_3) in their blood serums. The chylomicrons occur as transient components produced during the intestinal absorption of lipids.

(D.J.H./Ed.)

NUCLEIC ACIDS

Nucleic acids are of interest because they provide the genetic material of the cell and, by directing the process of protein synthesis, determine its inherited characteristics. Nucleic acids are naturally occurring complex phosphorus compounds, acidic in character, and capable of being broken down chemically to yield phosphoric acid, sugars, and a mixture of organic bases (purines and pyrimidines). About 1868, nuclei isolated from pus cells were found to contain an unusual phosphorus compound, which was named nuclein. In later years, complex phosphorus-containing acid materials were also isolated from a wide variety of cells; these appeared to be chemically similar to nuclein and came to be called nucleic acids.

General considerations

CLASSIFICATION

There are two classes of nucleic acids: ribonucleic acids (RNA) and deoxyribonucleic acids (DNA). Both RNA and DNA are macromolecules that can be distinguished from each other by their base and sugar contents. DNA, a major constituent of chromosomes in the nuclei of all cells, is also found in other cellular components (*e.g.*, mitochondria). RNA is present in both the nucleus and cytoplasm of many cells. The bulk of cytoplasmic RNA is associated with ribosomes, small particles composed of RNA and proteins that are the site of protein synthesis.

BASIC COMPONENTS

Polynucleotides

Nucleic acids are polynucleotides, long chain compounds consisting of repeating structural units called nucleotides (Figure 11). They may be composed of more than 1,000,000 of these nucleotides. The nucleotides themselves consist of three subunits. Each of them contains a pentose (or five-carbon) sugar, a purine or pyrimidine base, and a phosphate residue. The pentose sugar is ribose in RNA and 2-deoxyribose in DNA. The major purine and pyrimidine bases are adenine, guanine, cytosine, and thymine (or uracil in RNA).

The nucleotides that serve as physiological building blocks in the synthesis of nucleic acids often are esters (when an acid and an alcohol react they form water and an ester) not of phosphoric acid but of condensed relatives of it, pyrophosphoric or triphosphoric acids.

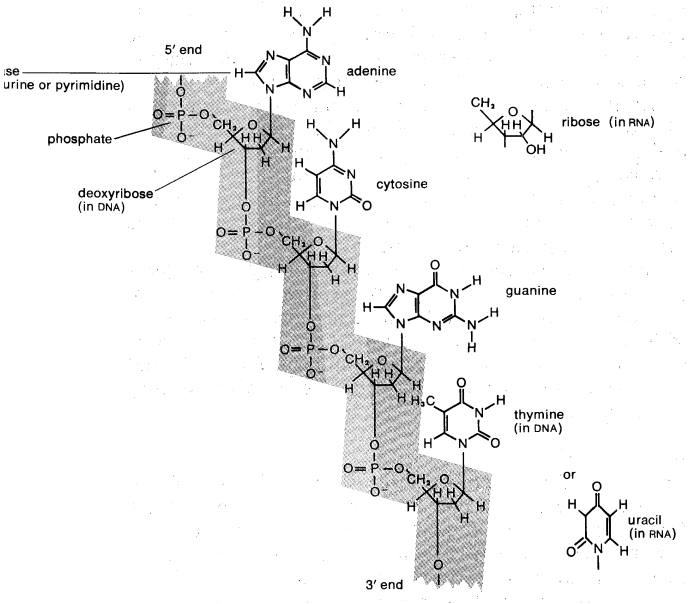


Figure 11: Portion of polynucleotide chain of deoxyribonucleic acid.

From J.D. Watson, *Molecular Biology of the Gene*, copyright © (1965), W.A. Benjamin, Inc., Menlo Park, California

Enzymatic breakdown of nucleic acids results in the release of nucleotide units in which a phosphate residue is attached to the deoxyribose sugar at one of two possible positions on the sugar molecule. These internucleotide linkages are known as phosphodiester bonds. The internucleotide linkage is the same in RNA.

It was the fact that adenine and thymine are present in approximately equal amounts in DNA, as are guanine and cytosine, together with information from X-ray crystallography of DNA that led Nobel Prize winners J.D. Watson and F.H.C. Crick to postulate that the DNA molecule consists of two chains or strands of polynucleotides coiled around each other to form a double helix, the bases of one strand being paired with complementary bases of the other by hydrogen bonds: adenine paired with thymine and cytosine with guanine. RNA has unequal proportions of the four bases and, in addition, contains unusual bases (*e.g.*, pseudouridine, various methylated purines).

Nucleic acids can be separated from other cellular constituents by treating a tissue with cold acid. Most of the contents of the tissue go into solution, but both RNA and DNA are insoluble in cold acid and can be removed from the mixture. RNA and DNA, in turn, can be separated by treatment with alkali; in this case, RNA is broken down by the alkali into nucleotide units, but DNA remains unchanged. If acid is added to this mixture, DNA precipitates (comes out of solution), and the RNA nucleotide units remain in solution.

The DNA found in cell nuclei (as chromosomes) and in other cell components usually is bound to proteins called histones. The protein bound to the DNA in sperm cells is known as protamine. Bacterial DNA is not associated with protein. DNA–protein complexes from animal tissues, known as deoxyribonucleoproteins, are molecules of very high molecular weight (from 10,000,000 to more than 100,000,000 times the weight of a hydrogen atom). Approximately 25 to 50 percent of the dry weight of this complex is nucleic acid.

Characteristics of DNA

PROPERTIES, STRUCTURE, AND BASE SEQUENCE

Physical properties. Many of the physical properties of DNA depend on the methods used to purify it. If, for example, fragmentation of DNA molecules by either mechanical means or enzymes is avoided, DNA preparations of very high molecular weight (*e.g.*, 120,000,000), corresponding to a chromosome or to the entire nucleic acid complement of a virus or a bacterium, can be obtained. Solutions of such preparations are viscous, and almost any manipulation (*e.g.*, stirring) can break the molecules into fragments of lower molecular weight.

Because of their purine and pyrimidine base content, DNA preparations absorb ultraviolet light. If a solution of DNA is heated to a critical temperature, it absorbs more ultraviolet light and becomes less viscous because the orderly helical structure of the molecules breaks down. DNA molecules become irregularly coiled structures during this process, which is called thermal denaturation of DNA. The "melting" temperature at which thermal denaturation takes place is dependent on the base composition of the DNA molecule. DNA molecules with a high content of guanine and cytosine, for example, are more stable at high temperatures than those high in adenine and thymine because the hydrogen bonding between guanine and cytosine is stronger. At temperatures slightly above the melting temperature, the two strands of DNA separate. If the DNA solution is cooled slowly, sometimes recombination of the strands and partial restoration of the double helix occurs.

If a concentrated salt solution is spun in a centrifuge at high speed for a long period of time, an equilibrium is eventually attained in which the concentration, and, therefore, the density, of the salt solution increases gradually from the top of the tube to the bottom. If the salt solution also contains DNA, these molecules migrate to the level in the tube in which the density of the salt solution equals their own. This is an important method for determining with great precision the density of nucleic acids and for separating DNA molecules of different densities. The density of DNA molecules with a high proportion of guanine and cytosine is slightly greater than that of molecules with a lower proportion of these bases. Denaturation also causes a slight increase in density. Although DNA usually is double-stranded, there are single-stranded forms (for example, the small bacterial virus designated φX 174), which do not show the denaturation phenomena of the double-stranded molecules.

Importance of hydrogen bonds

Structure. The long polynucleotide chains that comprise DNA molecules would form flexible threadlike molecules, instead of coils, were it not for cross-links (hydrogen bonds) between bases of each chain. Measurements indicate that the space between DNA chains agrees with values calculated for hydrogen bond linkage of a purine base to a pyrimidine base (the space is too small for two purines and too large for two pyrimidines). Three crosslinks occur between a guanine residue (purine base) and its complementary base, cytosine (a pyrimidine), in two complementary chains; on the other hand, two crosslinks occur between adenine (purine base) and its complementary base, thymine (a pyrimidine). Each purine base is linked to its complementary pyrimidine base in the opposite chain by either two or three hydrogen bonds.

Double helix

The sugar molecules (deoxyribose in DNA) are linked by phosphodiester bonds to form the backbone of each DNA chain. The bases, with their large hydrophobic (water-hating) surfaces, are stacked together on the inside of the molecule like a pile of coins. These two complementary chains coil around each other to form a double helix. In other words, DNA resembles a spiral staircase in which the

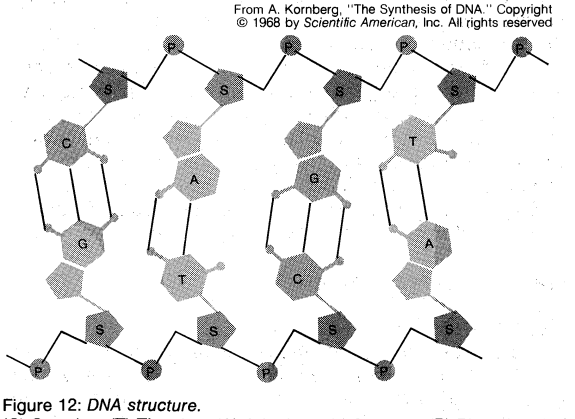

Figure 12: *DNA structure.*
(C) Cytosine. (T) Thymine. (A) Adenine. (G) Guanine. (P) Phosphate. (S) Deoxyribose (sugar).

bases are the steps and the sugar phosphate residues are the bannisters. The DNA molecule derives stability from hydrogen bonding between base pairs in complementary chains from hydrophobic "base-stacking forces" between neighbouring bases on the same chain. The DNA of mammalian chromosomes and DNA-containing viruses generally consist of long unbranched double-helical threads of the type described above. The DNA of many viruses (including φX 174) and of mitochondria are circular, and, in some cases, there is evidence that such cyclic double helices are twisted into a supercoiled form. A single break in either chain of the helix releases the molecule, and an untwisted structure results.

Base sequence. The biological function of DNA molecules, whether single- or double-stranded, cyclic or unbranched, is to provide a genetic message encoded in a sequence of purine and pyrimidine bases. Although there are ways to determine the sequences of the units in some macromolecules like proteins (see *Proteins*), it is extremely difficult to do so for DNA molecules, which generally are of much higher molecular weight. In addition, nucleic acids are composed of fewer kinds of units (*i.e.*, the purine and pyrimidine nucleotides) than are found in proteins (*i.e.*, about 20 amino acids). It is also more difficult to obtain a single molecule of pure DNA than it is to purify proteins. Progress has, however, been made in the base sequence determination of the relatively small DNA of the φX 174 virus, which contains about 5,500 nucleotide units; thus far it has been possible to obtain only statistical evidence abut the order in which these nucleotides are arranged. The usual experimental approach takes advantage of the fact tha the purine bases of DNA are removed by acid, while the pyrimidine bases retain their original positions in the molecule. Pyrimidine nucleotides have been shown to occur frequently in clusters.

LABORATORY SYNTHESIS

Experiments with living cells have tended to confirm the hypothesis that DNA is synthesized by a process in which the two strands of an existing molecule separate while new complementary strands are synthesized using the old strands as templates, or patterns. For a detailed discussion of the biosynthesis of DNA, see GENETICS AND HEREDITY: *The gene.* The product of DNA synthesis in the cell is the formation of two molecules, each containing one strand from the original DNA and a newly synthesized complementary strand.

Enzymes purified from mammalian and bacterial cells catalyze the synthesis of DNA in the test tube. The reaction takes place only in the presence of the nucleoside triphosphates of the four bases (adenine, cytosine, guanine, and thymine) and preformed DNA, which serves as a template. That the product has the same nucleotide sequence as the template has been demonstrated by the technique of "nearest neighbour frequency analysis." One of the four necleotides contains radioactive phosphorus. During DNA synthesis these radioactive phosphorus residues form internucleotide links with nucleotides next to them in the newly forming chain. The newly synthesized DNA is degraded with enzymes that split the radioactive phosphorus from the molecule to which it was originally attached. The result is that the radioactive phosphorus becomes part of the structure of the nucleotide nearest the necleotide originally labelled. In this way it is possible to determine the frequency with which particular pairs of nucleotides are neighbours in polynucleotide chains. Such nearest neighbour frequencies vary markedly from one DNA source to another and are specific for each kind of DNA. Generally, the DNA produced by the DNA-synthesizing enzyme in the test tube cannot be shown to possess the biological activity of the template.

Nearest neighbour frequency analysis

When single-stranded circular DNA of the virus φX 174 is used as a template for DNA synthesis, however, a complementary (or −) strand is formed along the original (or +) strand. The free ends of the new (or −) strand can be joined by an enzyme to form a cyclic double-stranded molecule. If the cyclic double-stranded molecules are broken with another enzyme, random single breaks occur in a proportion of the molecules in either strand. The broken molecules can be eliminated leaving a number of intact synthetic cyclic (−) strands. When these are tested, they are found to be capable of infecting susceptible cells and of giving rise to a new generation of normal virus particles.

Characteristics of RNA

PROPERTIES, STRUCTURE, AND BASE SEQUENCE

Physical properties. Most DNA molecules share a common genetic function and structural pattern. RNA molecules, however, perform several functions in the cell, and their properties vary correspondingly. Three types of RNA have been studied chemically: ribosomal RNA (rRNA), transfer (soluble or adaptor) RNA (tRNA), and viral RNA. Messenger RNA, despite its biological importance, has not yet been the subject of extensive chemical investigation. The RNA's of some viruses (*e.g.*, reovirus, wound tumour virus) have properties in common with DNA, including a double helical structure and a critical melting temperature. Other viral RNA's (*e.g.*, tobacco mosaic virus) and ribosomal RNA, however, have less sharp melting characteristics and lack a complete double helical structure; instead the polynucleotide chains are folded back on themselves to provide small regions of base pairing and, therefore, hydrogen bonding and some helical sections. The small tRNA molecules are thought to be folded similarly into a cloverleaf structure, with regions of hydrogen bonding between base pairs forming hairpin-like helical sections.

The molecular weights of RNA molecules vary according to their type and source. Ribosomal particles, for example, contain a large fraction of the RNA in a cell; these particles can be split into two unequal subunits. The main component of ribosomal RNA from the larger of the subunits has a molecular weight of about 1,000,000; the RNA from the smaller subunit has a molecular weight of about 800,000. Ribosomes also contain RNA's of lower molecular weight (about 60,000). Transfer RNA is the smallest type of RNA molecule; its molecular weight varies from about 25,000 to 30,000. The molecular weights of messenger RNA molecules vary over a wide range.

Structure and base sequence. Research involving RNA structure has centred around tRNA (the type of RNA to which amino acids are attached during protein biosynthesis), the smallest nucleic acids (70 to 80 nucleotide units). The different tRNA molecules (each of the approximately 20 amino acids has at least one specific tRNA) in the cell can be separated and purified. In addition to their small size, tRNA molecules are distinguished from other forms of nucleic acids by their relatively high content of minor nucleotides (*e.g.*, pseudouridine, methylated bases). The relative ease with which these minor nucleotides can be identified has been useful in sequence determinations. By using enzymes that catalyze different specific reactions for various lengths of time on one type of tRNA, fragments of the polynucleotide are produced and can be separated and analyzed to determine the sequence of nucleotides in the intact molecule.

LABORATORY SYNTHESIS

It has been suggested that RNA is synthesized in the living cell by a process in which one of the two strands of a DNA molecule is used as a template (or pattern) for the formation of a complementary strand of RNA. For specifics regarding the biosynthesis of RNA, see GENETICS AND HEREDITY: *The gene.* Enzymes found in microorganisms and in animal tissues can catalyze the synthesis of RNA in the test tube. This synthesis occurs provided that a mixture of the proper nucleoside triphosphates and a small quantity of DNA are present. The composition of the newly synthesized RNA corresponds exactly to that of the DNA template (with uracil replacing thymine), and nearest neighbour sequence analysis indicates a similar correspondence in base sequence. In certain cases, a hybrid double helical molecule, which may form from template DNA and the RNA product, indicates an exact correspondence in structure between primer and product. In animal and bacterial cells infected with RNA viruses, the RNA of the virus acts as a template for the synthesis of more RNA.

(J.N.D./R.Y.T./Ed.)

VITAMINS

The substances commonly known as vitamins are diverse in chemical structure and function. Originally defined as organic compounds obtainable in a normal diet and capable of maintaining life and promoting growth, vitamins are distinct from carbohydrates, fats, and proteins in function, as well as in the quantities in which organisms require them. In general terms, vitamins are organic substances that usually are separated into water-soluble *(e.g.,* the B vitamins, vitamin C) and fat-soluble (*e.g.,* vitamins A, D, E, K) groups; small quantities (from 0.00002 percent to 0.005 percent of a diet) are necessary for normal health and growth in higher forms of animal life. A number of compounds (*e.g.,* choline, carnitine) once grouped with vitamins no longer are considered vitamins (see below *Vitamin-like substances*). If a vitamin is absent from the diet or is not properly absorbed by an organism, a specific deficiency disease may develop.

The term vitamin originated from "vitamine," a word first used in 1911 to designate a group of compounds considered vital for life; each was thought to have a nitrogen-containing component known as an amine. The final *e* of vitamine was dropped when it was discovered that not all of the vitamins contain nitrogen, and, therefore, not all are amines. The term accessory food factor sometimes is used instead of vitamin to refer to these substances.

Vitamins as essential nutrients

Since they generally cannot be synthesized by an animal (or, if synthesized, the amounts are insufficient to meet body needs) and must be obtained from the diet or from some synthetic source, vitamins are called essential nutrients. The requirements for some of the B vitamins may be met in part by bacterial synthesis in the intestines of some mammals. The amino acid tryptophan can be converted to nicotinic acid (or niacin, a water-soluble vitamin) and thus can serve as a source for part of the nicotinic acid required by an animal. Vitamin C (also a water-soluble vitamin) can be synthesized by some organisms in sufficient amounts so that the dietary requirement is eliminated; vitamin C usually is considered a vitamin, however, because it must be included in the diet of man. Vitamins are distinct from many other compounds, which, although indispensable for proper animal functions, can be synthesized in adequate quantities.

General characteristics

Definitions of provitamin, antivitamin

A provitamin is similar in structure to a specific vitamin and can be converted to it by a few metabolic reactions *(e.g.,* beta-carotene can be converted to vitamin A; 7-dehydrocholesterol can be converted to vitamin D_3). The amino acid tryptophan is called a precursor of the vitamin nicotinic acid because the conversion pathway is less direct than that of a provitamin. Antivitamins are compounds that prevent the normal function of certain vitamins. Antivitamins may act by binding a vitamin *(e.g.,* the antivitamin avidin binds the vitamin biotin), by destroying a vitamin (*e.g.,* the antivitamin thiaminase destroys thiamine), or by inhibiting the coenzyme function of a vitamin. A coenzyme is, as noted previously, a heat stable compound that combines with the protein component of an enzyme (*i.e.,* an organic catalyst) to form an active enzyme. Antivitamins that act by inhibiting the coenzyme function of a vitamin usually are known as antagonists or antimetabolites.

Letters originally were assigned to the vitamins, which were differentiated according to physiological function. As chemical structures of the vitamins became known, however, they were also given names and now are commonly known either by letter or by name. Currently accepted names for the vitamins, established by international agreement, are given in Tables 14 and 15.

BIOLOGICAL SIGNIFICANCE

Regulatory role. The vitamins regulate reactions that occur in metabolism, in contrast to other dietary components known as macronutrients (*e.g.,* fats, carbohydrates, proteins), which are the compounds utilized in the reactions regulated by the vitamins. Absence of a vitamin blocks one or more specific metabolic reactions in a cell and eventually may disrupt the metabolic balance within a cell and in the entire plant or animal as well.

With the exception of vitamin C (ascorbic acid), all of the water-soluble vitamins have a catalytic function; *i.e.,* they act as coenzymes of enzymes that function in energy transfer or in the metabolism of fats, carbohydrates, and proteins. The metabolic importance of the water-soluble vitamins is reflected by their presence in most plant and animal tissues involved in metabolism.

Some of the fat-soluble vitamins form part of the structure of biological membranes or assist in maintaining the integrity (and therefore, indirectly, the function) of membranes. Some fat-soluble vitamins also may function at the genetic level by controlling the synthesis of certain enzymes. The roles of the fat-soluble vitamins have not yet been established with certainty. Unlike the water-soluble ones, fat-soluble vitamins are necessary for specific functions in highly differentiated and specialized tissues; therefore, their distribution in nature tends to be more selective than that of the water-soluble vitamins.

Sources. Vitamins, which are found in all living organisms either because they are synthesized in the organism or are acquired from the environment, are not distributed equally throughout nature. Some are absent from certain tissues or species; for example, beta-carotene (provitamin A) is synthesized in plant tissues but not in animal tissues. On the other hand, vitamins A and D_3 occur only in animal tissues. Both plants and animals are important natural vitamin sources for man. Since vitamins are not distributed equally in foodstuffs, the more restricted the diet of an animal (man, for example), the more likely it is that he will lack adequate amounts of one or more vitamins. Food sources of vitamin D are limited, but it can be synthesized in the skin through ultraviolet radiation (from the Sun) on the provitamin, 7-dehydrocholesterol; therefore, with adequate exposure to sunlight, the dietary intake of vitamin D is of little significance.

All vitamins either can be synthesized or produced commercially from food sources and are available for human consumption in pharmaceutical preparations. Commercial processing of food (*e.g.,* milling of grains) frequently destroys (or removes) considerable amounts of vitamins. In most such instances, however, the vitamins are replaced by chemical methods. Some foods are "fortified" with vitamins not normally present in them (*e.g.,* vitamin D is added to milk). Loss of vitamins may also occur when food is cooked (*e.g.,* heat destroys vitamin A, water-soluble vitamins may be extracted from food to water and lost). Certain vitamins (*e.g.,* B vitamins, vitamin K) can be synthesized by microorganisms normally present in the intestines of some animals; however, the microorganisms usually do not supply the host animal with an adequate quantity of a vitamin.

Requirements of living things. The vitamins required by most organisms are fairly well established. Vitamin requirements vary according to species and the amount of a vitamin required by a specific organism is difficult to determine because of the numerous factors involved (*e.g.,* genetic variation; presence of specific disease states; therapeutic use of certain drugs that also may act as vitamin antagonists; infestation with parasites; relative proportions of other dietary constituents, food additives, or contaminants; environmental stresses; and stimulation of growth rate, as in animal husbandry). There is not uniform agreement concerning the vitamin requirements for man. Differences in opinion arise mainly from different ways by which requirements can be determined and from the scanty data available for the requirements for some of the vitamins. Recommended daily vitamin allowances, however, are sufficiently high to account for individual variation and normal environmental stresses. For detailed information on vitamin requirements in man, see NUTRITION.

Factors influencing vitamin requirements

A number of interrelationships exist among vitamins and between vitamins and other dietary constituents. The interactions may be synergistic (*i.e.,* cooperative) or antagonistic, reflecting, for example, overlapping metabolic roles (of the B vitamins in particular), protective roles (*e.g.,* vitamins A and E), or structural dependency (*e.g.,* cobalt in the vitamin B_{12} molecule).

Results of deficiencies. An inadequate intake of a specific vitamin results in a characteristic deficiency disease (or hypovitaminosis); the severity of the disease depends upon the degree of vitamin deprivation (see Figure 13).

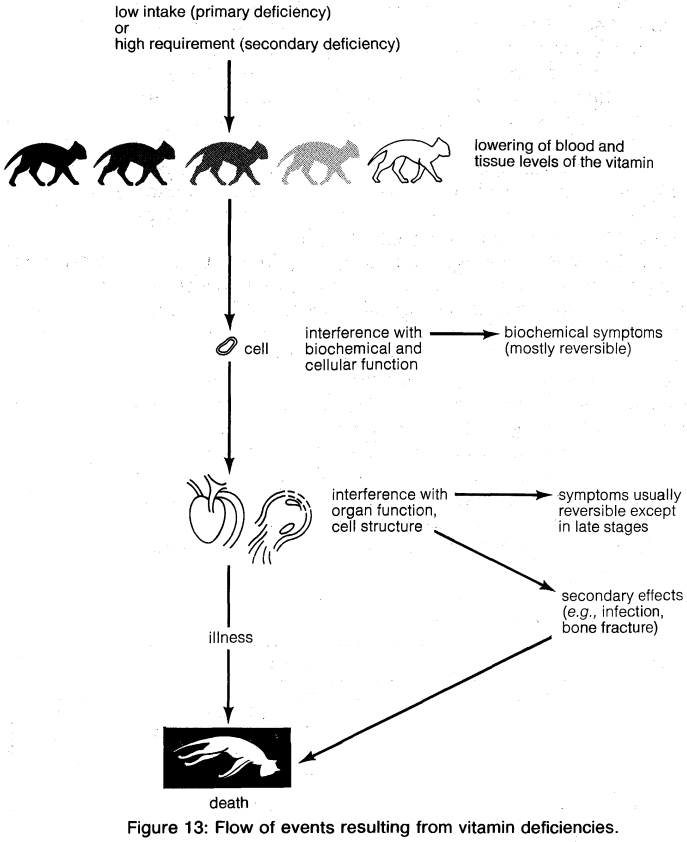

Figure 13: Flow of events resulting from vitamin deficiencies.

Symptoms of deficiencies

Symptoms may be specific (*e.g.,* functional night blindness of vitamin A deficiency) or nonspecific (*e.g.,* loss of appetite, failure to grow). All symptoms for a specific deficiency disease may not appear; in addition, the nature of the symptoms may vary with the species. Some effects of vitamin deficiencies cannot be reversed by adding the vitamin to the diet, especially if damage to nonregenerative tissue (*e.g.,* cornea of the eye, nerve tissue, calcified bone) has occurred.

Primary and secondary deficiencies

A vitamin deficiency may be "primary" (or dietary), in which case the dietary intake is lower than the normal requirement of the vitamin. A "secondary" (or conditioned) deficiency may occur (even though the dietary intake is adequate) if a pre-existing disease or state of stress is present (*e.g.,* malabsorption of food from the intestine, chronic alcoholism, repeated pregnancies and lactation). For more details on vitamin deficiencies in man, see NUTRITION: *Nutritional diseases and disorders.*

Evolution of vitamin-dependent organisms. Evolution of metabolic processes in primitive forms of life required the development of enzyme systems to catalyze the complex sequences of chemical reactions involved in metabolism. In the beginning, the environment presumably could supply all the necessary compounds (including the vitamin coenzymes); eventually, these compounds were synthesized within an organism. As higher forms of life evolved, however, the ability to synthesize certain of these vitamin coenzymes was gradually lost.

Since higher plants show no requirements for vitamins or other growth factors, it is assumed that they retain the ability to synthesize them. Among insects, however, nicotinic acid; vitamins B_1, B_2, B_6, and C; and pantothenic acid are required by a few groups. All vertebrates, including man, require dietary sources of vitamins A, D, B_1, B_2, B_6, and pantothenic acid; some vertebrates, particularly the more highly evolved ones, have additional requirements for other vitamins. The inability of man and a few other primates to synthesize vitamin C, however, may be a genetic disease (*i.e.,* an inborn error of metabolism), rather than the result of a true evolutionary process. For more details on the evolution of primitive forms, see LIFE.

METHODS USED IN VITAMIN RESEARCH

Determination of vitamin requirements. If a specific factor in food is suspected of being essential for the growth of an organism (either by growth failure or some other clinical symptoms that are alleviated by adding a specific food to the diet) a systematic series of procedures (described below) is used to characterize the factor.

The active factor (or principle) is isolated from specific foods and purified; then its chemical structure is determined, and it is synthesized in the laboratory. Structural determination and synthesis, which may be achieved only after long and intensive research, must be completed before the function and the quantitative requirements of the factor can be established accurately. Established organic and analytical chemical procedures are used to determine the structure of the factor and to synthesize it.

Biological studies may be performed to determine functions, effects of deprivation, and quantitative requirements of the factor in various organisms. The development in an organism of a deficiency either by dietary deprivation of the vitamin or by administration of a specific antagonist or antivitamin often is the method used. The obvious effects (*e.g.,* night blindness, anemia, dermatitis) of the deficiency are noted. Less obvious effects may be discovered after microscopic examination of tissue and bone structures. Changes in concentrations of metabolites or in enzymatic activity in tissues, blood, or excretory products are examined by numerous biochemical techniques (including the use of radioisotopes). The response of an animal to a specific vitamin of which it has been deprived usually confirms the deficiency symptoms for that vitamin. Effects of deprivation of a vitamin sometimes indicate its general physiological function, as well as its function at the cellular level. Biochemical function often is studied by observing the response of tissue enzymes (removed from a deficient host animal) after a purified vitamin preparation is added. The functions of most of the known vitamins have been reasonably well defined; however, the mechanism of action has not yet been established for some of them (*e.g.,* vitamins A, E, C.)

The procedure for determining the amount of a vitamin required by an organism is less difficult for microorganisms than for higher forms; in microorganisms, the aim is to establish the smallest amount of a vitamin that produces maximal growth (*i.e.,* maximal rate of multiplication) of the organisms when it is added to the culture medium. Among vertebrates, particularly man, a number of procedures are used together to provide estimates of the vitamin requirement. These procedures include determinations of: the amount of a vitamin required to cure a deficiency that has been developed under controlled, standard conditions; the smallest amount required to prevent the appearance of clinical or biochemical symptoms of the deficiency; the amount required to saturate body tissues (*i.e.,* to cause "spillover" of the vitamin in the urine; valid only with the water-soluble vitamins); the amount necessary to produce maximum blood levels of the vitamin plus some tissue storage (applicable only to the fat-soluble vitamins, particularly vitamin A); the amount required to produce maximum activity of an enzyme system if the vitamin has a coenzyme function; the actual rate of utilization, and hence the requirement, in healthy individuals (as indicated by measuring the excreted breakdown products of radioisotope-labelled vitamins).

Comparisons of intake in human populations

The above procedures are practical only with small groups of animals or human subjects and thus are not entirely representative of larger populations of a particular species. A less precise (but more representative) method

used among human populations involves comparing levels of dietary intake of a vitamin in a population that shows no deficiency symptoms with levels of intake of the vitamin in a population that reveals clinical or biochemical symptoms. The data for dietary intakes and incidence of deficiency symptoms are obtained by surveys of representative segments of a population.

Determination of vitamin sources. A quantitative analysis of the vitamin content of foodstuffs is important in order to identify dietary sources of specific vitamins (and other nutrients as well). Three methods commonly used to determine vitamin content are described below.

Physicochemical methods. The amount of vitamin in a foodstuff can be established by studying the physical or chemical characteristics of the vitamin; *e.g.,* a chemically reactive group on the vitamin molecule, fluorescence (for thiamin, riboflavin, vitamin A), absorption of light at a wavelength characteristic of the vitamin (for most vitamins), radioisotope dilution techniques (for vitamin B_{12}). These methods are accurate and can detect very small amounts of the vitamin. Biologically inactive derivatives of several vitamins have been found, however, and may interfere with such determinations; in addition, these procedures also may not distinguish between bound (*i.e.,* unavailable) and available forms of a vitamin in a food.

Microbiological assay. Microbiological assay is applicable only to the B vitamins. The rate of growth of a species of microorganism that requires a vitamin is measured in growth media that contain various known quantities of a foodstuff preparation containing unknown amounts of the vitamin. The response (measured as rate of growth) to the unknown amounts of vitamin is compared with that obtained from a known quantity of the pure vitamin. Depending on the way in which the food sample was prepared, the procedure may indicate the availability of the vitamin in the food sample to the microorganism.

Animal assay. All of the vitamins, with the exception of vitamin B_{12}, can be estimated by the animal-assay technique. One advantage of this method is that animals respond only to the biologically active forms of the vitamins. On the other hand, many other interfering and complicating factors may arise; therefore, experiments must be rigidly standardized and controlled. Simultaneous estimates usually are made using a pure standard vitamin preparation (as a reference) and the unknown food (whose vitamin content is being sought); each test is repeated using two or more different amounts of both standard and unknown in the assays listed below (*i.e.,* growth, reaction time, graded response, all-or-none).

Types of animal assays

In a growth assay, the rat, chick, dog (used specifically for niacin), and guinea pig (used specifically for vitamin C) usually are used. One criterion used in a vitamin assay is increase in body weight in response to different amounts of a specific vitamin in the diet. There are two types of growth assay. In a prophylactic growth assay, the increase in weight of young animals given different amounts of the vitamin is measured. In a curative growth assay, weight increase is measured in animals first deprived of a vitamin and then given various quantities of it. The curative growth assay tends to provide more consistent results than the prophylactic technique.

In a reaction time assay, an animal is first deprived of a vitamin until a specific deficiency symptom appears; then the animal is given a known amount of a food extract containing the vitamin, and the deficiency symptom disappears within a day or two. The time required for the reappearance of the specific symptoms when the animal again is deprived of the vitamin provides a measure of the amount of vitamin given originally. The graded response assay, which may be prophylactic or curative, depends on a characteristic response that varies in degree with the vitamin dosage. An example of the use of this technique is an assay for vitamin D in which the measured ash content of a leg bone of a rat or chick is used to reflect the amount of bone calcification that occurred as a result of administration of a specific amount of vitamin D. In an all-or-none assay, the degree of response cannot be measured; an arbitrary level is selected to separate positive responses from negative ones. The percent of positively reacting animals provides a measure of response; *i.e.,* vitamin E can be measured by obtaining the percent of fertility in successfully mated female rats.

Biochemistry of the water-soluble vitamins

BASIC PROPERTIES

Although the vitamins included in this classification are all water-soluble, the degree to which they dissolve in water is variable. This property influences the route of absorption, their excretion, and their degree of tissue storage and distinguishes them from fat-soluble vitamins, which are handled and stored differently by the body. The water-soluble vitamins (excluding vitamin C) popularly are termed the B-vitamins; these include B_1 (thiamine), B_2 (riboflavin), B_6 (pyridoxine), niacin (nicotinic acid), B_{12} (cyanocobalamin), folic acid, pantothenic acid, and biotin. These relatively simple molecules contain the elements carbon, hydrogen, and oxygen; some also contain nitrogen, sulfur, or cobalt.

The water-soluble vitamins, inactive in their so-called free states, must be activated to their coenzyme forms (see Table 14); addition of phosphate groups occurs in the activation of vitamins B_1, B_2, and B_6; a shift in structure activates biotin, and formation of a complex between the free vitamin and parts of other molecules is involved in the activation of nicotinic acid, pantothenic acid, folic acid, and vitamin B_{12}. After an active coenzyme is formed, it must combine with the proper protein component (called an apoenzyme) before enzyme-catalyzed reactions can occur. Vitamin antagonists (or antimetabolites) function by: (1) preventing coenzyme formation, (2) competing with the vitamin coenzyme for a site on the protein portion of the enzyme, (3) competing with a compound (whose transformation is catalyzed by the enzyme) for the active centre on the enzyme, or (4) inactivating an already formed coenzyme.

Activation

Table 14: The Water-Soluble Vitamins

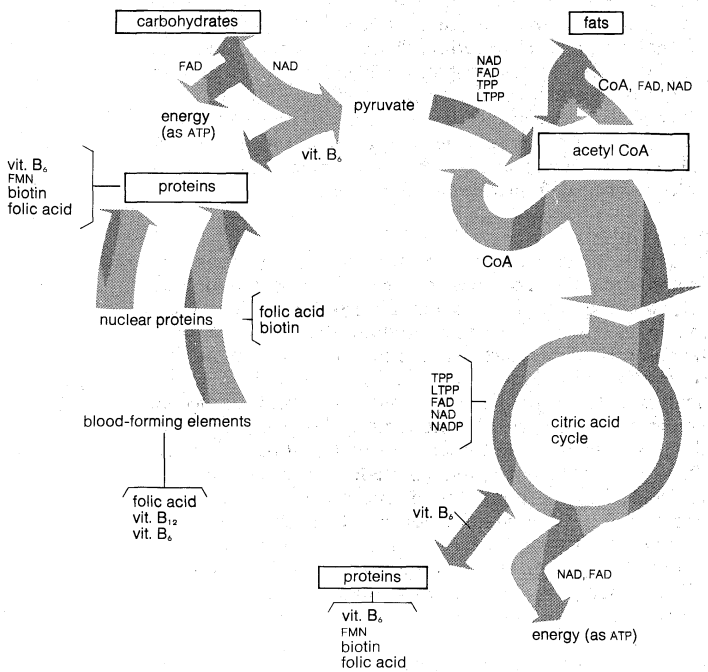
free form*	coenzyme form
Thiamine (vitamin B_1)	thiamine pyrophosphate (TPP) or cocarboxylase
	lipothiamide pyrophosphate (LTPP)
Riboflavin (vitamin B_2)	flavin mononucleotide (FMN)
	flavin–adenine dinucleotide (FAD)
Pyridoxine or pyridoxol† (vitamin B_6)	pyridoxal phosphate or codecarboxylase
also: Pyridoxal	
Pyridoxamine	
Nicotinic acid† (niacin, vitamin PP)	nicotinamide–adenine dinucleotide (NAD)
also: Nicotinamide (niacinamide)	nicotinamide–adenine dinucleotide phosphate (NADP)
Cyanocobalamin† (vitamin B_{12})	several cobamide coenzymes
also: Aquocobalamin (vitamin B_{12}^a)	
Hydroxocobalamin (vitamin B_{12}^b)	
Nitrotocobalamin (vitamin B_{12}^c)	
Pteroylglutamic acid (folic acid) (folic acid is now a general term for the family of pteroic acids and their salts)	tetrahydropteroylglutamic acid
Pantothenic acid	coenzyme A
Biotin	1′–N–carboxybiotin
Ascorbic acid (vitamin C)	none yet established

*The names of the free forms of the first six vitamins are those approved thus far by the IUPAC-IUB Commission of Nomenclature of Biological Compounds. Terms given in parentheses after the approved forms are older or "popular" terms. †Considered to be the basic or standard vitamin form. Those following also have vitamin activity.

FUNCTIONS

The B-vitamin coenzymes function in enzyme systems that transfer certain groups between molecules (see Figure 14); as a result, specific proteins, fats, and carbohydrates are formed and may be utilized to produce body tissues (including blood cells) or to store or release energy. The pantothenic acid coenzyme functions in the Krebs tricarboxylic acid (or citric acid) cycle, which interconnects carbohydrate, fat, and protein metabolism; this coenzyme (coenzyme A) acts at the hub of these reactions and thus is an important molecule in controlling the interconversion of fats, proteins, and carbohydrates and their conversion into metabolic energy. Thiamine (B_1) and pyridoxine (B_6) coenzymes control the conversion of carbohydrates and

proteins respectively into metabolic energy during the citric acid cycle. Nicotinic acid (niacin) and riboflavin (B_2) coenzymes facilitate the transfer of hydrogen ions or electrons (negatively charged particles), which occurs during the reactions of the citric acid cycle. All of these coenzymes also function in transfer reactions that are involved in the synthesis of structural compounds; these reactions are not part of the citric acid cycle (see Figure 14).



CoA—coenzyme A
FAD—flavine adenine dinucleotide
FMN—flavine mononucleotide
LTPP—lipothiamide pyrophosphate
NAD—nicotinamide-adenine dinucleotide
NADP—nicotinamide-adenine dinucleotide phosphate
TPP—thiamine pyrophosphate

Figure 14: Functions of B vitamin coenzymes in metabolism.

Although vitamin C (ascorbic acid) participates in some enzyme-catalyzed reactions, it has not yet been established that the vitamin is a coenzyme. Its function probably is related to its properties as a strong reducing agent (*i.e.*, it readily gives electrons to other molecules).

METABOLISM

The water-soluble vitamins are absorbed in the animal intestine, pass directly to the blood, and are carried to the tissues in which they will be utilized. Vitamin B_{12} requires a substance known as "intrinsic factor for absorption.

Utilization

Some of the B vitamins can occur in forms that cannot be used by an animal. Most of the nicotinic acid in some cereal grains (wheat, corn, rice, barley, bran), for example, is bound to another substance, and the complex is called niacytin; this compound is not absorbed in the animal intestine. Biotin can be bound by avidin, which is found in raw egg white; this complex cannot be absorbed or broken down by digestive-tract enzymes, and thus the biotin cannot be utilized. In animal products (*e.g.*, meat), biotin, vitamin B_6, and folic acid are bound to other molecules to form complexes or conjugated molecules; although none is active in the complex form, the three vitamins normally are released from the bound forms by the enzymes of the intestinal tract (for biotin and vitamin B_6) or in the tissues (for folic acid) and thus can be utilized. The B vitamins are distributed in most metabolizing tissues of plants and animals.

Water-soluble vitamins usually are excreted in the urine of man. Thiamine (B_1), riboflavin (B_2), pyridoxine (B_6), ascorbic acid (C), pantothenic acid, and biotin appear in urine as free vitamins (rather than as coenzymes); however, little free nicotinic acid is excreted in the urine. Products (also called metabolites) that are formed during the metabolism of thiamine, nicotinic acid, and pyridoxine also appear in the urine. Urinary metabolites of biotin, riboflavin, and pantothenic acid also are formed, although they have not yet been characterized. Excretion of these vitamins (or their metabolites) is low when intake is just sufficient for proper body function. If intake begins to exceed minimal requirements, excess vitamins are stored in the tissues. Tissue storage capacity is limited, however, and, as the tissues become saturated, the rate of excretion increases sharply. This knowledge is valuable in establishing the nutritional status of an individual with respect to the vitamins. Unlike the other water-soluble vitamins, however, vitamin B_{12} is excreted solely in the feces. Some folic acid and biotin also are normally excreted in this way. Although fecal excretion of water-soluble vitamins (other than vitamin B_{12}, folic acid, and biotin) occurs, their source probably is the intestinal bacteria (which synthesize the vitamins), rather than vitamins that have been eaten and utilized by an animal.

Toxicity

The water-soluble vitamins generally are not considered toxic if taken in excessive amounts. There is, however, one exception in man; large amounts (50–100 milligrams) of nicotinic acid produce dilation of blood vessels; in larger amounts, the effects are more serious and may result in impaired liver function. Thiamine given to animals in amounts 100 times the requirement (*i.e.*, about 100 milligrams) can cause death from respiratory failure. Therapeutic doses (100–500 milligrams) of thiamine have no known toxic effects in man (except rare instances of anaphylactic shock in sensitive individuals). There is no known toxicity for any other B vitamins.

Biochemistry of fat-soluble vitamin groups

The four fat (lipid) soluble vitamin groups are A, D, E, and K; they are related structurally in that all have as a basic structural unit of the molecule a five-carbon isoprene segment, which is

$$-CH=CH-\overset{\overset{CH_3}{|}}{C}=CH-$$

Each of the lipid-soluble vitamin groups contains several related compounds that have biological activity. The active forms and the accepted nomenclature of individual vitamins in each vitamin group are given in Table 15. The potency of the active forms in each vitamin group varies, and not all of the active forms now known are available from dietary sources; *i.e.*, some are produced synthetically.

Table 15: Lipid-Soluble Vitamins: Active Forms of Biological Importance

vitamin*	provitamin
Vitamin A group	
Retinol (vitamin A alcohol)	Alpha- and beta-carotene, cryptoxanthin
Retinal (vitamin A aldehyde, retinene)	
Retinyl ester (vitamin A ester)	
Retinoic acid (vitamin A acid)	
Vitamin D group	
Ergocalciferol (vitamin D_2, calciferol)	Ergosterol
Cholecalciferol (vitamin D_3)	7-dehydrocholesterol
Vitamin E group	
Alpha-tocopherol (vitamin E)	
Beta-tocopherol	
Gamma-tocopherol	
Delta-tocopherol	
Beta-tocotrienol (epsilon-tocopherol)	
Tocochromanol-3 (zeta-tocopherol)	
Plastochromanol-3 (eta-tocopherol)	
Vitamin K group	
Phylloquinone or Phylloquinone K (vitamin K_1 [20])†	
Menaquinone-4‡ or Menaquinone K_4 (vitamin K_2 [20])	
Menaquinone-6 or Menaquinone K_6 (vitamin K_2 [30])	
Menaquinone (vitamin K_3, menadione)	
also: vitamins K_4, K_5, K_6, K_7	

*Names of specific vitamins given are approved by the IUPAC-IUB Commission of Nomenclature of Biological Compounds. Terms given in parentheses after the approved forms are older or "popular" terms. Since there is disagreement as to which name is more appropriate; alternate names are included. †Number in brackets indicates total number of carbon atoms in side chain. ‡Number refers to number of isoprenoid units in side chain.

The characteristics of each lipid-soluble vitamin group are discussed below.

PRINCIPAL CHARACTERISTICS

Active forms of biological importance. *Vitamin A group.* Ten carotenes, coloured molecules synthesized only in plants, show vitamin A activity (*i.e.*, function like vitamin A); however, only the alpha- and beta-carotenes and cryptoxanthin are important to man, and beta-carotene is the most active. Retinol (vitamin A alcohol) is considered the primary active form of the vitamin, although retinal, or vitamin A aldehyde, is the form involved in the visual process in the retina of the eye. A metabolite of retinol with high biological activity may be an even more direct active form than retinol. The ester form of retinol is the storage form of vitamin A; presumably, it must be converted to retinol before it is utilized. Retinoic acid is a short-lived product of retinol; only retinoic acid of the vitamin A group is not supplied by the diet.

Retinol

Vitamin D group. Although about 10 compounds have vitamin D activity, the two most important ones are vitamins D_2 (or ergocalciferol) and D_3 (or cholecalciferol). Vitamin D_3 represents the dietary source, while vitamin D_2 occurs in yeasts and fungi. Both can be formed from their respective provitamins by ultraviolet irradiation; in man and other animals the provitamin (7-dehydrocholesterol), which is found in skin, can be converted by sunlight to vitamin D_3 and thus is an important source of the vitamin. Both vitamins D_2 and D_3 can be utilized by the rat and man; however, chicks cannot use vitamin D_2 effectively. The form of the vitamin probably active in man is 1, 25-di-hydroxycholecalciferol.

Vitamin E group. The tocopherols are a closely related group of biologically active compounds that vary only in number and position of methyl (*i.e.*, $-CH_3$) groups in the molecule; however, these structural differences influence the biological activity of the various molecules. The active tocopherols are named in order of their potency; *i.e.*, alpha-tocopherol is the most active. Some metabolites of alpha-tocopherol (*e.g.*, alpha-tocopherolquinone, alphatocopheronolactone) have activity in some mammals (*e.g.*, rats, rabbits); however, these metabolites do not support all the functions attributed to vitamin E.

Vitamin K group. Vitamin K_1 (20) is synthesized by plants; the members of the vitamin K_2 (30) series are of microbial origin. Vitamin K_2 (20) is the important form in mammalian tissue; all other forms are converted to K_2 (20) from vitamin K_3. Since vitamin K_3 does not accumulate in tissue, it does not furnish any dietary vitamin K. Vitamins K_4, K_5, K_6, and K_7 have been synthesized and have vitamin K activity, but they are not found in nature.

International Unit

Units of activity. For many years, the unit of measurement for the activity of vitamins A, D, and E has been the International Unit (IU); this is analogous with the United States Pharmocopeia unit (USP), which is based on a measured biological activity. The weight equivalents of these vitamins are found in Table 16.

Table 16: Weight Equivalents of International Units of Vitamins A, D, and E

vitamin	IU	weight equivalents
Vitamin A	1 IU of all-trans retinol	0.300 micrograms
	1 IU of all-trans retinyl acetate	0.344 micrograms
	1 IU of beta-carotene	0.600 micrograms
Vitamin D	1 IU of pure crystalline vitamin D_3	0.025 micrograms
Vitamin E	1 IU of synthetic *dl*-alpha-tocopherol acetate	1 milligram
	1.1 IU of *dl*-alpha-tocopherol	1 milligram
	1.36 IU of the natural form *d*-alpha-tocopherol acetate	1 milligram

Vitamin K activity is expressed only in micrograms. The activity of fat-soluble vitamins now is given on a weight basis (as is that of water-soluble vitamins) because pure vitamin preparations are available for use as references.

FUNCTIONS

The vitamin A group has at least one known function. In the retina of the eye, retinal is combined with a protein called opsin; the complex molecules formed as a result of this combination and known as rhodopsin (or visual purple) are involved in dark vision. Other metabolic functions of vitamin A have not yet been defined with certainty. The vitamin D group is required for growth (especially bone growth or calcification). The vitamin E group also is necessary for normal animal growth; without these tocopherols, animals are not fertile and develop abnormalities of the central nervous system, muscles, and organs (especially the liver). The vitamin K group is required for normal metabolism, including the conversion of food into cellular energy in certain biological membranes; vitamin K also is necessary for the proper clotting of blood.

Knowledge concerning the functions of the fat-soluble vitamins is not yet so extensive as that for the water-soluble ones. It appears, however, that most vitamins may be concerned with proper enzyme function.

METABOLISM

The fat-soluble vitamins are transported primarily by lymph from the intestines to the circulating blood. Bile salts are required for efficient absorption of fat-soluble metabolites in the intestine; anything that interferes with fat absorption, therefore, also inhibits absorption of the fat-soluble vitamins. Since a fatty acid (preferentially palmitic acid) is added to the vitamin A alcohol (retinol) molecule before it is transported by the lymph, this ester form predominates in the bloodstream during digestion. Vitamins D, E, and K do not require the addition of a fatty acid molecule for absorption. Small amounts of vitamin A alcohol (and possibly vitamin K) may be absorbed directly into the bloodstream; however, both vitamins A and D are bound to a protein during transport in the bloodstream.

Larger quantities of the fat-soluble vitamins than of water-soluble ones can be stored in the body. Vitamins A, D, and K are stored chiefly in the liver, with smaller amounts stored in other soft body tissues; however, most of the stored vitamin E is found in body fat, although large amounts also occur in the uterus of females and testis of males. The various forms of vitamin E are stored in tissues in different amounts; alpha-tocopherol is stored in higher concentrations than are the other forms. More vitamin A is stored (in ester form) than any other fat-soluble vitamin. Before its release in the bloodstream, the ester form of vitamin A is converted to retinol. In animals in the postabsorptive stage, retinol is the predominant form in the blood.

Excessive intakes of both vitamins A and D may produce toxicity (or hypervitaminosis A or D). Among natural foods, only seal liver and polar bear liver are known to contain sufficiently high concentrations of vitamin A to produce toxic effects. Toxicity of both vitamin A and vitamin D can easily occur, however, if pharmaceutical vitamin preparations are used in excess.

Toxic levels of vitamin A exceed the normal requirement by 100 times; *i.e.*, about 500,000 IU each day for a period of several months. Toxicity in infants may occur with doses of 18,000 to 60,000 IU per day. Excessive doses of the natural vitamins K_1 and K_2 have no obvious effects except that resistance may develop to therapy with dicumarol compounds (anticoagulants); however, vitamin K_3 is toxic to newborn infants if given in large doses. Vitamin E, even if given in large excess of the normal requirement, has no apparent obvious adverse effects.

Vitamin groups E and K belong to a class of organic compounds called quinones. These substances are changed to sugar-like substances known as alpha-lactones, which are excreted in the urine (probably as carbohydrates called glucuronides). Some vitamin K_1 also is excreted in the bile and thus appears in the feces. Vitamin A is broken down and excreted as a glucuronide and a number of compounds in bile (and, therefore, feces) and urine. Vitamin D and its breakdown products are excreted only in the feces.

Vitamin-like substances

There are a number of organic compounds that, although related to the vitamins in activity, cannot be defined as

true vitamins; normally they can be synthesized by man in adequate amounts and therefore are not required in the diet. These substances usually are classified with the B vitamins, however, because of similarities in biological function or distribution in foods.

Choline. Choline appears to be an essential nutrient for a number of animals (including some birds) and microorganisms that cannot synthesize adequate quantities to satisfy their requirements.

Importance of choline

Choline is a constituent of an important class of lipids called phospholipids, which form structural elements of cell membranes; choline is a component of the acetylcholine molecule, which is important in nerve function. Choline also serves as a source of methyl groups ($-CH_3$ groups) that are required in various metabolic processes. The effects of a dietary deficiency of choline itself can be alleviated by other dietary compounds that can be changed into choline. Choline also functions in the transport of fats from the liver; for this reason, choline may be called a lipotropic factor. A deficiency of choline in the rat results in an accumulation of fat in the liver. Choline deficiency symptoms vary among species; it is not yet known if choline is an essential nutrient for man since a dietary deficiency has not been demonstrated.

Myoinositol. The biological significance of myoinositol (also previously known as meso-inositol) has not yet been established with certainty. It is present in large amounts (principally as a constituent of phospholipids) in man. Inositol is a carbohydrate that closely resembles glucose in structure; inositol can be converted to phytic acid, which is found in grains and forms an insoluble (and thus unabsorbable) calcium salt in the intestines of mammals. Inositol has not yet been established as an essential nutrient for man; however, it is a required factor for the growth of some yeasts and fungi.

Para-aminobenzoic acid. Para-aminobenzoic acid (abbreviated to PABA) is required for the growth of several types of microorganisms; however, a dietary requirement by vertebrates has not yet been shown. The sulfa drug (sulfanilamide) can kill bacteria because it competes with PABA for a position in a coenzyme that is necessary for bacterial reproduction. Although a structural unit of folic acid, PABA is not considered a vitamin.

Carnitine. Carnitine (originally called vitamin B_T) is essential for the growth of mealworms. The role of carnitine in all organisms is associated with the transfer of fatty substances (*e.g.,* fatty acids) from the bloodstream to active sites of fatty acid oxidation within muscle cells. Carnitine, therefore, regulates the rate of oxidation of these acids; this function may afford means by which a cell can rapidly shift its metabolic patterns (*e.g.,* from fat synthesis to fat breakdown). Synthesis of carnitine occurs in insects and in higher animals; therefore, it probably should not be considered a true vitamin.

Role of carnitine

Lipoic acid. Lipoic acid has a coenzyme function similar to that of thiamine. Although it is apparently an essential nutrient for some microorganisms, no deficiency in mammals has yet been observed; therefore, lipoic acid is not considered a true vitamin.

Bioflavinoids. The bioflavinoids once were thought to prevent scurvy and were designated as vitamin Pc, but additional evidence refuted this claim. (M.J.B./Ed.)

HORMONES

Hormones are organic substances that are secreted by plants and animals and that function in the regulation of physiological activities and in maintaining homeostasis. They carry out their functions by evoking responses from specific organs or tissues that are adapted to react to minute quantities of them. The classical view of hormones is that they are transmitted to their targets in the bloodstream after discharge from the glands that secrete them. This mode of discharge (directly into the bloodstream) is called endocrine secretion. The meaning of the term hormone has been extended beyond the original definition of a blood-borne secretion, however, to include similar regulatory substances that are distributed by diffusion across cell membranes instead of by a blood system.

General features

RELATIONSHIPS BETWEEN ENDOCRINE AND NEURAL REGULATION

Hormonal regulation is closely related to that exerted by the nervous system, and the two processes have generally been distinguished by the rate at which each causes effects, the duration of these effects, and their extent; *i.e.*, the effects of endocrine regulation may be slow to develop but prolonged in influence and widely distributed through the body, whereas nervous regulation is typically concerned with quick responses that are of brief duration and localized in their effects. Advances in knowledge, however, have modified these distinctions.

Neurohormones

Nerve cells are secretory, for responses to the nerve impulses that they propagate depend upon the production of chemical transmitter substances, or neurohumors, such as acetylcholine and noradrenaline (norepinephrine), which are liberated at nerve endings in minute amounts and have only a momentary action. It now has been established, however, that certain specialized nerve cells, called neurosecretory cells, can translate neural signals into chemical stimuli by producing secretions called neurohormones. These secretions, which are often polypeptides (compounds similar to proteins but composed of fewer amino acids), pass along nerve-cell extensions, or axons, and are typically released into the bloodstream at special regions called neurohemal organs, where the axon endings

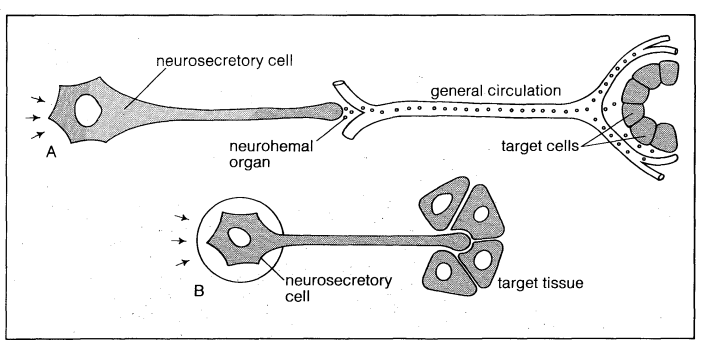


Figure 15: *The release of neurohormones from neurosecretory nerve cells.*
(A) Nerve signals (arrows) are translated into neurohormones, which enter the circulation at the neurohemal organ, reaching target cells via the bloodstream. (B) Release of neurohormone close to target cells without intervention of bloodstream.

are in close contact with blood capillaries (Figure 15A). Once released in this way, neurohormones function in principle similar to hormones that are transmitted in the bloodstream and are synthesized in the endocrine glands.

The distinctions between neural and endocrine regulation, no longer as clear-cut as they once seemed to be, are further weakened by the fact that neurosecretory nerve endings are sometimes so close to their target cells that vascular transmission is not necessary (Figure 15B). There is good evidence that hormonal regulation occurs by diffusion in plants and (although here the evidence is largely indirect) in lower animals (*e.g.,* coelenterates), which lack a vascular system.

THE EVOLUTION OF HORMONES

Hormones have a long evolutionary history, knowledge of which is important if their properties and functions are to be understood. Many important features of the vertebrate endocrine system, for example, are present in the lampreys and hagfishes, modern representatives of the primitively jawless vertebrates (Agnatha), and these features were presumably present in fossil ancestors that lived more than 500,000,000 years ago. The evolution of the

endocrine system in the more advanced vertebrates with jaws (Gnathostomata) has involved both the appearance of new hormones and the further evolution of some of those already present in agnathans; in addition, extensive specialization of target organs has occurred to permit new patterns of response.

ole in
hemical
egulation

The factors involved in the first appearance of the various hormones is largely a matter for conjecture, although hormones clearly are only one mechanism for chemical regulation, diverse forms of which are found in living things at all stages of development. Other mechanisms for chemical regulation include chemical substances (so-called organizer substances) that regulate early embryonic development and the pheromones that are released by social insects as sex attractants and regulators of the social organization. Perhaps, in some instances, chemical regulators including hormones appeared first as metabolic by-products. A few such substances are known in physiological regulation: carbon dioxide, for example, is involved in the regulation of the respiratory activity of which it is a product, in insects as well as in vertebrates. Substances such as carbon dioxide are called parahormones to distinguish them from true hormones, which are specialized secretions.

The hormones of vertebrates

HORMONES OF THE PITUITARY GLAND

The pituitary gland, or hypophysis (Figure 16), which dominates the vertebrate endocrine system, is formed of two distinct components. One is the neurohypophysis,

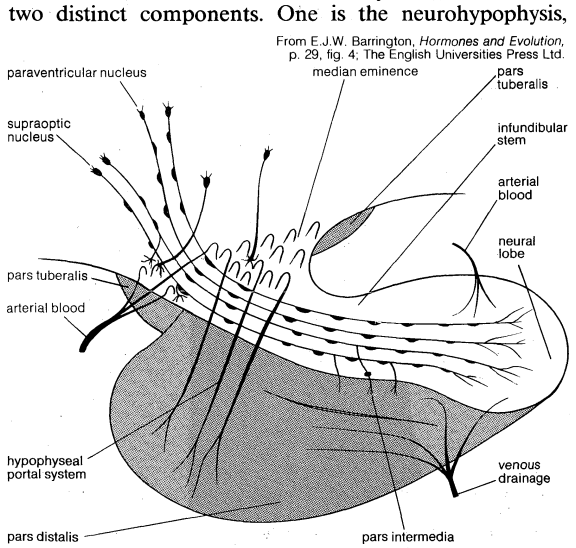

Figure 16: Elements in a generalized mammalian pituitary gland.

which forms as a downgrowth of the floor of the brain and gives rise to the median eminence and the neural lobe; these structures are neurohemal organs. The other is the adenohypophysis, which develops as an upgrowth from the buccal cavity (mouth region) and usually includes two glandular portions, the pars distalis and the pars intermedia, which secrete a number of hormones. The hormones secreted by the adenohypophysis are protein or polypeptide in nature and vary in complexity; as a result, their chemical constitution has not always been as fully characterized as has that of structurally simpler molecules of some other endocrine secretions. Functional analysis of these hormones also is difficult, for the targets of certain hormones of the adenohypophysis, called tropic, or trophic, hormones, are other endocrine glands. The action of such tropic hormones can be understood only in the light of the mode of function of the endocrine glands they regulate.

Adenohypophysis. *Growth hormone (somatotropin; STH).* Growth hormone is a protein, the primary structure of which has been fully established for the human and bovine forms of the hormone. It is probably universally distributed in gnathostomes (vertebrates with jaws), in which it is essential for the maintenance of growth, but its presence in agnathans (jawless vertebrates) has not yet been established with certainty. The physical and chemical properties of growth hormone (Table 17), which differ from species to species, are associated with marked differences in biological activity. Only part of the molecule, however, is actually responsible for its biological activity, for up to 25 percent of it can be lost without causing any decline in potency. Man responds to growth hormones obtained from other primates, but the rat responds to those from a wide range of species. Even more striking, growth of teleost (bony) fishes, which stops if the pituitary gland is removed, can be restarted by treatment with mammalian growth hormone; on the other hand, preparations of pituitary glands from these fishes have no effect on the growth of mammals. The growth hormones of lungfishes, which are closely related to the terrestrial vertebrates, and of sturgeons, which are primitive members of the evolutionary line that led to bony fishes, affect mammalian growth, perhaps because these hormones have a more generalized molecular structure.

Table 17: Some Physicochemical Properties of Growth Hormones of Mammals

	human	monkey	bovine	sheep	pig	whale
Molecular weight	21,500	23,000	45,000	47,800	41,600	39,900

Effects of growth hormone

Growth is such a complex process that definition of the growth hormone's mode of action is difficult. One of its known effects is an increase in the rate of protein synthesis, which is to be expected, since growth involves the deposition of new protein material. In addition, growth hormone affects the metabolism of certain ions (including sodium, potassium, and calcium), promotes the release of fats from fat stores, and influences carbohydrate metabolism in ways that tend to cause an increase in the level of glucose in the bloodstream. The last action creates a demand for an increased output of insulin (a hormone secreted by the pancreas), which acts to return the blood-glucose level to normal. Prolonged treatment of dogs with growth hormone can overstrain the pancreatic tissue in which insulin is synthesized and bring about a diabetic condition, in which insulin is formed in inadequate quantities. It is unlikely, however, that this is a factor in establishing diabetes mellitus in man. Excess secretion of growth hormone does, however, have damaging effects in man, for it produces overgrowth of the skeleton. If this occurs in youth, before the closure of the epiphyses (ends) of the long bones, it results in gigantism. If it occurs afterward, it causes acromegaly, in which the disturbance is more serious, with enlargement of the bones and soft tissues, and consequent distortion of the skull.

Prolactin. Prolactin is a protein hormone that in sheep has a molecular weight of about 23,000 (based on a molecular weight for hydrogen of one). It is doubtful that it is present in agnathans, but it is widely distributed in jawed vertebrates. In female mammals, prolactin initiates and maintains the secretion of milk, the mammary glands having been previously prepared for this function by the action of other hormones. In the female rat prolactin also maintains the secretion of the hormone progesterone, which is formed by the corpus luteum, an endocrine gland of the ovary; *i.e.*, prolactin, termed luteotropin in the rat, is a gonadotropin (see below *Hormones of the reproductive system*) in this animal, because its target is an endocrine gland. Evidence is accumulating that the molecular structures of prolactin and growth hormone are similar. This explains why they show some overlap in biological properties; in particular, administration of prolactin promotes some growth in many terrestrial vertebrates. Human growth hormone has prolactin-like luteotropic properties, and it is not yet certain that man actually has a distinct prolactin hormone.

Prolactin itself shows remarkable variety in biological action from one vertebrate group to another. It promotes the production of so-called crop-milk with which pigeons feed their young, and the associated changes in structure and arrangement of the wall of the crop provide a convenient means to assay the hormone. In certain newts (*Triturus* species) prolactin induces the change of behaviour that drives young animals into the water (water-drive action). In bony fishes, prolactin is concerned with the regulation of the level of sodium in blood plasma; it therefore is essential in some teleost species (*e.g., Poecilia lattipinna*) for the maintenance of life in fresh water. Although other teleosts (*e.g.,* eels) can survive in fresh water after hypophysectomy, this means only that prolactin is but one factor in a complex regulatory mechanism involving several factors. Mammalian prolactin can regulate sodium metabolism when given to eels and can maintain the life of hypophysectomized *Poecilia.* Yet, although other convincing evidence suggests that the hormone must be present in the pituitaries of these teleosts, preparations of their glands tested on pigeons do not have a typical crop-stimulating action. This evidence is best accounted for by supposing that the prolactin molecule has undergone evolutionary changes in its molecular structure and biological properties and has also established specific adaptive relationships with target organs such as the crop and mammary glands.

Adrenocorticotropic hormone (ACTH; corticotropin). ACTH is present in all jawed vertebrates but has not yet been decisively demonstrated in agnathans. It regulates the activity of part of the outer region (cortex) of the adrenal glands (considered below under *Hormones of the adrenal glands*). In mammals its action on the adrenal cortex is limited to areas called the zona reticularis and zona fasciculata, in which important steroid hormones (*e.g.,* cortisol and corticosterone, known as glucocorticoids) are formed; ACTH does not affect the synthesis of the mineralocorticoid hormone aldosterone, which takes place chiefly in the outer cortical region (zona glomerulosa). Evidence strongly suggests that the action of ACTH is mediated by a substance known as CAMP (cyclic 3′,5′-adenosine monophosphate), the rate of synthesis of which increases in adrenal tissue in the presence of ACTH; CAMP in turn promotes synthesis of enzymes necessary for the formation of cortisol and corticosterone. The relationship between ACTH and the adrenal cortex is an example of the negative feedback characteristic of endocrine systems; *i.e.,* a decrease in the level of glucocorticoids circulating in the bloodstream evokes an increase in the secretion of ACTH, which, by stimulating the secretory activity of its target gland (the adrenal cortex), tends to restore to normal the level of glucocorticoids in the bloodstream. The release of ACTH can also be influenced by the level of circulating adrenaline, which is not surprising in view of the close functional relationship between the hormones of the adrenal cortex and medulla.

Negative feedback

The ACTH of mammals is a polypeptide molecule consisting of 39 amino acids, only the first 20 of which are required for full activity. This region, often referred to as the active centre, is constant in composition in all mammals studied thus far; the remainder of the molecule varies slightly in amino-acid composition among different species. Since, however, the mammalian hormone is active in all vertebrates, ACTH structure probably varies little from one class to another. The concept that biological activity is localized in an active centre of a complex molecule is applicable to other polypeptide and protein hormones, including growth hormone, whose structure, as noted previously, can be partly lost without causing loss of activity. The concept of an active centre, however, raises the question of the function of the rest of the molecule. It may serve as the site of antigenic properties or of structural features important in establishing relations with specialized receptors in target cells.

Thyrotropin (thyroid-stimulating hormone; TSH). Thyrotropin regulates the thyroid gland through a feedback relationship similar to that for ACTH; thyrotropin increases the secretion of the hormones from the thyroid gland and, if its action is prolonged, evokes increase in cell number (hyperplasia) and increase in size of the gland. One consequence of an overactive thyroid in man is a bulging of the eyes (exophthalmos). The cause of this is obscure, although it has been thought to result from the action of a distinct exophthalmos-producing substance that, while closely associated with thyrotropin, can be chemically separated from it. Thyrotropin, which is probably absent from agnathans, is a glycoprotein; *i.e.,* a protein combined with carbohydrate. Its molecular weight is estimated to be about 26,000 to 30,000 in mammals. Some variability occurs in the degree of response obtained when a hormonal preparation from one species is tested on other species. This suggests, as with prolactin, that it has undergone molecular evolution.

Follicle-stimulating hormone (FSH). FSH is termed a gonadotropin because it is concerned with the regulation of the activity of the gonads, or sex organs, which are endocrine glands as well as the sources of eggs and sperm. FSH stimulates development of the graafian follicle, a small vesicle containing an egg, in the ovary of the female mammal; in the male, it promotes the development of the tubules of the testes and the differentiation of sperm. FSH, like thyrotropin, is a glycoprotein, with an estimated molecular weight (in man) of 41,000 to 43,000. The effects of FSH are discussed further in *Hormones of the reproductive system,* below.

Function of FSH

Luteinizing hormone (LH; interstitial-cell-stimulating hormone; ICSH). Luteinizing hormone is another gonadotropin, a glycoprotein with a molecular weight of 26,000 in man. In the female mammal it promotes the transformation, following release of the egg (ovulation), of the graafian follicle into the corpus luteum, an endocrine gland; its complex functional interrelationship with FSH is dealt with below in *Hormones of the reproductive system.* In the male, luteinizing hormone promotes the development of the interstitial tissue (Leydig cells) of the testes and hence promotes the secretion of the male sex hormone, testosterone. It may be associated with FSH in this function. The interrelationship of LH and FSH has made it difficult to establish with certainty that two separate hormones exist, particularly since both are glycoproteins. Although the existence of two hormones has been established in mammals, the situation in lower vertebrates is not yet certain. All vertebrates undoubtedly have gonadotropic activity in their pituitary glands; but, although FSH-like and LH-like effects are detectable, it is not yet clear that two distinct hormones always exist.

Effects of MSH

An unexpected property of mammalian FSH and LH is that both have a thyrotropic action (*i.e.,* stimulate secretion of thyroid hormones) in lower vertebrates. This so-called heterothyrotropic effect has led to the supposition that FSH, LH, and thyrotropin may have evolved by modification of a common ancestral glycoprotein molecule, resulting in an overlap of properties. Similar examples are pointed out in later sections.

Melanocyte-stimulating hormone (MSH; intermedin). This hormone, secreted by the pars intermedia region of the pituitary gland, regulates colour changes in animals by promoting the concentration of pigment granules in pigment-containing cells (melanocytes, chromatophores) in the skin of lower vertebrates; MSH acts in conjunction with the nervous system in bony fishes and reptiles. No response involving physiological colour change is found in birds and mammals, although the hormone is secreted by them, even in species in which a pars intermedia region is no longer distinguishable in the adenohypophysis. The reason for the presence of MSH in birds and mammals is not clear since the function of the hormone in these animals has not yet been established. MSH is known to influence the behaviour of mammals and the total amount of pigment in their skin, which darkens in man after administration of large doses of the hormone. This type of change, however, which results from a change in the total amount of pigment present, is called a morphological colour change, in contrast to the physiological one that occurs in the skin of lower vertebrates.

As noted above, MSH exists in two forms. α-MSH contains 13 amino acids, which are found in the same sequence in all species studied thus far; β-MSH has 18 amino acids, in sequences that differ in different species. Remarkable are the

ormone									amino acid sequence

Figure 17: Relationships between the structure of melanocyte-stimulating hormones (MSH) and the first 19 amino acids of adrenocorticotropin (ACTH).

Adapted from R.S. Harris, ed., *Vitamins and Hormones* (1961); Academic Press

facts that the 13 amino acids of α-MSH are identical with the first 13 amino acids of ACTH and that both α and β forms of MSH have a heptapeptide (seven-amino-acid) sequence that has some melanocyte-stimulating activity, and that is identical with an amino-acid sequence of ACTH (see Figure 17). This close correspondence in sequence can hardly be coincidental and suggests, as has been postulated above for FSH, LH, and thyrotropin, that ACTH and α- and β-MSH may have differentiated within the adenohypophysis by evolutionary modification of a common ancestral molecule. A change in biological activity results from modifications in the amino-acid composition; β-MSH preparations from the pig and the horse, for example, are five times more effective than those of the ox in evoking pigment dispersion in frogs. MSH molecules do not show ACTH activity, which is dependent on the presence of amino acids that occur in the region of the molecule not found in MSH. On the other hand, ACTH does have a slight effect on pigment dispersion, presumably because its structure contains the heptapeptide sequence mentioned above.

Evidence shows that each of the adenohypophysial hormones is secreted by a specific cell type. The cell types can be differentiated by staining sections of the pituitary gland, and known changes in the output of an individual hormone, induced experimentally or correlated with phases in the life cycle, can be shown to correspond with changes in the appearance of the corresponding cell type.

Regulation of adenohypophysial activity

The regulation of the activity of the secretory cells of the adenohypophysis depends upon its association with the floor of the brain and results from the existence of a neurosecretory system located mainly, perhaps entirely, in the hypothalamic region there. Much remains to be learned about this system, which involves the passage into the adenohypophysis of neurosecretions from the hypothalamus called hypothalamic releasing factors. Chemical characterization of these factors shows them to be simple polypeptides, in which respect they resemble the hypothalamic polypeptide hormones (discussed in the next section). This neurosecretory system is best understood in mammals, in which good evidence has been found for the existence of a separate releasing factor for each hormone secreted by the pars distalis region of the adenohypophysis; a similar arrangement probably exists in other gnathostomes. The situation in agnathans is obscure, but the anatomical organization of the pituitary glands of these animals implies at least some form of chemical communication between the hypothalamus and the pituitary gland.

Chemical communication is achieved by two routes. One route is by the entry of neurosecretory-cell fibres from the hypothalamus into the adenohypophysis, so that the hypothalamic factors, when released, are either in immediate contact with the secretory cells (Figure 15B) or in blood capillaries very closely related to them. This route is characteristic of the pars intermedia region, in which neurosecretory fibres from the hypothalamus control the functioning of the secretory cells. If the pars intermedia is separated from its direct connection with the floor of the brain, for example, MSH secretion in amphibians increases, and prolonged darkening of the skin results. Secretory activity of the pars intermedia cannot then be regulated again until the nerve fibres have regenerated.

Direct innervation similar to that of the pars intermedia is also found in the pars distalis of bony fishes. Here neurosecretory fibres arise from a localized region of the hypothalamus, called the nucleus lateralis tuberis, and end in contact either with the various types of secretory cells or with blood capillaries related to them. The other route of chemical communication to the pars distalis is found in many fishes and in all terrestrial vertebrates; it is a vascular route that depends upon the median eminence, which lies at the front end of the neurohypophysis (see Figure 16). The median eminence is a neurohemal organ containing a capillary bed into which hypothalamic neurosecretory fibres discharge their releasing factors. These are then transmitted through blood vessels known as the hypophysial portal system, into the capillaries of the pars distalis, where each factor influences its specific target cells (compare Figure 15A).

Both hypothalamic neurosecretory routes have the same physiological significance; *i.e.*, they provide chemical communication between the adenohypophysis and the central nervous system, thus making it possible for the latter to regulate the activity of the gland (and also of the endocrine glands its tropic hormones influence) in response to the demands of both the internal and external environments. The hypothalamic neurosecretory system is also involved in the function of the negative-feedback mechanisms that regulate the secretion of the tropic hormones. As already mentioned for ACTH, the secretions of tropic hormones from the adenohypophysis are controlled by bloodstream levels of the hormones secreted by their target glands; the hormones of the target glands may act directly on specific adenohypophysial cells or indirectly by influencing the output of releasing factors from the hypothalamus.

Neurohypophysis and the polypeptide hormones of the hypothalamus. Another neurosecretory system, which involves the hypothalamic region of the brain and the neurohypophysis of the pituitary gland, originates in groups of neurosecretory cells in the hypothalamus called, in mammals, the nucleus supraopticus and the nucleus paraventricularis and, in lower vertebrates, the nucleus preopticus. Neurohormones from these regions pass along the axons of the neurosecretory cells to the neural lobe (see Figure 16) bound to a protein called neurophysin (molecular weight of 20,000 to 25,000). In the neural lobe, which is the neurohemal organ of this neurosecretory system, the hormones separate from neurophysin and are released into the bloodstream.

Effects of hypothalamic polypeptide hormones

In most mammals, the neurohormones are oxytocin and arginine vasopressin. Both have relatively simple and very similar molecular structures; each is composed of nine amino acids arranged as a ring, which is formed by the linkage of two molecules of the amino acid cysteine (a disulfide linkage —S—S—), and a short side chain (Table 18). The two hormones differ in structure only at amino acids numbered 3 and 8. In some species of the family Suidae (pig, peccary, hippopotamus) arginine vasopressin is replaced by lysine vasopressin; in others, both may be present. The difference between the two vasopressin hormones is that one has the amino acid lysine (Lys) at position 8; the other has arginine (Arg). Both the vasopressins and oxytocin show some overlap of activity, which is a consequence of the similarities in their molecular structures. Preparations of the three hormones evoke responses from the mammalian kidney, from the epithelial-cell layer of the frog bladder, and from the smooth muscle in blood vessels, uterus, and milk glands. The slight variation in amino-acid composi-

tion, however, affects the levels of the responses; *i.e.*, the vasopressins differ slightly from each other in response, and oxytocin differs markedly from both. Each, therefore, is said to have a characteristic pharmacological spectrum, and all have some medical use.

The primary actions of oxytocin are the promotion of uterine contraction (of value in obstetrical medicine) and the release of milk during suckling. The stimulation exerted upon the nipples during suckling leads to the transmission of nerve impulses to the hypothalamus. These bring about the discharge of oxytocin, which causes contraction of the smooth muscle of the small ducts of the mammary glands and the release of milk. Although the vasopressins cause an increase in blood pressure in mammals through vasoconstriction (*i.e.*, contraction of blood vessels), this action requires a high concentration of hormone and is probably not a normal physiological effect. The primary action of the vasopressins is on the kidneys; it brings about a reduction in the output of urine. As a result arginine vasopressin is commonly called the antidiuretic hormone (ADH). A lack of this hormone in man results in a copious flow of urine, a condition called diabetes insipidus, which is readily alleviated by preparations containing arginine vasopressin from bovine sources.

The antidiuretic action of vasopressin is thought to depend upon its binding to the outer surface of the kidney tubule, resulting in an increase in the uptake of sodium from the urine into the tubule cells and, concurrently, an increase in the uptake of water. The amount of water, however, is greater than can be accounted for merely by increased diffusion of sodium into tubule cells, suggesting that ADH increases either the number of or the size of pores on the surfaces of the cells. One stimulus that increases the release of vasopressin is a rise in the concentration of certain substances—chloride, for example—in blood plasma. These substances act directly upon the neurosecretory cells, although other receptors may also be involved. Another stimulus is a lowering of plasma volume, which probably acts chiefly through receptors in the vascular system, particularly in the heart and in the carotid blood sinuses. Both conditions necessitate increased retention of fluid; as soon as normal conditions are restored in the bloodstream, the secretion of ADH is reduced by negative feedback.

Origin of hypothalamic hormones

Oxytocin and the vasopressins are members of a series of hormones of which seven members have thus far been fully characterized. The existence of others is suspected (see Table 18). All show the same molecular structure but differ with respect to individual amino acids. The hormones are believed to have been derived from each other by mutations that resulted in one amino-acid substitution at a time; the starting point in the series is arginine vasotocin, which is the only one of the series found in agnathans. Two types of molecule are found in gnathostomes—a result, presumably, of a genetic duplication that established two lines of evolution. One line (basic vasopressor principles) is constituted mainly of arginine vasotocin, which is present in all gnathostomes except mammals; amino-acid substitution in the molecule gave rise to the vasopressins of mammals. The second line (neutral oxytocin-like principles) is represented by oxytocin, isotocin, glumitocin, and mesotocin. Each evolutionary line tends to have characteristic molecules, but the molecular history in the second line is not clear. Oxytocin is thought to exist in some lower gnathostomes, and it is not yet certain whether it or mesotocin is phylogenetically the older molecule.

The functions of the hypothalamic polypeptide hormones in lower vertebrates are not yet clear, except to some extent in amphibians, in which arginine vasotocin evokes the so-called Brunn (water-balance) response; that is, water accumulates within the body as a result of a combination of increased water uptake through the skin and the wall of the bladder and decreased urinary output. This response, which also involves the uptake of sodium by the skin, is found only in the more terrestrial members of the Amphibia, in which it is an adaptation that enables them to conserve water. It is not yet known whether or not comparable adaptive specializations are associated with the molecules characteristic of the other groups of lower vertebrates. There is some evidence that hypothalamic polypeptides may be involved in the movements of water and ions (charged particles) in fishes. Changes in the functions of the polypeptide hypothalamic hormones during vertebrate evolution have occurred, partly as a result of evolution of their targets; *e.g.*, water balance in amphibians is mediated by a hormonal molecule that was already present in agnathans and was thus a part of the earliest hormonal endowment of vertebrates.

Table 2: The Structure and Distribution of the Hypothalamic Polypeptide Hormones of Vertebrates*

Basic Vasopressor Principles

1. Arginine vasotocin

Cys	Tyr	Ile	Gln	Asn	Cys	Pro	Arg	Gly(NH_2)
1	2	3	4	5	6	7	8	9

Exists in all fishes; possibly in all vertebrates, at some stage of development

2. Arginine vasopressin

Cys—Phe—Cys—Arg—

Exists in most mammals except the pig family

3. Lysine vasopressin

Cys—Phe—Cys—Lys—

Exists in mammals of the pig family

Neutral Oxytocinlike Principles

4. Oxytocin

Cys—Ile—Cys—Leu—

Exists in mammals, birds, reptiles, amphibia (?), Dipnoi (?), and holocephalians (?)

5. 8 Ile oxytocin (Mesotocin)

Cys—Ile—Cys—Ile—

Exists in reptiles, amphibia, and Dipnoi

6. 4 Ser, 8 Ile oxytocin (ichthyotocin, isotocin)

Cys—Ile • Ser—Cys—Ile—

Exists in teleost, holostean, and brachiopterygian fishes

7. 4 Ser, 8 Glu(NH_2) oxytocin (glumitocin)

Cys—Ile • Ser—Cys—Gln—

Exists in elasmobranch fishes, particularly the skate

8. Unknown elasmobranch oxytocic principle (EOPI) (Val, Ser peptide[s]?).
Exists in *Squalus acanthias* and perhaps other sharks

*Amino acids indicated only by lines are the same as those present in arginine vasotocin.

HORMONES OF THE THYROID GLAND

Biosynthesis. The two thyroid hormones, thyroxine (3,5,3′,5′-tetraiodothyronine) and 3,5,3′-triiodothyronine, are formed by the addition of iodine to an amino-acid (tyrosine) component of a glycoprotein called thyroglobulin. Thyroglobulin is stored within the gland in follicles as the main component of a substance called the thyroid colloid. This arrangement, which provides a reserve of thyroid hormones, perhaps reflects the frequent scarcity of environmental iodine, particularly on land and in fresh water. Iodine is most abundant in the sea, where thyroidal biosynthesis probably first evolved. Although the possibility that the thyroid hormones originated as metabolic by-products is suggested by the widespread occurrence in animals of the binding of iodine to tyrosine, the binding commonly results only in the formation of iodotyrosines, not the thyroid hormones. On present evidence, only the vertebrates and the closely related protochordates have a mechanism to synthesize significant amounts of biologically active thyroid hormones.

The synthesis of thyroid hormones in vertebrates begins with the active uptake by thyroid-gland cells of inorganic iodide circulating in the bloodstream; the inorganic iodide is oxidized (combined with oxygen) during a reaction catalyzed by an enzyme (iodide peroxidase). The product of this reaction (active iodine) combines with tyrosine components of the thyroglobulin molecule to form two compounds (3-monoiodotyrosine and 3,5-diiodotyrosine), which then join to form the active hormones. The synthesis of the thyroid hormones is inhibited by certain chemical agents called goitrogens, which reduce the output of thyroid hormones, thereby causing, through negative feedback, an increased output of thyrotropin and hence an enlargement of the thyroid gland (see below). Some goitrogens (*e.g.,* thiocyanates) reduce or inhibit the uptake of iodide; others (*e.g.,* thiourea, thiouracil) inhibit the peroxidase system and thus prevent the binding of iodine to thyroglobulin.

Release of the thyroid hormones into the bloodstream begins when the thyroid cells take up droplets of the stored thyroid colloid. The thyroglobulin in these droplets is then hydrolyzed (broken down in a reaction involving the elements of water) by an enzyme to form both iodotyrosines and the hormones. Normally, only the latter pass out of the cells in significant quantities. The iodine is removed from the iodotyrosines, which are not hormonally active, by an enzyme (deiodinase), and the iodine thus is conserved and used again. The hormones, usually bound to proteins (globulin and albumin) in the bloodstream, where they constitute the protein-bound iodine of the plasma, must be unbound from the proteins before they can function. The iodine is removed from the hormones largely in the liver and in the kidneys, and most of it returns to the thyroid gland, an economy that again emphasizes the need for conservation; some iodine, however, is lost in the alimentary tract.

Conservation of iodine

Synthesis of the thyroid hormones is regulated by the level of circulating hormones (*i.e.,* a negative-feedback mechanism) operating, as indicated earlier, partly by direct action on the thyrotropin-secreting cells of the pituitary gland and partly by indirect action on the hypothalamus and its thyrotropin-releasing factor. Thyrotropin attaches to the cells of the thyroid gland and may exert its effect by stimulating CAMP synthesis. It causes resorption of thyroid colloid and increases the rates of both glucose metabolism and protein synthesis as secretion of thyroid hormones increases in response to it. After the thyroid gland of the rat has been under thyrotropin stimulation for two or three hours, an increase in the size of the cells of the gland occurs, along with an increase in iodide uptake into them; prolonged thyrotropin action causes a marked enlargement of the gland (goitre), which in man may become externally apparent as a swelling. Goitres, which are of various types, result from a negative-feedback reaction that attempts to maintain output from the thyroid gland.

Effects. One established effect of the thyroid hormones in mammals is an increase in metabolic rate and in oxygen consumption, but the effects of the hormones undoubtedly are more wide-ranging than this. On the one hand, impairment of the thyroid function in mammals results in disturbances in the processes of growth and maturation. Both growth and maturation disturbances occur in the cretinous dwarfism resulting from thyroid deficiency in newborn infants; on the other hand, the metabolic effect is not apparent in lower vertebrates (*e.g.,* fish), even though treatment of these animals with thyroid hormones promotes an increase in the growth rate, provided pituitary growth hormone is also secreted. In addition, evidence suggests that, in lower vertebrates, the thyroid hormones are active during moments of stress in the life cycle (*e.g.,* migration and reproduction) and affect the activity of the central nervous system. Disturbance of thyroid output also affects reproduction in mammals, impairing the functioning of the ovary, for example, and causing irregularities of the ovarian cycle.

Effects of thyroid hormones on frog metamorphosis

The complex effects of thyroid hormones are well documented in the metamorphosis, or change in body form, of the amphibian tadpole into a frog. Metamorphosis, which involves a diversity of integrated morphological and biochemical changes, requires the presence of the thyroid gland and depends upon a delicate balance between the changing output of its hormones and changing sensitivities of the target tissues. Studies involving the tail of the frog tadpole show that the thyroid hormones directly promote the formation of the enzymes needed for reduction of the tail and suggest that the diverse effects produced in vertebrates by the thyroid hormones might depend upon their capacity to regulate protein metabolism, in which case the target cells would have to be adapted to respond by appropriate patterns of enzyme synthesis.

Ultimobranchial tissue and calcitonin. The discovery of calcitonin (thyrocalcitonin) in 1961 demonstrated the importance of comparative studies in endocrinology. It originally had been thought that this hormone, which is present in preparations made from mammalian thyroid glands, was secreted by the parathyroid glands, which in some species are combined with the thyroid gland. Later, the hormone was concluded to be a secretion of the thyroid gland itself. In fact, calcitonin is not a product of either of them. Its actual source is the ultimobranchial tissue, represented in vertebrates from fishes upward by the ultimobranchial gland, which develops from the hinder part of the pharynx. Ultimobranchial tissue is the source of distinctive cells (called light, C, or parafollicular cells), which are found in the thyroid gland of mammals; in birds, however, the ultimobranchial gland is separate, thus making it possible to remove the gland and to show that it is the source of the hormone. The molecular structure of hog calcitonin is that of a polypeptide, containing 32 amino acids and having a molecular weight of about 3,600. The calcitonin of the salmon, which is more potent than that of the pig, has the same number (but some different types) of amino acids, and the molecular weight is 3,427.

Effects of calcitonin

Calcitonin lowers the level of calcium in the blood (hypocalcemic action) when it rises above the normal level. Its secretion probably is regulated by a negative-feedback relationship between the gland and the blood plasma. The hormone affects bone, which is an active tissue. It undergoes not only growth but also remodelling as it adapts to the changing patterns of stress to which it is subjected; its calcium exchanges continuously with that of the plasma. The effect of calcitonin is to decrease the mobilization (resorption) of calcium from the skeleton into the blood plasma. In this respect, as is discussed in the next section, it is opposite in direction to the effect of parathormone of the parathyroid glands. Little is known of the action of calcitonin in the lower vertebrates, but its presence in fish raises interesting functional problems. Elasmobranch fishes (*e.g.,* sharks) lack bone, and many bony fishes have a type of bone that cannot be remodelled; the hormone, therefore, cannot act in these vertebrates as it does in higher ones. It is possible that in these fishes the hormone may control the level of plasma calcium by regulating its movement across cell membranes.

PARATHORMONE OF THE PARATHYROID GLAND

The parathyroid glands, which are found only in terrestrial vertebrates (amphibians, birds, reptiles, and mam-

mals), develop from certain pharyngeal pouches, which are embryonic remnants of the gill slits of fish. The parathyroid glands secrete a hormone called parathormone (PTH), which is a polypeptide of variable amino-acid composition. PTH, which consists of 83 to 85 amino acids in the human, regulates calcium metabolism in conjunction with calcitonin; its evolution in terrestrial vertebrates may have been an adaptation to the increased demand for continuous skeletal adjustments imposed by the evolution of terrestrial locomotion. Skeletal adjustments must be made without disturbing the delicate calcium balance of the rest of the body, for calcium is involved in maintaining the transport of substances through cell membranes; hence, it has an important role in muscle contractility, excitability of motor end plates in the nervous system, and coagulation of blood.

Removal of the parathyroid glands in mammals causes a fall in the level of calcium in the blood plasma, which, if sufficiently severe, is accompanied by convulsions and other symptoms resulting from increased excitability of the motor nerves. These symptoms can be corrected by injection of appropriate preparations of parathyroid glands. The activity of the glands, like that of the ultimobranchial tissue, is regulated by negative feedback; *i.e.,* lowering of the plasma calcium level increases the output of parathormone (but decreases the output of calcitonin). The hypercalcemic effect (*i.e.,* increase in level of blood calcium) of the hormone depends largely upon its action on bone, since it promotes the transfer of calcium from this tissue into the plasma, probably by a direct action on the active bone-forming cells (osteocytes). In addition, however, parathormone promotes the formation of new bone tissue, and thus also increases its metabolic activity and the turnover of its structural material. Other effects of parathormone, at least in part, contribute to the elevation of plasma calcium; *i.e.,* PTH increases both the absorption of calcium by the intestine and its resorption by the kidney tubule. Since, however, the hypercalcemia induced by the hormone results in more of it passing into the kidney tubule, the net result may be increased excretion of calcium despite the increased resorption. Other actions of the hormone, less easy to relate to its well-defined influence upon calcium metabolism, include a regulatory influence upon the level of magnesium in blood plasma and upon the rate of removal of phosphate from urine.

In general, therefore, the action of parathormone is opposite in direction to that of calcitonin. Parathormone keeps the level of blood calcium up to its normal value; on the other hand, calcitonin ensures, through its hypocalcemic action, that the level does not rise far above this critical point. The combined actions of the two hormones serve to illustrate the importance of endocrine regulation in homeostasis. Vitamin D is a third factor in calcium regulation; its absence in young children results in skeletal malformations (rickets). Parathormone is unable to regulate the absorption and mobilization of calcium in the absence of vitamin D, which is also associated with the hormone in promoting mobilization of magnesium from bone and perhaps in the movement of phosphate within the kidney tubule.

Role of vitamin D in calcium regulation

HORMONES OF THE PANCREAS

Insulin. The vertebrate pancreas contains, in addition to the zymogen cells that secrete digestive enzymes, groups of endocrine cells called the islets of Langerhans. Certain of these cells (the B, or beta, cells) secrete the hormone insulin, inadequate production of which is responsible for the condition called diabetes mellitus. Insulin and the characteristic B cells are present in gnathostomes and in agnathans; in the latter, however, the islet cells are not associated with zymogen cells to form a typical pancreas. Insulin is, as mentioned earlier, a polypeptide molecule composed of two chains of amino acids, an A chain of 21 amino acids containing an intrachain disulfide linkage (—S—S—) and a B chain of 30 amino acids. The two chains are linked by two other disulfide linkages, the destruction of which destroys the activity of the molecule. It is thought that the molecule first appears in the B cell as the single-chain compound proinsulin, which is disrupted by an enzyme-catalyzed reaction to form the two chains of the active hormone. As with other polypeptide hormones, extensive variation in amino-acid composition of the molecule occurs among different species, with the differences tending to be greater between the more widely separated species—*e.g.,* between fish and mammal. The variations in amino-acid composition have little effect on the biological activity of the molecules, but certainly influence their immunological reactions; this suggests that the two properties depend on the amino-acid sequences at different parts of the molecule.

Injection of insulin lowers blood-sugar (glucose) levels, but this so-called hypoglycemic effect is only one expression of the wide-ranging influence of insulin on storage and mobilization of energy, in which the target tissues of primary importance are muscle, adipose (fat) tissue, and liver. The actions of insulin on these tissues are varied. First, it promotes the use of the sugar glucose as an energy source; at the same time, it encourages the storage of excess carbohydrate as glycogen, the storage carbohydrate of animals. Second, insulin reduces the use of fat as an energy source and promotes its storage. Third, it reduces the use of protein as an energy source and promotes the formation of proteins from amino acids.

Insulin probably acts on carbohydrate metabolism in muscle by increasing the ability of glucose to pass through the muscle-cell membranes. This effect depends on a specific interaction between the cell membrane and the hormone; although the same effect occurs in adipose (fat) tissue, it does not occur either in the liver or in the central nervous system, despite the latter's complete dependence upon glucose for its energy supply. After the entry of glucose into a muscle cell, phosphate is added to the molecule, and two compounds form in succession, first glucose-6-phosphate, then glucose-1-phosphate; after these reactions, the metabolism of glucose is probably aided by two secondary actions of insulin (see also METABOLISM). The hormone stimulates the synthesis of an enzyme (glycogen synthetase), thus promoting the transformation of glucose-1-phosphate into glycogen; it also aids in the breakdown of glucose, thus providing energy to the cell. All of these effects contribute to the hypoglycemic (blood-glucose-lowering) action of the hormone. Insulin has other effects on muscle cells—it slows the breakdown of fat and increases the formation of proteins from amino acids. Insulin affects carbohydrate and protein metabolism in adipose tissue much as it does in muscle and also promotes storage of fat.

The action of insulin in liver differs from that in muscle in that it has no direct influence upon the transport of glucose into liver cells; probably, however, insulin promotes the metabolism of glucose within liver cells in much the same way that it does in those of muscle, resulting in increased uptake of glucose from the bloodstream. In addition, insulin decreases gluconeogenesis (the formation of glucose in the liver from amino acids and other noncarbohydrate sources). These various effects cause a decrease in the level of blood glucose. Other actions of the hormone upon the liver include, as in adipose tissue, increases in fat deposition and protein synthesis.

Effects of insulin in liver

The diverse effects of insulin apparently are adaptively linked to regulating the storage and release of energy, but it is difficult to judge whether or not all of the effects result from a single mode of action of the hormone. The interaction of insulin with the muscle-cell membrane suggests that all of its effects might be produced by similar interactions between it and membranes within cells. The mechanism, however, has not yet been established with certainty.

The B cells of the islets of Langerhans respond directly through negative feedback to the level of glucose in the blood that reaches them; *i.e.,* an increase in blood glucose above the normal level (80 to 100 milligrams per 100 millilitres in man) brings about increased synthesis and release of insulin with the result that the level of blood glucose falls. As a consequence, the rate of insulin output then decreases. This, however, is only part of the complex hormonal mechanism that regulates carbohydrate metabolism. Another factor is the hormone glucagon, which is

secreted in the islets of Langerhans by a second cell type, the A (alpha, or A_2) cells. (The function of a third type, the D (gamma, or A_1) cells, has not yet been established.)

Glucagon. Glucagon, which is present in gnathostomes but absent from agnathans, is a polypeptide molecule consisting of 29 amino acids. It strongly opposes the action of insulin, primarily through a hyperglycemic (blood-glucose-raising) effect that results from its promotion of the breakdown of glycogen (glycogenolysis) in the liver, a process that results in the formation of glucose. Glucagon exerts its action by increasing the availability of the enzyme required for the reaction by which glucose units are released from the glycogen molecule. It also reduces the rate of synthesis of glycogen, promotes the breakdown of protein, promotes the use of fat as an energy source, and evokes increased glucose uptake by muscle cells. The last effect, however, may be a consequence of hyperglycemia induced by the increased secretion of insulin.

Another form of glucagon, called gastronintestinal glucagon, is secreted into the blood when glucose is ingested. Its only action appears to be to stimulate insulin secretion, an effect that may provide information to the islet cells of the pancreas about the entry of glucose into the bloodstream. It is also possible that pancreatic glucagon, which is secreted in the islets by the A cells, may directly stimulate the release of insulin from the adjacent B cells without actually entering the bloodstream.

Other hormones that affect insulin release

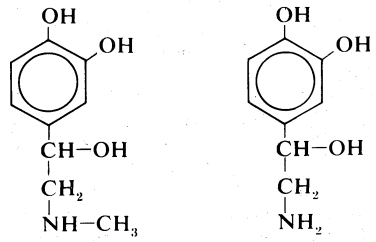
A number of other hormones also influence the release of insulin, mainly through their own actions upon blood-sugar levels. Growth hormone, thyroxine, adrenaline, and cortisol, *e.g.*, may increase insulin release because they can promote a rise in blood sugar through effects upon carbohydrate metabolism. Growth hormone and cortisol can also probably act directly upon the B cells.

The complexity and delicacy of the control of metabolism by insulin and other hormones in mammals illustrate again the importance of homeostasis, the control of which may not be as well organized in the lower vertebrates. Some of the responses in mammals, however, do occur in lower forms; for example, removal of pancreatic islet tissue from fishes produces hyperglycemia. Thyroxine induces hyperglycemia in amphibians, and corticosteroids promote gluconeogenesis in them. Far more information is needed, however, before the evolution of these remarkable regulating mechanisms can be determined.

HORMONES OF THE ADRENAL GLANDS

Chromaffin tissue of the medulla. The adrenal gland of mammals is composed of an outer region, the cortex, which consists of adrenocortical tissue that secretes steroid hormones (steroids are fat-soluble organic compounds), and an inner region, the medulla, which is composed of chromaffin tissue, so called because its cells contain granules that can be characteristically coloured by certain reagents. Chromaffin tissue secretes two hormones, adrenaline (epinephrine) and noradrenaline (norepinephrine), which are members of a class of compounds called catecholamines. Both chromaffin and adrenocortical tissues are present in gnathostomes and probably in agnathans (although the evidence on the latter point is not yet decisive), but the tissues vary in the degree to which they are associated, being completely separated in elasmobranch fishes.

Noradrenaline and adrenaline are each composed of a benzene ring containing two hydroxyl (— OH) groups and an amine (NH_2-containing) side chain as shown below:



adrenaline (epinephrine) noradrenaline (norepinephrine)

Figure 18: The structures of noradrenaline and adrenaline.

During the synthesis of these hormones, a sequence of enzyme-catalyzed reactions in the chromaffin granules of the secretory tissue transforms tyrosine into a compound commonly called dopa (dihydroxyphenylalanine), which then forms dopamine; dopamine then is hydroxylated (*i.e.*, an —OH group is added) to form noradrenaline. Adrenaline is formed from noradrenaline by methylation (the addition of a methyl, or $-CH_3$, group), a reaction that occurs outside the granules of the chromaffin cells. Noradrenaline (but not adrenaline) is also formed in certain neurons (nerve cells), where it functions as one of the chemical transmitter substances.

After their release, both hormones are so rapidly metabolized that they probably remain in the bloodstream only for a few seconds. The first step in the breakdown, which usually occurs in the liver and kidneys, is methylation of one of the hydroxyl groups of the benzene ring; the products (metanephrine or normetanephrine), or compounds derived from them, are excreted in the urine. Small quantities (about 2 to 5 percent of the daily secretion of the gland in man) of nonmetabolized hormones are also found in the urine.

Table 19: Effects of Adrenaline and Noradrenaline in Man

	adrenaline	noradrenaline
Heart rate	increase	decrease
Cardiac output	increase	variable
Total peripheral resistance	decrease	increase
Blood pressure	rise	greater rise
Respiration	stimulates	stimulates
Skin vessels	constriction	less constriction
Muscle vessels	dilation	constriction
Bronchus	dilation	less dilation
Eosinophil count	increase	no effect
Metabolism	increase	slight increase
Oxygen consumption	increase	no effect
Blood sugar	increase	slight increase
Central nervous system	anxiety	no effect
Uterus in late pregnancy	inhibits	stimulates
Kidney	vasoconstriction	vasoconstriction

Effects of noradrenaline and adrenaline

Adrenaline and noradrenaline evoke diverse and widespread responses but differ from each other in certain of their effects (see Table 19 for their effects on man). Both influence the heart and blood vessels in ways which, although opposed to each other in a few respects, generally result in an increase in blood pressure and in output of blood from the heart. Both hormones also have metabolic actions. Adrenaline, for example, like glucagon, stimulates glycogenolysis (breakdown of glycogen to glucose) in the liver, which results in the raising of the level of blood sugar; in addition, it increases oxygen consumption and the output of blood from the heart, probably contributing thereby to the regulation of body temperature in mammals. Adrenaline has effects upon the nervous system, which are recognizable subjectively in man by feelings of anxiety and of increased mental alertness.

The chromaffin tissue is closely related to the sympathetic nerves of the autonomic nervous system, which innervates the components of circulation and digestion and controls their involuntary functions; in fact, the two may be said to form a sympatheticochromaffin complex. It is generally assumed that this complex acts to increase the capacity of the animal for effective action in emergencies. At such times, cardiac output increases, blood is distributed with maximum effectiveness, respiration is enhanced, and the nervous system is stimulated. The sympathetic nerves initiate these reactions and directly promote the release of adrenaline and noradrenaline because these nerves directly innervate the chromaffin cells. The hormones are thus able to develop and prolong an integrated set of responses; noradrenaline functions both as a neurohumor chemical transmitter of the sympathetic nervous system and also as a hormone of the chromaffin tissue.

The fact that adrenaline and noradrenaline, which have very similar molecular structures (see above), can exert different actions is probably in part a consequence of the

specialization of their target tissues. It has been suggested by some researchers that the target tissues possess two different kinds of receptors, the alpha type, which responds to noradrenaline, and the beta type, which responds to adrenaline. Evidence for this theory is that adrenaline has a vasodilator effect (*i.e.*, it expands blood vessels), which can be blocked by certain drugs, and noradrenaline has an opposing vasoconstrictor effect, which can be blocked by other drugs. The actions of both hormones are thought to be mediated by CAMP; alpha responses are associated with reduced synthesis of this mediator and beta ones with increased synthesis.

The interpretation of the function of these hormones in mammals has not yet been established as applicable to lower vertebrates in which the hormones are present, but they are known to influence metabolism and heartbeat in some genera. It is possible that in early stages of vertebrate evolution, the sympatheticochromaffin complex evoked more generalized physiological responses than it now does and that more precise action developed in mammals as part of their high level of homeostatic organization. Laboratory studies show that even in mammals the complex is not essential for life; animals from which it has been removed, however, are much less able to resist environmental stresses than are those whose complex is functional.

Adrenocortical tissue of the cortex. The adrenocortical tissue develops from coelomic epithelium (a cell layer surrounding the body cavity, or coelom). In this respect it resembles the endocrine tissue of the gonads, a resemblance emphasized by the fact that both the adrenocortical hormones (corticoids) and the sex hormones are steroids produced by similar metabolic pathways (the structures of some steroid hormones are illustrated below).

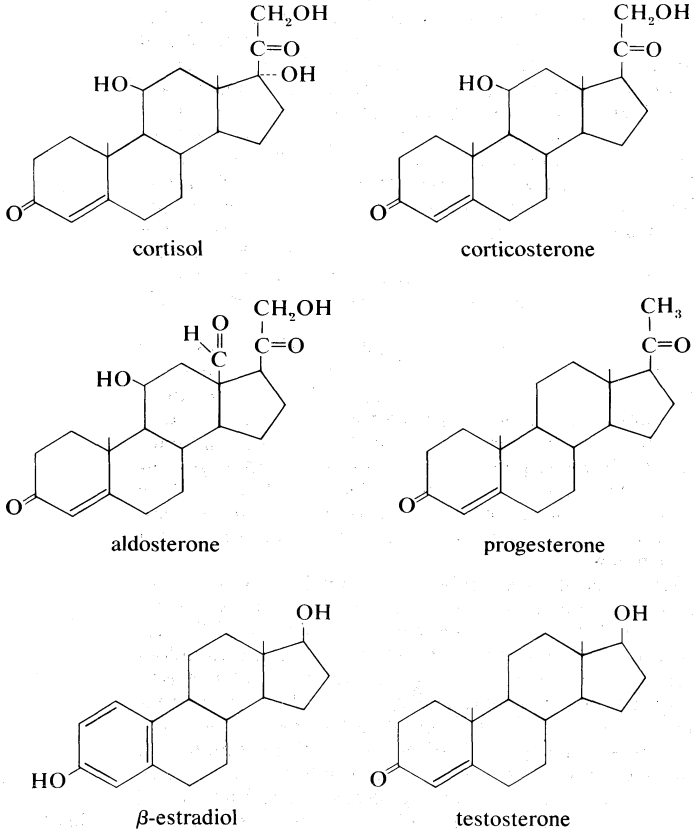

Figure 19: Some steroid hormones of vertebrates.

Active adrenocortical hormones

Many steroids have been isolated from the adrenal cortex, but in most vertebrate groups only three of them are active as hormones; they are cortisol (hydrocortisone; compound F), corticosterone (compound B), and aldosterone. Their biosynthesis is outlined in Figure 20.

The principal sterol of animals is cholesterol, which is formed by a complex series of reactions from a two-carbon compound (acetate). Progesterone, which is derived from

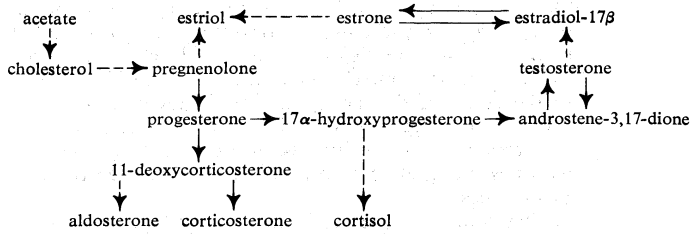

Figure 20: Metabolic pathways involved in the biosynthesis of steroid hormones. Broken lines indicate that more than one step is involved.

Adapted from D.M. Greenberg, ed., *Metabolic Pathways* (1960); Academic Press

cholesterol, can be used to form either corticosterone and aldosterone or cortisol. All three corticoids are bound to proteins during transfer in the bloodstream to their targets; cortisol, for example, is bound to a glycoprotein called transcortin. Some inactivation of the corticoids takes place in the kidney and in the alimentary tract, but most of it occurs in the liver. The metabolic products, which eventually appear in the urine, provide a basis for determination of the output of adrenocortical hormones in man.

The normal secretion of the hormones is best determined by direct measurement of the contents of the venous blood leaving the adrenal gland. In man, the daily secretion rates of the hormones, as determined by this procedure, are cortisol, 20 milligrams; corticosterone, two to five milligrams; aldosterone, 75 to 150 micrograms (one microgram = 1,000,000th of a gram). Very small amounts of aldosterone are secreted, because the molecule has a high level of activity. Animal tissues maintained in culture fluid together with compounds from which the hormones are formed (*e.g.*, acetate, cholesterol, or progesterone containing radioactive isotopes of carbon or hydrogen) show that cortisol and corticosterone are produced in all vertebrates, including the agnathans, although the proportion of each is species-dependent; elasmobranch fishes are unique, however, in having 1-α-hydroxycorticosterone as the principal hormone. Aldosterone is produced by all terrestrial vertebrates. It has also been found in bony fishes, although its function in them has not yet been established as a hormonal one. The presence of aldosterone has not yet been established in elasmobranchs and agnathans, but whether or not this particular molecule occurs in them, the ability to synthesize corticoids must have evolved very early in vertebrate history.

In contrast to the chromaffin tissue of the adrenal medulla, the adrenocortical tissue is essential for life. Two primary functions of the corticosteroids are distinguishable in mammals. One, which contributes to the regulation of carbohydrate metabolism, is an action of cortisol and corticosterone, which are therefore called glucocorticoids. These hormones promote gluconeogenesis (formation of glucose) in the liver and are thus important in maintaining normal blood-sugar levels, particularly during glucose shortage; lack of them results in low levels of blood sugar and an increase in the sensitivity of the liver to insulin (whose effect there is to decrease gluconeogenesis). In addition, lack of the glucocorticoids is associated with a decrease in the entry of amino acids into muscles and an increase in their uptake by the liver, where enzymes required to convert amino acids to glucose must be synthesized.

In contrast to glucocorticoid action is the so-called mineralocorticoid action of aldosterone, which is manifested in mammals in the regulation of sodium metabolism. In the absence of aldosterone, sodium is lost from the body by excretion in urine; secondary consequences include a decrease in blood volume and in the filtration rate of substances through kidney structures called glomeruli. Cortisol and corticosterone also play a minor part in mineral regulation, so that slight overlap in function occurs between the two corticoid types.

The action of aldosterone is exerted mainly upon the distal segment of the nephron (kidney tubule), where it promotes an increase in the permeability of the tubule membrane to the passage of sodium, and also an increase in the quantity of sodium removed into the blood from

the fluid passing through the kidney tubule. At the same time, potassium and hydrogen pass into the fluid from the blood. Aldosterone also exerts other effects. It promotes sodium retention in salivary glands, in sweat glands, and in the colon of the large intestine; it also promotes the excretion of magnesium in the urine. The effects of aldosterone result in an increase in the rate of synthesis of enzymes required to transport these substances through membranes.

Other actions of the corticoids are apparent in patients suffering from Addison's disease, which is caused by a general deficiency in corticoid production. A deficiency of corticoids causes disturbances in urinary output and fat metabolism, diminished resistance to stress, muscular weakness, and nervous disturbances manifested by depression and a general lack of mental alertness. The adrenocortical hormones, then, like the hormones of the chromaffin tissue of the medulla, are involved in resistance to stress. It has been postulated that the response to alarm stimuli initially involves both the sympatheticochromaffin complex and the adrenocortical secretion; then a stage of full resistance occurs that may be followed by mental exhaustion if the alarm stimuli are prolonged. Although a close functional relationship is known to exist between the adrenocortical and chromaffin tissues in mammals, the function of the corticoids in the lower vertebrates has not yet been established. Indications are, however, that the general pattern of action may be similar; for example, the cortisol type of corticoid promotes gluconeogenesis in fish and removal of adrenocortical tissue impairs the metabolism of water and ions in the eel. Any interpretation of corticoid action in teleost, or bony, fishes has to incorporate prolactin, for, as has been noted previously, this hormone also influences the movement of ions.

Resistance to stress

In contrast to the chromaffin cells, the adrenocortical cells are not innervated. Both cortisol and corticosterone production are regulated by the action of ACTH from the pituitary gland on the zona reticularis and the zona fasciculata. The regulation of aldosterone secretion in the zona glomerulosa, however, is associated with the so-called renin–angiotensin system, which is best characterized in mammals. Renin, an enzyme with a molecular weight of about 40,000, is formed in the kidney and is released into the bloodstream, where it catalyzes the formation of angiotensin, a polypeptide molecule. Angiotensin acts upon smooth muscle and raises blood pressure. In man it reduces sodium excretion, probably by a direct action on kidney filtration, and may, in fact, be a true hormone, acting to aid sodium retention. In addition, however, angiotensin contributes to sodium retention by increasing aldosterone secretion. The exact physiological significance of the renin–angiotensin system is not yet known. In one form or another the system is probably widely distributed in vertebrates.

HORMONES OF THE REPRODUCTIVE SYSTEM

The hormones of the reproductive system of vertebrates (sex hormones) are steroids that are secreted, like those of the adrenal cortex, by tissues derived from the coelomic epithelium. Both types of secretory tissues also share biosynthetic pathways (see above *Adrenocortical tissue of the cortex*).

Female hormones. The sex hormones, together with the hypothalamic region of the forebrain and the pituitary gland, form a regulatory system, which is most complex in the female mammal. It is common for sexual activity of vertebrates to be cyclical and for the cycles to be coordinated with the seasons of the year; this ensures that the young are born at the most favourable time. In mammals, however, reproduction is complicated by the need to provide for the intrauterine life of the developing fetus and to ensure that interference by another generation of embryos cannot occur.

Estrogens. Two types of gonadal hormone, estrogens and progestins (Figure 18) are secreted in the female mammal. Estrogens are substances that evoke the cyclical onset of heat, or estrus, during which the animal is sexually active and receptive to the male. Estrus in this sense is not found in human females, but estrogens contribute to the events of the menstrual cycle, bringing about cyclical changes in the reproductive system that are comparable with those accompanying estrus in other mammals.

Types of estrogens

Hormones are secreted from the mammalian ovary by the ovarian follicle, or vesicle, including the granulosa cells immediately surrounding the ovum, or egg, and the cells of the theca, which forms a supporting outer wall for the follicle. The main estrogen secreted is called β-estradiol. The close relationship between the female and the male sex hormones is revealed by the fact that testosterone (the main male hormone) is an intermediate compound in the pathway that leads to the synthesis of estradiol, although another route, which avoids the formation of testosterone, is possible. Other estrogens are also known; the most familiar ones in man and other mammals, estrone and estriol, are much less active than estradiol, estriol being the weakest. Estrone can be converted to estradiol and vice versa in the ovary and in other tissues; *e.g.,* estradiol is converted, particularly in the liver, to estriol, which is an excretory product. The metabolism of these compounds is complex; they may be combined in part with other substances, or they may pass through the bile into the intestine for reabsorption and circulation through the body before excretion in the urine occurs. Their urinary concentrations provide an important clinical index of reproductive function.

Estrogens are concerned not only with reproductive behaviour but also with the general maintenance of the sexual organization of the female. When estradiol is administered to a mammal, the hormone becomes bound to uterine tissue, where it increases the rates of protein synthesis, of uptake of water and glucose, and, eventually, of growth of the lining epithelium and underlying muscular tissue (endometrium) of the uterus. Estradiol also evokes changes in the vagina, including hardening of the epithelium, a phenomenon that, in the laboratory rat, is used to determine its sexual condition. Estradiol and other estrogens have also been found in fishes and in other lower vertebrates. As with the corticosteroids, the sex hormones evolved very early in vertebrate history. Indeed, they have even been identified in invertebrates—in the eggs of the lobster, for example, and in the ovaries of starfishes, where, however, they may be no more than by-products of the metabolism of other steroids. Estrogenic activity is not necessarily restricted to steroids; for example, the estrogen mirestrol from a Thailand plant is not a steroid, nor is the very potent synthetic estrogen, stilbestrol, which is widely used in medicine.

Progestins. Progestins, of which the most important is progesterone, are concerned with the maintenance of pregnancy. Progesterone, therefore, evolved in viviparous mammals; *i.e.,* those that produce living young. Its chemical origin is demonstrable, since it is also an important intermediate compound in the biosynthetic pathways leading to corticoid and estrogen production. Mammals thus converted to hormonal use a substance that was synthesized by vertebrates long before the evolution of terrestrial vertebrates.

Some progesterone is probably formed in the ovarian follicle, but the main site of production is the corpus luteum, which is formed by a transformation of the follicle after ovulation; the secretory cells are formed from granulosa cells. The functions of the two important follicular phases, preceding and following ovulation, therefore, are continuous. The hormone is metabolized in several ways, but one important product is pregnanediol; formed mainly in the liver, it appears in part in the urine, where it can be measured to determine the degree of ovarian function.

Role of progesterone

The transformation of the follicle into the corpus luteum is an important turning point in the diphasic menstrual cycle of women and in the ovarian cycles of other mammals, from which the human cycle evolved. Progesterone prepares the uterus for the implantation of fertilized eggs, and it is also needed for the maintenance of pregnancy once implantation has taken place. It evokes a reduction in the ability of the uterine walls to contract, a proliferation of the glands of the endometrium, and the formation of glycogen. In addition, through its feedback action upon pituitary secretion, progesterone inhibits further ovulation

(see below), thus ensuring undisturbed fetal development. Ovulation in women occurs at about the middle of the monthly cycle, and the follicular phase is succeeded by the luteal phase. The vaginal bleeding at the end of the cycle is an indication that ovulation has not been followed by implantation of a fertilized egg and is immediately followed by the inception of a new cycle. If implantation does take place, the uterus provides metabolic support for the fetus until birth (see also REPRODUCTION AND REPRODUCTIVE SYSTEMS: *Menstruation*).

The vertebrate reproductive cycle depends upon delicate interrelationships between the sex hormones and the pituitary gonadotropic hormones (FSH and LH). As mentioned, it is uncertain whether or not there are two distinct gonadotropins in lower forms, but their separate action is well defined in mammals. Broadly speaking, FSH (follicle-stimulating hormone), with some support from LH (luteinizing hormone), promotes growth and secretory activity of the follicle. The increasing output of estrogen from the ovary eventually tends, by feedback to the pituitary gland, to reduce FSH output and to stimulate the secretion of LH; it is a sudden peak release of the latter hormone that evokes ovulation in many mammals. In others, such as the cat and rabbit, however, ovulation occurs as a response to the stimulus of copulation. Although some progesterone may be secreted by the granulosa cells of the follicle, the development of the corpus luteum greatly increases its secretion. Luteotropic activity in one form or another (the action of prolactin, for example, in the rat) is important in the early stage of this phase. Progesterone, in conjunction with the estrogen that is also being secreted (in part, probably, by the corpus luteum), suppresses further ovulation. This interaction of the two hormones is the basis of the design of contraceptive pills.

The corpus luteum continues to function during pregnancy, supplemented (in eutherian, or placental, mammals but not in marsupials) by endocrine secretions of the placenta (the organ through which contact between mother and fetus is maintained). The hormonal activity of the placenta varies with the species; in man, for example, the placenta secretes two gonadotropins called human chorionic gonadotropin (HCG) and human placental lactogen (HPL). HCG, like the pituitary gonadotropins, is a glycoprotein, with a molecular weight of 25,000 to 30,000. HPL is a protein, with a molecular weight variously estimated at about 19,000 or 30,000. One or perhaps both of these hormones, which become detectable during the early weeks of human pregnancy, probably stimulate luteal secretion. After two months the human placenta begins to manufacture estrogen and progestin; as a consequence, the corpus luteum is no longer needed for the maintenance of pregnancy. Much of the estrogen, although synthesized in the placenta, is derived from a compound (dehydroepiandrosterone) formed in the adrenal glands of the fetus. The placenta and the fetus thus form an integrated endocrine complex, a striking index of the high level of specialization found in the regulation of mammalian reproduction. (See also REPRODUCTION AND REPRODUCTIVE SYSTEMS: *Pregnancy*.)

The placenta probably secretes a luteotropin in all mammalian species, thereby contributing to prolongation of the life of the corpus luteum. In the mare and the monkey the placenta also secretes estrogen and progesterone, as in man, but in the mouse and rabbit it secretes only estrogen, and in the hamster and rat it secretes neither. In these last four species and in others like them, in which the placenta cannot substitute completely for the corpus luteum, ovariectomy (removal of the ovaries) of a pregnant female leads to the termination of pregnancy unless progesterone is administered to the female.

The interrelationships between the ovarian and the pituitary hormones are based upon negative feedback involving both the cells of the pituitary and those of the hypothalamus, which contains centres that are excited or inhibited by gonadotropin released from the pituitary gland. It is the hypothalamic involvement that enables vertebrate reproductive cycles to be adjusted by the central nervous system relative to external stimuli, particularly the seasonal fluctuations of daylight and other environmental factors that determine the onset of reproduction in many vertebrate species.

Male hormones. The sex hormones of the male follow a much simpler pattern than do those of the female, although the same principle of interaction exists between the pituitary gland and the gonads. The latter organs, the testes, secrete steriods called androgens, which are responsible for the maintenance of male characteristics and behaviour. FSH (follicle-stimulating hormone) from the pituitary gland stimulates the growth of the seminiferous tubules that constitute much of the structure of the testes and promotes within them the cell divisions that result in the production of mature sperm. LH (luteinizing hormone) from the pituitary gland promotes the development within the testes of endocrine tissue, which is composed of groups of cells (interstitial tissue) between the seminiferous tubules. The interstitial tissue of certain bony fishes, however, is represented by cells, called lobule boundary cells, situated within the tubule tissue.

Androgens

Under the influence of LH (often called ICSH, or interstitial-cell-stimulating hormone, in males), the interstitial tissue secretes the steroid hormone testosterone, which is the most important vertebrate androgen. The fact that it is an intermediate compound in the metabolic pathway of estrogen synthesis accounts for the origin of some forms of abnormal sexual organization in man; for example, the testes may secrete predominantly estrogen instead of androgen, resulting in markedly female appearance and behaviour in a male. Although testosterone may be secreted by the adrenal cortex, occasionally producing sexual disturbances, the amount of secretion is not normally significant. Testosterone, which is bound to a protein as it circulates in human blood, can be converted to the compound (androstenedione) from which it is formed, especially in the liver and in muscle; both compounds are metabolized, mainly in the liver, to substances that are excreted in urine. Very small quantities of testosterone can also be excreted in urine, and the quantities of testosterone and compounds derived from it frequently are measured to provide an index of testicular condition.

In addition to promoting male characteristics, male behaviour, and the maintenance of the spermatic tubules, testosterone, in the presence of normal amounts of growth hormone, also promotes growth of the bony skeleton. The reason for rapid growth at puberty is that the secretion of androgen markedly increases. The hormone brings about the closure of the epiphyses (ends) of the long bones, which completes the process of growth (estrogens have a similar action in the female). Thus, as often occurs among animals, growth ceases before full reproductive activity is attained, and competition between two processes, both of which make heavy demands upon the resources of the body, is avoided.

HORMONES OF THE DIGESTIVE SYSTEM

In vertebrates, the muscular and secretory activities of the alimentary canal and its associated glands are regulated by nervous and hormonal mechanisms. The hormones comprise a self-contained complex that functions at a relatively primitive level of organization and is distinguished by peculiar features; for example, specialized glandular tissues that secrete the hormones cannot be identified, although certain cells that can be seen in the wall of the alimentary canal are thought to be involved in their production. In addition, the digestive hormones regulate the system that produces them and are largely independent of the rest of the endocrine system, although certain relationships may not yet have been discovered.

Functions of digestive hormones

The functions of digestive hormones are best understood in mammals, in whom at least three are well characterized; the existence of others has been postulated. The three hormones—gastrin, secretin, and cholecystokinin/pancreozymin (CCK-PZ)—are polypeptide molecules whose amino-acid sequences are known. When food enters the stomach, the wall of its pyloric end (the area at which the stomach joins the small intestine) releases a hormone called gastrin, which promotes the flow of acid from the gastric glands in the stomach. These glands also release pepsinogen, which is the inactive form of the protein-

digesting enzyme pepsin, but this process is primarily under nervous control. The entry of the acidified stomach contents into the first part of the small intestine (duodenum) releases secretin and cholecystokinin/pancreozymin. Secretin evokes the discharge of fluid and bicarbonate ions from the pancreas (hydrelatic action) and promotes the secretion of bile from the liver (chloretic action). Cholecystokinin/pancreozymin, so-called because its two main actions were formerly attributed to two separate hormones, evokes the release of enzymes from the pancreas (ecbolic action) and causes contraction of the gallbladder (cystokinetic action), thereby promoting the entry of bile into the duodenum.

Little is known regarding hormonal control of alimentary activities in lower vertebrates; however, hydrelatic, ecbolic, and cystokinetic activities are present in preparations of the alimentary tracts of both agnathans and gnathostomes, indicating that substances able to regulate digestive activity appeared very early in the evolution of the vertebrate alimentary tract. Evidence suggests that the appearance of these hormones may have resulted in molecular diversification similar to examples previously discussed. The structure of the glucagon molecule from the pancreas, for example, is similar to that of secretin in that each molecule includes the same 15 amino acids located in the same positions. It has therefore been suggested that the two hormones may have evolved from a common ancestral molecule.

ENDOCRINE-LIKE GLANDS AND SECRETIONS

In addition to the well-defined hormones, other substances, which are found in blood and in tissues and are of uncertain function, may be concerned in various ways with physiological regulation in vertebrates, although their hormonal status has not yet been established.

Blood contains kinins, which are polypeptides that originate in the blood and perhaps elsewhere; bradykinin, for example, causes contraction of most smooth muscles and has a very potent action in dilating certain blood vessels. Its function, which is not yet established, may be to regulate the rate of blood flow or to participate in the inflammatory response of an animal to injury.

Some endocrine-like glands are associated with organs. One example in mammals is the carotid bodies, which are found on the carotid arteries that supply blood to the head. The carotid glands are stimulated by a decrease in the oxygen content of the blood and are considered to be the source of a substance, the nature of which has not yet been established with certainty, that promotes the process of red-blood-cell formation (erythropoiesis).

The pineal organ is an endocrine-like body found in the brain of all vertebrates. In lower vertebrates, it contains sensory and supporting cells and functions as a light-sensitive organ; in higher vertebrates, beginning with amphibians, the pineal gland has secretory functions, and in mammals, it is exclusively a secretory organ, producing from an amino acid (tryptophan) the compound serotonin (5-hydroxytryptamine, or 5HT) and a derivative of serotonin called melatonin. Preparations of melatonin, when given to amphibians, stimulate the concentration of pigment granules in chromatophores, an effect comparable with that of intermedin (MSH) but much more powerful. The normal physiological function of melatonin in higher vertebrates has not yet been established, although involvement in the regulation of reproduction is suspected. Serotonin is widely distributed in animals, especially in the brain and alimentary tract of vertebrates; it may function as a neurohumor in the invertebrate mollusks, but its significance in other animals is not yet certain.

The thymus is essential for the normal development in mammals of the system responsible for immunological responses. Its removal in newborn mice results in a deficiency of one type of white blood cells (lymphocytes) and a consequent likelihood of early death from infection. Preparations of thymus glands from various species contain a protein component, called thymosin, that promotes the development of lymphocytes. Although thymosin is sometimes regarded as a possible thymus hormone, the evidence is not yet complete.

Urohypophysis and corpuscles of Stannius

The urohypophysis, an organ found only in elasmobranch and bony fishes, probably developed independently in each group. The neurosecretory cells comprising the urohypophysis are concentrated at the hind end of the spinal cord, where they are associated with a vascular plexus to form a neurohemal organ. The urohypophysis resembles the neurosecretory system of the hypothalamus and the neural lobe (see above *Neurohypophysis and the polypeptide hormones of the hypothalamus*), but its functions have not yet been established.

The corpuscles of Stannius, found only in bony fishes, are sac-like bodies in the kidney. Although they were once thought to be a form of adrenocortical tissue, they differ from it in embryological origin as well as in cytological characteristics; moreover, although the corpuscles of Stannius are capable of limited steroid biosynthesis, they cannot convert cholesterol into corticoids, a process that occurs in adrenocortical tissue. Evidence suggests that these corpuscles secrete some substance, as yet uncharacterized, which plays a part in maintaining ionic homeostasis, perhaps in conjunction with the corticoid hormones.

The hormones of invertebrates

Some form of endocrine regulation probably occurs in all invertebrates; in arthropods (as exemplified in insects and crustaceans) it attains a level of complexity similar to that of vertebrates.

HORMONES OF INSECTS

Insects secrete hormones from neurosecretory cells and also from endocrine glands. Important neurosecretory centres occur in the pars intercerebralis region of the brain. The several cell types found in these centres indicate that more than one hormone is produced there.

Neurohormones. One of the brain hormones is thoracotropic hormone. This is released from nerve endings located in a neurohemal organ called the corpus cardiacum; the relationship between the corpus cardiacum and the brain closely parallels that between the neural lobe of the pituitary gland and the hypothalamic region of the brain of vertebrates. The thoractropic hormone is transferred in the blood to the thoracic glands in the body region called the thorax. It stimulates the production and release from the glands of ecdysone, a hormone that initiates molting, which is the periodic shedding of the outer skeleton that typically occurs in insects and other arthropods. The thoracotropic hormone is probably a polypeptide molecule.

A neurosecretion of the insect brain distinct from the thoracotropic hormone and called bursicon acts directly on the adult cuticle (skin) of arthropods to stimulate darkening and hardening processes. Bursicon is almost certainly a polypeptide, with a molecular weight of about 40,000. The brain of insects also produces a third neurohormone, which has a hyperglycemic (increase in level of blood glucose) effect in a tissue mass called the fat body, and a fourth neurohormone, which acts on the malpighian tubules (excretory organs) and rectum to facilitate the removal of excess fluid taken in with food; these two hormones, which may actually be one hormone with two effects, are also probably polypeptides. Another more active hyperglycemic hormone is formed within the corpora cardiaca, perhaps under the control of cerebral neurosecretion.

Molting hormones. Ecdysone is a steroid compound derived from cholesterol. Two forms are found in insects—α-ecdysone and β-ecdysone; ecdysones of unknown biological significance are also present in plants. Unlike vertebrates, insects cannot synthesize cholesterol, and they thus must obtain it from their food. Evidence concerning the mode of action of ecdysone indicates that it has a direct action upon the synthesis of the ribonucleic acid (RNA) that controls protein synthesis in the cell.

Juvenile hormone

The distinction in insects between molts that occur within the larval stage of development and those that result in the transformation of larvae to other stages (pupae, adults) in the life cycle is controlled by another hormone, called juvenile hormone, which is secreted in epithelial glands, called the corpora allata, near the brain. The hormone

controls the appearance of juvenile characters in larval stages, presumably by suppressing the activity of genes concerned with the expression of adult characters; reduction in the amount of or absence of the hormone at later molts results in the appearance of mature characters. The hormone nevertheless may continue to function in adults and often is necessary for normal egg production in females. Juvenile hormone is a lipoidal (fatlike) compound of similar structure from all sources. Many synthetic compounds mimic its effect, as do certain natural products—*e.g.*, substances in the balsam fir tree (*Abies*). Substances that mimic the action of juvenile hormone sometimes are used as insecticides, for if they are present in abnormal amounts in the later stages of the life cycle, they kill the insects.

Pheromones. Pheromones are important as insect sex attractants and as regulators of the social organization of social insects; *e.g.*, bees. The sex attractant of the female silk moth (*Bombyx mori*) is called bombykol. A related compound, gyptol, is the sex attractant of the female gypsy moth (*Porthetria dispar*), and gyplure is a synthetic compound that acts as an even more powerful attractant. The use of these compounds in the chemical control of insect pests is probably more promising than is the use of juvenile hormone.

The odour of the sex attractant of the honeybee (*Apis mellifera*), 9-oxodecenoic acid, stimulates the olfactory receptors of the drones (males). Secreted by the queen bee in the hive, the pheromone inhibits the development of the ovaries of the worker bees (sterile females) but is entirely effective only when it acts in conjunction with another inhibitory pheromone, 9-hydroxydecenoic acid. Removal of the queen from the hive results in the building of new queen cells by the workers and the development of functional ovaries in the drones. The mechanism by which these inhibitory substances function is not yet understood; some effect upon the nervous system presumably is involved.

HORMONES OF CRUSTACEANS

The endocrine systems of crustaceans resemble those of insects; important differences occur, however, implying extensive independent evolution in the two groups. The main sources of neurohormones are groups of cells (the X-organs) located in the optic ganglia of the eyestalks; the most important neurohemal organ is the sinus gland beside the eyestalks. Less important neurosecretory centres and neurohemal organs also occur. The pericardial organ of decapods, for example, is a group of nerve fibres and nerve endings in the walls of the pericardium, which encloses the heart; the pericardial organ secretes a substance, perhaps a polypeptide neurohormone, that accelerates the heartbeat.

In crustaceans, neurosecretory control is exerted over many functions, including the movement of pigment in the chromatophores, which determine body colour, and in the retina of the compound eye. Neurosecretions also regulate molting and the metabolic functions associated with it by actions exerted upon the so-called Y-organ in the head; this organ so closely resembles the thoracic gland of insects that the two may share a common ancestry. In crustaceans, however, the neurosecretion inhibits secretions from the Y-organ, and the molt is initiated by the withdrawal of the inhibitory hormone (in insects, the thoracotropic hormone from the corpus cardiacum stimulates the secretion of the molting hormone, ecdysone, from the thoracic gland). Neurosecretory hormones of crustaceans have diverse chemical and biological characteristics but apparently are polypeptides, as are the neurosecretory hormones of vertebrates.

Androgenic gland

Unlike insects, crustaceans have an androgenic gland, which typically is located on the genital duct (vas deferens) of the male. The androgenic gland secretes a hormone, possibly steroid in nature, that controls both the differentiation of the gonad of the male into a testis and the male characteristics of its limbs. The absence of the androgenic gland in the female results in the formation of an ovary, which subsequently synthesizes one or more hormones that, in female amphipods, promote the development of brood chambers (in which the young are hatched) and other structures associated with reproduction.

OTHER INVERTEBRATE HORMONES

The characterization of the hormones of other invertebrates awaits further study. Evidence indicates that the brain of polychaete worms produces neurosecretions that regulate growth and reproduction; in *Nereis* and *Nephtys* the neurosecretory fibres apparently have a close and presumably functional relationship with an epithelial gland (infracerebral organ), which is formed from coelomic epithelium and is situated on the wall of the brain.

Neurosecretory cells probably are present in mollusks such as gastropods and lamellibranchs. Experimental studies indicate an endocrine relationship in gastropods between the gonad (ovotestis) and possible neurosecretory cells in the tentacles and the brain; one ganglion of the gastropod *Lymnaea* may secrete a neurohormone with a diuretic (urine producing) action. Epithelial glands in mollusks are important; in the cephalopods, which are the most advanced invertebrates in some respects, optic glands on the optic stalks (eyestalks) secrete a hormone that promotes development and maturation of the gonads. In immature cephalopods the activity of the glands is inhibited by the central nervous system, apparently by a chemical mediator that diffuses from nerve fibres.

The nerve net, which constitutes the very primitive nervous system of the coelenterates, probably the most primitive multicellular animals, apparently contains neurosecretory cells; indirect but convincing evidence suggests that the cells release a secretion that promotes growth and inhibits sexual reproduction.

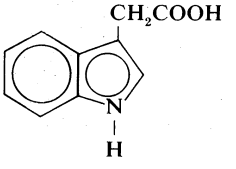
The hormones of plants

Growth in plants is regulated by four categories of phytohormones—auxins, gibberellins, cytokinins, and inhibitors.

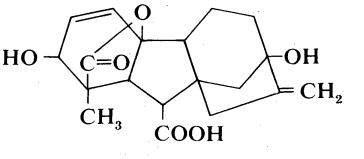
GROWTH PROMOTERS

Auxins. The distribution of auxins, which promote the lengthwise growth of plants, is correlated with the distribution of the growth regions of the plant. The most important auxin, whose structure is represented below, is β-indolylacetic acid (IAA), which is formed either from the amino acid tryptophan or from the breakdown of carbohydrates known as glycosides. The hormone affects plants by its action on chemical bonds of carbohydrates comprising plant cell walls. The process permits the cells to be irreversibly deformed and is accompanied by the entry of water and the synthesis of new cell-wall material. Many animal hormones may exert their effects by influencing protein synthesis, and evidence suggests that auxins may act in a similar way.

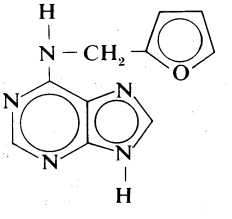
Many other naturally occurring and synthetic compounds



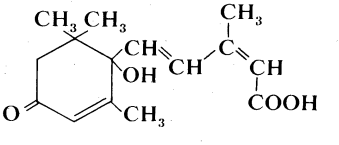
β-indolylacetic acid



gibberellic acid



kinetin (6-furfurylaminopurine)



abscisic acid

Figure 21: The structures of plant hormones.

called auxins also have growth-promoting properties, but they are not always as active as IAA. Some of these compounds, however, resist the enzymatic destruction that is the normal fate of IAA within the plant; this feature is of great value in research and in horticulture, because auxin action can be prolonged. Other auxin-like compounds are used as selective weed killers (*e.g.,* to disturb the leaf growth of dicotyledonous plants either in fields containing monocotyledonous cereal crops or on lawns) and as agents that remove leaves from dicotyledonous plants (defoliating agents).

Effects of indolylacetic acid

The hormonal characteristics of IAA are readily demonstrated in grass seedlings, in which the hormone is synthesized at the tip of the coleoptile (the protective sheath of the emerging plumule, or embryonic bud) and passes downward to its point of action in the growing region, where it evokes elongation of the coleoptile cells; growth stops if the tip is removed. The movement of the hormone downward from the tip of the coleoptile depends upon an interaction between the hormone and the cells through which the movement normally takes place.

In addition to promoting normal growth in plant length, auxins influence the growth of stems toward the light (phototropism) and against the force of gravity (geotropism). The phototropic response occurs because greater quantities of auxin are distributed to the side away from the light than to the side toward it; the geotropic response occurs because more auxin accumulates along the lower side of the coleoptile than along the upper side. The downward growth of roots is also associated with a greater quantity of auxin in their lower halves. This effect, which is the opposite to that found in coleoptiles, is attributed to an inhibitory action of auxins on root growth, but this aspect of auxin action is not yet fully understood. Auxins have actions other than those associated with promoting growth; *e.g.,* they play a role in cell division, in cell differentiation, in fruit development, in the formation of roots from cuttings, and in leaf fall (abscission). In experimental conditions, auxins tend to inhibit the progress of plant aging, perhaps because of their stimulating effect upon protein synthesis.

Gibberellins. Gibberellins are named after the fungus *Gibberella fujikuroi,* which produces excessive growth and poor yield in rice plants. One gibberellin is gibberellic acid (GA_3), which is present in higher plants as well as in fungi; many related compounds have structural variations that correlate with marked differences in effectiveness.

Gibberellins, abundant in seeds, are also formed in young leaves and in roots; they move upward from the roots in the xylem (woody tissue) and thus do not show the movement characteristic of auxins. Evidence suggests that gibberellins promote the growth of main stems, especially when applied to the whole plant. Unlike the auxins, gibberellins have little effect upon pieces of coleoptile in tissue culture. Gibberellins promote the growth of dwarf peas and are involved in the bolting (elongation) of rosette plants such as the carrot. Elongation of rosette plants occurs after exposure to certain environmental stimulation (*e.g.,* cold, or long periods of daylight), which is accompanied by an increase in the gibberellin content of the affected plant. In experimental conditions gibberellins tend, like auxins, to retard senescence.

Cytokinins. Cytokinins are compounds derived from a nitrogen-containing compound (adenine). One cytokinin is 6-furfurylaminopurine (kinetin); other compounds derived from adenine with effects similar to those of kinetin, and certain compounds derived from another nitrogen-containing compound, urea, are conveniently referred to as cytokinins, although not all are natural products. Cytokinins are synthesized in roots, from which, like the gibberellins, they move upward in the xylem and pass into the leaves and the fruit. Required for normal growth and differentiation, cytokinins act, in conjunction with auxins, to promote cell division and to retard senescence, which, at least in its early stages, is an organized phase of metabolism and not just a breakdown of tissue. An example of senescence is the yellowing of isolated leaves, which occurs as proteins are broken down and chlorophyll is destroyed. Cytokinins, which prevent yellowing by stabilizing the content of protein and chlorophyll in the leaf and the structure of chloroplasts, are used commercially in the storage of green vegetables.

Synthesis of cytokinins

GROWTH INHIBITORS

Growth inhibitors of various types have been identified in plants. The best characterized one is abscisic acid, which is chemically related to the cytokinins. It is probably universally distributed in higher plants and has a variety of actions; for example, it promotes abscission (leaf fall), the development of dormancy in buds, and the formation of potato tubers. The mode of action of abscisic acid has not yet been clarified but is thought to involve the direct inhibition of the synthesis of RNA and protein.

Another growth inhibitor is ethylene, which is a natural product of plants, formed possibly from linolenic acid (a fatty acid) or from methionine (an amino acid). Ethylene promotes abscission in senescent leaves, perhaps by facilitating the destruction of auxin. Its effects extend beyond that of inhibiting growth; in fruit, for example, ethylene is regarded as a ripening hormone. Involved in its action in fruit is another factor, perhaps auxin or another growth-regulating hormone, which influences the ethylene sensitivity of the tissues.

Hormonal interaction

The hormonal interaction conspicuous in animals is found also in plants; one example is the control of abscission, which requires the synthesis of enzymes at an abscission zone, at the base of the structure concerned, to catalyze reactions involving breakdown of cell walls. Auxin reaching the abscission zone from the tip of the structure promotes abscission; if auxin reaches the structure from the opposite direction, however, it tends to inhibit the process, probably by its influence on metabolism. Other hormones are also involved in abscission; ethylene stimulates the synthesis of the enzymes, and abscisic acid accelerates the associated senescence. Gibberellin tends to inhibit abscission by promoting growth.

Another example of hormonal interaction occurs during the germination of cereal seeds. The embryo (germ) is first activated by uptake of water, which enables it to produce gibberellin. Gibberellin acts on the living cells (aleurone layer) surrounding the food reserves (endosperm). This action induces the aleurone cells to produce enzymes that break down starch to sugars and release tryptophan from the protein of the endosperm. The tryptophan migrates to the coleoptile tip and is transformed into indolylacetic acid, which in turn moves to the growth zone and weakens the cell walls, thus permitting water uptake.

The target tissues probably play a role in such sequential actions, and it is likely that changes in their responsiveness to hormonal action, perhaps correlated with environmental stimuli, contribute to adaptive integration. The similarities in the hormonal mechanisms of plants and animals, two groups that are so profoundly different in their structure and mode of life, effectively illustrate the fundamental uniformity of biological organization.

Nucleic acids: E. CHARGAFF and J.N. DAVIDSON (eds.), *The Nucleic Acids: Chemistry and Biology,* 3 vol. (1955–60), a classical modern text, basic chemistry valid but biological sections out of date; E. CHARGAFF, *Essays on Nucleic Acids* (1963); D. COHEN, *The Biological Role of the Nucleic Acids* (1965), a short general monograph; J.N. DAVIDSON and W.E. COHN (eds.), *Progress in Nucleic Acid Research and Molecular Biology,* 11 vol. (1963–71), series of essays published irregularly; D.W. HUTCHINSON, *Nucleotides and Coenzymes* (1964), an elementary monograph; J.C. KENDREW, *The Thread of Life: An Introduction to Molecular Biology* (1966), a popular book based on a series of TV programs; A. KORNBERG, *Enzymatic Synthesis of DNA* (1962), three classical lectures; G. PARKER, W.A. REYNOLDS, and R. REYNOLDS, *DNA: The Key to Life* (1966), a programmed series of questions and answers; R.M.S. SMELLIE, *A Matter of Life: DNA* (1969), a popular paperback; and T.L.V. ULBRICHT, *Introduction to Nucleic Acids and Related Natural Products* (1966), an elementary monograph. College-level textbooks on this subject include: J.N. DAVIDSON, *The Biochemistry of the Nucleic Acids,* 6th ed. (1969); E. HARBERS, G.F. DOMAGK, and W. MULLER, *Introduction to Nucleic Acids: Chemistry, Biochemistry and Functions* (1968; orig. pub. in German, 1964); V.M. INGRAM, *The Biosynthesis of Macromolecules* (1965); A.M. MICHELSON, *The Chemistry of Nucleosides and Nucleotides* (1963); A.R. PEACOCKE and R.B. DRYSDALE, *The Molecular Basis of Heredity* (1965); STEPHEN NEIDLE (ed.), *Topics in Nucleic Acid Structure* (1981).

(J.N.D./R.Y.T./Ed.)

Vitamins: J.L. RODALE *et al., Complete Book of Vitamins* (1966), and J. MARKS, *Vitamins in Health and Disease* (1968), are among various popular works on vitamins. The following references are more advanced and require some background knowledge of biochemistry: G.H. BEATON and E.W. MCHENRY (ed.), *Nutrition: A Comprehensive Treatise,* vol. 2, *Vitamins, Nutrient Requirements and Food Selection* (1964), a discussion of the requirements and metabolism of vitamins and of deficiency diseases; S.A. KOSER, *Vitamin Requirements of Bacteria and Yeasts* (1968), on the requirements and metabolism of vitamins in microorganisms; F.A. ROBINSON, *The Vitamin Cofactors of Enzyme Systems* (1966), on the coenzyme function of vitamins; W.H. SEBRELL, JR. and R.S. HARRIS (eds.), vols. 1–5, P. GYORGY and W.N. PEARSON (eds.), vol. 6, 7, *The Vitamins,* 2nd ed. (1967), on the chemistry, biochemistry, and metabolism of vitamins, see esp. vol. 6 and 7 for a discussion of the methodology used in vitamin research; A.F. WAGNER and K. FOLKERS, *Vitamins and Coenzymes* (1964), a text with emphasis on molecular structure, organic synthesis and biosynthesis, chemical reactions, and metabolic roles of vitamins; ROMAN J. KUTSKY, *Handbook of Vitamins, Minerals, and Hormones,* 2nd ed. (1981).

(M.J.B.)

Hormones: E.J.W. BARRINGTON, *Hormones and Evolution* (1964), for students and general readers, concerned with the molecular structure and mode of action of hormones in relation to evolutionary theory; G.K. BENSON and J.G. PHILLIPS (eds.), *Hormones and the Environment* (1970), a wide-ranging review and research symposium, primarily for specialists but also of general interest; W.R. BUTT, *Hormone Chemistry* (1967), a correlation of research on the major mammalian hormones, requiring some knowledge of chemistry; R.E. COUPLAND, *The Natural History of the Chromaffin Cell* (1965), an integrated treatment of research on structure and function, considered at all levels of analysis, from the gross anatomical to the molecular; J. EBLING and K.C. HIGHNAM, *Chemical Communication* (1969), a concise elementary introduction for high school and first-year university students; B.E. FRYE, *Hormonal Control in Vertebrates* (1967), an elementary introduction, with emphasis on general principles and physiological adaptation; M. GABE, *Neurosecretion* (1966), an authoritative and comprehensive treatment for advanced students; G.W. HARRIS, *Neural Control of the Pituitary Gland* (1955), an authoritative monograph for students and research workers; M. PICKFORD, *The Central Role of Hormones* (1969), an elementary treatment for students and general readers with some knowledge of vertebrate biology; and C.T. SAWIN, *The Hormones: Endocrine Physiology* (1969), a clear treatment of hormone action for university students.

(E.J.W.B./Ed.)

The Biological Sciences

Biology may be defined as an area of learning that deals with all of the physicochemical aspects of life. But as a result of the modern tendency to unify scientific knowledge and investigation, there has been an overlapping of the field of biology with other scientific disciplines. Modern principles of other sciences—chemistry and physics, for example—are integrated with those of biology in such areas as biochemistry and biophysics.

Because biology is such a broad subject, it is subdivided into separate branches for convenience of study. Despite apparent differences, all the subdivisions are interrelated by basic principles. Thus, though it was once the custom to separate the study of plants (botany) from that of animals (zoology), and the study of the structure of organisms (morphology) from that of function (physiology), the current practice is to investigate those biological phenomena that all living things have in common.

Biology is often approached today on the basis of levels that deal with fundamental units of life. At the level of molecular biology, for example, life is regarded as a manifestation of chemical and energy transformations that occur among the many chemical constituents that comprise an organism. As a result of the development of more powerful and precise laboratory instruments and techniques, it is now possible to understand and define more exactly not only the invisible ultimate physiochemical organization (ultrastructure) of the molecules in living matter but also how living matter reproduces at the molecular level.

Cell biology, the study of the fundamental unit of structure and function in a living organism, may be said to have begun in the 17th century, with the invention of the compound microscope. Before that, the individual organism was studied as a whole (organismic biology), an area of research still regarded as an important level of biological organization. Population biology deals with groups or populations of organisms that inhabit a given area or region. Included at this level are studies of the roles that specific kinds of plants and animals play in the complex and self-perpetuating interrelationships that exist between the living and nonliving world, as well as studies of the built-in controls that maintain these relationships naturally.

These broadly based levels may be further subdivided into such specializations as morphology, taxonomy, biophysics, biochemistry, genetics, eugenics, and ecology.

In another way of classification, a field of biology may be especially concerned with the investigation of one kind of living thing—*e.g.*, botany, the study of plants; zoology, the study of animals; ornithology, the study of birds; ichthyology, the study of fishes; mycology, the study of fungi; microbiology, the study of microorganisms; protozoology, the study of one-celled animals; herpetology, the study of amphibians and reptiles; entomology, the study of insects; and physical anthropology, the study of man. For a list of both *Macropædia* and *Micropædia* articles on the subject areas, see *Propædia*: Part Three.

The article is divided into the following sections:

Basic concepts of biology

BIOLOGICAL PRINCIPLES

Homeostasis. The concept of homeostasis—*i.e.,* that all living things maintain a constant internal environment—was first suggested by Claude Bernard, a 19th-century French physiologist, who stated that "all the vital mechanisms, varied as they are, have only one object: that of preserving constant the conditions of life."

As originally conceived by Bernard, homeostasis applied to the struggle of a single organism to survive. The concept was later extended to include any biological system from the cell to the entire biosphere, all the areas of the Earth inhabited by living things.

Unity. All living organisms, regardless of their uniqueness, have certain biological, chemical, and physical characteristics in common. All, for example, are composed of the same basic units, or cells, and the same chemical substances, which, when analyzed, exhibit noteworthy similarities, even in such disparate organisms as bacteria and man. Furthermore, since the action of any organism is determined by the manner in which its cells interact and since all cells interact in much the same way, the basic functioning of all organisms is also similar.

There is not only unity of basic living substance and functioning but also unity of origin of all living things. According to a theory proposed in 1855 by Rudolf Virchow, a German pathologist, "all living cells arise from pre-existing living cells." This theory appears to be true for all living things at the present time under existing environmental conditions. If, however, life originated more than once in the past, the fact that all organisms have a sameness of basic structure, composition, and function would seem to indicate that only one original type succeeded.

Similarities between man and slime molds

A common origin of life would explain why in man or slime mold—and in all forms of life in between—the same chemical substance, deoxyribonucleic acid (DNA), in the form of genes accounts for the ability of all living matter to replicate itself exactly and to transmit genetic information from parent to offspring. Furthermore, the mechanisms for this transmittal follow a pattern that is the same in all organisms.

Whenever a change in a gene (a mutation) occurs, there is a change of some kind in the organism that contains the gene. It is this universal phenomenon that gives rise to the differences (variations) in populations of organisms from which nature selects for survival those that are best able to cope with changing conditions in the environment.

Evolution. In his theory of natural selection, which is discussed in greater detail later, Charles Darwin suggested that "survival of the fittest" was the basis for organic evolution (the modification of living things with time). Evolution itself is a biological phenomenon common to all living things, even though it has led to their differences. Evidence to support the theory of evolution has come primarily from the fossil record, from comparative studies of structure and function, and from studies of embryological development.

Diversity. Despite the basic biological, chemical, and physical similarities found in all living things, a diversity of life exists not only among and between species but also within every natural population. The phenomenon of diversity has had a long history of study because so many of the variations that exist in nature are visible to the eye. The fact that organisms changed during prehistoric times and that new variations are constantly evolving can be verified by paleontological records as well as by breeding experiments in the laboratory. Long after Darwin had assumed that variations existed, biologists discovered that they are caused by a change in the genetic material (DNA). This change can be a slight alteration in the sequence of the constituents of DNA (nucleotides), a larger change such as a structural alteration of a chromosome, or a complete change in the number of chromosomes. In any case, a change in the genetic material in the reproductive cells manifests itself as some kind of structural or chemical change in the offspring. The consequence of such a mutation depends upon the interaction of the mutant offspring with its environment.

Adjusting to changing conditions

It has been suggested that sexual reproduction became the dominant type of reproduction among organisms because of its inherent advantage of variability, which is the mechanism that enables a species to adjust to changing conditions. New variations are potentially present in genetic differences, but how preponderant a variation becomes in a gene pool depends upon the number of offspring the mutants or variants produce (differential reproduction). It is possible for a genetic novelty (new variation) to spread in time to all members of a population, especially if the novelty enhances the population's chances for survival in the environment in which it exists. Thus, when a species is introduced into a new habitat, it either adapts to the change by natural selection or by some other evolutionary mechanism or else it eventually dies off. Because each new habitat means new adaptations, habitat changes have been responsible for the millions of different kinds of species and for the heterogeneity within each species.

The total number of animal and plant species is estimated at between 2,000,000 and 4,500,000; authoritative estimates of the number of extinct species range from 15,000,000 up to 16,000,000,000. Although the use of classification as a means of producing some kind of order out of this staggering number of different types of organisms appears as early as the book of Genesis—with references to cattle, beasts, fowl, creeping things, trees, etc.—the first scientific attempt at classification is attributed to the Greek philosopher Aristotle, who tried to establish a system that would indicate the relationship of all things to each other. He arranged everything along a scale, or "ladder of nature," with nonliving things at the bottom; plants were placed below animals, and man was at the top. Other schemes that have been used for grouping species include large anatomical similarities, such as wings or fins, which indicate a natural relationship, and also similarities in reproductive structures.

At the present time taxonomy is based on two major assumptions: one is that similar body construction can be used as a criterion for a classification grouping; the other that, in addition to structural similarities, evolutionary and molecular relationships between organisms can be used as a means for determining classification.

Behaviour and interrelationships. As was mentioned earlier, the study of the relationships of living things to each other and to their environment is known as ecology. Because these interrelationships are so important to the welfare of Earth and because they can be seriously disrupted by man's activities, ecology is becoming one of the most important branches of biology.

Continuity. Whether an organism is man or a bacterium, its ability to reproduce is one of the most important characteristics of life. Because life comes only from preexisting life, it is only through reproduction that successive generations can carry on the properties of a species.

THE STUDY OF STRUCTURE

Living things are defined in terms of the activities or functions that are missing in nonliving things. The life processes of every organism are carried out by specific materials assembled in definite structures. Thus, a living thing can be defined as a system, or structure, that reproduces, changes with its environment over a period of time, and maintains its individuality by constant and continuous metabolism. This pattern of action or function results from and occurs in a pattern of organization.

Cells and their constituents. Knowledge of the structure and function of the cell has resulted from technological developments and methods.

Biologists once depended on the light microscope to study the morphology of cells found in higher plants and animals. The functioning of cells in unicellular and in multicellular organisms was then postulated from observation of the structure; the discovery of the chloroplastids in the cell, for example, led to the investigation of the process of photosynthesis. With the invention of the electron microscope, the fine organization of the plastids could be utilized for further quantitative studies of the different parts of this process.

Quantitative studies make use of histochemistry to identi-

fy proteins, carbohydrates, and other chemical constituents of cells. Histochemistry has also been used to identify RNA and DNA in various cell parts.

Tracing the movement of substances

A valuable method useful in tracing the movement of substances in living matter is radioautography: when radioactive nutrients, which can be incorporated into cells, are injected into animals, they give off detectable rays by which their presence and location can be determined. Thymidine, for example, can be made radioactive and, when injected, becomes part of the DNA being synthesized in the nucleus before cell division; the nuclei then can be identified by their radioactivity and the process of the origin of new DNA studied. Radioautography has been used to locate the site of protein synthesis and enzyme storage in cells.

Advanced technological developments—the microspectrophotometer, the X-ray probe, laser beam, computer, stereoscopic microscope, quartz-fibre microbalance, and television microscopy—are used to study the action of enzymes in living cells. The elucidation of such processes as lipid synthesis, active transport of large particles from the blood into cells, and continuous formation of taste cells has been dependent on similar instrumentation.

Tissues and organs. Early biologists viewed their work as a study of the organism. The organism, then considered the fundamental unit of life, is still the prime concern of some modern biologists, and the maintenance of organisms is still an important part of biological research.

In 1912 an experiment showed that cells can be kept alive indefinitely if proper conditions are maintained. Utilizing stringent laboratory techniques, workers have kept bits of chicken heart tissue alive for more than 30 years. Techniques for keeping organs alive in preparation for transplants stem from such experiments.

Modern biological research deals with the study of structure and function at all levels of biological organization from the molecule to the organism. Electronics, mathematics, and computers have become increasingly important in solving problems at all of these levels.

THE STUDY OF FUNCTION

To maintain life, an organism not only repairs or replaces (or both) its structures by a constant supply of the materials of which it is composed but also keeps its life processes in operation by a steady supply of energy. The initial source of this energy is the environment outside of the organism. The process by which the organism provides the necessary raw materials for the continuation of life is called nutrition. Plants obtain their nutrients from water, from minerals, and from the carbohydrates they manufacture. Animals, which cannot manufacture their own food, need at least the following kinds of nutrients: water, minerals, organic carbon, organic nitrogen, vitamins, certain amino acids, and fatty acids.

Many experiments have been directed toward solving the problem of biological differentiation. It has been determined that, although all genes of an organism are present in every cell, they do not all act at the same time: some genes act only at certain times during development; others never act in some cells. Whether a gene is active is sometimes the result of an interaction between cells. Cells seem to develop differently in different locations. How this is controlled is not definitely known; one possibility is the presence of an electrical communication between cells or of a substance that diffuses out of the cell. The latter idea is suggested by experiments demonstrating that the formation of the tissues of organs such as the eye, kidney, and liver are directly influenced by the tissues bordering them. Many of these experiments make use of tissue culture techniques, which permit the growth of cells outside of the body. It is possible to grow a single embryonic muscle cell into a colony of differentiated muscle. It is through such experiments that the questions about development and its implications may eventually be answered. (E.R.G.)

The history of biology

There are moments in the history of all sciences when remarkable progress is made in relatively short periods of time. Such leaps in knowledge result in great part from two factors: one is the presence of a creative mind—a mind sufficiently perceptive and original to discard hitherto accepted ideas and formulate new hypotheses; the second is the technological ability to test the hypotheses by appropriate experiments. The most original and inquiring mind is severely limited without the proper tools to conduct an investigation; conversely, the most sophisticated technological equipment cannot of itself yield insights into any scientific process.

Creative minds and technology

An example of the relationship between these two factors was the discovery of the cell. For hundreds of years there had been speculation concerning the basic structure of both plants and animals. Not until optical instruments were sufficiently developed to reveal cells, however, was it possible to formulate a general hypothesis, the cell theory, that satisfactorily explained how plants and animals are organized. Similarly, the significance of Gregor Mendel's studies on the mode of inheritance in the garden pea remained neglected for many years, until technological advances made possible the discovery of the chromosomes and the part they play in cell division and heredity. Moreover, as a result of the relatively recent development of extremely sophisticated instruments, such as the electron microscope and the ultracentrifuge, biology has moved from being a largely descriptive science—one concerned with entire cells and organisms—to a discipline that increasingly emphasizes the subcellular and molecular aspects of organisms and attempts to equate structure with function at all levels of biological organization.

THE EARLY HERITAGE

Although it is not known when the study of biology originated, early man must have had some knowledge of the animals and plants around him. His very survival depended upon the accurate recognition of nonpoisonous food plants and upon an understanding of the habits of dangerous predators. Archaeological records indicate that even before the development of civilization, man had domesticated virtually all the amenable animals available to him and had developed an agricultural system sufficiently stable and efficient to satisfy the needs of large numbers of people living together in communities. It is clear, therefore, that much of the history of biology predates the time at which man began to write and to keep records.

Earliest biological records. *Biological practices among Assyrians and Babylonians.* Much of the earliest recorded history of biology is derived from bas-reliefs the Assyrians and Babylonians made of their cultivated plants and from carvings depicting their veterinary medicine. Illustrations on certain seals reveal that the Babylonians had learned that the date palm reproduces sexually and that pollen could be taken from the male plant and used to fertilize female plants. Although a precise dating of these early records is lacking, a Babylonian business contract of the Hammurabi period (*c.* 1800 BC) mentions the male flower of the date palm as an article of commerce, and descriptions of date harvesting date back to about 3500 BC.

Another source of information concerning the extent of biological knowledge of these early peoples was the discovery of several papyri that pertain to medical subjects; one, believed to date back to 1600 BC, contains anatomical descriptions; another (*c.* 1500 BC) indicates that the importance of the heart had been recognized. Because these ancient documents, which contained mixtures of fact and superstition, probably summarized then-current knowledge, it may be assumed that some of their contents had been known by earlier generations.

Biological knowledge of Egyptians, Chinese, and Indians. Papyri and artifacts found in tombs and pyramids indicate that the Egyptians also possessed considerable medical knowledge. Their well-preserved mummies demonstrate that they had a thorough understanding of the preservative properties of herbs required for embalming; plant necklaces and bas-reliefs from various sources also reveal that the ancient Egyptians were well aware of the medicinal value of certain plants 2,000 years before Christ. Even earlier (*c.* 2800 BC), a work now ascribed to the Chinese emperor Shen Nung described the therapeutic powers of

Early use of medicinal plants

numerous medicinal plants and included descriptions of many important food plants, such as the soybean. Furthermore, the ancient Chinese not only utilized the silkworm *Bombyx mori* to produce silk for commerce but also understood the principle of biological control, employing one type of insect, an entomophagous (insect-eating) ant, to destroy insects that bored into trees.

As early as 2500 BC the people of northwestern India had a well-developed science of agriculture. The ruins at Mohenjodaro have yielded seeds of wheat and barley that were cultivated at this time. Millet, dates, melons, and other fruits and vegetables, as well as cotton, were known to this civilization. Plants were not only a source of food, however. A document, believed to date back to the 6th century BC, described the use of about 960 medicinal plants and included information on such topics as anatomy, physiology, pathology, and obstetrics.

The Greco-Roman world. Although the Babylonians, Assyrians, Egyptians, Chinese, and Indians amassed much biological information, they lived in a world believed to be dominated by unpredictable demons and spirits. Hence, learned men in these early cultures directed their studies toward an understanding of the supernatural, rather than the natural, world. Anatomists, for example, dissected animals not to gain an understanding of their structure but to study their organs in order to predict the future. With the emergence of the Greek civilization, however, these mystical attitudes began to change. Around 600 BC there arose a school of Greek philosophers who believed that every event has a cause and that a particular cause produces a particular effect. This concept, known as causality, had a profound effect on subsequent scientific investigation. Furthermore, these philosophers assumed the existence of a "natural law" that governs the universe and can be comprehended by man through the use of his powers of observation and deduction. Although they established the science of biology, the greatest contribution the Greeks made to science was the idea of rational thought.

Theories about man and the origin of life. One of the earliest Greek philosophers, Thales of Miletus (*c.* 7th century BC), maintained that the universe contained a creative force that he called physis, an early progenitor of the term physics; he also postulated that the world and all living things in it were made from water. Anaximander, a student of Thales, did not accept water as the only substance from which living things were derived; he believed that in addition to water, living things consisted of earth and a gaslike substance called *apeiron,* which could be divided into hot and cold. Various mixtures of these materials gave rise to the four elements: earth, air, fire, and water.

Early evolutionary theory

Although he was one of the first to describe the Earth as a sphere rather than as a flat plane, Anaximander proposed that life arose spontaneously in mud and that the first animals to emerge had been fishes covered with a spiny skin. The descendants of these fishes eventually left water and moved to dry land, where they gave rise to other animals by transmutation (the conversion of one form into another). Thus, an early evolutionary theory was formulated.

At Crotone in southern Italy, where an important school of natural philosophy was established by Pythagoras about 500 BC, one of his students, Alcmaeon, investigated animal structure and described the difference between arteries and veins, discovered the optic nerve, and recognized the brain as the seat of the intellect. As a result of his studies of the development of the embryo, Alcmaeon may be considered the founder of embryology.

Although the Greek physician Hippocrates, who established a school of medicine on the Aegean island of Cos around 400 BC, was not an investigator in the sense of Alcmaeon, he did recognize through observations of patients the complex interrelationships involved in the human body. He also understood how the environment can influence human nature and suggested that sharply contrasting climates tend to produce a powerful type of inhabitant, while an even, temperate climate is conducive to indolence.

Hippocrates and his predecessors were all concerned with the central philosophical question of how the cosmos and its inhabitants were created. Although they accepted the physis as the creative force, they differed with regard to the importance of the roles played by earth, air, fire, water, and other elements. Although Anaximenes, for example, who may have been a student of Anaximander, adhered to the then-popular precept that life originated in a mass of mud, he postulated that the actual creative force was to be found in the air and that it was influenced by the heat of the Sun. Members of the Hippocratic school also believed that all living bodies were made up of four humours—blood, black bile, phlegm, and yellow bile—which supposedly originated in the heart, spleen, brain, and liver, respectively. An imbalance of the humours was thought to cause an individual to be sanguine, melancholy, phlegmatic, or choleric. The persistence of these words in current vocabulary attests to the lengthy popularity of the idea of humoral influences. For centuries it was also believed that an imbalance in the humours was the cause of disease, a belief that resulted in the common practice of bloodletting to get rid of excessive humours.

Aristotelian concepts. Around the middle of the 4th century BC, ancient Greek science reached a climax with Aristotle, who was interested in all branches of knowledge, including biology. Using his own observations and theories, Aristotle was the first to attempt a system of animal classification, in which he contrasted animals containing blood with those that were bloodless. The animals with blood included those now grouped as mammals (except the whales, which he placed in a separate group), birds, amphibians, reptiles, and fishes. The bloodless animals were divided into the cephalopods, the higher crustaceans, the insects, and the testaceans, the last group being a collection of all the lower animals. His careful examination of animals led to the understanding that mammals have lungs, breathe air, are warm-blooded, and suckle their young. Aristotle was the first to show any understanding of an overall systematic taxonomy and to recognize units of different degrees within the system.

Aristotle's classification of animals

The most important part of Aristotle's work was that devoted to reproduction and the related subjects of heredity and descent. He identified four means of reproduction, including the abiogenetic origin of life from nonliving mud, a belief held by Greeks of that time. Other modes of reproduction recognized by him included budding (asexual reproduction), sexual reproduction without copulation, and sexual reproduction with copulation. Aristotle described sperm and ova and believed that the menstrual blood of viviparous organisms (those that give birth to living young) was the actual generative substance.

Although Aristotle recognized that species are not stable and unalterable and although he attempted to classify the animals he observed, he was far from developing any pre-Darwinian ideas concerning evolution. In fact, he rejected any suggestion of natural selection and sought teleological explanations (*i.e.,* all phenomena in nature are shaped by a purpose) for any given observation. Nevertheless, many important scientific principles, some of which are often thought of as 20th-century concepts, can be ascribed to Aristotle. The following are a few such: (1) Using birds as an example, he formulated the principle that all organisms are structurally and functionally adapted to their habits and habitats. (2) Nature is parsimonious; it does not expend unnecessary energy. (3) In classifying animals, Aristotle rejected the idea of dividing them solely by their external structures (*e.g.,* animals with wings and those without wings). He recognized instead a basic unity of plan among diverse organisms, a principle that is still conceptually and scientifically sound. Further, Aristotle also believed that the entire living world could be described as a unified organization rather than as a collection of diverse groups. (4) By his observations, Aristotle realized the importance of structural homology, basically similar organs in different animals, and functional analogy, different structures that serve somewhat the same function—*e.g.,* the hand, claw, and hoof are analogous structures. These principles constitute the basis for the biological field of study known as comparative anatomy. (5) Aristotle's observations also led to the formulation of the principle that general structures appear before specialized ones and that tissues differentiate before organs.

Biological principles formulated by Aristotle

Botanical investigations. Of all the works of Aristotle that have survived, none deals with what was later differentiated as botany, although it is believed that he wrote at least two treatises on plants. Fortunately, however, the work of Theophrastus, one of Aristotle's students, has been preserved to represent plant science of the Greek period. Like Aristotle, Theophrastus was a keen observer, although his works do not express the depth of original thought exemplified by his teacher. In his great work, *De historia et causis plantarum* (*The Calendar of Flora,* 1761), in which the morphology, natural history, and therapeutic use of plants are described, Theophrastus distinguished between the external parts, which he called organs, and the internal parts, which he called tissues. This was an important achievement because Greek scientists of this period had no established scientific terminology by which a specific structure could be referred to with a scientific term. For this reason, both Aristotle and Theophrastus were obliged to write very long descriptions of structures that can be described rapidly and simply today. Because of this difficulty, Theophrastus sought to develop a scientific nomenclature by giving special meaning to words that were then in more or less current use; for example, *karpos* for fruit and *perikarpion* for seed vessel.

Development of scientific terminology

Although he did not propose an overall classification system for plants, over 500 of which are mentioned in his writings, Theophrastus did unite many species into what are now considered genera. In addition to writing the earliest detailed description of how to pollinate the date palm by hand and the first unambiguous account of sexual reproduction in flowering plants, he also recorded observations on seed germination and development.

Post-Grecian biological studies. With Aristotle and Theophrastus, the great Greek period of scientific investigation came to an end. The most famous of the new centres of learning were the library and museum in Alexandria. From 300 BC until around the time of Christ all significant biological advances were made by physicians at Alexandria. One of the most outstanding of these men was Herophilus, who dissected human bodies and compared their structures to those of other large mammals. He recognized the brain, which he described in detail, as the centre of the nervous system and the seat of intelligence. Based on his knowledge, he wrote a general anatomical treatise, a special one on the eyes, and a handbook for midwives.

Erasistratus, a younger contemporary and reputed rival of Herophilus who also worked at the museum in Alexandria, studied the valves of the heart and the circulation of blood. Although he was wrong in supposing that blood flows from the veins into the arteries, he was correct in assuming that small interconnecting vessels exist. He thus suspected (but did not see) the presence of capillaries; he thought, however, that the blood changed into air, or *pneuma,* when it reached the arteries, to be pumped throughout the body.

Perhaps the last of the ancient biological scientists of note was Galen of Pergamum, a Greek physician who practiced in Rome during the middle of the 2nd century AD. His early years were spent as a surgeon at the gladiatorial arena, which gave him the opportunity to observe details of human anatomy. But this was an age when it was considered improper to dissect human bodies, and, as a result, detailed study was not possible. Thus, though Galen's research on animals was thorough, his knowledge of human anatomy was faulty. Because his work was extensive and clearly written, Galen's writings, nevertheless, dominated medicine for centuries to come.

The Arab world and the European Middle Ages. After Galen there were no further biological investigations for many centuries. It is sometimes claimed that the rise of Christianity was the cause of the decline in science; this, however, is not a tenable viewpoint, for science was already virtually dead by the end of the 2nd century AD, a time when Christianity was still an obscure sect. It is true, however, that the rise of Christianity did not favour the questioning attitude of the Greeks.

The decline of science

Arab domination of biology. During the almost 1,000 years that science was dormant in Europe, the Arabs, who by the 9th century had extended their sphere of influence as far as Spain, became the custodians of science and dominated biology, as they did other disciplines. At the same time, as the result of a revival of learning in China, new technical inventions flowed from there to the West. The Chinese had discovered how to make paper and how to print from movable type, two achievements that were to have an inestimable effect upon learning. Another important advance that also occurred during this time was the introduction into Europe from India of the so-called Arabic numerals.

From the 3rd until the 11th century biology was essentially an Arab science. Although they themselves were not great innovators, they discovered the works of such men as Aristotle and Galen, translated them into Arabic, studied them, and wrote commentaries about them. Of the Arab biologists, al-Jāḥiẓ, who died about 868, is particularly noteworthy. Among his biological writings is *Kitāb al-ḥayawān* ("Book of Animals"), which, although revealing some Greek influence, is primarily an Arabic work. In it, the author emphasized the unity of nature and recognized relationships between different groups of organisms. Because al-Jāḥiẓ believed that the Earth contained both male and female elements, he found the Greek doctrine of spontaneous generation (life emerging from mud) to be quite reasonable.

Ibn Sīnā, or Avicenna as he is better known, was an outstanding Persian scientist around the beginning of the 11th century; he was the true successor to Aristotle. His writings on medicine and drugs, which were particularly authoritative and remained so until the Renaissance, did much to bring the works of Aristotle back to Europe, where they were translated into Latin from Arabic.

Development of botany and zoology. During the 12th century the growth of biology was sporadic. Nevertheless, it was during this time that botany was developed from the study of plants with healing properties; similarly, from veterinary medicine and the pleasures of the hunt came zoology. Because of the interest in medicinal plants, herbs in general began to be described and illustrated in a realistic manner. Although Arabic science was well developed during this period and was far in advance of Latin, Byzantine, and Chinese cultures, it began to show signs of decline. Latin learning, on the other hand, rapidly increasing, was best exemplified perhaps by a mid-13th-century German scholar, Albertus Magnus (Albert the Great), who was probably the greatest naturalist of the Middle Ages. His biological writings (*De vegetabilibus,* seven books, and *De animalibus,* 26 books) were based on the classical Greek authorities, predominantly Aristotle. But in spite of this classical basis, a significant amount of his work contained new observations and facts; for example, he described with great accuracy the leaf anatomy and venation of the plants he studied.

Albert was particularly interested in plant propagation and reproduction and discussed in some detail the sexuality of plants and animals. Like his Greek predecessors, he believed in spontaneous generation; he also believed that animals were more perfect than plants because they required two individuals for the sexual act. Perhaps one of Albert's greatest contributions to medieval biology was the denial of many superstitions believed by his contemporaries, a skepticism that, together with the reintroduction of Aristotelian biology, was to have profound effects on subsequent European science.

One of Albert's pupils was Thomas Aquinas, who endeavoured to reconcile Aristotelian philosophy and the teachings of the church. Because Aquinas was a rationalist, he declared that God created the reasoning mind; hence, by true intellectual processes of reasoning, man could not arrive at a conclusion that was in opposition to Christian thought. Acceptance of this philosophy made possible a revival of rational learning that was consistant with Christian belief.

Revival of rational learning

Revitalization of anatomy. Italy, during the Middle Ages, became the most active scientific centre, although its major interests were concentrated on agriculture and medicine. A development of particular significance at this time was the introduction of dissection into medical schools, a step that revitalized the study of anatomy. Be-

cause of what it reveals about medieval anatomy in general, the work of Mondino dei Liucci, the most famous of the Italian anatomists at the beginning of the 14th century, is particularly important. First, because there was no way of preserving cadavers, organs that spoiled quickly had to be dissected rapidly. Furthermore, it was the custom for the teacher to leave the actual dissection to an underling, who, not wishing to offend the teacher, agreed with all of his statements. Thus, although Mondino performed all of his own dissections and, from his observations, could have corrected the errors of the Greeks and Arabs, he did not choose to contradict any of the authorities. Even when the authorities contradicted themselves, Mondino sought to harmonize their views. Perhaps Mondino exemplifies the difficulty that was so characteristic of the era; namely, the problem of breaking away from established authority.

The Renaissance. *Resurgence of biology.* Beginning in Italy during the 14th century there was a general ferment within the culture itself, which, together with the rebirth of learning (partly as a result of the rediscovery of Greek work), is referred to as the Renaissance. Interestingly, it was the artists, rather than the professional anatomists, who were intent upon a true rendering of the bodies of animals and men and thus were motivated to gain their knowledge firsthand by dissection. No individual better exemplifies the Renaissance than Leonardo da Vinci, whose anatomical studies of the human form during the late 1400s and early 1500s were so far in advance of the age that they included details not recognized until a century later. Furthermore, while dissecting animals and examining their structure, Leonardo compared them to the structure of man. In doing so he was the first to indicate the homology between the arrangements of bones and joints in the leg of the human and that of the horse, despite the superficial differences. Homology was to become an important concept in uniting outwardly diverse groups of animals into distinct units, a factor that is of great significance in the study of evolution.

Leonardo's discovery of homologous structures

Other factors had a profound effect upon the course of biology in the 1500s, particularly the introduction of printing around the middle of the century, the increasing availability of paper, and the perfected art of the wood engraver, all of which meant that illustrations as well as letters could be transferred to paper. In addition, after the Turks had conquered Byzantium in 1453, many Greek scholars took refuge in the West; the scholars of the West thus had direct access to the scientific works of antiquity, rather than indirect access through Arabic translations.

Advances in botany. Otto Brunfels, the German theologian and botanist, published in 1530 a book about medicinal herbs, *Herbarum vivae eicones,* which, with its fresh and vigorous illustrations, contrasted sharply with earlier texts, whose authors had been content merely to copy from old manuscripts. In addition to books on the same subject, Hieronymus Bock (Latinized to Tragus) and Leonhard Fuchs also published around the mid-1500s descriptive, well-illustrated texts about common wild flowers. The books published by the three men, who are often referred to as the German fathers of botany, may be considered the forerunners of modern botanical floras (treatises on or lists of the plants of an area or period).

Throughout the 16th century, interest in botanical study also existed in such other countries as the Netherlands, Switzerland, Italy, and France. During this time there was a great improvement in the classification of plants, which had been described in ancient herbals merely as trees, shrubs, or plants and, in later books, were either listed alphabetically or arranged in some arbitrary grouping. The necessity for a systematic method to designate the increasing number of plants being described became obvious. Accordingly, using a binomial system very similar to modern biological nomenclature, Gaspard Bauhin, a Swiss botanist of the late 16th and early 17th centuries, designated plants by a generic and a specific name. Although affinities between plants were indicated by the use of common generic names, Bauhin did not speculate on their common kinship.

Bauhin's botanical nomenclature

Pierre Belon, a French naturalist who travelled extensively in the Middle East, where he studied the flora, illustrates the wide interest of the 16th-century biologists. Although his botanical work was limited to two volumes, one on trees and one on horticulture, his books on travel included numerous biological entries, and his two books on fishes reveal much about the current state of systematics, including not only fishes but also such other aquatic creatures as mammals, crustaceans, mollusks, and worms. In his *L'Histoire de la nature des oyseaux* ("Natural History of Birds"), however, in which Belon's taxonomy was remarkably similar to that being used today, he showed a clear grasp of comparative anatomy, particularly of the skeleton, publishing the first picture of a bird skeleton beside a human skeleton to point out the homologies. Numerous other European naturalists who travelled extensively also brought back accounts of exotic animals and plants, and most of them wrote voluminous records of their excursions. Two other factors contributed significantly to the development of botany at this time: first was the establishment of botanical gardens by the universities, as distinct from the earlier gardens that had been established for medicinal plants; second was the collection of dried botanical specimens, or herbaria.

It is perhaps surprising that the great developments in botany during the 16th century had no parallel in zoology. Instead, there arose a group of biologists known as the Encyclopedists, best represented by Conrad Gesner, a 16th-century Swiss naturalist, who compiled books on animals that were illustrated by some of the finest artists of the day (Albrecht Dürer, for example). But because the descriptions of many of the animals were grossly inaccurate, in many cases continuing the legends of the Greeks, apart from their aesthetic value the books did little to advance zoological knowledge.

Advances in anatomy. Like that of botany, the beginning of the scientific study of anatomy can be traced to a combination of humanistic learning, Renaissance art, and the craft of printing. Although Leonardo da Vinci initiated anatomical studies of human cadavers, his work was not known to his contemporaries. Rather, the appellation father of anatomy must be accorded to the Belgian anatomist Andreas Vesalius, who studied at the rather conservative schools in Louvain and Paris, where he became a successful teacher very familiar with Galen's work. As a result of disagreements with his superiors, however, Vesalius moved at the end of 1537 to Padua, where he became noted for far-reaching teaching reforms. Most important, Vesalius abolished the practice of having someone else do the actual dissection; instead, he dissected his own cadavers and lectured to students from his findings. His text, *De humani corporis fabrica libri septem* (1543; "Seven Books on the Structure of the Human Body"), was the first modern book on the subject of anatomy and, as such, constituted a foundation of great importance for biology. Perhaps Vesalius' greatest contribution, however, was that he inspired a group of younger scientists to be critical and to accept a description only after they had verified it. Thus, as anatomists became more questioning and critical of the works of others, the stranglehold of Galen was finally broken. Of Vesalius' successors, Michael Servetus, a Spanish theologian and physician, discovered the pulmonary circulation of the blood from the right chamber of the heart to the lungs and stated that the blood did not pass through the central septum (wall) of the heart, as had previously been believed.

The father of anatomy

ADVANCES TO THE 20TH CENTURY

Seventeenth-century advances in biology included the establishment of scientific societies for the dissemination of ideas and progress in the development of the microscope, through which man discovered a hitherto invisible world that had far-reaching effects on biology. Systematizing and classifying, however, dominated biology throughout much of the 17th and 18th centuries, and it was during this time that the importance of the comparative study of living organisms, including man, was realized. During the 18th century the long-held idea that living organisms could originate from nonliving matter (spontaneous generation) began to crumble, but it was not until after the mid-19th century that it was finally disproved by Louis Pas-

teur. Biological expeditions added to the growing body of knowledge of plant and animal forms and led to the 19th-century development of the theory of evolution. The 19th century was one of great progress in biology: in addition to the formulation of the theory of evolution, the cell theory was established, the foundations for modern embryology were laid, and the laws of heredity were discovered.

The discovery of the circulation of blood. William Harvey, an Englishman who studied at Padua with one of Vesalius' students, is credited with the discovery of the circulation of the blood. Prior to Harvey, the Aristotelian-Galenistic theory of circulation supposed that the blood sucked up by the heart during its expansion ebbed away during contraction; further, the theory also suggested that the blood flowed through pores between the two halves of the heart and that the heart produced a vital heat, which was tempered by the air from the lungs. In his own work, however, Harvey demonstrated that the heart expands passively and contracts actively. Also, by measuring the amount of blood flowing from the heart, he concluded that the body could not continuously produce that amount. Finally, he was able to show that blood was returned to the heart through the veins, postulating a connection (the capillaries) between the arteries and veins that was not to be discovered for another century. Harvey was also interested in embryology, to which he made a significant contribution by suggesting that there is a stage (the egg) in the development of all animals during which they are undifferentiated living masses. A biological dictum, *ex ovo omnia* ("everything comes from the egg"), is a summation of this concept.

Postulation of the existence of blood capillaries

The establishment of scientific societies. A development of great importance to science was the establishment in Europe of academies or societies; they consisted of small groups of men who met to discuss subjects of mutual interest. Although some of the groups enjoyed the financial patronage of princes and other wealthy members of society, the members' interest in science was the sole sustaining force. The academies also provided freedom of expression, which, together with the stimulus of exchanging ideas, contributed greatly to the development of scientific thought. One of the earliest of these organizations was the Italian Academy of the Lynx, founded in Rome around 1603. Galileo Galilei made a microscope for the society; another of its members, Johannes Faber, an entomologist, gave the instrument its name. Other academies in Europe included the French Academy of Science (founded in 1666), a German Academy in Leipzig, and a number of small academies in England that in 1662 became incorporated under royal charter as the Royal Society of London, an organization that was to have considerable influence on scientific developments in England.

In addition to providing a forum for the discussion of scientific matters, another important aspect of these societies was their publications. Before the advent of printing there were no convenient means for the wide dissemination of scientific knowledge and ideas; hence, scientists were not well informed about the works of others. To correct this deficiency in communications, the early academies initiated several publications, the first of which, *Journal des Savants,* was published in 1665 in France. Three months later, the Royal Society of London originated its *Philosophical Transactions.* At first this publication was devoted to reviews of work completed and in progress; later, however, the emphasis gradually changed to accounts of original investigations that maintained a high level of scientific quality. Gradually, specialized journals of science made their appearance, though not until at least another century had passed.

Early publications

The development of the microscope. The magnifying power of segments of glass spheres was known to the Assyrians before the time of Christ; during the 2nd century AD, Claudius Ptolemy, an astronomer, mathematician, and geographer at Alexandria, wrote a treatise on optics in which he discussed the phenomena of magnification and refraction as related to such lenses and to glass spheres filled with water. Despite this knowledge, however, glass lenses were not used extensively until around 1300, when some anonymous person invented spectacles for the improvement of vision. This invention aroused curiosity concerning the property of lenses to magnify, and in the 16th century several papers were written about such devices. Then, near the end of the 16th century, it was discovered that if certain lenses are mounted together in a tube, they form what physicists now call a Galilean telescope when viewed through one end, and a Galilean microscope when viewed through the other. When, in the early 1600s, Galileo used this instrument to examine the stars and planets, he was able to record such new discoveries as the rings of Saturn and the four satellites of Jupiter. Although Galileo is often credited with making the first biological observations with the microscope, he did not make any further contributions to its development.

Following subsequent technological improvements in the instrument and the development of a more liberal attitude toward scientific research, five microscopists emerged who were to have a profound affect on biology: Marcello Malpighi, Antonie van Leeuwenhoek, Jan Swammerdam, Nehemiah Grew, and Robert Hooke.

The classical microscopists

Malpighi's animal and plant studies. Marcello Malpighi, an Italian biologist and physician, conducted extensive studies in animal anatomy and histology (the microscopic study of the structure, composition, and function of tissues). He was the first to describe the inner (malpighian) layer of the skin, the papillae of the tongue, the outer part (cortex) of the cerebral area of the brain, and the red blood cells. He wrote a detailed monograph on the silkworm; a further major contribution was a description of the development of the chick, beginning with the 24-hour stage. In addition to these and other animal studies, Malpighi made detailed investigations in plant anatomy. He systematically described the various parts of plants, such as bark, stem, roots, and seeds, and discussed such processes as germination and gall formation; he may even have suspected that plants were made up of cells, a concept that had not yet been introduced. Many of Malpighi's drawings of plant anatomy remained unintelligible to botanists until the structures were rediscovered in the 19th century. Although Malpighi was not a technical innovator, he does exemplify the functioning of the educated 17th-century mind, which, together with curiosity and patience, resulted in many advances in biology.

The discovery of "animalcules." Antonie van Leeuwenhoek, a Dutchman who spent most of his life in Delft, sold cloth for a living. As a young man, however, he became interested in grinding lenses, which he mounted in gold, silver, or copper plates. Indeed, he became so obsessed with the idea of making perfect lenses that he neglected his business and was ridiculed by his family and neighbours. Using single lenses rather than compound ones (a system of two or more), Leeuwenhoek achieved magnifications from 40 to 270 diameters, a remarkable feat for hand-ground lenses. Among his most conspicuous observations was the discovery in 1675 of the existence in stagnant water and prepared infusions of many protozoans, which he called animalcules. He observed the connections between the arteries and veins; gave particularly fine accounts of the microscopic structure of muscle, the lens of the eye, the teeth, and other structures; and recognized bacteria of different shapes, postulating that they must be on the order of 25 times as small as the red blood cell. Because this is the approximate size of bacteria, it indicates that his observations were correct. Leeuwenhoek's fame was consolidated when he confirmed the observations of a student that male seminal fluid contains spermatozoa. Furthermore, he discovered spermatozoa in other animals as well as in the female tract following copulation; the latter destroyed the idea held by others that the entire future development of an animal is centred in the egg, and that sperm merely induce a "vapour," which penetrates the womb and effects fertilization. Although this theory of preformation, as it is called, continued to survive for some time longer, Leeuwenhoek initiated its eventual demise.

The discovery of sperm

Leeuwenhoek's animalcules raised some disquieting thoughts in the minds of his contemporaries. The theory of spontaneous generation, held by the ancient world and passed down unquestioned, was now being criticized. Christiaan Huygens, a scientific friend of Leeuwenhoek,

hypothesized that these little animals might be small enough to float in the air and, on reaching water, reproduce themselves. At this time, however, criticism of spontaneous generation went no further.

Swammerdam's innovative techniques. In contrast to Leeuwenhoek, who was virtually unschooled, his contemporary fellow countryman Jan Swammerdam was an educated and highly systematic worker who confined his attention to studying relatively few organisms in great detail. He employed highly innovative techniques; for example, he injected wax into the circulatory system to hold the blood vessels firm, he dissected fragile structures under water to avoid destroying them, and he used micropipettes to inject and inflate organisms under the microscope. In 1669 Swammerdam published *Algemeene Verhandeling van bloedeloose diertjens* (*The Natural History of Insects,* 1792), in which he described the structure of a large number of insects as well as spiders, snails, scorpions, fishes, and worms. He regarded all of these animals as insects, distinguishing between them according to their mode of development. Although this classification was erroneous, Swammerdam did discover a great deal of information concerning insect development.

Unfortunately, Swammerdam was subject to fits of mental instability, which, combined with financial difficulties, led to periods of depression. It was while in a state of mental disturbance that he produced his classic *Ephemeri vita* ("Life of the Ephemera") in 1675, a book about the life of the mayfly noteworthy for its extremely detailed illustrations. Sometime after his death at the age of 43, Swammerdam's works were published collectively as the *Bijbel der Natuure* (1737; "Bible of Nature"), which is considered by many authorities to be the finest collection of microscopic observations ever produced by one man.

Grew's anatomical studies of plants. Nehemiah Grew was educated at Cambridge and is regarded by some as one of the founders of plant anatomy. In 1672 he published the first of his great books, *An Idea of a Philosophical History of Plants,* followed in 1682 by *The Anatomy of Plants.* Although Grew clearly recognized cells in plants, referring to them as vesicles, or bladders, their biological significance evaded him. He is best known for his recognition of flowers as the sexual organs of plants and for his description of their parts. He also described the individual pollen grains and observed that they are transported by bees, but he did not realize the significance of this observation. Twelve years after the publication of *The Anatomy of Plants,* a German physician utilized Grew's anatomical studies in experiments to verify sexual reproduction in plants.

The discovery of cells. Of the five microscopists, Robert Hooke was perhaps the most intellectually preeminent. As curator of instruments at the Royal Society of London, he was in touch with all new scientific developments and exhibited interest in such disparate subjects as flying and the construction of clocks. In 1665 Hooke published his *Micrographia,* which was primarily a review of a series of observations that he had made while following the development and improvement of the microscope. Hooke described in detail the structure of feathers, the stinger of a bee, the radula, or "tongue," of mollusks, and the foot of the fly. It is Hooke who coined the word cell; in a drawing of the microscopic structure of cork, he showed walls surrounding empty spaces and refers to these structures as cells. He described similar structures in the tissue of other trees and plants and discerned that in some tissues the cells were filled with a liquid while in others they were empty. He therefore supposed that the function of the cells was to transport substances through the plant.

Contributions of the classical microscopists

Although the work of any of the classical microscopists seems to lack a definite objective, it should be remembered that these men embodied the concept that observation and experiment were of prime importance, that mere hypothetical, philosophical speculations were not sufficient. It is remarkable that so few men, working as individuals totally isolated from each other, should have recorded so many observations of such fundamental importance. The great significance of their work was that it revealed, for the first time, a world in which living organisms display an almost incredible complexity.

Unfortunately, work with the compound microscope languished for nearly 200 years, mainly because the early lenses tended to break up white light into its constituent parts. This technical problem was not solved until the invention of achromatic lenses, which were introduced about 1830. In 1878 a modern achromatic compound microscope was produced from the design of the German physicist Ernst Abbe. Abbe subsequently designed a substage illumination system, which, together with the introduction of a new substage condenser, paved the way for the biological discoveries of that era.

The development of taxonomic principles. In 1687 in England Isaac Newton, mathematician, physicist, and astronomer, published his great work *Principia,* in which he described the universe as fixed, with the Earth and other heavenly bodies moving harmoniously in accordance with mathematical laws. This approach of systematizing and classifying was to dominate biology in the 17th and 18th centuries. One reason was that the 16th-century "fathers of botany" had been content merely to describe and draw plants, assembling an enormous and diverse number that continued to increase as explorations of foreign countries made it evident that every country had its own native plants and animals.

Aristotle began the process of classification when he used mode of reproduction and habitat to distinguish groups of animals. Indeed, the words genus and species are translations of the Greek *genos* and *eidos* used by Aristotle. As mentioned earlier, it was the Swiss botanist Bauhin who introduced a binomial system of classification, using a generic name and a specific name. Most classification schemes proposed before the 17th century were confused and unsatisfactory, however.

The use of structure for classifying organisms. Two systematists of the 17th and 18th centuries were John Ray and Carolus Linnaeus, also known as Carl von Linné. Ray, an English naturalist who studied at Cambridge, was particularly interested in the work of the ancient compilers of herbals, especially those who had attempted to formulate some means of classification. Recognizing the need for a classification system that would apply to both plants and animals, Ray employed in his classification schemes extremely precise descriptions for genera and species. By basing his system on structures, such as the arrangement of toes and teeth in animals, rather than colour or habitat, Ray introduced a new and very important concept to taxonomic biology.

The need for a common classification system

Reorganization of groups of organisms. Prior to Linnaeus, a Swedish botanist and taxonomist, most taxonomists started their classification systems by dividing all the known organisms into large groups and then subdividing these into progressively smaller groups. Unlike his predecessors, Linnaeus began with the species, organizing them into larger groups or genera, then arranging analogous genera to form families and related families to form orders and classes. Probably utilizing the earlier work of Grew and others, Linnaeus chose the structure of the reproductive organs of the flower as a basis for grouping the higher plants. Thus he distinguished between plants with real flowers and seeds (phanerogams) and those lacking real flowers and seeds (cryptogams), subdividing the former into hermaphroditic (bisexual) and unisexual forms. For animals, following Ray's work, Linnaeus relied upon teeth and toes as the basic characteristics of mammals; he used the shape of the beak as the basis for bird classification. Having demonstrated that a binomial classification system based on concise and accurate descriptions could be used for the grouping of organisms, Linnaeus established taxonomic biology as a discipline.

Later developments in classification were initiated by three French biologists, the Comte de Buffon, Jean-Baptiste Lamarck, and Georges Cuvier, all of whom made lasting contributions to biological science, particularly in comparative studies. Subsequent systematists have been chiefly interested in the relationships between animals and have endeavoured to explain not only their similarities but also their differences in broad terms that encompass, in addition to structure, composition, function, genetics, evolution, and ecology.

The development of comparative biological studies. Once the opprobrium attached to the dissection of human bodies had been dispelled in the 16th century, anatomists directed their efforts toward a better understanding of human structure. In doing so they generally ignored other animals, at least until the latter part of the 17th century, when biologists began to realize that important insights could be gained by comparative studies of all animals, including man. One of the first of such anatomists was Edward Tyson, an English physician who studied the anatomy of an immature chimpanzee in detail and compared it with that of man. In making further comparisons between the chimpanzee and other primates, Tyson clearly recognized points of similarity between these animals and man. Not only was this a major contribution to physical anthropology but also an indication—nearly two centuries before Darwin—of the existence of relationships between man and other primates.

Among those who gave comparative studies their greatest impetus was Georges Cuvier, a French naturalist who utilized large collections of biological specimens sent to him from all over the world to work out a systematic organization of the animal kingdom. In addition to establishing a connection between systematic and comparative anatomy, he believed that there was a "correlation of parts" according to which a given type of structure (*e.g.,* feathers) is related to a certain anatomical formation (*e.g.,* a wing), which in turn is related to other specific formations (*e.g.,* the collarbone), and so on. In other words, he felt that a great deal of anatomical information could be deduced about an organism even if the whole specimen were not available. This was to be of great practical importance in the study of fossils, in which Cuvier played a leading role. Indeed, the 1812 publication of Cuvier's *Recherches sur les ossemens fossiles de quadrupèdes* (translated as *Research on Fossil Bones* in 1835) laid the foundation for the science of paleontology. But in order to reconcile his scientific findings with his personal religious beliefs, Cuvier postulated a series of catastrophic events that could account for both the presence of fossils and the immutability of existing species.

The founding of paleontology

The study of the origin of life. *Spontaneous generation.* If a species can develop only from a preexisting species, then how did life originate? Among the many philosophical and religious ideas advanced to answer this question, one of the most popular was the theory of spontaneous generation, according to which, as already mentioned, living organisms could originate from nonliving matter. With the increasing tempo of discovery during the 17th and 18th centuries, however, investigators began to examine more critically the Greek belief that flies and other small animals arose from the mud at the bottom of streams and ponds by spontaneous generation. Then, when Harvey announced his biological dictum *ex ovo omnia* ("everything comes from the egg"), it appeared that he had solved the problem, at least insofar as it pertained to flowering plants and the higher animals, all of which develop from an egg. But Leeuwenhoek's subsequent disquieting discovery of animalcules demonstrated the existence of a densely populated but previously invisible world of organisms that had to be explained.

A 17th-century Italian physician and poet, Francesco Redi, was one of the first to question the spontaneous origin of living things. Having observed the development of maggots and flies on decaying meat, Redi in 1668 devised a number of experiments, all pointing to the same conclusion: if flies are excluded from rotten meat, maggots do not develop. On meat exposed to air, however, eggs laid by flies develop into maggots. But renewed support for spontaneous generation came from the publication in 1745 of a book, *An Account of Some New Microscopical Discoveries,* by John Turberville Needham, an English Catholic priest; he found that large numbers of organisms subsequently developed in prepared infusions of many different substances that had been exposed to intense heat in sealed tubes for 30 minutes. Assuming that such heat treatment must have killed any previous organisms, Needham explained the presence of the new population on the grounds of spontaneous generation. The experiments appeared irrefutable until Lazzaro Spallanzani, an Italian biologist, repeated them and obtained conflicting results. He published his findings around 1775, claiming that Needham had not heated his tubes long enough nor had he sealed them in a satisfactory manner. Although Spallanzani's results should have been convincing, Needham had the support of the influential French naturalist Buffon; hence the matter of spontaneous generation remained unresolved.

Conflicting experimental results

The death of spontaneous generation. After a number of further investigations had failed to solve the problem, the French Academy of Sciences, in January 1860, offered a prize for contributions that would "attempt, by means of well-devised experiments, to throw new light on the question of spontaneous generation." In response to this challenge, Louis Pasteur, who at that time was a chemist, subjected flasks containing a sugared yeast solution to a variety of conditions. Pasteur was able to demonstrate conclusively that any microorganisms that developed in suitable media came from microorganisms in the air, not from the air itself, as Needham had suggested. Support for Pasteur's findings came in 1876 from an English physicist, John Tyndall, who devised an apparatus to demonstrate that air had the ability to carry particulate matter. Because such matter in air reflects light when the air is illuminated under special conditions, Tyndall's apparatus could be used to indicate when air was pure. Tyndall found that no organisms were produced when pure air was introduced into media capable of supporting the growth of microorganisms. It was these results, together with Pasteur's findings, that put an end to the doctrine of spontaneous generation.

When Pasteur later showed that parent microorganisms generate only their own kind, he thereby established the study of microbiology. Moreover, he not only succeeded in convincing the scientific world that microbes are living creatures, which come from preexisting forms, but also showed them to be an immense and varied component of the organic world, a concept that was to have important implications for the science of ecology. Further, by isolating various species of bacteria and yeasts in different chemical media, Pasteur was able to demonstrate that they brought about chemical change in a characteristic and predictable way, thus making a unique contribution to the study of fermentation and to biochemistry.

The origin of primordial life. In the 1920s a Soviet biochemist, A.I. Oparin, and other scientists suggested that life may have come from nonliving matter under conditions that existed on the primitive Earth, when the atmosphere consisted of the gases methane, ammonia, water vapour, and hydrogen. According to this concept, energy supplied by electrical storms and ultraviolet light may have broken down the atmospheric gases into their constituent elements, and organic molecules may have been formed when the elements recombined.

The notion of life from atmospheric gases

Some of these ideas have been verified by advances in geochemistry and molecular genetics; experimental efforts have succeeded in producing amino acids and proteinoids (primitive protein compounds) from gases that may have been present on the Earth at its inception, and amino acids have been detected in rocks that are more than 3,000,000,000 years old. With improved techniques it may be possible to produce precursors of or actual self-replicating living matter from nonliving substances. But whether it is possible to create the actual living heterotrophic forms from which autotrophs supposedly developed remains to be seen.

Although it may never be possible to determine experimentally how life originated or whether it originated only once or more than once, it would now seem—on the basis of the ubiquitous genetic code found in all living organisms on Earth—that life appeared only once and that all the diverse forms of plants and animals evolved from this primitive creation.

Biological expeditions. Although a number of 16th- and 17th-century travellers provided much valuable information about the plants and animals in the Orient, America, and Africa, most of this information was collected by curious individuals rather than trained observers. A devel-

opment that occurred during the 18th and 19th centuries was the organization of scientific expeditions, usually under the auspices of a particular government. The most notable of these efforts were the voyages of the "Endeavour," the "Investigator," the "Beagle," and the "Challenger," all sponsored by the English government.

Captain James Cook sailed the "Endeavour" to the South Sea islands, New Zealand, New Guinea, and Australia in 1768; the voyage provided Joseph Banks, a young naturalist, with the opportunity to make a very extensive collection of plants and notes, which helped establish him as a leading biologist. Another expedition to the same area in the "Investigator" in 1801 included a botanist, Robert Brown, whose work on the plants of Australia and New Zealand became a classic; especially important were his descriptions of how certain plants adapt to different environmental conditions. Brown is also credited with discovering the cell nucleus and analyzing sexual processes in higher plants.

Darwin's voyage on the HMS "Beagle"

One of the most famous biological expeditions of all time was that of the "Beagle" in 1831, the members including Charles Darwin. Although Darwin's primary interest at the time was geology, his visit to the Galápagos Islands aroused his interest in biology and caused him to speculate about their curious insular animal life and the significance of isolation in space and time for the formation of species. During the "Beagle" voyage, Darwin collected specimens of and accumulated copious notes on the plants and animals of South America and Australia, for which he received great acclaim on his return to England.

The voyage of the "Challenger" from 1872 to 1876 was organized by the British Admiralty to study oceanography, meteorology, and natural history. Under the leadership of Charles Wyville Thomson, the chief naturalist, vast collections of plants and animals were made, the importance of plankton (minute free-floating aquatic plants and animals) as a source of food for larger marine organisms was recognized, and many new planktonic species were discovered. A particularly significant aspect of the "Challenger" voyage was the interest it stimulated in the new science of marine biology.

In spite of these expeditions, the contributions made by individuals were still very important. Such an individual was the English naturalist Alfred Russel Wallace, who undertook explorations of the Malay Peninsula from 1854 to 1862. In 1876 he published his book *The Geographical Distribution of Animals,* in which he divided the landmasses into six zoogeographical regions and described their characteristic fauna. Wallace also contributed to the theory of evolution, publishing in 1870 a book expressing his views, *Contributions to the Theory of Natural Selection.*

The development of the cell theory. Although the microscopists of the 17th century had made detailed descriptions of plant and animal structure and though Hooke had coined the term cell for the compartments he had observed in cork tissue, their observations lacked an underlying theoretical unity. It was not until 1838 that Matthias J. Schleiden, a German botanist interested in plant anatomy, stated, "the lower plants all consist of one cell, while the higher ones are composed of (many) individual cells." When Schleiden's friend, the German physiologist Theodor Schwann, extended the cellular theory to include animals, he thereby brought about a rapprochement between botany and zoology. The formation of the cell theory—all plants and animals are made up of cells—marked a great conceptual advance in biology, and it resulted in renewed attention to the living processes that go on in cells.

Uniting of botany and zoology

In 1846, after several investigators had described the streaming movement of the cytoplasm in plant cells, Hugo von Mohl, a German botanist, coined the word protoplasm to designate the living substance of the cell. The concept of protoplasm as the physical basis of life led to the development of cell physiology.

A further extension of the cell theory was the development of cellular pathology by Rudolf Virchow, who established the relationship between abnormal events in the body and unusual cellular activities. This gave a new direction to the study of pathology and resulted in advances in medicine.

The detailed description of cell division was contributed by Eduard Strasburger, a German botanist, who observed the mitotic process in plant cells and further demonstrated that nuclei arise only from preexisting nuclei. The parallel work in mammals was done by the German anatomist Walther Flemming, who published his most important findings in *Zellsubstanz, Kern und Zelltheilung* ("Cell Substance, Nucleus and Cell Division") in 1882.

The theory of evolution. As knowledge of plant and animal forms accumulated during the 16th, 17th, and 18th centuries, a few biologists began to speculate about the ancestry of these organisms, though the prevailing view was that promulgated by Linnaeus—namely, the immutability of the species. Among the early speculations voiced during the 18th century, Erasmus Darwin, an English physician and the grandfather of Charles Darwin, concluded that species descend from common ancestors and that there is a struggle for existence among animals. A French naturalist, Jean-Baptiste Lamarck, who was probably the most important of the 18th-century evolutionists, recognized the role of isolation in species formation; he also saw the unity in nature and conceived the idea of the evolutionary tree.

A complete theory of evolution was not announced, however, until the publication in 1859 of Charles Darwin's *On the Origin of Species by Means of Natural Selection or the Preservation of Favoured Races in the Struggle for Life.* In his book Darwin stated that all living creatures multiply so rapidly that, if left unchecked, they would soon overpopulate the world. According to Darwin, the checks on population size are maintained by competition for the means of life. Hence, if any member of a species differs in some way that makes it better fitted to survive, then it will have an advantage that its offspring would be likely to perpetuate. Darwin's work reflects the influence of a British economist, Thomas Robert Malthus, who in 1838 published an essay on population in which he warned that if man multiplies more rapidly than his food supply, competition for existence would result. Darwin was also influenced by a British geologist, Charles Lyell, who realized from his studies of geological formations that the relative ages of deposits could be estimated by means of the proportion of living and extinct mollusks. But it was not until after his travels in the "Beagle" in 1831, during which he observed a great richness and diversity of island fauna, that Darwin began to develop his theory of evolution. Alfred Russel Wallace had reached conclusions similar to those of Darwin following his studies of plants and animals in the Malay Peninsula. A short paper dealing with this subject sent by Wallace to Darwin finally resulted in the publication of Darwin's own theories.

Influences on Darwin's work

Conceptually, the theory was of the utmost significance, accounting as it did for the formation of new species. Following the subsequent discovery of the chromosomal basis of inheritance and the laws of heredity, it could be seen that natural selection does not involve the sharp alternatives of life or death but results from the differential survival of variants. Today, the universal principle of natural selection, which is the central concept of Darwin's theory, is firmly established.

The study of the reproduction and development of organisms. *Preformation versus epigenesis.* A question posed by Aristotle was whether the embryo is preformed and therefore only enlarges during development or whether it differentiates from an amorphous beginning. Two conflicting schools of thought had been based on this question: the preformation school maintained that the egg contains a miniature individual that develops into the adult stage in the proper environment; the epigenesis school believed that the egg is initially undifferentiated and that development occurs as a series of steps. Prominent supporters of the preformation doctrine, which was widely held until the 18th century, included Malpighi, Swammerdam, and Leeuwenhoek. In the 19th century, as criticism of preformation mounted, Karl Ernst von Baer, an Estonian embryologist, provided the final evidence against the theory. His discovery of the mammalian egg and his recognition of the formation of the germ layers out of which the embryonic organs develop laid the foundations of modern embryology.

The fertilization process. Despite the many early descriptions of spermatozoa, their essential role in fertilization was not proven until 1879, when Hermann Fol, a Swiss physician and zoologist, observed the penetration of a spermatozoon into an ovum. Prior to this discovery, during the period from 1823 to 1830, the existence of the sexual process in flowering plants had been demonstrated by Giovanni Battista Amici, an Italian astronomer and botanist, and confirmed by others. The discovery of fertilization in plants was of great importance to the development of plant hybrids, which are produced by cross-pollination between different species; it was also of great significance to the studies of genetics and evolution.

The universal occurrence and remarkable similarity of the fertilization process, regardless of the organism in which it occurs, provoked many of the leading investigators of the time to search for the underlying mechanism. It was realized that there must be some way by which the number of chromosomes is reduced before fertilization; otherwise the chromosome number would double every time a spermatozoon fused with an egg. In 1883 Edouard van Beneden, a Belgian cytologist, showed that the eggs and spermatozoa in the worm *Ascaris* contain half the number of chromosomes found in the body cells. To account for the halving of the chromosomes in the sex cells, a process that is called meiosis, in 1887 August Weismann, a German biologist, suggested that there must be two different types of cell division, and by 1900 the details of meiosis had been elucidated.

Van Beneden's work on chromosomes

The study of heredity. *Pre-Mendelian theories of heredity.* The fundamental laws of heredity were discovered in 1865 by Gregor Mendel, an Austrian monk and biologist, but his work was ignored until its rediscovery in 1900. There were, however, a number of views on the subject that had been expressed long before Mendel. The Greek philosophers, for example, believed that the traits of individuals were acquired from contact with the environment and that such acquired characteristics could be inherited by offspring. Because Lamarck was the most famous proponent of the inheritance of acquired characteristics, the theory is called Lamarckism. This concept, which emphasized the use and disuse of organs as the significant factor in determining the characteristics of an individual, postulated that any alterations in the individual could be transmitted to the offspring through the gametes. Yet the inheritance of acquired characteristics has never been experimentally verified, despite many attempts. Furthermore, many of Lamarck's examples, such as the long neck of the giraffe, can be more satisfactorily explained by means of natural selection.

In 1885 Weismann suggested that hereditary characteristics were transmitted by what he called germ plasm—as distinguished from the somatoplasm (body cells)—which linked the generations by a continuous stream of dividing germ cells. In stating definitely seven years later that the material of heredity was in the chromosomes, Weismann anticipated the chromosomal basis of inheritance.

Francis Galton, a 19th-century English anthropologist, made a number of important contributions to genetics, one of which was a study of the hereditary nature of ability, from which he developed the concept that judicious breeding could improve the human race (eugenics). Galton's most significant work was the demonstration that each generation of ancestors makes a proportionate contribution to the total makeup of the individual. Thus, he suggested that if a tall man marries a short woman, each should contribute half of the total heritage, and the resultant offspring should be intermediate between the two parents.

Mendelian laws of heredity. The fame of Gregor Mendel, the father of genetics, rests on experiments he did with garden peas, which possess sharply contrasting characteristics—*e.g.,* tall versus short; round seed versus wrinkled seed. When Mendel fertilized short plants with pollen from tall plants, he found the offspring (first filial generation) to be uniformly tall. But if he allowed the plants of this generation to self-pollinate (fertilize themselves), their offspring (the second filial generation) exhibited the characters of the grandparents in a rather consistent ratio of three tall to one short. Furthermore, if allowed to self-pollinate, the short plants always bred true—*i.e.,* never produced anything but short plants. From these results Mendel developed the concept of dominance, based on the supposition that each plant carried two trait units, one of which dominated the other. Nothing was known at that time about chromosomes or meiosis, yet Mendel deduced from his results that the trait units, later called genes, could be a kind of physical particle that was transmitted from one generation to another through the reproductive mechanism.

Discovery of dominance

Mendel's most important concept was the idea that the paired genes present in the parent separate or segregate during the formation of the gametes. Moreover, in later experiments in which he studied the inheritance of two pairs of traits, Mendel showed that one pair of genes is independent of another. Thus, the principles of segregation and of independent assortment were established.

Mendel's findings were ignored for 35 years, probably for two reasons. Because the distinguished Swiss botanist Karl Wilhelm von Nägeli failed to recognize the significance of the work after Mendel had sent him the results, he did nothing to encourage Mendel. Nägeli's great prestige and the lack of his endorsement indirectly weighed against widespread recognition of Mendel's work. Moreover, when the work was published, little was known about the cell, and the processes of mitosis and meiosis were completely unknown. Mendel's work was finally rediscovered in 1900, when three botanists independently recognized the worth of his studies from their own research and cited his publication in their work.

Elucidation of the hereditary mechanism. By 1901 it was understood how the hereditary units postulated by Mendel are distributed; it was also known that the somatic (body) cells have a double, or diploid, complement of chromosomes, while the reproductive cells have a single, or haploid, chromosome number. The experimental demonstration of the chromosomal basis for heredity had been firmly established by the German biologist Theodor Boveri soon after the turn of the century and subsequently confirmed by others. To account for the large number of observed hereditary characters, Boveri suggested that each chromosome in a pair can exchange the hereditary factors it carries with those of the other chromosome. At first the U.S. geneticist Thomas Hunt Morgan dismissed this concept, but later, when he found that it agreed with his own laboratory findings, Morgan and his collaborators assigned the hereditary units (genes) specific positions, or loci, within the chromosomes. With the genes established as the carriers of hereditary traits, William Bateson, an English biologist, coined the name genetics for the experimental study of heredity and evolution.

BIOLOGY IN THE 20TH CENTURY

Just as the 19th century can be considered the age of cellular biology, the 20th century has been characterized by developments in molecular biology.

The rise of molecular biology

Important conceptual developments. By utilizing modern methods of investigation, such as X-ray diffraction and electron microscopy, to explore levels of cellular organization beyond that visible with a light microscope—*i.e.,* the ultrastructure of the cell—new concepts of cellular function have been produced. Not only has the study of the molecular organization of the cell probably had the greatest impact upon biology during the 20th century but it also has led directly to the convergence of many different scientific disciplines in order to acquire a better understanding of life processes.

Another 20th-century development has been the realization that man is as dependent upon the Earth's natural resources as are other animals. The progressive destruction of the environment can be attributed, in part, to an increase in population pressure as well as to certain technological advances. Thus, though lifesaving advances in medicine have resulted in a dramatic drop in the death rate, they have also been a factor contributing to the explosive increase in the human population. Moreover, chemical contaminants being introduced into the environment by manufacturing processes, pesticides, automobile

emissions, and other means are seriously endangering all forms of life. It is for these reasons that biologists are beginning to pay much greater attention to the relationships of living things to each other as well as to their biotic and abiotic environments.

Intradisciplinary work. There are many important categories in the biological sciences. Botany, zoology, and microbiology deal with types of organisms and their relationships with each other. Such disciplines are subdivided into more specialized categories; for example, ichthyology is the study of fishes, algology the study of algae. All of them draw upon paleontology, taxonomy, morphology, and evolution.

Disciplines such as embryology and physiology, which deal with the development and function of an organism, may be divided further according to the kind of organism studied; for example, invertebrate embryology and mammalian physiology. In the past few decades, many developments in physiology and embryology have resulted from studies in cell biology, biophysics, and biochemistry. This has given rise to cell physiology, cytochemistry, and ultrastructural studies, which aim at correlating structure with function. Ecology, the study of the relations of a group of organisms to its environment, includes both the physical features of the environment and other organisms that may compete for food and shelter. Ecology may be subdivided according to the environment—for example, freshwater ecology and marine ecology—and draws upon animal behaviour. One aspect of cell biology, formerly called cytology, is the investigation of the structure, composition, and function of cells; biochemistry and biophysics provide important information.

Thus, biology encompasses a number of disciplines; in fact, it has become common to divide biology into its several levels of organization rather than separating the disciplines. It is useful, for example, to differentiate between organismic biology, the study of the whole organism, and cell biology. Similarly the technological advances of the 20th century have allowed increased understanding of the molecules comprising living things and their aggregation and organization into such structures as chromosomes and membranes. Knowledge of this aspect, called molecular biology, represents the molecular level of organization. The fourth level, population biology, involves the complex interaction of population of animals and plants with the environment.

Importance of technological advances

Relations with other disciplines. In the 17th century, with the invention of the microscope, which made possible study of the cellular level of organization, biology began to receive the benefits of scientific developments in physics. In the 18th century such developments in chemistry as a better understanding of the nature of oxygen, carbon dioxide, and water began to have important implications for biology. Today, through the disciplines of biochemistry and biophysics, both chemistry and physics have continued to make significant contributions to biology, particularly in the area of molecular biology.

Biology is also very closely related to the disciplines of medicine and agriculture, out of which it developed as an independent discipline. In a sense, the roles have been reversed in the 20th century, for it is basic research being conducted in biology that is contributing to major advances currently being made in medicine and agriculture. It was biological research in the structure and function of viruses, for example, that led directly to the development of a vaccine against poliomyelitis.

Another scientific discipline, that of geology, is closely related to the biological study of paleontology. The technique of radiocarbon dating, which was developed by chemists to determine the age of biological remains, has been of great use in the fields of archaeology and anthropology as well as biology. A new discipline, space biology, has arisen through the activities of the scientists and engineers concerned with the exploration of space. The conceptual framework of biology has had to be altered to accommodate newly discovered facts. In the process biology has received contributions from and made contributions to many other disciplines, in the humanities as well as in the sciences. (S.H.J./E.R.G.)

Changing social and scientific values. The biologist's role in society as well as his moral and ethical responsibility in the discovery and development of new ideas has led to a reassessment of his social and scientific value systems. A scientist can no longer ignore the consequences of his discoveries; he is as concerned with the possible misuses of his findings as he is with the basic research in which he is involved. This emerging social and political role of the biologist and all other scientists requires a weighing of values that cannot be done with the accuracy or the objectivity of a laboratory balance. As a member of society, it is necessary for a biologist now to redefine his social obligations and his functions, particularly in the realm of making judgments about such ethical problems as man's control of his environment or his manipulation of genes to direct further evolutionary development.

Coping with problems of the future. As a result of recent discoveries concerning hereditary mechanisms, genetic engineering, by which human traits are made to order, may soon be a reality. As desirable as it may seem to be, such an accomplishment would entail many value judgments. Who would decide, for example, which traits should be selected for change? In cases of genetic deficiencies and disease, the desirability of the change is obvious, but the possibilities for social misuse are so numerous that they may far outweigh the benefits.

Genetic engineering

Probably the greatest biological problem of the future, as it is of the present, will be to find ways to curb environmental pollution without interfering with man's constant effort to improve the quality of his life. Many scientists believe that underlying the spectre of pollution is the problem of surplus human population. A rise in population necessitates an increase in the operations of modern industry, the waste products of which increase the pollution of air, water, and soil. With predictions that, at the present rate of reproduction, the Earth's population will be approximately 7,000,000,000 by the year 2000, the question of how many people the resources of the Earth can support is one of critical importance.

Although the solutions to these and many other problems are yet to be found, they do indicate the need for biologists to work with social scientists and other members of society in order to determine the requirements necessary for maintaining a healthy and productive planet. For although many of man's present and future problems may seem to be essentially social, political, or economic in nature, they have biological ramifications that could affect the very existence of life itself. (E.R.G.)

The study of biological structure and function

MORPHOLOGY

Morphology is a term used in biology for the study not only of shape and structure in plants, animals, and microorganisms but also of the size, shape, structure, and relations of the parts comprising them. The term morphology connotes the general aspects of biological form and arrangement of the parts of a plant or an animal. The term anatomy also refers to the study of biological structure but usually connotes study of the details of either gross or microscopic structure. In practice, however, the two terms are used almost synonymously.

Typically, morphology is contrasted with physiology, which deals with studies of the functions of organisms and their parts; function and structure are so closely interrelated, however, that their separation is somewhat artificial. Morphologists were originally concerned with the bones, muscles, blood vessels, and nerves comprising the bodies of animals and the roots, stems, leaves, and flower parts comprising the bodies of higher plants. The development of the light microscope made possible the examination of some structural details of individual tissues and single cells; the development of the electron microscope and of methods for preparing ultrathin sections of tissues created an entirely new aspect of morphology—that involving the detailed structure of cells. Electron microscopy has gradually revealed the amazing complexity of the many structures comprising the cells of plants and animals. Other physical techniques have permitted biologists to investigate the

morphology of complex molecules such as hemoglobin, the gas-carrying protein of blood, and deoxyribonucleic acid (DNA), of which most genes are composed. Thus, morphology encompasses the study of biological structures over a tremendous range of sizes, from the macroscopic to the molecular.

A thorough knowledge of structure (morphology) is of fundamental importance to the physician, to the veterinarian, and to the plant pathologist, all of whom are concerned with the kinds and causes of the structural changes that result from specific diseases.

Historical background. Evidence that prehistoric man appreciated the form and structure of his contemporary animals has survived in the form of paintings on the walls of caves in France, Spain, and elsewhere. During the early civilizations of China, Egypt, and the Near East, as man learned to domesticate certain animals and to cultivate many fruits and grains, he also acquired knowledge about the structures of various plants and animals.

Aristotle was interested in biological form and structure, and his *Historia animalium* contains excellent descriptions, clearly recognizable in extant species, of the animals of Greece and Asia Minor. He was also interested in developmental morphology and studied the development of chicks before hatching and the breeding methods of sharks and bees. Galen was among the first to dissect animals and to make careful records of his observations of internal structures. His descriptions of the human body, though they remained the unquestioned authority for more than 1,000 years, contained some remarkable errors, for they were based on dissections of pigs and monkeys rather than of humans.

Emergence of modern morphology

Although it is difficult to pinpoint the emergence of modern morphology as a science, one of the early landmarks was the publication in 1543 of *De humani corporis fabrica* by Andreas Vesalius, whose careful dissections of human bodies and accurate drawings of his observations revealed many of the inaccuracies in Galen's earlier descriptions of the human body.

In 1661 an Italian physiologist, Marcello Malpighi, the founder of microscopic anatomy, demonstrated the presence of the small blood vessels called capillaries, which connect arteries and veins. The existence of capillaries had been postulated 30 years earlier by the English physician William Harvey, whose classic experiments on the direction of blood flow in arteries and veins indicated that minute connections must exist between them. Between 1668 and 1680, the Dutch microscopist Antonie van Leeuwenhoek used the recently invented microscope to describe red blood cells, human sperm cells, bacteria, protozoans, and various other structures.

Cellular components

Cellular components—the nucleus and nucleolus of plant cells and the chromosomes within the nucleus—and the complex sequence of nuclear events (mitosis) that occur during cell division were described by various scientists throughout the 19th century. *Organographie der Pflanzen* (1898–1901; *Organography of Plants*, 1900–05), the great work of a German botanist, Karl von Goebel, who was associated with morphology in all its aspects, remains a classic in the field. The Scot John Hunter and the Frenchman Georges Cuvier were early 19th-century pioneers in the study of similar structures in different animals—*i.e.,* comparative morphology. Cuvier in particular was among the first to study the structures of both fossils and living organisms and is credited with founding the science of paleontology. A British biologist, Sir Richard Owen, developed two concepts of basic importance in comparative morphology—homology, which refers to intrinsic structural similarity, and analogy, which refers to superficial functional similarity. Although the concepts antedate the Darwinian view of evolution, the anatomical data on which they were based became, largely as a result of the work of the German comparative anatomist Carl Gegenbaur, important evidence in favour of evolutionary change, despite Owen's steady unwillingness to accept the view of diversification of life from a common origin.

One of the major thrusts in contemporary morphology has been the elucidation of the molecular basis of cellular structure. Techniques such as electron microscopy have revealed the complex details of cell structure, provided a basis for relating structural details to the particular functions of the cell, and shown that certain cellular components occur in a variety of tissues. Studies of the smallest components of cells have clarified the structural basis not only for the contraction of muscle cells but also for the motility of the tail of the sperm cell and the hairlike projections (cilia and flagella) found on protozoans and other cells. Studies involving the structural details of plant cells, although begun somewhat later than those concerned with animal cells, have revealed fascinating facts about such important structures as the chloroplasts, which contain chlorophyll that functions in photosynthesis. Attention has also been focussed on the plant tissues composed of cells that retain their power to divide (meristems), particularly at the tips of stems, and their relationship with the new parts to which they give rise. The structural details of bacteria and blue-green algae, which are similar to each other in many respects but markedly different from both higher plants and animals, have been studied in an attempt to determine their origin.

Morphology continues to be of importance in taxonomy because morphological features characteristic of a particular species are used to identify it. As biologists have begun to devote more attention to ecology, the identification of plant and animal species present in an area and perhaps changing in numbers in response to environmental changes has become increasingly significant.

Fundamental concepts. *Homology and analogy.* Homologous structures develop from similar embryonic substances and thus have similar basic structural and developmental patterns, reflecting common genetic endowments and evolutionary relationships. In marked contrast, analogous structures are superficially similar and serve similar functions but have quite different structural and developmental patterns. The arm of a man, the wing of a bird, and the pectoral fins of a whale are homologous structures in that all have similar patterns of bones, muscles, nerves, blood vessels, and similar embryonic origins; each, however, has a different function. The wings of birds and those of butterflies, in contrast, are analogous structures—*i.e.,* both allow flight but have no developmental processes in common.

Application to molecular structure

The terms homology and analogy are also applied to the molecular structures of cellular constituents. Because the hemoglobin molecules from different vertebrate species contain remarkably similar sequences of amino acids, they may be termed homologous molecules. In contrast, hemoglobin and hemocyanin, the latter of which is present in crab blood, are termed analogous molecules because they have a similar function (oxygen transport) but differ considerably in molecular structure. Corresponding similarities occur in the structures of other proteins from different species—*e.g.,* cytochrome c and other enzymes (biological catalysts) such as the lactic dehydrogenases in birds and mammals.

Body plan and symmetry. The bodies of most animals and plants are organized according to one of three types of symmetry: spherical, radial, or bilateral. A spherically symmetrical body is similar throughout and can be cut in any plane through the centre to yield two equal halves. A few of the simplest plants and animals are spherically symmetrical—*e.g.,* protozoans such as Radiolaria and Heliozoia. Radially symmetrical bodies, such as those of starfishes and mushrooms, have a distinguishable top and bottom and usually have a cylindrical shape, with the body parts radiating from the central axis. A starfish can be cut into two equal halves by any plane that includes the line, or axis, running through its centre from top to bottom. The anterior, or oral, end usually contains the mouth; a posterior, or aboral, end may have an anus. In the bilaterally symmetrical body of higher animals including man, only a cut from head to foot exactly in the centre divides the body into equivalent halves. An anterior, or head, end and a posterior, or tail, end can be distinguished; and the dorsal, or back, side can be distinguished from the ventral, or belly, side. But because some internal organs of man are not symmetrical (*e.g.,* the heart), even the right and left halves of the human body are not exactly equivalent.

A few organisms—amoebas, slime molds, and certain sponges—with an irregular form, or one that changes as the organism moves, have no plane of symmetry.

Morphological basis of classification. The features that distinguish closely related species of plants and animals are usually superficial differences such as colour, size, and proportion. In contrast, the major divisions, or phyla, of the plant and animal kingdoms are distinguished by characteristics that, though usually not unique to a single division or phylum, occur in unique combinations in each.

One morphological feature useful in classifying animals and in determining their evolutionary relationships is the presence or absence of cellular differentiation—*i.e.,* animals may be either single celled or composed of many kinds of cells specialized to perform particular functions. Some multicellular animals have only two embryonic cell, or germ, layers: an ectoderm (outer layer) and an endoderm (inner layer), which lines the digestive tract. Other animals have these, in addition to a mesoderm, which lies between the ectoderm and endoderm. Animals may have one of two types of body cavity. The bodies of the Coelenterata (invertebrates such as the jellyfish) and other primitive many-celled animals consist of a double-walled sac surrounding a single cavity with a mouth. Higher animals have two cavities, and their bodies are constructed on a so-called tube-within-a-tube plan. An inner tube, or digestive tract, is lined with endoderm and opens at each end to form the mouth and the anus. An outer tube, or body wall, is covered with ectoderm. Between the two tubes a second cavity, or coelom, lies within the mesoderm and is lined by it. Another major distinguishing morphological feature of animal phyla is the presence or absence of segmentation. The members of several phyla have bodies characterized by the presence of a row of segments, or body units, of the same fundamental structure. Segmented animals include the vertebrates, the annelids (invertebrates such as the earthworm), and the arthropods (invertebrates such as insects); in some segmented animals such as man and most vertebrates, however, the segmental character of the body is obscured. An evolutionary tendency in many animal phyla has been the progressive differentiation of the anterior end to form a head with conspicuous sense organs and an accumulation of nervous tissues, a brain; the tendency is termed cephalization. Some morphological structures are found only in one phylum; for example, only the Coelenterata have stinging cells (nematocysts); the Echinodermata (invertebrates such as starfishes) have a peculiar water vascular system, and only the Chordates (*e.g.,* reptiles, birds) have a dorsally located, hollow nerve cord.

Segmentation and cephalization

Like animals, plants may be either single celled or composed of many kinds of specialized cells. The bodies of most of the lower plants, such as algae and fungi, are comprised of the least differentiated and least specialized type of plant cells, parenchyma cells. The embryonic tissues of higher plants, unlike those of animals, remain extremely active throughout the life of the plant. In addition, the different types of cells characteristic of the body of higher plants arise from meristems, specific regions in the plant body where cells divide and enlarge. In all but the simplest forms, the plant body is composed of various types of cells associated in more or less definite ways to form systems of units called tissue systems—*e.g.,* the vascular system consisting of conductive tissues. The arrangement of the components of the vascular system is a distinguishing morphological feature of various plant groups. The character and relative extent of the two phases in the life history of a plant—the sexual phase, or gametophyte, and the sporophyte—vary considerably among the plant groups and are useful in distinguishing them.

Areas of study. *Anatomy.* The best known aspect of morphology, usually called anatomy, is the study of gross structure, or form, of organs and organisms. It should not be inferred however, that even the human body, which has been extensively studied, has been so completely explored that nothing remains to be discovered. It was found only in 1965, for example, that the nerve to the pineal gland, which lies on the upper surface of the brain of mammals, is a branch from the sympathetic nerves; the sympathetic nerves receive nerve impulses from a small branch of the nerves that transmit impulses from the eye to the brain (optic nerves). Thus the pineal gland responds by a very indirect route to quantitative changes in the environmental lighting and secretes appropriate amounts of the substance it forms, the hormone melatonin.

Detailed comparisons of the morphological features of different animals, termed comparative anatomy, provide strong arguments for the evolutionary relationships among different species. In the course of evolution, animals and plants tend to undergo adaptive morphological changes that enable them to survive under certain environmental conditions. As a result, animals only remotely related evolutionarily may come to resemble each other superficially because of common adaptations to similar environments, a phenomenon known as convergent evolution. Structural similarities—streamlined shape, dorsal fins, tail fins, and flipper-like forelimbs and hindlimbs, for example—have evolved in such varied animal groups as the dolphins and porpoises, both of which are mammals; the extinct ichthyosaurs, which were reptiles; and both the bony and cartilaginous fishes. In a like manner, the mole, an insectivore, and the gopher, a rodent, have both evolved shovellike forelimbs, an adaptation for digging.

An opposite phenomenon, divergent evolution, occurs when animals originally closely related adapt to different environments and come to be superficially quite different. Although sea lions and seals, for example, are carnivores and thus closely related to bears, cats, and dogs, their adaptations to an aquatic existence have resulted in morphological characteristics distinct from those of the terrestrial carnivores. In the course of mammalian evolution, many features have changed to permit specific animal groups to adapt to particular environments—*e.g.,* the number and shape of the teeth, the length and number of bones in the limbs, the number and attachment sites of muscles, the thickness and colour of the hair or fur, and the length and shape of the tail.

Careful study of adaptive morphological aspects has permitted inferences about the course of the evolutionary history of various animals and of their successive adaptations to changing environments. The present-day Australian tree-climbing kangaroos, for example, are the descendents of a ground-dwelling marsupial, from whom evolved forms that began to live in trees and eventually developed limbs adapted to tree climbing. But the events may have occurred in the reverse sequence; that is, specialized limbs may have evolved before the animal adopted an arboreal mode of life. In any event, some of the tree-dwelling kangaroos subsequently left the trees, became readapted to life on the ground (*i.e.,* their hindlegs became adapted for leaping), and then went back to the trees but with legs so highly specialized for leaping as to be useless in grasping a tree trunk; consequently, present-day tree kangaroos climb by bracing their feet against a tree trunk, as do bears. Careful comparisons of the feet of the many kinds of living Australian marsupials reveal the stages in this complicated process of adaptation and re-adaptation.

Relationship of morphological phenomena to evolution

Changes in genes (mutations) constantly occur and may cause a decrease in size and function of an organ; on the other hand, a change in the environment or in the mode of life of a species may make an organ unnecessary for survival. As a result, many plants and animals contain organs or parts of organs that are useless, degenerate, undersized, or lacking some essential part when compared to homologous structures in related organisms. The human body, for instance, has more than 100 such organs—*e.g.,* the appendix, the fused tail vertebrae (coccyx), the wisdom teeth, the muscles that wiggle the ears, and the hair on the body.

Changes in genes and in environment

The parts of a seed plant include roots, stems, leaves, and reproductive organs in the flowers. The evolution of specialized conducting tissues called xylem and phloem has enabled seed plants to survive on land and to attain large sizes. Roots anchor the plant; enable it to maintain an upright position; and absorb water, minerals, and other nutrients from the soil. The roots of plants such as carrots, beets, and yams serve as sites for food storage. The stem links the roots with the leaves, where photosynthesis oc-

curs, and its xylem and phloem are continuous with those of root and leaf. The stem supports leaves, flowers, and fruits. Each year, the stems of woody plants add a layer of xylem and phloem, the annual ring, the width of which varies with climatic conditions. A leaf consists of a petiole (stalk), by which it is attached to the stem, and a blade, typically broad and flat, that contains bundles, or veins, of xylem and phloem on the undersurface. The flower contains pollen-producing anthers and egg-producing ovules. After fertilization the base of the flower, or ovary, enlarges and forms the fruit, which is a mature ovary containing seeds, or mature ovules. The bodies of ferns and mosses also are composed of roots, stems, and leaves, but those of lower plants such as mushrooms and kelps are much more simple and lack true roots, stems, and leaves.

Histology. A major trend in the evolution of both plants and animals has resulted in the specialization of cells and a division of labour among them. The cells comprising a tree or a man are quite different; each is specialized to carry out certain functions. Although specialization may permit a cell to function efficiently, it also increases the interdependence of body parts; an injury to or the destruction of one part, therefore, may result in death of the whole organism. The study of the structure and arrangement of tissues, defined as groups or layers of cells that together perform certain special functions, is termed histology. Each kind of tissue is composed of cells with characteristic features such as size, shape, and relationship to adjacent cells and may also contain noncellular material—connective tissue fibres or a bony material.

Types of tissues and their roles

Morphologists usually separate animal tissues into six groups; epithelial, connective, muscular, blood, nervous, and reproductive tissues. The cells composing epithelial tissues form a continuous layer or sheet that either covers the surface of the body or lines some cavity within the body, thus protecting the underlying cells from mechanical and chemical injury or from invasion by microorganisms. Epithelial tissues absorb nutrients and water, secrete a wide variety of substances, and may play a role in the reception of sensory stimuli. The connective tissues—bone, cartilage, ligaments, and fibrous connective tissue—support and hold together the other cells of the body. The cells of the connective tissues secrete large quantities of nonliving material (matrix), the characteristics of which largely determine the nature and the function of the specific types of connective tissue; the matrix secreted by fibrous connective tissue cells, for example, is a thick matted network of microscopic fibres surrounding the connective tissue cells. Connective tissue holds skin to muscle, keeps glands in position, makes up the tough outer walls of the blood vessels, and forms a sheath around nerve fibres and muscle cells. Tendons are flexible, cable-like cords of specialized fibrous connective tissue that join muscles to each other or muscle to bone. Ligaments are somewhat elastic cords of specialized fibrous connective tissue that join one bone to another.

Muscular tissues are composed of elongated, cylindrical, or spindle-shaped cells, each of which contains many small fibres called myofibrils. Muscle cells perform mechanical work by contracting—that is, by becoming shorter and thicker. The three types of vertebrate muscles include the cardiac muscle, which is found only in the walls of the heart; smooth muscles, which are found in the walls of the digestive tract and in other internal organs; and skeletal muscles, which make up the bulk of the muscle masses attached to the bones of the body. Skeletal and cardiac muscles have alternating light and dark stripes the relative sizes of which change during the contraction process. Evidence from electron microscopy indicates that two types of filaments occur in muscle; during contraction, one type of filament slides past the other.

Nerve tissue is made of cells, called neurons, which are specialized to conduct nerve impulses. Two or more thin hairlike fibres, called axons and dendrites, extend from the enlarged cell body containing the nucleus. The neurons extending from the spinal cord to the end of an appendage (*e.g.*, arm, leg) may extend to a metre (about three feet) or more in man and to several metres in an elephant or a whale.

Egg cells in the female and sperm cells in the male are reproductive tissues adapted for the production of offspring. The egg cell is modified by the accumulation of considerable amounts of yolk and other food reserves. The highly specialized spermatozoon contains a tail, the beating of which propels it to the egg.

Blood is composed of red cells, which are specialized for the transport of oxygen and carbon dioxide, and white cells, which engulf bacteria and produce antibodies (proteins formed in response to foreign substances called antigens). Blood also contains platelets, small fragments of cells from the bone marrow that play a key role in initiating the clotting of blood.

Types of plant tissues

The cells of higher plants may be differentiated into meristematic, protective, fundamental, and conductive tissues. Meristematic tissues, which are composed of small, thin-walled cells with few or no vacuoles (cavities), differentiate into the other types of plant tissue and are found in the rapidly growing parts of the plant—*e.g.*, at the tips of roots and stems. Protective tissues are composed of thick-walled cells that protect the underlying thin-walled cells from mechanical abrasion and dehydration; examples of protective tissues include the epidermis of leaves and the cork layers of stems and roots. The fundamental tissues comprising the body of a plant include the soft parts of the leaf, the components of the pith and the cortex of stems, the roots, and the soft parts of flowers and fruits. These tissues function in the production and storage of food. Two types of conductive tissues occur in higher plants: xylem conducts water and dissolved salts, and phloem conducts dissolved organic materials such as sugars. Both types are composed of elongated cells that fuse end to end with other cells to form the sieve tubes through which substances are transported in phloem and xylem vessels.

Cytology. The living material of most organisms is organized into discrete units termed cells; the study of their features is known as cytology. The cellular contents, when viewed through a microscope at low magnification, usually appear to consist of granules or fibrils of dense material, droplets of fatty substances, and fluid-filled vacuoles suspended in a clear, continuous, semifluid substance called cytoplasm. The remarkable structural complexity of the cell is more fully revealed at the higher magnifications attainable with the electron microscope; structural details of various cellular components, or organelles, as revealed by the technique known as X-ray diffraction analysis, have provided information concerning the relationships between the structures of the cellular components and of the molecules comprising them. Although most cells have certain features in common, the kinds and amounts of components vary considerably. Cellular components include structures such as mitochondria, chloroplasts, endoplasmic reticulum, Golgi complex, lysosomes, oil droplets, granules, and fibrils. The membrane around the cell is a three-layered structure called a unit membrane; similar membranes surround many cellular components—*e.g.*, the mitochondria.

A small spherical or oval organelle, the nucleus, is typically found near the centre of a cell. The genes within the nucleus control the development of the various traits of the cell by controlling the synthesis of specific proteins. The nuclear components are separated from those of the cytoplasm by the nuclear membrane. The structure of the nucleolus, a spherical body within the nucleus, is extremely variable in most cells. Although more than one nucleolus may occur in a nucleus, each cell of an animal or plant species has a fixed number of nucleoli. The nucleoli apparently play a role in the synthesis of the ribonucleic acid (RNA) constituent of the cellular components called ribosomes, which function in protein synthesis. Adjacent to the nucleus in the cells of animals and certain lower plants are two small, cylindrical bodies, the centrioles, which, during cell division, separate, migrate to opposite sides of the cell, and organize a structure called a spindle between them.

Within the cytoplasm of both plant and animal cells are components called mitochondria, which may be shaped like spheres, rods, or threads. Each mitochondrion is bounded by a double membrane, the outer layer of which

forms the smooth outer boundary of the mitochondrion; the inner layer, folded repeatedly into shelflike folds called cristae, contains enzymes that play an essential role in the conversion of the energy of foodstuffs into the energy used for cellular activities. The cells of most plants contain plastids, small bodies involved in the synthesis and storage of foodstuffs. The most important plastids, the chloroplasts, function in trapping the energy of sunlight during photosynthesis. They are disk-shaped structures with a platelike arrangement of tightly stacked membranes.

The cytoplasmic components important in protein synthesis, the ribosomes, are composed of nucleic acid and protein. Clusters of five or more ribosomes, termed polysomes, appear to be the functional unit in protein synthesis.

Lysosomes are membrane-bound structures containing a variety of enzymes that can break down the large molecular constituents of the cell. The membrane surrounding lysosomes presumably prevents the enzymes from digesting the cell contents before the cell dies.

Embryology. The structures and the relationships among the various parts of a mature plant or animal are usually better understood if the successive developmental stages are studied. Thus, morphologists have traditionally been interested in the study of embryos and their developmental patterns—*i.e.,* the science of embryology.

Development typically begins in animals with the cleavage, or division, of the fertilized egg (zygote) to form a hollow ball of cells called the blastula; the blastula then develops into a hollow cuplike body of two layers of cells, the gastrula, from which the embryo ultimately is formed. At one time, the techniques available to embryologists enabled them to study only whole embryos at different developmental stages. The science of experimental embryology began during the first half of the 20th century, when microsurgical techniques became available either for the removal and study of certain structures from tiny embryos or for their transplantation to other regions of the embryo. Advances in understanding the mechanism by which biological information is transferred in DNA and the means by which this information results in the production of specific proteins have led to efforts to describe development in biochemical terms. Although hypotheses regarding the reasons for the appearance of a specific enzyme or some other protein at a specific time during development have been formulated and tested, the biochemical basis of morphogenesis itself—that is, the reason for the development of particular structures—has not yet been established.

Development of microsurgical techniques

The development of the seed plant is basically different from that of an animal. The egg cell of a seed plant is retained within the enlarged lower part, or ovary, of the seed-bearing organ (pistil) of a flower; two sperm nuclei pass through a structure called a pollen tube to reach the egg. One sperm nucleus unites with the egg nucleus to form the zygote from which the new plant will develop; the second sperm nucleus unites with two nuclei, called polar nuclei, to form a body called a triploid endosperm, the cells of which divide to form a nutritive mass within the seed. The zygote undergoes several cell divisions to form the embryo, which is surrounded by the endosperm. The embryo develops one or two seed leaves, or cotyledons, which may become thick and fleshy with stored foodstuffs. The epicotyl, which consists of a growing point enclosed by a pair of folded miniature leaves, develops above the point of attachment of the seed leaves. Below the seed leaves extends the hypocotyl, the tip, or radicle, of which forms the primary root of the embryonic plant. The factors involved in initiating and controlling morphogenesis in plants have been studied by growing cells, tissues, and organs derived from plants. Indeed, an entire carrot plant has been grown from one cell of a mature carrot; this provides striking evidence that the cell from the adult plant contains all of the genetic information needed to produce an entire plant, including roots, stems, and leaves. The technique of growing plants from isolated plant parts has been useful in studies involving the characteristics of embryonic growth, the correlated growth of plant parts, and the nature of differentiation and regeneration (the replacement of lost parts).

Methods in morphology. *Chemical techniques.* The methods of investigating gross structure depend on careful dissection, or cutting apart, of an organism and on accurate descriptions of the parts. The study of the structure of tissues and cells has been extended by the techniques of autoradiography and histochemistry. In the former, a tissue is supplied with a radioactive substance and allowed to utilize it for an appropriate period of time, after which the tissue is prepared and placed in contact with a special photographic emulsion. Silver grains in the emulsion in contact with radioactive substances darken; thus, the location of the dark spots indicates the position at which the radioactive substance was concentrated in the tissue. Histochemistry involves the differential staining of cells (*i.e.,* using dyes that stain specific structural and molecular components) to reflect the chemical differences of the constituents. By choosing appropriate dyes, the histochemist is able, for example, to determine the acidity or alkalinity of the chemical compounds comprising cell components. In addition, dyes that stain specific molecular constituents such as glycogen, DNA, RNA, and protein also are used. The histochemist is able to locate a specific enzyme in a thin slice of tissue, to provide the specific substance with which the enzyme reacts to form a product, and to add a compound that reacts with the product to form an insoluble coloured compound the location of which is relatively easy to determine. In this way, information has been obtained about the specific location of enzymes within the cell.

Dissection and description

Microscopic techniques. Histologists and cytologists utilize microscopic techniques—light microscopy, phase contrast microscopy, interference microscopy, polarization microscopy, fluorescent microscopy, and electron microscopy—to investigate certain aspects of cell structure. Phase contrast microscopy is widely used to study the structure of living cells because, with such apparatus, internal structures can be observed without killing and staining the cell. In addition, motion pictures of dividing cells or moving cells can be made using phase contrast microscopy.

The interference microscope involves passing two separate beams of light through the specimen. With the appropriate instrument, the mass of material per unit area of the specimen can be determined, and contour mapping of small objects is possible.

Crystalline or fibrous elements, both of which are characterized by an orderly or layered molecular structure, are studied with a polarizing microscope; the polarizing microscope has been particularly useful in studying the detailed structure of bone.

Fluorescence microscopy

In fluorescence microscopy, the images seen are molecules of fluorescent dyes added to cells that attach to specific cellular components. Appropriate filters are required to insure that only the light of longer wavelength contributes to the image. Fluorescent antibodies have been used to locate specific kinds of proteins and other materials in certain cells of a tissue or in certain regions of a cell. The antibodies are prepared by injecting into a rabbit an antigen (*e.g.,* the protein myosin), which stimulates white blood cells called lymphocytes to synthesize antibodies that react specifically with the antigen. After the antibodies are isolated and purified, the fluorescent dye, fluorescein, becomes attached to them by a chemical reaction. If the fluorescent antibodies are spread over a tissue, they attach specifically to the molecules that stimulated their formation (myosin). The fluorescence microscope reveals the sites containing the antigen–antibody complex as bright luminescent areas in a dark background.

Electron microscopy

In the scanning electron microscope, a moving spot of electrons (negatively charged particles) is used to scan an object and to produce an image similar to that which appears on a television screen. In this manner, photographs with a three-dimensional appearance can be produced. With the transmission electron microscope, a beam of electrons passes through an object, such as a cell, and is focussed on the other side onto a fluorescent screen or a photographic plate. The beam of electrons in the scanning electron microscope is focussed and then scanned across the specimen. The electrons that leave the specimen, which are not necessarily the same electrons that strike it,

are then used to control the beam of a cathode-ray picture tube. Scanning electron microscopes allow photographs to be taken not only of large molecules such as DNA but of very small objects—individual atoms of elements such as uranium or thorium.

(C.A.V.)

PHYSIOLOGY

The word physiology was first used by the Greeks around 600 BC to describe a philosophical inquiry into the nature of things. The use of the term with specific reference to vital activities of healthy humans, which began in the 16th century, also is applicable to many current aspects of physiology. In the 19th century, curiosity, medical necessity, and economic interest stimulated research concerning the physiology of all living organisms. Discoveries of unity of structure and functions common to all living things resulted in the development of the concept of general physiology, in which general principles and concepts applicable to all living things are sought. Since the mid-19th century, therefore, the word physiology has implied the utilization of experimental methods, as well as techniques and concepts of the physical sciences, to investigate causes and mechanisms of the activities of all living things.

Historical background. The philosophical natural history that comprised the physiology of the Greeks has little in common with modern physiology. Many ideas important in the development of physiology, however, were formulated in the books of the Hippocratic school of medicine (before 350 BC), especially the humoral theory of disease in the treatise *De natura hominis* ("On the Nature of Man"). Other contributions were made by Aristotle (*Lykaion,* about 325 BC) and Galen of Pergamum (*c.* AD 130–*c.* 200). Significant in the history of physiology was the teleology of Aristotle, who assumed that every part of the body is formed for a purpose and that function, therefore, can be deduced from structure. The work of Aristotle was the basis for Galen's *De usu partium* ("On the Use of Parts") and a source for many early misconceptions in physiology. The tidal concept of blood flow, the humoral theory of disease, and Aristotle's teleology, for example, led Galen into a basic misunderstanding of the movements of blood that was not corrected until William Harvey's work on blood circulation in the 17th century.

The publication in 1628 of Harvey's *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (*An Anatomical Dissertation Upon the Movement of the Heart and Blood in Animals*) usually is identified as the beginning of modern experimental physiology. Harvey's study was based only on anatomical experiments; despite increased knowledge in physics and chemistry during the 17th century, physiology remained closely tied to anatomy and medicine. In 1747 in Berne, Switzerland, Albrecht von Haller, eminent as anatomist, physiologist, and botanist, published the first manual for physiology. Between 1757 and 1766 he published eight volumes entitled *Elementa Physiologiae Corporis Humani* (*Elements of Human Physiology*); all were in Latin and characterized his definition of physiology as anatomy in motion. At the end of the 18th century, Antoine Lavoisier wrote about the physiological problems of respiration and the production of heat by animals in a series of memoirs that still serve as a foundation for understanding these subjects.

Progress in the 19th century

Physiology as a distinct discipline utilizing chemical, physical, and anatomical methods began to develop in the 19th century. Claude Bernard in France; Johannes Müller, Justus von Liebig, and Carl Ludwig in Germany; and Sir Michael Foster in England may be numbered among the founders of physiology as it now is known. At the beginning of the 19th century, German physiology was under the influence of the romantic school of *Naturphilosophie.* In France, on the other hand, romantic elements were opposed by rational and skeptical viewpoints. Bernard's teacher, François Magendie, the pioneer of experimental physiology, was one of the first men to perform experiments on living animals. Both Müller and Bernard, however, recognized that the results of observations and experiments must be incorporated into a body of scientific knowledge, and that the theories of natural philosophers must be tested by experimentation. Many important ideas in physiology were investigated experimentally by Bernard, who also wrote books on the subject. He recognized cells as functional units of life and developed the concept of blood and body fluids as the internal environment (*milieu intérieur*) in which cells carry out their activities. This concept of physiological regulation of the internal environment occupies an important position in physiology and medicine; Bernard's work had a profound influence on succeeding generations of physiologists in France, Russia, Italy, England, and the United States.

Müller's interests were anatomical and zoological, whereas Bernard's were chemical and medical, but both men sought a broad biological viewpoint in physiology rather than one limited to human functions. Although Müller did not perform many experiments, his textbook *Handbuch der Physiologie des Menschen für Vorlesungen* and his personal influence determined the course of animal biology in Germany during the 19th century.

Methods

It has been said that, if Müller provided the enthusiasm and Bernard the ideas for modern physiology, Carl Ludwig provided the methods. During his medical studies at the University of Marburg in Germany, Ludwig applied new ideas and methods of the physical sciences to physiology. In 1847 he invented the kymograph, a cylindrical drum that still is used to record muscular motion, changes in blood pressure, and other physiological phenomena. He also made significant contributions to the physiology of circulation and urine secretion. His textbook of physiology, published in two volumes in 1852 and 1856, was the first to stress physical instead of anatomical orientation in physiology. In 1869 at Leipzig, Ludwig founded the Physiological Institute (*neue physiologische Anstalt*), which served as a model for research institutes in medical schools all over the world. The chemical approach to physiological problems, developed first in France by Lavoisier, was expanded in Germany by Justus von Liebig, whose books on *Organic Chemistry and its Applications to Agriculture and Physiology* (1840) and *Animal Chemistry* (1842) created new areas of study both in medical physiology and agriculture. German schools devoted to the study of physiological chemistry evolved from Liebig's laboratory at Giessen.

The British tradition of physiology is distinct from that of the continental schools. In 1869 Sir Michael Foster became Professor of Practical Physiology at University College in London, where he taught the first laboratory course ever offered as a regular part of instruction in medicine. The pattern Foster established still is followed in medical schools in Great Britain and the United States. In 1870 Foster transferred his activities to Trinity College at Cambridge, England, and a postgraduate medical school emerged from his physiology laboratory there. Although Foster did not distinguish himself in research, his laboratory produced many of the leading physiologists of the late 19th century in Great Britain and the United States. In 1877 Foster wrote a major book (*Textbook of Physiology*), which passed through seven editions and was translated into German, Italian, and Russian. He also published *Lectures on the History of Physiology* (1901). In 1876, partly in response to increased opposition in England to experimentation with animals, Foster was instrumental in founding the Physiological Society, the first organization of professional physiologists. In 1878, again due largely to Foster's activities, the *Journal of Physiology,* which was the first journal devoted exclusively to the publication of research results in physiology, was initiated.

Founding of the Physiological Society

Foster's teaching methods in physiology and a new evolutionary approach to zoology were transferred to the United States. in 1876 by Henry Newell Martin, a professor of biology at Johns Hopkins University in Baltimore, Md. The American tradition drew also on the continental schools. S. Weir Mitchell, who studied under Claude Bernard, and Henry P. Bowditch, who worked with Carl Ludwig, joined Martin to organize the American Physiological Society in 1887, and in 1898 the society sponsored publication of the *American Journal of Physiology.* In 1868 Eduard Pflüger, professor at the Institute of Physiology at Bonn, founded the *Archiv für die gesammte Physiologie,*

which became the most important journal of physiology in Germany.

Physiological chemistry followed a course partly independent of physiology. Müller and Liebig provided a stronger relationship between physical and chemical approaches to physiology in Germany than prevailed elsewhere. Felix Hoppe-Seyler, who founded his *Zeitschrift für physiologische Chemie* in 1877, gave identity to the chemical approach to physiology. The American tradition in physiological chemistry initially followed that in Germany; in England, however, it developed from a Cambridge laboratory founded in 1898 to complement the physical approach started earlier by Foster.

Physiology in the 20th century is a mature science; during a century of growth, physiology became the parent of a number of related disciplines, of which biochemistry, biophysics, general physiology, and molecular biology are the most vigorous examples. Physiology, however, retains an important position among the functional sciences that are closely related to the field of medicine. Although many research areas, especially in mammalian physiology, have been fully exploited from a classical-organ and organ-system point of view, comparative studies in physiology may be expected to continue. The solution of the major unsolved problems of physiology will require technical and expensive research by teams of specialized investigators. Unsolved problems include the unravelling of the ultimate bases of the phenomena of life. Research in physiology also is aimed at the integration of the varied activities of cells, tissues, and organs at the level of the intact organism. Both analytical and integrative approaches uncover new problems that also must be solved. In many instances, the solution is of practical value in medicine or helps to improve the understanding of both human beings and other animals.

Intradisciplinary work. The anatomical and medical origins of physiology still are reflected in university courses and textbooks that concentrate on functional organ systems of animals; *e.g.,* frog, dog, cat, and rat. The trend in physiology, however, is to emphasize function rather than structure; *i.e.,* comprehensive functional specializations such as nutrition, transport, metabolism, and information have replaced earlier structural studies of organ systems. This trend can be explained in part by the fact that the analysis of an organ system typically involves studies at the levels of cells and molecules, and functional emphasis accommodates such studies better than the organ-system approach.

Functional and comparative emphasis

Early in the 20th century, the emphasis on cells as units of function resulted in a view that all physiology is essentially cell physiology and that all teaching therefore should pivot around the properties of cells. In later years successful analyses of cellular mechanisms involving synthesis, control, and inheritance led to similar emphasis at a new and more fundamental level, the molecules that comprise cells. The study of physiology now encompasses molecules, cells, organs, and many types of animals, including man. The comparisons resulting from such studies not only strengthen human physiology but also generate new problems that extend into evolution and ecology. Much of the impetus for comparative physiology has resulted from the economic or medical importance to man of parasites, insects, and fishes.

Most of the physiology of microorganisms and plants developed independently of animal physiology. The concept of comparative biochemistry provided the foundations for a physiology of microorganisms that extended beyond the parasitic forms that are of medical importance and resulted in recognition of the fundamental roles of microorganisms in the biosphere. Botanists and agriculturists explore the physiology of higher plants, but fundamental differences in the modes of life of animals and plants leave little common ground above the molecular and cellular levels. In a little-known textbook, Claude Bernard stated that there is only one way to live, only one physiology of all living things. The goal of general physiology is to abstract this single physiology from the physiologies of all types of organisms. Although common or general features usually are found at the cellular and molecular levels of organization, multicellular structures also are studied. Processes that underlie cell function are emphasized in an approach based on analyses in terms of physical and chemical principles.

Areas of study. *Metabolism.* In the late 19th century the principle of conservation of energy was derived in part from observations that fermentation and muscle contraction are essentially problems in energetics. Biological energetics began with studies that established the basic equation of respiration as:

$$\text{Fuel} + \text{oxygen} \rightarrow \text{carbon dioxide} + \text{water} + \text{heat}.$$

It was realized that the heat produced in fermentation and the work performed during muscle contraction must originate in similar processes, and that fuel in the equation above is a source of potential energy. Early in the 20th century studies of animal calorimetry verified these concepts in man and other animals. Calorimetry studies showed that the energy produced by the metabolism of foodstuffs in an animal equals that produced by the combustion of these foodstuffs outside the body. After these studies, measurement of the basal metabolic rate (BMR) was used in the diagnosis of certain diseases, and data relating the composition of foodstuffs to their value as sources of metabolic energy were obtained.

Calorimetry

Early in the 20th century it was established that measurable amounts of the carbohydrate glycogen are converted to lactic acid in frog muscles contracting in the absence of oxygen. This observation and studies of alcoholic fermentation confirmed that the energy for fermentation or muscle contraction depends on a series of reactions now known as glycolysis. In order to show that the conversion of glycogen to lactic acid could provide the necessary energy for muscular contraction, extremely delicate measurements of the heat produced by contracting muscles were required. As a result of glycolysis studies, adenosine triphosphate (ATP) was recognized as an important molecule in cellular energy transfer and utilization; *e.g.,* movement, generation of electricity, transport of materials across cell membranes, and production of light by cells. Soon it was discovered that a muscle protein called myosin acts as an enzyme (organic catalyst) by liberating the energy stored in ATP and that ATP in turn can modify the physical properties of myosin molecules. It was also shown that a muscle fibre has an elaborate and ordered structure, which is based on a precise arrangement of myosin and another muscle protein called actin.

Glycolysis is an anaerobic process (*i.e.,* it does not require oxygen) and may represent one of the oldest mechanisms for cellular energy transfer, since the process could have evolved before there was free oxygen in the Earth's atmosphere. Most cells, however, derive their energy from a series of reactions involving oxygen and called the Krebs tricarboxylic acid cycle. The enzymes for the cycle are part of the structure of a mitochondrion, which is an elaborate cellular component filled with membranes and often shaped like a very small bean. In the course of the oxidation, three molecules of energy-rich ATP are generated for each oxygen atom used to form a molecule of water. The mitochondrion, therefore, is the cellular site of respiratory combustion first clearly demonstrated in whole animals by Lavoisier.

The ultimate source of foodstuffs used by animals is plants. Early 19th-century studies of photosynthesis were closely related to those of respiration and began with Joseph Priestley's demonstration that plants could restore the air used during respiration or combustion. The most important equations for living things therefore, are mutually inverse. In respiration:

$$\underset{\text{carbohydrate}}{(CH_2O)_n} + \underset{\text{oxygen}}{nO_2} \rightarrow \underset{\text{carbon dioxide}}{nCO_2} + \underset{\text{water}}{nH_2O} + \text{heat}.$$

In photosynthesis:

$$nCO_2 + nH_2O + \text{light} \rightarrow (CH_2O)_n + nO_2.$$

In the 1930s, it was shown that photosynthesis involves splitting hydrogen from water and that the oxygen liberated in photosynthesis comes from water. During the light reactions, light energy is captured by a green pigment

called chlorophyll and used to generate reactive hydrogen and ATP that are used during dark reactions in which carbohydrates and other cell constituents are synthesized.

Integration of classical, chemical, and comparative approaches

The classical fields of organ-system physiology have a role subsidiary to that of cellular metabolism. Feeding and digestion, for example, become a means for the enzyme-catalyzed breakdown of organic compounds into relatively small molecules that can be transported readily; nutrition, therefore, is a way to supply animals with sufficient sources of energy and specific substances that they cannot synthesize. Comparative animal studies, which were of practical importance in the discovery of some vitamins, led also to the general observation that the specific nutrient requirements of animals are consequences of a slow evolutionary deterioration in which synthetic abilities are lost through changes or mutations in hereditary material.

Nutrition and digestion, however, also have been important in obtaining information at the cellular and molecular levels. It was through studies of digestion, for example, that the existence and nature of enzymes were first disclosed clearly. In addition, early recognition of similarities between digestion and fermentation foreshadowed knowledge of the important role of fermentation in cellular metabolism. Finally, the study of vitamin nutrition was closely integrated with that of cellular oxidation, in which certain vitamins play an essential catalytic role.

In intact organisms, the chemical activities of individual cells do not interfere with the functions of the organism. Much of the study of physiology now is concerned with the ways by which cells obtain their nutrients and dispose of their waste products. Knowledge of the mechanism of protein synthesis and its connections with inheritance and cellular control mechanisms have initiated new inquiries into functions at all levels; *i.e.,* cells, organs, and organisms.

Circulation of blood

Transport. Many important advances in surgery and medicine have been based on the physiology of circulation, which was first studied in 1628. The measurement of blood pressure, for example, was introduced on a practicable basis late in the 19th century and has become an important part of medical diagnosis. The physiology of circulation is concerned with the origin of blood pressure in the force of the heartbeat and the regulation of heart rate, blood pressure, and the flow of blood.

Variations in heart rate that led Aristotle to consider the heart as the seat of the emotions—a myth that persists even now—were among the phenomena whose explanation revealed the existence of the autonomic nervous system. Variations in heart rate are less important to the circulatory system, however, than is the ability of the heart to adjust the strength of its beat to meet certain demands of the body.

The peripheral control of blood pressure and blood flow depends upon a maze of interacting control mechanisms, most significant of which are direct control of the diameter of small arterial branches that enlarge or dilate in response to chemical products formed during metabolism. Increased metabolic activity of tissues such as muscles or the intestine, therefore, automatically induces increased blood flow through the dilated vessels. This action, which could result in a fall in blood pressure, is offset by central-reflex controls that constrict arterial branches not dilated as a result of local chemical effects. Certain regions of the skin and the intestines serve as reservoirs for blood that may be diverted to muscles or the brain if necessary. Peripheral control may break down if excessive demands are made upon it in hot weather (heat stroke), during vigorous exercise after meals (muscle cramp), and after extensive loss of blood or tissue damage (wound shock) or extreme emotion with consequent activation of the autonomic nervous system (emotional shock). A remarkable adaptation occurs in air-breathing vertebrates—reptiles, birds, and mammals—which dive for food or protection. During a dive, the flow of blood to all parts of the body except the brain and the heart is reduced substantially. The energy for muscle contraction is provided by the anaerobic process of glycolysis because the oxygen in the blood goes to the brain and heart, which cannot function without a constant supply of oxygen.

Comparative studies have disclosed two major patterns in circulatory systems. Among vertebrates and a few invertebrates—notably annelid worms and cephalopod mollusks—the blood flows entirely in closed channels or vessels, never coming into direct contact with cells and tissues; blood pressure and the velocity of flow are high and relatively constant, and the volume of blood is small. In many invertebrates—especially arthropods and mollusks other than cephalopods—the blood flows for part of its course in large sinuses or lacunae and comes directly into contact with the tissues. Blood pressure and the velocity of flow are low and variable in these invertebrates, and the large volume of blood is comparable to the total volume of all body fluids in vertebrates.

Consideration of the blood as a transport system has centred especially on the transport of oxygen and carbon dioxide. The colour of blood changes as it passes through the lungs; venous blood is dark purple and arterial blood is bright red because of the properties of a blood pigment called hemoglobin. The complete structure of hemoglobin now has been determined, and minute variations in this structure have enabled man to study fundamental questions of heredity at the molecular level. The development of blood-banks and the techniques involved in blood transfusions depend on knowledge of the physical, chemical, and biological properties of blood. These properties include a remarkable diversity of hemoglobin, both among individuals and species and also within an individual during development. In many instances variations in protein composition better adapt a species to its circumstances.

Transport through cell membranes

Studies of membrane transport at the cellular level are an important part of general physiology. Although quantitative theories of diffusion and osmosis that developed around 1900 were applied to cell physiology, a number of phenomena (*e.g.,* movement through membranes of certain ions and other compounds of biological importance) did not behave according to established physical principles. As a result of studies of osmotic and ionic regulation in freshwater animals, the concept of active transport was formulated. Crucial to the acceptance of this concept were studies with frog skin, which can transport sodium ions against chemical and electrical forces; the transport, specific for sodium ions, is dependent on a continuing input of metabolic energy. Efforts have been directed toward establishing a molecular mechanism that may involve an enzyme found in surface membranes of cells. This enzyme breaks down ATP and releases the energy in the molecule only if sodium and potassium ions are present.

Information transfer. The physiology of animals differs from that of plants in the rapid response of animals to stimuli. René Descartes, responsible for the concept of the reflex that dominated neurophysiology for most of its history, thought a sensory impulse was "reflected" from the brain to produce a reaction in muscles. Later studies of the effects of ions on nerves suggested that a nerve must be surrounded by a membrane and that a nerve impulse results from a change in the ability of the membrane to allow passage of potassium ions. When it was shown that nerves are made up of thousands of tiny fibres, which are processes that extend from cells located in the brain or spinal cord, the nerve impulse hypothesis was applied to individual nerve fibres rather than to whole nerves. Electronic technology provided the techniques and giant nerve fibres of squids provided the experimental material that enabled two Nobel prize winners for physiology, Alan Lloyd Hodgkin and Andrew Fielding Huxley, to extend this hypothesis into a theory of the excitation of nerve cells in which sodium ions and potassium ions play principal roles.

Reflex concept

The reflex concept, however, was not dependent on understanding the molecular basis of excitation, conduction, and transmission. Early in the 20th century the role of interaction of nervous centres in controlling muscle contractions was established. The reflex now is conceived as a unit in which nerve impulses initiated in sensory neurons or nerve cells are conducted to a centre in the brain or spinal cord. In the centre, impulses initiated in motor neurons are conducted to muscles and induce a reflex response. Two processes can occur in the centre; one is

associated with central excitatory states, the other with central inhibitory states. The net effect of any stimulus or group of stimuli, therefore, can be interpreted as an interaction of these opposing states in the centre.

After the demonstration that the effects of the vagus nerve in slowing the heart are mediated by a chemical substance, subsequently identified as acetylcholine, the concept of chemical transmission of nervous impulses was extended to the central nervous system. Typically, transmission of excitation from cell to cell is accomplished by the liberation of a chemical transmitter from a nerve ending.

The reflex concept gave rise to premature attempts to develop a psychology based on reflexes. These attempts (behaviourism) were advanced by the Russian I.P. Pavlov's discovery of conditioned responses. Originally known as conditioned reflexes, these responses have been found in most animals with central nervous systems. More complex than simple reflexes, their mechanism has not yet been established with certainty.

Sensory functions at cellular level

The analysis of sensory functions also extends to the cellular level. Sense organs are diverse in structure and sensitivity to specific stimuli. It may be that the common molecular basis for the differences in sensitivity is a change in permeability of a special region of the membrane surrounding a sensory cell. This change in permeability could allow a nerve fibre to become excited and initiate a nerve impulse. Neurophysiology has borrowed from, and contributed to, the information theory used in communications engineering. The function of sense organs is to gather information both from the environment and the organism. The central nervous system integrates this information and translates it into a program of response involving the entire organism. In addition, the brain can store information previously received (memory) and has the ability to initiate actions without obvious external stimulation (spontaneity). Some aspects of memory and integrative function have been modelled in electronic computers; in fact the development of computers was closely connected with the development of ideas about the functions of the central nervous system.

The analytical interpretation of central nervous function remains, however, a complex and difficult field, even though recent progress has brought closer together the study of behaviour in terms of nerve function and behavioral models. Considerable effort now is directed to the localization of brain function. Although specific centres for reception of sensory information and integration of motor programs are known, the integrative functions that tie them together, as well as the functions of memory, are not so well established.

Regulation. The concept of internal regulations is attributed to Claude Bernard, who thought of blood as an internal environment in which cells function; according to Bernard, maintenance of the internal environment at a constant level was a major responsibility of all body functions. Bernard showed in studies of the formation and breakdown of glycogen in the liver that internal organs can secrete materials into the blood. Other investigators demonstrated such a secretion and used the word hormone to describe the substance. One classical study concerned control of the secretion of digestive fluids by the pancreas; an active substance secretin was purified, as have been a number of similar materials from the digestive tract. The field of endocrinology now is a major part of physiology.

Complementary roles of hormones and nerves

The endocrine system complements the nervous system in control and coordination. Hormones, liberated into blood and other body fluids by endocrine glands and transported throughout the body, usually act either on specific target organs or on certain activities of many organs. Nervous coordination most often is concerned with rapid responses of short duration; endocrine coordination, however, usually is involved in slower responses of longer duration. Stationary-state regulation, or homeostasis, depends on the action of hormones at many points. The hormones insulin and glucagon, both formed in specialized endocrine tissue in the pancreas, control the level of sugar in blood. Vasopressin from the pituitary gland at the base of the brain and aldosterone from the adrenal glands near the kidneys control salt and water balance of the blood. Hormonal regulation, however, is not confined to homeostasis. The cyclic events of the female reproductive cycles in mammals, for example, are determined by a complex sequence of endocrine interactions involving hormones of the pituitary gland and the ovary.

Interaction of hormones

The pervasive regulatory action of hormones is part of a large system of interactions to which the term feedback generally is applied. Hormones involved in homeostatic regulation, for example, influence their own secretion. The secretion of certain steroid hormones, which have a significant action on the conversion of amino acids to glycogen, is controlled by another hormone called the adrenocorticotropic hormone (ACTH), which is formed in the anterior pituitary gland. In turn the secretion of ACTH is controlled by a releasing factor formed in the midbrain and liberated from the stalk of the pituitary gland. ACTH liberation normally is controlled by the concentration of steroids in the blood, so that an increase in steroid concentration inhibits ACTH secretion; this negative feedback, however, may be overcome in certain conditions of intense nervous stimulation.

A similar pattern of releasing factors, by which the nervous system interacts with the endocrine system, also is known for other anterior pituitary hormones; *e.g.,* those involved in the reproductive cycle and in responses of the thyroid gland to temperature changes. In addition, neurosecretory cells—nerve cells specialized for endocrine function—liberate hormones (*e.g.,* vasopressin) that act directly on a specific target. Comparative studies show that neurosecretory cells are important in developmental and regulatory functions of most animals. Discrete endocrine glands, however, occur less frequently; in insects and crustaceans, cycles of growth, molting (shedding of the cuticle), and development are controlled by hormones. The identification of insect hormones may be useful in controlling pests through specific interference with processes of growth and development.

(B.T.S.)

TAXONOMY

Taxonomy, the science of classification in a broad sense, is usually restricted to biological classification and specifically to the classification of plants and animals. The term is derived from the Greek *taxis* ("arrangement") and *nomos* ("law"). Taxonomy is, therefore, the methodology and principles of systematic botany and zoology and sets up arrangements of the kinds of plants and animals in hierarchies of superior and subordinate groups.

Popularly, classifications of living organisms arise according to need and are often superficial. Anglo-Saxon terms such as worm and fish have been used to refer, respectively, to any creeping thing—snake, earthworm, intestinal parasite, or dragon—and to any swimming or aquatic thing. Although the term fish is common to the names shellfish, crayfish, and starfish, there are more anatomical differences between a shellfish and a starfish than there are between a bony fish and a man. Vernacular names vary widely. The American robin (*Turdus migratorius*), for example, is not the English robin (*Erithacus rubecula*), and the mountain ash (*Sorbus*) has only a superficial resemblance to a true ash.

Biologists, however, have attempted to view all living organisms with equal thoroughness and thus have devised a formal classification. A formal classification provides the basis for a relatively uniform and internationally understood nomenclature, thereby simplifying cross-referencing and retrieval of information.

The usage of the terms taxonomy and systematics with regard to biological classification varies greatly. American evolutionist Ernst Mayr has stated that "taxonomy is the theory and practice of classifying organisms" and "systematics is the science of the diversity of organisms"; the latter in such a sense, therefore, has considerable interrelations with evolution, ecology, genetics, behaviour, and comparative physiology that taxonomy need not have.

Historical background. People who live close to nature usually have an excellent working knowledge of the elements of the local fauna and flora important to them and also often recognize many of the larger groups of living

things (*e.g.*, fishes, birds, and mammals). Their knowledge, however, is according to need, and such people generalize only rarely.

From the Greeks to the Renaissance. The first great generalizer in classification was Aristotle, who virtually invented the science of logic, of which for 2,000 years classification was a part. Greeks had constant contact with the sea and marine life, and Aristotle seems to have studied it intensively during his stay on the island of Lesbos. In his writings, he described a large number of natural groups, and, although he ranked them from simple to complex, his order was not an evolutionary one. He was far ahead of his time, however, in separating invertebrate animals into different groups and was aware that whales, dolphins, and porpoises had mammalian characters and were not fish. Lacking the microscope, he could not, of course, deal with the minute forms of life.

Aristotle's classification into natural groups

The Aristotelian method dominated classification until the 19th century. His scheme was, in effect, that the classification of a living thing by its nature—*i.e.*, what it really is, as against superficial resemblances—requires the examination of many specimens, the discarding of variable characters (since they must be accidental, not essential), and the establishment of constant characters. These can then be used to develop a definition that states the essence of the living thing—what makes it what it is and thus cannot be altered; the essence is, of course, immutable. The model for this procedure is to be seen in mathematics, especially geometry, which fascinated the Greeks. Mathematics seemed to them the type and exemplar of perfect knowledge, since its deductions from axioms were certain and its definitions perfect, irrespective of whether a perfect geometrical figure could ever be drawn. But the Aristotelian procedure applied to living things is not by deduction from stated and known axioms; rather, it is by induction from observed examples and thus does not lead to the immutable essence but to a lexical definition. Although it provided for centuries a procedure for attempting to define living things by careful analysis, it neglected the variation of living things. It is of interest that the few people who understood Charles Darwin's *Origin of Species* in the mid-19th century were empiricists who did not believe in an essence of each form.

Aristotle and his pupil in botany, Theophrastus, had no notable successors for 1,400 years. In about the 12th century AD, botanical works necessary to medicine began to contain accurate illustrations of plants, and a few began to arrange similar plants together. Encyclopaedists also began to bring together classical wisdom and some contemporary observations. The first flowering of the Renaissance in biology produced, in 1543, Andreas Vesalius' treatise on human anatomy and, in 1545, the first university botanic garden, founded in Padua, Italy. After this time, work in botany and zoology flourished. John Ray summarized in the late 17th century the available systematic knowledge, with useful classifications. He distinguished the monocotyledonous plants from the dicotyledonous ones in 1703, recognized the true affinities of the whales, and gave a workable definition of the species concept, which had already become the basic unit of biological classification. He tempered the Aristotelian logic of classification with empirical observation.

Botany and zoology of the Renaissance

The Linnaean system. Carolus Linnaeus, who is usually regarded as the founder of modern taxonomy and whose books are considered the beginning of modern botanical and zoological nomenclature, drew up rules for assigning names to plants and animals and was the first to use binomial nomenclature consistently (1758). Although he introduced the standard hierarchy of class, order, genus, and species, his main success in his own day was providing workable keys, making it possible to identify plants and animals from his books. For plants he made use of the hitherto neglected smaller parts of the flower.

Linnaeus attempted a natural classification but did not get far. His concept of a natural classification was Aristotelian; *i.e.*, it was based on Aristotle's idea of the essential features of living things and on his logic. He was less accurate than Aristotle in his classification of animals, breaking them up into mammals, birds, reptiles, fishes, insects, and worms. The first four, as he defined them, are obvious groups and generally recognized; the last two incorporate about seven of Aristotle's groups.

The standard Aristotelian definition of a form was by genus and differentia. The genus defined the general kind of thing being described; the differentia gave its special character. A genus, for example, might be "Bird" and the species "Feeding in water," or the genus might be "Animal" and the species "Bird." The two together made up the definition, which could be used as a name. Unfortunately, when many species of a genus became known, the differentia became longer and longer. In some of his books Linnaeus printed in the margin a catch name, the name of the genus and one word from the differentia or from some former name; in this way he created the binomial, or binary, nomenclature. Thus, modern man is *Homo sapiens,* Neanderthal man *Homo neanderthalensis,* the gorilla *Gorilla gorilla,* and so on.

Creation of binary nomenclature

Classification since Linnaeus. Classification since Linnaeus has incorporated newly discovered information and more closely approaches a natural system. When the life history of barnacles was discovered, for example, they could no longer be associated with mollusks because it became clear that they were arthropods (jointed-legged animals such as crabs and insects). Jean-Baptiste Lamarck, an excellent taxonomist despite his misconceptions about evolution, first separated spiders and crustaceans from insects as separate classes; he also introduced the distinction, no longer accepted by all workers as wholly valid, between vertebrates—*i.e.*, those with backbones, such as fishes, amphibians, reptiles, birds, and mammals—and invertebrates, which have no backbones. The invertebrates, defined by a feature they lack rather than by those they have, constitute in fact about 90 percent of the diversity of all animals. The mixed group "Infusoria," which included all the microscopic forms that would appear when hay was let stand in water, was broken up into empirically recognized groups by the French biologist Felix Dujardin. The German biologist Ernst Haeckel proposed the term Protista in 1866 to include chiefly the unicellular plants and animals because he realized that, at the one-celled level, there could no longer be a clear distinction between plants and animals.

The process of clarifying relationships continues—only in 1898 were agents of disease discovered (viruses) that would pass through the finest filters, and it was not until 1935 that the first completely purified virus was obtained. Primitive spore-bearing land plants (Psilophyta) from the Cambrian Period, which dates from 570,000,000 years ago, were discovered in Canada in 1859. The German botanist Wilhelm Hofmeister in 1851 gave the first good account of the alterations of generations in various nonflowering (cryptogamous) plants, on which many major divisions of higher plants are based. The phylum Pogonophora (beardworms) was recognized only in the 20th century.

The immediate impact of Darwinian evolution on classification was negligible for many groups of organisms, and unfortunate for others. As taxonomists began to accept evolution, they recognized that what had been described as natural affinity—*i.e.*, the more or less close similarity of forms with many of the same characters—could be explained as relationship by evolutionary descent. In groups with little or no fossil record, a change in interpretation rather than alteration of classifications was the result. Unfortunately, some authorities, believing that they could derive the group from some evolutionary principle, would proceed to reclassify it. The classification of earthworms and their allies (Oligochaeta), for example, which had been studied by using the most complex organism easily obtainable and by then arranging progressively simple forms below it, was changed after the theory of evolution appeared. The most simple oligochaete, the tiny freshwater worm *Aeolosoma,* was considered to be most primitive, and classifiers arranged progressively complex forms above it. Later, when it was realized that *Aeolosoma* might well have been secondarily simplified (*i.e.*, evolved from a more complex form), the tendency was to start in the middle of the series, and work in both directions. Biassed names for the major subgroups (Archioligochaeta,

Neoligochaeta) were widely accepted, when in fact there was no evidence for the actual course of evolution of this and other animal groups. Groups with good fossil records suffered less from this type of reclassification because good fossil material allowed the placing of forms according to natural affinities; knowledge of the strata in which they were found allowed the formulation of a phylogenetic tree (*i.e.,* one based on evolutionary relationships), or dendrite (also called a dendrogram), irrespective of theory.

The formulation of phylogenetic trees

The long-term impact of Darwinian evolution has been different and very important. It indicates that the basic arrangement of living things, if enough information were available, would be a phylogenetic tree rather than a set of discrete classes. Many groups are so poorly known, however, that the arrangement of organisms into a dendrite is impossible. Extensive and detailed fossil sequences—the laying out of actual specimens—must be broken up arbitrarily. Many groups, especially at the species level, show great geographical variation, so that a simple definition of species is impossible. Difficulties of classification at the species level are considerable. Many plants show reticulate (chain) evolution, in which species form, then subsequently hybridize, resulting in the formation of new species. And because many plants and animals have abandoned sexual reproduction, the usual criteria for the species—interbreeding within a pool of individuals—cannot be applied. Nothing about the viruses, moreover, seems to correspond to the species of higher organisms.

The objectives of biological classification. A classification or arrangement of any sort cannot be handled without reference to the purpose or purposes for which it is being made. An arrangement based on everything known about a particular class of objects is likely to be the most useful for many particular purposes. One in which objects are grouped according to easily observed and described characteristics allows easy identification of the objects. If the purpose of a classification is to provide information unknown to or not remembered by the user but relating to something the name of which is known, an alphabetical arrangement may be best. Specialists may want a classification relating only to one aspect of a subject. A chemist analyzing the essential oils of plants, for instance, is interested only in the oil content of plants and probably requires such information in far greater detail than would anyone else.

Keys and characters in biological classification

Classification is used in biology for two totally different purposes, often in combination, namely, identifying and making natural groups. The specimen or a group of similar specimens must be compared with descriptions of what is already known. This type of classification, called a key, provides as briefly and as reliably as possible the most obvious characteristics useful in identification. Very often they are set out as a dichotomous key with opposing pairs of characters. The butterflies of a region, for example, might first be separated into those with a lot of white on the wings and those with very little; then each group could be subdivided on the basis of other characters. One disadvantage of such classifications, which are useful for well-known groups, is that a mistake may produce a ridiculous answer, since the groups under each division need have nothing in common but the chosen character (*e.g.,* white on the butterfly wings). In addition, if the group being keyed is large or given to great variation, the key may be extremely complex and may rely on characters difficult to evaluate. Moreover, if the form in question is a new one or one that is not in the key (being, perhaps, unrecorded from the region to which the key applies), it may be identified incorrectly. Many unrelated butterflies have a lot of white on the wings—a few swallowtails, the well-known cabbage whites, some of the South American dismorphiines, and a few satyrids. Should identification of an undescribed form of fritillary butterfly containing much white on the wings be desired, the use of a key could result in an incorrect identification of the butterfly. In order to avoid such mistakes, it is necessary to consider many characters of the organism: not merely one aspect of the wings but their anatomy and the features of the various stages in the life cycle.

Unfortunately, little is known about many of the vast variety of living things. In poorly known groups—and most living things are poorly known—the first objective is identification. There are, for example, about 250,000 species of beetles; many are known only from a single specimen of the adult. In such groups the tendency is to produce classifications which, though purporting to be natural ones, are actually dichotomous keys. Although most common earthworms have on each body segment four pairs of special bristles (chaetae) that are used in locomotion, some species have many chaetae arranged in a complete ring around the body on each segment (perichaetine condition). Because the chaetae are an easily observed character, the latter species were once placed together as a natural group, the family Perichaetidae; knowledge of other aspects of earthworm anatomy, however, made it obvious that several different groups had independently evolved the perichaetine condition. Many current so-called natural groups, especially those at the lower levels of classification, are probably not natural at all but are based on some easily observed characters.

A natural classification is advantageous in that it groups together forms that seem fundamentally to be related. Information utilized in the definition of a group thus need not be repeated for each constituent. This provides concision and efficient information storage. A certain amount of prediction is also possible—a new form with a few ascertained characters similar to those of a natural group probably has other similar characters. As long as no difficult intermediary forms are found, all of the different types can be classified into definite discrete categories. Biological classification has progressed from artificial or key classifications to a natural classification; it has also been realized that division into sharply separated groups often is not possible. Formal classification thus sometimes obscures actual relationships.

The taxonomic process. Basically, no special theory lies behind modern taxonomic methods. In effect, taxonomic methods depend on: (1) obtaining a suitable specimen (collecting, preserving and, when necessary, making special preparations); (2) comparing the specimen with the known range of variation of living things; (3) correctly identifying the specimen if it has been described, or preparing a description showing similarities to and differences from known forms, or, if the specimen is new, naming it according to internationally recognized codes of nomenclature; (4) determining the best position for the specimen in existing classifications and determining what revision the classification may require as a consequence of the new discovery; and (5) using available evidence to suggest the course of the specimen's evolution. Prerequisite to these activities is a recognized system of ranks in classifying; recognized rules for nomenclature; and a procedure for verification, irrespective of the group being examined. A group of related organisms to which a taxonomic name is given is called a taxon (plural taxa).

Ranks. The goal of classifying is to place an organism into an already existing group or to create a new group for it, based on its resemblances to and differences from known forms. To this end, a hierarchy of categories is recognized; for example, an ordinary flowering plant, on the basis of gross structure, is clearly one of the higher green plants, not a fungus, bacterium, or animal, it can easily be placed in the Kingdom Plantae (or Metaphyta). If the body of the plant has distinct leaves, roots, a stem, and flowers, it is placed with the other true flowering plants in the division Magnoliophyta (or Angiospermae), one subcategory of the Plantae. If it is a lily, with sword-like leaves, with the parts of the flowers in multiples of three, and with one cotyledon (the incipient leaf) in the embryo, it belongs with other lilies, tulips, palms, orchids, grasses, and sedges in a subgroup of the Magnoliophyta, which is called the class Liliatae (or Monocotyledones).

The hierarchy of categories

In this class, it is placed, rather than with orchids or grasses, in a subgroup of the Liliatae, the order Liliales; this procedure is continued to the species level. Should the plant be different from any lily yet known, a new species is named, as well as higher taxa, if necessary. If the plant is a new species within a well-known genus, a new species name is simply added to the appropriate genus. If the

plant is very different from any known monocot it might require, even if only a single new species, the naming of a new genus, family, order, or higher taxon; there is no restriction on the number of forms in any particular group. The number of ranks that is recognized in a hierarchy is a matter of widely varying opinion. Shown in Table 1 are seven ranks that are accepted as obligatory by zoologists and botanists. In botany, the term division is often used as an equivalent to the term phylum of zoology. The number of ranks is expanded as necessary by using the prefixes sub-, super-, and infra- (*e.g.,* subclass, superorder) and by adding other intermediate ranks, such as brigade, cohort, section, or tribe. Given in full, the zoological hierarchy for the timber wolf of the Canadian subarctic would be as follows:

Kingdom Animalia
Subkingdom Metazoa
Phylum Chordata
Subphylum Vertebrata
Superclass Tetrapoda
Class Mammalia
Subclass Theria
Infraclass Eutheria
Cohort Ferungulata
Superorder Ferae
Order Carnivora
Suborder Fissipeda
Superfamily Canoidea
Family Canidae
Subfamily Caninae
Tribe (none described for this group)
Genus *Canis*
Subgenus (none described for this group)
Species *Canis lupus* (wolf)
Subspecies *Canis lupus occidentalis* (northern timber wolf)

Name endings

Although the name of the species is binomial (*e.g., Canis lupus*) and that of the subspecies trinomial (*C. lupus occidentalis* for the northern timber wolf; *C. lupus lupus* for the northern European wolf), all other names are single words. In zoology, convention dictates that the names of superfamilies end in *-oidea,* and the code dictates that the names of families end in *-idae,* those of subfamilies in *-inae,* and those of tribes in *-ini.* Unfortunately, there are no widely accepted rules for other major divisions of living things because each major group of animals and plants has its own taxonomic history, and old names tend to be preserved. Apart from a few accepted endings, the names of groups of high rank are not standardized and must be memorized.

The discovery of the only living coelacanth fish of the genus *Latimeria,* in 1938, caused virtually no disturbance of the accepted classification, since the suborder Coelacanthi was already well known from fossils. When certain unusual worms were discovered in the depths of the oceans about ten years later, however, it was necessary to create a new phylum, Pogonophora, for them since they showed no close affinities to any other known animals. The phylum Pogonophora, as usually classified, has one class—the animals in the phylum are relatively similar—but there are two orders, several families and genera, and more than 100 species. Both of these examples have been widely accepted by authorities in their respective areas of taxonomy and may be considered stable taxa.

Table 1: Obligatory Hierarchy of Ranks

	animals	plants
Kingdom	Animalia	Plantae
Phylum	Chordata	Tracheophyta
Class	Mammalia	Pteropsida
Order	Primates	Coniferales
Family	Hominidae	Pinaceae
Genus	*Homo*	*Pinus*
Species	*Homo sapiens* (man)	*Pinus strobus* (white pine)

It cannot be too strongly emphasized that there are no explicit taxonomic characters that define a phylum, class, order, or other rank. A feature characteristic of one phylum may vary in another phylum among closely related members of a class, order, or some lower group. The complex carbohydrate cellulose is characteristic of two kingdoms of plants; among animals, however, cellulose occurs only in one subphylum of one phylum. It would simplify the work of the taxonomist if characters diagnostic of phylum rank in animals were always taken from one feature, the skeleton, for example; those of class rank, from the respiratory organs; and so on down the taxonomic hierarchy. Such a system, however, would produce an unnatural classification.

The taxonomist must first recognize natural groups and then decide on the rank that should be assigned them. Are seasquirts, for instance, so clearly linked by the structure of the extraordinary immature form (larva) to the phylum Chordata, which includes all the vertebrates, that they should be called a subphylum; or should their extremely modified adult organization be deemed more important, with the result that seasquirts might be recognized as a separate phylum, albeit clearly related to the Chordata? At present, this sort of question has no precise answer.

"Numerical taxonomy" as a system of quantifying characteristics

Some biologists believe that "numerical taxonomy," a system of quantifying characteristics of taxa and subjecting the results to multivariate analysis, may eventually produce quantitative measures of overall differences among groups, and that agreement can be achieved so as to establish the maximal difference allowed each taxonomic level. Although such agreement may be possible, many difficulties exist. An order in one authority's classification may be a superorder or class in another. Most of the established classifications of the better known groups result from a general consensus among practicing taxonomists. It follows that no complete definition of a group can be made until the group itself has been recognized, after which its common (or most usual) characters can be formally stated. As further information is obtained about the group, it is subject to taxonomic revision.

Nomenclature. Communication among biologists requires a recognized nomenclature, especially for the units in most common use. The internationally accepted taxonomic nomenclature is the Linnaean system, which, although founded on Linnaeus' rules and procedures, has been greatly modified through the years. There are separate international codes of nomenclature in botany (first published in 1901), in zoology (1906), and in microbiology (bacteria and viruses, 1948). The Linnaean binomial system is not employed for viruses. There is also a code, which was established in 1953, for the nomenclature of cultivated plants, many of which are artificially produced and are unknown in the wild.

The codes, the authority for each of which stems from a corresponding international congress, differ in various details, but all include the following elements: the naming of species by two words treated as Latin; a law of priority that the first validly published and validly binomial name for a given taxon is the correct one and that any others must become synonyms; recognition that a valid binomen can apply to only one taxon, so that a name may be used both in botany and in zoology but for only one plant taxon and one animal taxon; that if taxonomic opinion about the status of a taxon is changed, the valid name can change also; and, lastly, that the exact sense in which a name is used be determined by reference to a type. Rules are also given for the obligate categories of the hierarchy and for what constitutes valid publication of a name. Finally, recommendations are given on the process of deriving names.

Linnaeus believed that there were not more than a few thousand genera of living things, each with some clearly marked character, and that the good taxonomist could memorize them all, especially if their names were well chosen. Thus, although the naming of the species might often involve much research, the genus at least could be easily found.

At the present time, in many taxa, the species has a definite biological meaning—it is defined as a group of

Ability to interbreed as a criterion of species

individuals that can breed among themselves but do not normally breed with other forms. Among microorganisms and other groups in which sexual reproduction need not occur, this criterion fails.

In botanical practice, matters more usually resemble the Linnean situation. Many sorts of chromosomal variants (individuals with different arrangements of chromosomes, or hereditary material, which prevent interbreeding) and marked ecotypes (individuals whose external form is affected by the conditions of soil, moisture, and other environmental factors), as well as other forms, that would clearly be classified as separate species by the zoologist may be lumped together unrecognized or considered subspecies by the botanist. Botanists commonly use the terms variety and form to designate genetically controlled variants within plant populations below the subspecies level.

The use of a strictly biological species definition would enormously increase rather than reduce the number of names in use in botany. A recognized species of flowering plant may consist of several "chromosomal races"—*i.e.,* identical in external appearance but genetically incompatible and, thus, effectively separate species. Such various forms are often identifiable only by cytological examination, which requires fresh material and extensive laboratory work. Many botanists have said that there has been so little stability in the accepted nomenclature that further upheavals would be intolerable and render identification impossible for many applied botanists who may not require such refinements. To postpone recognition of such forms, however, will probably cause upheaval in the future.

Some species of birds are widespread over the archipelagos of the Southwest Pacific, where nearly every island may have a form sufficiently distinct to be given some kind of taxonomic recognition. For example, 73 races are currently recognized for the golden whistler (*Pachycephala pectoralis*). Before the realization that species could vary geographically, each island form was named as a separate species (as many of the races of *P. pectoralis* actually were). It is often believed—and often it is only belief rather than fact—however, that all of these now genetically isolated populations arose as local differentiations of a single stock; thus, they are now usually classed in zoological usage as subspecies of one polytypic species. The term

Polytypic species

polytypic indicates that a separate description (and type specimen) is needed for each of the distinct populations, instead of one for the entire species. The use of a trinomial designation for each subspecies (*e.g., Pachycephala pectoralis bougainvillei*) indicates that it is regarded as simply a local representative (in this case, on Bougainville Island in the Solomons) of a more widely distributed species. The decision on whether to consider such island forms as representatives of one species depends partly on whether, in the judgment of the taxonomist, populations from adjacent islands are sufficiently similar to allow free interbreeding.

Verification and validation by type specimens. The determination of the exact organism designated by a particular name usually requires more than the mere reading of the description or the definition of the taxon to which the name applies. New forms, which may have become known since the description was written, may differ in characteristics not originally considered; or later workers may discover, by inspection of the original material, that the original author inadvertently confused two or more forms. No description can be guaranteed to be exhaustive for all time. Validation of the use of a name requires examination of the original specimen. It must, therefore, be unambiguously designated.

At one time an author might have taken his description from a series of specimens, or partly (or even wholly) from other authors' descriptions or figures, as Linnaeus often did. Much of the controversy over the validity of certain names in current use, especially those dating from the late 18th century, stems from the difficulty in determining the identity of the material used by the original authors. In modern practice, a single type specimen must be designated for a new species or subspecies name. The type should always be placed in a reliable public institution, where it can be properly cared for and made available to taxonomists. For many microorganisms, type cultures are maintained in qualified institutions. Because of the short generation time of microorganisms, however, they may actually evolve during storage.

Nomenclature associated with type specimens

A complex nomenclature is applied to the different sorts of type specimens. The holotype is a single specimen designated by the original describer of the form (a species or subspecies only) and available to those who want to verify the status of other specimens. When no holotype exists, as is frequently the case, a neotype is selected and so designated by someone who subsequently revises the taxon; the neotype occupies a position equivalent to that of the holotype. The first type validly designated has priority over all other type specimens. Paratypes are specimens used, along with the holotype, in the original designation of a new form; they must be part of the same series (*i.e.,* collected at the same immediate locality and at the same time) as the holotype. For a taxon above the species level, the type is a taxon of the next lower rank (for a genus, for instance, it is a species); from the level of the genus to that of the superfamily there are rules regarding the formation of a group name from the name of the type group. The genus *Homo* (man) is the type genus of the family Hominidae, for example, and the code forbids its removal from the family Hominidae as long as the Hominidae is treated as a valid family and the name *Homo* is taxonomically valid. Whatever the remainder of its contents, the family that contains the genus *Homo* must be the Hominidae.

Indiscriminate collecting is of little use today, but huge areas of the Earth still are poorly known biologically, at least as far as many groups are concerned, and there remain many groups for which the small number of properly collected and prepared specimens precludes any thorough taxonomic analysis. Even in well-studied groups, such as the higher vertebrates, new methods of analyzing material often necessitate special collecting. The determination of variation within species or populations may necessitate the study of more specimens than are available, even when (as is usual) the specialist can utilize material from many institutions. Usually, collecting is done to fill gaps (in geographical range, geological formations, or taxonomic categories) already brought to light by specialists reviewing the available material. The well-informed collector of living things knows where to go, what to look for, and how to spot anything especially valuable or extraordinary.

The actual techniques of collecting and preserving vary greatly from one group of organisms to another—soil protozoa, fungi, or pines are neither collected nor preserved in the same manner as birds. Some animals can be preserved only in weak alcohol; others macerate (decompose) in it. Certain earthworms "preserved" in weak alcohol simply flow out of their own skins when lifted out. Special methods are used after long experience to preserve characters of special value in taxonomy. Some methods make specimens difficult to observe; this is especially true of material that has to be sectioned or otherwise made into preparations suitable for microscopic observation.

After taxonomic material has been collected and preserved, its value can be lost unless it is accurately and completely labelled. Only rarely is unlabelled or insufficiently labelled material of any use. The taxonomist normally

Labelling the specimens

must know the locality of collection of each specimen (or lot of specimens), often the habitat (*e.g.,* type of forest, marsh, type of seawater), the date, the name of the collector, and the original field number given to the specimen or lot. To this information is added the catalog number of the collection and the sex (if not already determined in the field and if relevant). The scientific identity of the specimen, as determined by an acknowledged specialist, is usually added to the label at the museum. Also included is the name of the specialist who identified the specimen. Later revisions of the classification and additional knowledge of the organism may result in later alterations of the scientific name, but the original labels must still be kept unaltered.

Other information may also be required; for example, the males and females of some insect groups are extremely different in appearance, and males and females of the

same species may have to be identified. The capture of a pair in the wild actually in copulation gives a strong (but, surprisingly, not absolute) indication that the male and female belong to the same species; the labels of each specimen (if they are separated) indicate the specimen with which it was mating.

Evaluating taxonomic characters. Comparison of material depends to some extent on the purposes of the comparison. For mere identification, a suitable key, with attention given only to the characters in it, may be enough in well-known groups. If the form is likely to be a new one, its general position is determined by observing as many characters as possible and by comparing them with the definitions and descriptions in a natural classification. The new specimen is compared with its nearest known relatives, usually with reference to type material. Any character may be of taxonomic use. In general, taxonomists tend to work from preserved material, so that their findings can be checked. For extinct forms, of course, only preserved material (fossils) is available.

Many biochemical, physiological, or behavioral characters may be at least as good as anatomical characters for discriminating between closely related species or for suggesting relationships. There has been a tendency in recent years rather to discount anatomical characters, but when they are obtainable in quantity (as for most plants and animals), they probably represent as large a sample of the effects of the organism's heredity as can be got, short of complete genetic analysis. Enthusiasts in genetics often stress that the only real basis for classification is the actual genotype of each organism—*i.e.,* the hereditary information by which the organism is formed. It is impossible to obtain such information for extinct forms, and the time required to obtain it for most existing ones would be enormous, even if the techniques were available. An important development, however, has been the hybridization technique employing deoxyribonucleic acid (DNA), the substance by which hereditary information is coded. With this technique, it has been possible to determine similarities in parts of DNA molecules from different organisms but not the nature of their differences.

The role of convergent resemblances

In making comparisons, resemblances resulting from convergence must be considered. Whales and bony fishes, for example, have similar body shapes for the same function—progression through water; their internal features, however, are widely different. In this case, the convergence is evident because of the large number of characters that link whales to other mammals and not to the fishes and because the fossil record for the vertebrates provides a fair indication of the actual evolutionary sequence from primitive fishes through primitive amphibians to primitive reptiles, mammal-like reptiles, and mammals. In the absence of a good fossil record it may be difficult or impossible to identify positively a case of convergence; yet it has been asserted that the occurrence of convergence must not be stated unless it has been "proved." To obey this assertion would be to make the method of analysis dictate in part the results achieved.

In some forms, especially internal parasites, great modification has occurred in adapting to a parasitic way of life. The "root system" of the "tumour" (in reality a parasite) found under the abdomen ("tail") of some crabs, for example, penetrates through the crab's body; the parasite is unrecognizable as a close relative of the barnacles (crustaceans not far removed from the crabs themselves) without the free-swimming larval stage, which shows its affinities. Transient or inconspicuous characters may be of great importance in indicating affinities; the complete life cycle of a specimen may have to be observed before its affinities can be determined. Although such characters may be useless for identification and for definition of a natural group if only a few forms in a group show them, they may be of the utmost importance in understanding relationships. Characters are therefore weighted to some extent by the taxonomist according to their utility for different purposes. Any characters intrinsic to the organism can be used in classification. Extrinsic characters, including the position of fossils in a geological sequence and geographical distribution of fossil and recent forms, may force the taxonomist to look more closely at the intrinsic characters.

Weighting of characters

Weighting or nonweighting (*i.e.,* by the degree of importance) of characters has been a subject of great dispute. On the one hand it has been pointed out that weighting is often demonstrably arbitrary and always imprecise. On the other, it has been said that if characters were actually examined without weighting, some obvious cases of extreme convergence would have to be classed with each other instead of in their proper place. A classification based on unweighted characters is called a phenetic one (based on appearances) as opposed to a phyletic one, in which characters are weighted by their presumed importance in indicating lines of descent. The quarrel results in part from a misunderstanding of aims.

At present, the classification of living things is a rough, non-quantitative sketch of their diversity. A properly surveyed map of this diversity would advance classification enormously. If, on such a map, the diving petrels (*Pelecanoides*) of the Southern Hemisphere and the little auk (*Plautus*) of the Northern Hemisphere were closer to each other than to their own phylogenetic relatives (the other petrels, fulmars, and albatrosses; and the guillemots, terns, gulls, and shorebirds, respectively), this would show the extent of their convergence, which is certainly great, but it would not be a reason for combining them in a separate group. In recent years numerical techniques have been developed for estimating overall resemblance or phenetic distance. For these methods, it is necessary to use large numbers of characters taken from each form and, as far as possible, at random; this involves enormous labour. The mathematical techniques are not as yet wholly satisfactory, some having been borrowed from statistical analysis and applied to taxonomic problems without any consideration of whether they were designed to answer the questions asked by the taxonomist.

It is worth noting that if there were a complete fossil record for any group, then simply placing any form nearest to those most like it (which must be its immediate ancestors or descendants) would produce an arrangement in which all cases of parallelism and convergence would be revealed. Since evolution occurs by descent with modification, this arrangement would presumably reflect the greatest use of the information available about the group and thus would also be the most useful general arrangement. For such groups, the phenetic arrangement is the phyletic one also.

Making a classification. When some idea has been obtained of the constituent forms in a group and of the similarity and dissimilarity that they bear to each other, it is necessary to fit a hierarchical system to them. As already indicated, for groups with good fossil records, a dendritic, or branching, arrangement is desired, and classification must be partly arbitrary because of lack of knowledge.

Compact and scattered groups of species

If the taxonomist has two compact groups of species, those within each group agreeing closely with each other in many characters and differing sharply from members of the other group in others, there is no difficulty in classification except in ranking. If each group contains a scattering of forms, any one close to another but the most divergent members in each group less like each other than they are like certain of the other group, breaking up the groups into definite classes becomes arbitrary.

A particularly difficult case arises when these forms also occur in time series: the present-day dogs, cats, hyenas, and other carnivores differ greatly from each other, but at one time their ancestors were much alike; presumably, therefore, they came from one ancestral stock. Paleontologists trace back each taxonomic line and are inclined to carry their separations of taxonomic groups as far backward in time as possible, until the earliest members of related groups are far more like each other than each is to the rest of the later members of the group to which it is assigned. This separation of groups is extreme phyletic splitting, but cutting off a large basal group containing all the primitive members may require arbitrary breaks in the many lines of descent and will obscure the evolutionary relationships. There is no answer to this dilemma except to avoid extremes.

A similar difficulty arises when the same character complex has arisen independently in related lines. The American paleontologist George Gaylord Simpson, for example, has pointed out that mammalian characters such as the single jawbone (dentary) have arisen several times in groups of the extinct mammal-like reptiles. To use Sir Julian Huxley's useful terminology, the definition of the Mammalia expresses a grade of organization (the attainment of a particular level of advancement), not a clade (a single phyletic group or line). Some taxonomists insist that in an evolutionary classification every group must be truly monophyletic—that is, spring from a single ancestral stock. Usually, this cannot be ascertained; the fossil material is insufficient or, as with many soft-bodied forms, nonexistent. Definite convergence must not be overlooked if it can be detected.

How far groups should be split to show phyletic lines and what rank should be given each group and subgroup thus are matters for reasonable compromise. The resulting classification, if fossils are unknown, may be frankly "natural" or phenetic, as is often explicitly the case with the flowering plants and is actually the case with many animal groups. If sufficient fossils are available, the resulting classification may be consonant with what is known about the evolution of the group or with what is merely conjectured. In reality, many classifications are conjectural or tendentious, and simpler and more natural ones might be closer to the available facts.

Form group classification of fossil remains

Even when only mere fragments are dealt with, a classification of some sort may still be necessary. Large numbers of leaves, some stems, trunks or roots, many seeds, and few flowers are known as fossils and may be of interest to the evolutionist. It may be many decades before a particular sort of fossilized leaf can be associated with a particular sort of branch, let alone trunk, flower, or seed. It is customary to construct form groups (*i.e.,* a genus or species name is assigned to the fossilized material based on its structure) in order to classify fossilized remains and to give them valid binomial names. When (if ever) two or more bits of fossil material are identified as belonging to one organism, one name only is retained. This procedure is best known for plants, but one phylum of animals (the Conodonta) is made up of enigmatic structures that are obviously some part of something animal. (A.J.Ca.)

Current systems of classification. *Division of organisms into kingdoms.* As long as the only known plants were those that grew fixed in one place and all known animals moved about and took in food, the greater groups of organisms were obvious. Even in the time of Linnaeus, however, many biologists wondered about such animal groups as corals and sponges, which were fixed in position and in some ways even flowerlike. Were they zoophytes—animal-plants—intermediate between the two kingdoms?

A more serious problem of classification arose with the invention of the microscope and the discovery of microscopic forms of life. It became apparent that many of these microorganisms held both animal and plant characteristics and could not simply be classified in either kingdom. For example, *Euglena* is a unicellular organism with chlorophyll characteristic of a plant, yet with such animal features as an eyespot and locomotion by means of a flagellum.

Some microorganisms are parasitic inside animals and ingest complicated materials as food, while related microorganisms obtain their nutrients through photosynthesis. It has been proposed that the unicellular forms of microorganisms be placed in a separate kingdom, the Protista. Some biologists do not find this to be a happy solution, however, as some of the "unicellular" plants occur in "colonies" of various numbers of cells and may even have specialized reproductive cells.

In the mid-20th century, biologists recognized two vastly different cell types, procaryote (prokaryote) and eucaryote (eukaryote), and based a division of the living and extinct world on these two broad categorizations. The divisions were based primarily on the absence or presence, respectively, of a membrane-bound nucleus containing the genetic material of the cell, as well as on other organizational and structural features. Many classifications of living organisms adopted such a division and further created two superkingdoms, Prokaryota and Eukaryota. Within the Prokaryota was placed the kingdom Monera (the bacteria, blue-green algae, and a recently described bacterial group called the Archaebacteria [also called Archaeobacteria]). The Eukaryota comprised all other living organisms.

Viruses are far more difficult to classify. They are known only as parasites; no free-living forms have been found. They have a far simpler structure than bacteria and reproduce by injecting their hereditary material, which is either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) but not both (as in all other living things), into cells of other organisms. In effect, viruses utilize the host's protein-synthesizing mechanism to reproduce. The individual virus particle (virion), therefore, does not grow and divide by fission as do bacteria. Some biologists have speculated that viruses are genes that have gotten out of control and become parasitic; others have denied that viruses can be considered living at all. Many are highly important disease producers in plants, animals, and bacteria.

The principal characteristic shared by bacteria and viruses is that the hereditary material is not contained within a special nuclear membrane. Such a procaryotic condition might be postulated by evolutionists as primitive when compared with forms with a complex nucleus, as in eucaryotic organisms. Viruses, as they now exist, may be the simplest of living things, but it is not known how much they are modified from ancestral forms that are assumed not to have been parasitic and that were evidently on the main line of evolution; nor is their relation to bacteria known.

The blue-green algae

Another procaryotic group, the blue-green algae, is traditionally placed with the other algae (*e.g.,* seaweeds) and studied more by botanists than by microbiologists. Blue-green algae may be either unicellular or filamentous, and they behave like true plants, photosynthesizing in a way that resembles green plants rather than bacteria. Many move by gliding, as do some bacteria and some true unicellular algae. They are often extremely abundant around hot springs or at the edges of muddy ponds, and, though they are resistant to harsh environments, blue-green algae are killed by many drugs (*e.g.,* antibiotics) used against bacteria. Perhaps they are best regarded as representing a group close to the main evolutionary line that gave rise to the eucaryotic plants.

Another problem relates to the position of the fungi, a large group including such familiar forms as mushrooms, toadstools, molds, and yeasts. (Although some authorities place the true slime molds [Myxomycetes] with the fungi, others point to the many characteristics they share with the protists.) The fungi are eucaryotic, lack chlorophyll (and therefore cannot photosynthesize as do green plants), and have rigid walls to the "cells," or filaments (hyphae) that sometimes contain cellulose, as do green plants. Some fungi walls or filaments are made of chitin, the major constituent of the external skeleton of insects and other arthropods, or even of other structural compounds. A fungal "cell" usually contains many nuclei. Asexual and sexual spores are usually produced; some produce motile spores with flagella, like the spores of some algae. The sexual cycle is often very complex. Because fungi in general grow and produce "fruit" like ordinary plants, they have traditionally been included with them; but the differences between the fungi and the plants seem considerable.

The preceding considerations exemplify the difficulties inherent in producing a generally accepted classification, even at the highest levels. Since the earliest attempts at classifying the living world into two kingdoms, Plantae and Animalia, biologists have debated the relationships among all organisms. Most biologists, however, accept the fundamental differences in cell structure that separates the superkingdoms Eukaryota and Prokaryota.

The two-kingdom classification of organisms has not been a suitable alternative since the discovery of a microscopic group of organisms. One four-kingdom classification (Table 2) recognizes the kingdoms Virus, Monera, Plantae, and Animalia within the superkingdoms Prokaryota and Eukaryota. Separate kingdoms are not recognized for the microorganisms (Protista) or for the fungi, which

Table 2: The Four-Kingdom Scheme of Classification

kingdom	members
Virus	
Monera	bacteria, blue-green algae, archaebacteria, and prochlorophytes
Plantae	algae, slime molds, true fungi, bryophytes (mosses, liverworts, and hornworts), ferns, psilophytes, lycopodiophytes, conifers, gnetophytes, ginkgophytes, cycads, and flowering plants
Animalia	protozoans, sponges, corals, flatworms, tapeworms, arthropods, mollusks, lamp shells, annelids, bryozoans, echinoderms, hemichordates, and chordates, including the vertebrates

are placed in the plant kingdom. Another classification recognizes Protista (including the fungi and protozoans) rather than viruses.

A classification of living organisms. Recent advances in biochemical and electron microscopic techniques, as well as in testing that investigates the genetic relatedness among species, have redefined previously established taxonomic relationships and have fortified support for a five-kingdom classification of living organisms. This alternative scheme is presented below and is used in the major biological articles in the *Macropædia.* In it, the procaryotic Monera continue to comprise the bacteria, although techniques in genetic homology have defined a new group of bacteria, the Archaebacteria, that some biologists believe may be as different from bacteria as bacteria are from other eucaryotic organisms. The eucaryotic kingdoms now include the Plantae, Animalia, Protista, and Fungi, or Mycota.

The protists are predominantly unicellular, microscopic, nonvascular organisms that do not generally form tissues. Exhibiting all modes of nutrition, protists are frequently motile organisms, primarily using flagella, cilia, or pseudopodia. The fungi, also nonvascular organisms, exhibit an osmotrophic type of heterotrophic nutrition. Although the mycelium may be complex, they also exhibit only simple tissue differentiation, if any at all. Their cell walls usually contain chitin, and they commonly release spores during reproduction. The plants are multicellular, multitissued, autotrophic organisms with cellulose-containing cell walls. The vascular plants possess roots, stems, leaves, and complex reproductive organs. Their life cycle shows an alternation of haploid (gametophyte) and diploid (sporophyte) generations. The animals are multicellular, multitissued, heterotrophic organisms whose cells are not surrounded by cell walls. Animals generally are independently motile, which has led to the development of organ and tissue systems. The monerans, the only procaryotic kingdom in this classification scheme, is principally made up of the bacteria. They are generally free-living, unicellular organisms that reproduce by fission. Their genetic material is concentrated in a non-membrane-bound nuclear area. Motility in bacteria is by a flagellar structure that is different from the eucaryotic flagellum. Most bacteria have an envelope that contains a unique cell wall, peptidoglycan, the chemical nature of which imparts a special staining property that is taxonomically significant (*i.e.,* gram-positive, gram-negative, acid-fast).

The use of "division" by botanists and "phylum" by zoologists for equivalent categories leads to a rather awkward situation in the Protista, a group of interest to both botanists and zoologists. As used below, the terms follow prevailing usage: phylum for the primarily animal-like protozoa and division for other protistan groups that are more plantlike and of interest primarily to botanists.

The discussion above shows the difficulty involved in classification; for example, one traditional classification of the Aschelminthes, presented below and in the *Macropædia* article ASCHELMINTHS, divides the phylum Aschelminthes into five classes: Rotifera, Gastrotricha, Kinorhyncha, Nematoda, and Nematomorpha. An alternative classification elevates these classes to phyla, and still another classification establishes different relationships between the groups: phylum Gastrotricha, phylum Rotifera, phylum Nematoda (containing classes Adenophorea, Secernentea, and Nematomorpha), and phylum Introverta (containing classes Kinorhyncha, Loricifera, Priapulida, and Acanthocephala). The true relationships between these pseudocoelomates remain to be established.

KINGDOM MONERA (bacteria, archaebacteria, and blue-green algae)

KINGDOM PROTISTA (protists)
Algae other than the blue-green algae, protozoa, and slime molds.

KINGDOM FUNGI (fungi)

KINGDOM PLANTAE (METAPHYTA or EMBRYOPHYTA; nonvascular and vascular plants)
Includes mosses, liverworts, hornworts, whisk ferns, club mosses, horsetails, ferns, cycads, conifers, gnetophytes, ginkgophytes, and flowering plants.

Division Bryophyta (mosses, liverworts, and hornworts)

Division Psilotophyta (whisk ferns or psilopsids)

Division Lycophyta (club mosses and quillworts)

Division Sphenophyta (horsetails)

Division Polypodiophyta (ferns)

Division Coniferophyta
Includes pines, yews, spruces, firs, junipers, redwoods, and others.

Division Ginkgophyta (ginkgoes)

Division Cycadophyta (cycads)

Division Gnetophyta (gnetophytes)

Division Magnoliophyta (flowering plants)
Includes monocots (grasses, rushes, sedges, cattails and pondweeds, palms, pineapple and other bromeliads, lilies, bananas, ginger, orchids, and others) and dicots or broad-leaved plants (most trees, buttercups, poppies, roses, violets, cacti, mints, squashes, sunflowers, and many others).

KINGDOM ANIMALIA (or METAZOA)

Subkingdom Parazoa (sponges)

Phylum Porifera (sponges)

Subkingdom Eumetazoa

Phylum Mesozoa (mesozoans)

Phylum Cnidaria (or *Coelenterata;* cnidarians)

Phylum Ctenophora (ctenophores)

Phylum Platyhelminthes (flatworms)

Phylum Nemertea (or *Rhynchocoela;* ribbonworms)

Phylum (or class) Acanthocephala (spiny-headed worms)

Phylum Aschelminthes

Phylum Priapulida (priapulids)

Phylum Annelida (annelid worms)

Phylum Tardigrada

Phylum Onychophora

Phylum Arthropoda (arthropods)

Phylum Mollusca (mollusks)

Phylum Bryozoa (or *Ectoprocta;* bryozoans)

Phylum Phoronida (phoronid worms)

Phylum Brachiopoda (brachiopods)

Phylum Sipuncula (sipunculid worms)

Phylum Chaetognatha (arrowworms)

Phylum Echiurida (spoonworms)

Phylum Echinodermata (echinoderms)

Phylum Hemichordata (hemichordates)

Phylum Pogonophora (beardworms)

Phylum Chordata (chordates)

(Ed.)

BIOPHYSICS

The birth of biophysics

In its broadest sense, biophysics is concerned with the solution of biological problems in terms of the concepts of physics and other physical sciences. The relatively recent emergence of biophysics as a scientific discipline may be attributed, in particular, to the spectacular success of biophysical tools in unravelling the molecular structure of deoxyribonucleic acid (DNA), the fundamental hereditary material, and in establishing the precisely detailed

structure of proteins such as hemoglobin in order that the position of each atom may be known. Biophysics and the intimately related subject molecular biology now are firmly established as cornerstones of modern biology.

Historical background. The origin of biophysics antedates the division of natural sciences into separate disciplines. Bioluminescence must be considered among the most ancient objects of biophysical exploration, because the emission of light by living organisms has long stimulated the curiosity of natural philosophers. Perhaps the first scientific investigation of animal luminescence was that of Athanasius Kircher, a 17th-century German Jesuit priest, who devoted two chapters of his book *Ars Magna Lucis et Umbrae* to bioluminescence. In the midst of his more scientific observations, Kircher found time to expose as a fallacy the notion that an extract made from fireflies could be used to light houses.

The relation between electricity and biology became a subject of speculation in the 17th century and one of intense exploration in the 18th and 19th. Sir Isaac Newton in the *Principia* (1687) wrote of "a certain most subtle spirit which pervades and lies hid in all gross bodies," and that "all sensation is excited, and the members of animal bodies move at the command of the will, namely, by the vibrations of this spirit, mutually propagated along the solid filaments of the nerves, from the outward organs of sense to the brain, and from the brain into the muscles." Man's fascination with animal electricity is illustrated in a letter written by John Walsh in 1773 to the American inventor and statesman Benjamin Franklin; Walsh wrote the details of his discovery of the electrical nature of the discharge from the torpedo or electric ray:

> I am concerned that other engagements have prevented me from giving to the Royal Society, before their recess, a complete account of my experiments on the electricity of the torpedo; a subject not only serious in itself, but opening a large field of interesting inquiry, both to the electrician in his walk of physics, and to all who consider, particularly or generally, the animal oeconomy.

Typical of the unity of science that then prevailed were the advances sometimes made either by professors of physics who were interested in biological phenomena or professors of anatomy, a subject that at that time included physiology. Thus Abbé Giovanni Beccaria, professor of physics in Turin and Italy's leading student of electricity in the mid-18th century, carried out experiments on the electrical stimulation of muscles. Albrecht von Haller, professor of anatomy and surgery at Göttingen, discussed "the nervous fluid" and conjectured as to whether "electrical matter" and "animal spirits" were the same. In 1786 Luigi Galvani, a physician in Bologna, made the crucial experiment that helped end this controversy. Galvani supposedly was performing experiments with a machine in the company of friends, when, by chance, one member of the party idly probed with a knife the nerves of the thigh of a skinned frog to be used for soup. As the muscles of the frog leg suddenly and unexpectedly contracted, Galvani's wife noted that a spark had been produced by the electrical machine and "fancied that there was an agreement in point of time." Although Galvani's own account of the occurrence differed somewhat in detail from the preceding, it is certain that the experiment was repeated and verified, setting the stage for a long controversy between the advocates of Galvani's view that current generated by an animal can cause contraction and those of Alessandro Volta, who claimed that the frog leg served only as a detector of minute differences in electrical potential external to it. The Galvani partisans performed an experiment in which no external sources of electricity were present, thus proving that current generated by an animal could cause the muscle contraction. But it was also possible to cause contraction by contact with metals; Volta performed such investigations, and they culminated in his invention of the electrical battery, which was so important that it overshadowed Galvani's research. As a result, the study of electrical potential in animals disappeared from scientific consideration until 1827.

Electrical stimulation of muscles

Because for many years the frog leg was the most sensitive detector of differences in electrical potential, final acceptance of the view that currents can be generated by living tissues had to await the construction of galvanometers sensitive enough to measure the minute currents generated in muscles and the small potential differences across nerve membranes. Galvanometers were built by the great German 19th-century electrophysiologist Du Bois-Reymond, professor of physiology in Berlin. His investigations of muscular current and electrical potential of nerves depended upon a galvanometer of his own devising that required 3.17 miles (5.10 kilometres) of wire wound in 24,000 turns. Research in this subject, called neurophysiology, grew in stature with increased understanding of both electrical phenomena and cellular physiology; it served as one point of origin for biophysics.

Biophysics also grew out of investigations on diffusion gradients and osmotic pressure—two forces responsible for the passive flow of matter in living organisms. Osmotic pressure, the pressure that develops in a solution separated from a solvent by a membrane permeable only to solvent, was first described by Abbé J.A. Nollet, who became professor of experimental physics at the College of Navarre. The semipermeable membranes required to produce the fluid flow that characterizes osmotic phenomena initially came from biological sources; French scientist René Dutrochet wrote in 1828, "it appears from these new studies that the endosmotic and exosmotic phenomena, which I discovered, belong to a new class of physical phenomena, whose powerful intervention in the vital phenomenon is no longer doubtful." Following the first quantitative measurements by the botanist W.F.P. Pfeffer, the fundamental laws governing diffusion were enunciated by Adolf Fick, who in 1856 published what is probably the first biophysics text, *Die medizinische Physik* ("Medical Physics"). Fick developed the laws of diffusion not from experiment but by analogy with the laws governing the flow of heat; subsequent laboratory experiments proved the analogy to be quantitatively exact.

The development of physical chemistry

Physical and chemical investigation coalesced in physical chemistry, a subject that began to develop with the emergence of the *Zeitschrift für Physikalische Chemie* in 1887, a journal founded by Dutch chemist Jacobus van't Hoff and German chemist Wilhelm Ostwald. The first volume contains contributions from the most noted physical chemists of the time, including van't Hoff, Ostwald, François Raoult, and Svante Arrhenius. They were concerned with reactions in solution, a central topic in biology because the interior milieu of all living cells is aqueous, and the chemical reactions that sustain life take place in water. The scientific interests of van't Hoff in particular transcended the boundaries between disciplines. He stressed the importance of the laws of osmosis, which he had clearly delineated, to the economy of all living processes.

Biophysics matured in the 20th century. British biophysicist A.V. Hill described the modern biophysicist in these terms:

> Biological phenomena, like many others, show aspects and relations susceptible of physical analysis and interpretation. It is by the choice of problems and by the intellectual processes with which they are formulated and attacked, more than by the particular techniques employed, that a subject can be most clearly defined. There are people to whom physical intuitions come naturally, who can state a problem in physical terms, who can recognize physical relations when they turn up, who can express results in physical terms. These intellectual qualities, more than any special facility with physical instruments and methods, are essential to the make-up of a biophysicist. Equally essential, however, are the corresponding qualities, intuitions, and experience of the biologist. A physicist who cannot develop the biological approach, who has no curiosity about vital processes and functions, who is not willing to spend time in learning the habits of living things, who regards biology simply as a branch of physics has no important future in biophysics. (From *Science,* Dec. 21, 1956.)

Most biophysical research has been carried out by physicists with an interest in biology; therefore, there must be a way by which scientists educated in physics and physical chemistry can find their way into biology and become familiar with problems that may be open to a physical interpretation. Although classically oriented biology departments often offer positions to biophysicists, they are

not substitutes for centres in which biophysical research is of central importance.

Tools of the biophysicist

The biophysicist possesses the ability to separate biological problems into segments that are amenable to exact physical interpretation and to formulate hypotheses that can be tested by experiment. The primary tool of the biophysicist is an attitude of mind. To this might be added the ability to use complex physical theory to study natural objects—for example, that involved in the X-ray diffraction techniques used to determine the structure of large molecules such as proteins. The biophysicist usually recognizes the utility of new physical tools—*e.g.*, nuclear magnetic resonance and electron spin resonance—in the study of specific problems in biology. But he may also, through previous experience in building specialized equipment to solve physical problems, not have to rely on commercially built instruments.

The development of instruments for biological purposes is an important aspect of a new area—applied biophysics. Biomedical instrumentation is probably most widely used in hospitals. Applied biophysics is important in the field of therapeutic radiology, in which the measurement of dose is critical to treatment, and in diagnostic radiology, particularly with techniques involving isotope localization and whole body scanning to aid in tumour diagnosis. As aids in diagnosis and patient care, computers are of increasing importance. Automation of the chemical analyses routinely carried out in hospitals will soon be a reality. The opportunities for the applications of biophysics seem limitless because the lengthy delay between the development of a research instrument and its application means that many scientific instruments based on physical principles already known will be shown to have important potential for medicine.

Interdisciplinary work. The biophysical approach is unified by a consideration of biological problems in the light of physical concepts, so that biophysics is, perforce, interdisciplinary. Biophysics may be thought of as the central circle in a two-dimensional array of overlapping circles, which include physics, chemistry, physiology, and general biology. Relations with chemistry are mediated through biochemistry and chemistry; those with physiology, through neurophysiology and sensory physiology. Biology, which may be viewed as a general subject pervading biophysical study, is evolving from a purely descriptive science into a discipline increasingly devoted to understanding the nature of the prime movers of biological events. The evolution of biology in these directions has received great impetus from the biophysical and biochemical discoveries of the 20th century. An understanding of the physical principles governing biological effects is the proper end of biophysics.

Areas of study. The content and methods of biophysics are illustrated by examining several notable contributions to science.

Protein structure. Within two days after the initial publication of Wilhelm Röntgen's discovery of X-rays in 1895, a surgeon in Scotland used X-rays to observe a needle as he extracted it from the palm of an unfortunate seamstress. Although this medical application resulted in the development of radiological diagnosis and treatment of disease by radiation, physical aspects of Röntgen's discovery also provided the means for elucidating the structure

The significance of X-rays

of proteins and other large molecules. The laws governing the diffraction of X-rays were discovered by the two Braggs, Sir William and Sir Lawrence, who were father and son. At the Cavendish Laboratory at the University of Cambridge, where Sir Lawrence was professor, J.D. Bernal was studying the use of X-ray diffraction for the determination of the structure of large biological molecules. He had already used X-rays to define the size and shape of the tobacco mosaic virus and showed it to have a regular internal structure. At the Cavendish Laboratory the group that formed around Bernal, a man of wide public and scientific interests, included the Nobel Prize winners Max Perutz and John Kendrew, who in 1937 began to use X-rays to analyze two proteins fundamental to life, myoglobin and hemoglobin, both of which function in the transport of gases in the blood. Twenty-two years passed before the structures of these proteins were established; the significance of the work is that it provided the basis for an understanding of the mechanism of the action of enzymes and other proteins, an active and fruitful subject of modern investigation.

Deoxyribonucleic acid. Interest in biophysics at the Cavendish Laboratory resulted in another important discovery, the structure of deoxyribonucleic acid (DNA), the genetic material. This achievement by a British biophysicist, Francis H.C. Crick, and by a U.S. biochemist, James Watson, was based on X-ray data obtained by Maurice Wilkins at King's College, London. When Crick first went to the Cavendish Laboratory for education in biophysics, he worked under Perutz's direction; when Watson went to the Cavendish, he and Crick began the collaboration that led to the establishment of the structure of DNA, for which Watson, Crick, and Wilkins later were awarded a Nobel Prize.

Much impetus for biophysical investigation following World War II came from the desire of physicists to move away from physics and into biology; this drive was strengthened by the publication in 1944 of Erwin Schrödinger's book *What Is Life?* Schrödinger, the Austrian physicist who contributed substantially to the development of wave mechanics, was anxious to determine whether biological events could be accounted for in terms of known laws of physics and chemistry, or whether a full explanation would require the formulation of physical laws not yet known to exist. Because biological reproduction seemed to pose intractable problems, he devoted a chapter of his book to a consideration of the gene. The discussion was based on the model put forward by Max Delbrück, a physicist who had for some years been studying the genetics of viruses that infect bacteria (bacteriophages). Delbrück's summer course on bacteriophages in 1945 at Cold Spring Harbour in New York set in motion the chain of events that led to understanding the genetic code by which the sequence of the nucleotides in DNA is translated into the sequence of amino acids in a protein. The use of bacteriophage also provided an opportunity for experiments with a primitive living organism that could be studied without anatomic complexities. This aspect of biophysics has become more biochemically oriented as it has developed and is now known as molecular biology; sometimes it is considered a distinct discipline, and other times it is subsumed under the biophysical sciences.

The nerve impulse. Important aspects of biophysics have been derived from physiology, especially in studies involving the conduction of nerve impulses. One important scientific product of World War II—the development of vastly improved electronics—largely resulted from radar devices that had been used primarily for locating aircraft. Another product, the atomic bomb, was constructed by way of nuclear reactors that could, in peace time, provide an abundant supply of radioactive isotopes, which are now of great value not only in biophysical research but also in biochemistry and medicine. These two disparate advances were important to the work of two Nobel Prize winners, Alan Hodgkin and Andrew Huxley, who showed how the flow of sodium and potassium across the membranes of nerves can be coupled to produce the action potential, a brief electrical event that initiates the action potential, which propagates the nervous signal.

A model of the nerve axon proposed by Hodgkin and Huxley grew from a 19th-century confluence of ideas. Julius Bernstein, an experimental neurophysiologist, used physical chemical theories to develop a membrane theory of nervous conduction; Hodgkin's initial experiments were designed to test specific predictions of the Bernstein hypothesis. Early in 1938 Hodgkin learned of the important results of a newly developed technique that allowed examination of the time course of nervous conduction. After World War II, Hodgkin, joined by Huxley, again took up the research. They presented their explanation of the mechanism of nervous conduction in five scientific papers between October 1951 and March 1952.

Biological membranes. The availability of radioactive isotopes provided the technology necessary for understanding how molecules are transported across biological

membranes, which are the very thin boundaries of living cells; the environment maintained by membranes in cells differs from the external environment and permits cellular function. The Danish physiologist August Krogh laid the groundwork in this subject; his pupil, Hans Ussing, developed the conceptual means by which the transport of ions (charged atoms) across membranes can be identified. Ussing's definition of active transport made possible an understanding, at the cellular level, of the way in which ions and water are pumped into and out of living cells in order to regulate the ionic composition and water balance in cells, organs, and organisms. The molecular mechanism by which these processes occur, however, remains to be discovered.

Conceptual explanation of active transport

In addition to the function of transport, membranes also are utilized as templates on which such molecules as enzymes, which must function in a sequential fashion, can be kept in the requisite order. Although great progress has been made in understanding the mechanisms by which specific atoms are assembled into large biological molecules, the principles involved in the assembly of molecules into membranes, which are organized structures of a higher degree of complexity than large molecules, are not yet very well understood. There is reason to believe that the incorporation of a molecule into a membrane endows it with properties that differ from those of a molecule in solution. A primary task of biophysics is to understand the physical character of these cooperative interactions that are essential to life.

Muscle contraction. A.V. Hill developed exquisitely sensitive temperature sensors for measuring heat generated during muscular contraction; he initiated studies relating this heat to the thermodynamic parameters responsible for it. The electron microscope in the years following World War II made possible the description of muscular contraction at a structural level, though the mechanisms involved in the flow of heat during the process are not yet known. Simultaneously, in the 1960s, but independently, various physicists postulated the sliding-filament theory of muscular contraction, according to which muscles contract by the sliding of one filament along another and not by a springlike coiling. Remarkable advances, based on the use of techniques such as X-ray diffraction and electron microscopy, have made it possible to visualize many of the molecules involved in the process. The entire process of muscular contraction, in terms of an identification of the molecules and a description of the chemical reactions in the muscle fibre, has been almost completely explained.

Sensory communication. The above comprise a few specific examples of the scope of biophysics. One area, difficult to discuss in specific terms, is that of sensory communication. Because stimuli, particularly those of a visible or auditory nature, can easily be specified in exact physical terms, they have excited the interest of physical scientists since before 1850. Modern electronic techniques make it relatively easy to distinguish true signals from noise; in addition, computers make possible the performance of significant experiments concerning the complex relationship between stimulus and action. Quantitative analysis of sensory response is very difficult, however, because it involves a synthesis of the action of many cells. It has been pointed out that

> An adequate theory of sensory function implies an adequate theory of brain function. And an adequate theory of brain function in its turn requires that the nervous system's behavioral repertory be predictably related to the behaviour of the elements that compose it.

(A.K.S.)

BIOCHEMISTRY

Biochemistry is the study of substances found in living organisms and of the changes they undergo during development and life of the organism. It deals with the chemistry of life, and as such it draws on the techniques of analytical, organic, and physical chemistry, as well as those of physiologists concerned with the molecular basis of vital processes. All chemical changes within the organism—either the degradation of substances, generally to gain necessary energy, or the buildup of complex molecules necessary for life processes—are collectively termed metabolism. These chemical changes depend on the action of organic catalysts known as enzymes, and enzymes, in turn, depend for their existence on the genetic apparatus of the cell. It is not surprising, therefore, that biochemistry enters into the investigation of chemical changes in disease, drug action, and other aspects of medicine, as well as in nutrition, genetics, and agriculture.

The term biochemistry is synonymous with two somewhat older terms: physiological chemistry and biological chemistry. Those aspects of biochemistry that deal with the chemistry and function of very large molecules (*e.g.*, proteins and nucleic acids) are often grouped under the term molecular biology. Biochemistry is a young science, having been known under that term only since about 1900. Its origins, however, can be traced much further back; its early history is part of the early history of both physiology and chemistry.

Historical background. The particularly significant past events in biochemistry have been concerned with placing biological phenomena on firm chemical foundations.

Prelude to biochemistry

Before chemistry could contribute adequately to medicine and agriculture, however, it had to free itself from immediate practical demands in order to become a pure science. This happened in the period from about 1650 to 1780, starting with the work of Robert Boyle and culminating in that of Antoine-Laurent Lavoisier, the father of modern chemistry. Boyle questioned the basis of the chemical theory of his day and taught that the proper object of chemistry was to determine the composition of substances. His contemporary John Mayow observed the fundamental analogy between the respiration of an animal and the burning, or oxidation, of organic matter in air. Then, when Lavoisier carried out his fundamental studies on chemical oxidation, grasping the true nature of the process, he also showed, quantitatively, the similarity between chemical oxidation and the respiratory process. Photosynthesis was another biological phenomenon that occupied the attention of the chemists of the late 18th century. The demonstration, through the combined work of Joseph Priestley, Jan Ingenhousz, and Jean Senebier, that photosynthesis is essentially the reverse of respiration was a milestone in the development of biochemical thought.

In spite of these early fundamental discoveries, rapid progress in biochemistry had to wait upon the development of structural organic chemistry, one of the great achievements of 19th-century science. A living organism contains many thousands of different chemical compounds. The elucidation of the chemical transformations undergone by these compounds within the living cell is a central problem of biochemistry. Clearly, the determination of the molecular structure of the organic substances present in living cells had to precede the study of the cellular mechanisms, whereby these substances are synthesized and degraded.

There are few sharp boundaries in science, and the boundaries between organic and physical chemistry, on the one hand, and biochemistry, on the other, have always shown much overlap. Biochemistry has borrowed the methods and theories of organic and physical chemistry and applied them to physiological problems. Progress in this path was at first impeded by a stubborn misconception in scientific thinking—the error of supposing that the transformations undergone by matter in the living organism were not subject to the chemical and physical laws that applied to inanimate substances and that consequently these "vital" phenomena could not be described in ordinary chemical or physical terms. Such an attitude was taken by the vitalists, who maintained that natural products formed by living organisms could never be synthesized by ordinary chemical means. The first laboratory synthesis of an organic compound, urea, by Friedrich Wöhler in 1828, was a blow to the vitalists but not a decisive one. They retreated to new lines of defense, arguing that urea was only an excretory substance—a product of breakdown and not of synthesis. The success of the organic chemists in synthesizing many natural products forced further retreats of the vitalists. It is axiomatic in modern biochemistry that the chemical laws that apply to inanimate materials are equally valid within the living cell.

At the same time that progress was being impeded by a misplaced kind of reverence for living phenomena, the practical needs of man operated to spur the progress of the new science. As organic and physical chemistry erected an imposing body of theory in the 19th century, the needs of the physician, the pharmacist, and the agriculturalist provided an ever-present stimulus for the application of the new discoveries of chemistry to various urgent practical problems.

The contributions of Liebig and Pasteur

Two outstanding figures of the 19th century, Justus von Liebig and Louis Pasteur, were particularly responsible for dramatizing the successful application of chemistry to the study of biology. Liebig studied chemistry in Paris and carried back to Germany the inspiration gained by contact with the former students and colleagues of Lavoisier. He established at Giessen a great teaching and research laboratory, one of the first of its kind, which drew students from all over Europe.

Besides putting the study of organic chemistry on a firm basis, Liebig engaged in extensive literary activity, attracting the attention of all scientists to organic chemistry and popularizing it for the layman as well. His classic works, published in the 1840s, had a profound influence on contemporary thought. Liebig described the great chemical cycles in nature. He pointed out that animals would disappear from the face of the Earth if it were not for the photosynthesizing plants, since animals require for their nutrition the complex organic compounds that can be synthesized only by plants. The animal excretions and the animal body after death are also converted by a process of decay to simple products that can be re-utilized only by plants.

In contrast with animals, green plants require for their growth only carbon dioxide, water, mineral salts, and sunlight. The minerals must be obtained from the soil, and the fertility of the soil depends on its ability to furnish the plants with these essential nutrients. But the soil is depleted of these materials by the removal of successive crops; hence the need for fertilizers. Liebig pointed out that chemical analysis of plants could serve as a guide to the substances that should be present in fertilizers. Agricultural chemistry as an applied science was thus born.

In his analysis of fermentation, putrefaction, and infectious disease, Liebig was less fortunate. He admitted the similarity of these phenomena but refused to admit that living organisms might function as the causative agents. It remained for Pasteur to clarify that matter. In the 1860s Pasteur proved that various yeasts and bacteria were responsible for "ferments," substances that caused fermentation and, in some cases, disease. He also demonstrated the usefulness of chemical methods in studying these tiny organisms and was the founder of what came to be called bacteriology.

Later, in 1877, Pasteur's ferments were designated as enzymes, and, in 1897, the German chemist E. Buchner clearly showed that fermentation could occur in a press juice of yeast, devoid of living cells. Thus a life process of cells was reduced by analysis to a nonliving system of enzymes. The chemical nature of enzymes remained obscure until 1926, when the first pure crystalline enzyme (urease) was isolated. This enzyme and many others subsequently isolated proved to be proteins, which had already been recognized as high-molecular-weight chains of subunits called amino acids.

The mystery of how minute amounts of dietary substances known as the vitamins prevent diseases such as beriberi, scurvy, and pellagra became clear in 1935, when riboflavin (‡vitamin B_2) was found to be an integral part of an enzyme. Subsequent work has substantiated the concept that many vitamins are essential in the chemical reactions of the cell by virtue of their role in enzymes.

In 1929 the substance adenosine triphosphate (ATP) was isolated from muscle. Subsequent work demonstrated that the production of ATP was associated with respiratory (oxidative) processes in the cell. In 1940 F.A. Lipmann proposed that ATP is the common form of energy exchange in many cells, a concept now thoroughly documented. ATP has been shown also to be a primary energy source for muscular contraction.

Isotopes as tools

The use of radioactive isotopes of chemical elements to trace the pathway of substances in the animal body was initiated in 1935 by two U.S. chemists, R. Schoenheimer and D. Rittenberg. That technique provided one of the single most important tools for investigating the complex chemical changes that occur in life processes. At about the same time, other workers localized the sites of metabolic reactions by ingenious technical advances in the studies of organs, tissue slices, cell mixtures, individual cells, and, finally, individual cell constituents, such as nuclei, mitochondria, ribosomes, lysosomes, and membranes.

In 1869 a substance was isolated from the nuclei of pus cells and was called nucleic acid, which later proved to be deoxyribonucleic acid (DNA), but it was not until 1944 that the significance of DNA as genetic material was revealed, when bacterial DNA was shown to change the genetic matter of other bacterial cells. Within a decade of that discovery, the double helix structure of DNA was proposed by Watson and Crick, providing a firm basis for understanding how DNA is involved in cell division and in maintaining genetic characteristics.

Advances have continued since that time, with such landmark events as the first chemical synthesis of a protein, the detailed mapping of the arrangement of atoms in some enzymes, and the elucidation of intricate mechanisms of metabolic regulation, including the molecular action of hormones.

Areas of study. A description of life at the molecular level includes a description of all the complexly interrelated chemical changes that occur within the cell—*i.e.,* the processes known as intermediary metabolism. The processes of growth, reproduction, and heredity, also subjects of the biochemist's curiosity, are intimately related to intermediary metabolism and cannot be understood independently of it. The properties and capacities exhibited by a complex multicellular organism can be reduced to the properties of the individual cells of that organism, and the behaviour of each individual cell can be understood in terms of its chemical structure and the chemical changes occurring within that cell. When all the chemical changes within a cell are completely described and understood, man will have achieved as complete an understanding of life as can be achieved by the intellect alone. Living processes are sufficiently complex, however, to guarantee the biochemist enough unsolved problems to last into the unforeseeable future.

Chemical composition of living matter. Every living cell contains, in addition to water and salts or minerals, a large number of organic compounds, substances composed of carbon combined with varying amounts of hydrogen and usually also of oxygen. Nitrogen, phosphorus, and sulfur are likewise common constituents. In general, the bulk of the organic matter of a cell may be classified as (1) protein, (2) carbohydrate, and (3) fat, or lipid. Nucleic acids and various other organic derivatives are also important constituents. Each class contains a great diversity of individual compounds. Many substances that cannot be classified in any of the above categories also occur, though usually not in large amounts.

Proteins are fundamental to life, not only as structural elements (*e.g.,* collagen) and to provide defense (as antibodies) against invading destructive forces but also because the essential biocatalysts are proteins. The chemistry of proteins is based on the researches of the German chemist Emil Fischer, whose work from 1882 demonstrated that proteins are very large molecules, or polymers, built up of about 24 amino acids. Proteins may vary in size from small—insulin with a molecular weight of 5,700 (based on the weight of a hydrogen atom as 1)—to very large—molecules with molecular weights of more than 1,000,000. The first complete amino acid sequence was determined for the insulin molecule in the 1950s. By 1963 the chain of amino acids in the protein enzyme ribonuclease (molecular weight 12,700) had also been determined, aided by the powerful physical techniques of X-ray-diffraction analysis. In the 1960s, Nobel Prize winners J.C. Kendrew and M.F. Perutz, utilizing X-ray studies, constructed detailed atomic models of the proteins hemoglobin and myoglobin (the respiratory pigment in muscle), which were later

Protein size

confirmed by sophisticated chemical studies. The abiding interest of biochemists in the structure of proteins rests on the fact that the arrangement of chemical groups in space yields important clues regarding the biological activity of molecules.

Carbohydrates include such substances as sugars, starch, and cellulose. The second quarter of the 20th century witnessed a striking advance in the knowledge of how living cells handle small molecules, including carbohydrates. The metabolism of carbohydrates became clarified during this period, and elaborate pathways of carbohydrate breakdown and subsequent storage and utilization were gradually outlined in terms of cycles (*e.g.,* the Embden–Meyerhof glycolytic cycle and the Krebs cycle). The involvement of carbohydrates in respiration and muscle contraction was well worked out by the 1950s. Refinements of the schemes continue.

Fats, or lipids, constitute a heterogeneous group of organic chemicals that can be extracted from biological material by nonpolar solvents such as ethanol, ether, and benzene. The classic work concerning the formation of body fat from carbohydrates was accomplished during the early 1850s. Those studies, and later confirmatory evidence, have shown that the conversion of carbohydrate to fat occurs continuously in the body. The liver is the main site of fat metabolism. Fat absorption in the intestine, studied as early as the 1930s, still is under investigation by biochemists. The control of fat absorption is known to depend upon a combination action of secretions of the pancreas and bile salts. Abnormalities of fat metabolism, which result in disorders such as obesity and rare clinical conditions, are the subject of much biochemical research. Equally interesting to biochemists is the association between high levels of fat in the blood and the occurrence of arteriosclerosis ("hardening" of the arteries).

Significance of nucleic acids

Nucleic acids are large, complex compounds of very high molecular weight present in the cells of all organisms and in viruses. They are of great importance in the synthesis of proteins and in the transmission of hereditary information from one generation to the next. Originally discovered as constituents of cell nuclei (hence their name), it was assumed for many years after their isolation in 1869 that they were found nowhere else. This assumption was not challenged seriously until the 1940s, when it was determined that two kinds of nucleic acid exist: deoxyribonucleic acid (DNA), in the nuclei of all cells and in some viruses; and ribonucleic acid (RNA), in the cytoplasm of all cells and in most viruses.

The profound biological significance of nucleic acids came gradually to light during the 1940s and 1950s. Attention turned to the mechanism by which protein synthesis and genetic transmission was controlled by nucleic acids (see below *Genes*). During the 1960s, experiments were aimed at refinements of the genetic code. Promising attempts were made during the late 1960s and early 1970s to accomplish duplication of the molecules of nucleic acids outside the cell—*i.e.,* in the laboratory. By the mid-1980s genetic engineering techniques had accomplished, among other things, in vitro fertilization and the recombination of DNA (so-called gene splicing).

Nutrition. Biochemists have long been interested in the chemical composition of the food of animals. All animals require organic material in their diet, in addition to water and minerals. This organic matter must be sufficient in quantity to satisfy the caloric, or energy, requirements of the animals. Within certain limits, carbohydrate, fat, and protein may be used interchangeably for this purpose. In addition, however, animals have nutritional requirements for specific organic compounds. Certain essential fatty acids, about ten different amino acids (the so-called essential amino acids), and vitamins are required by many higher animals. The nutritional requirements of various species are similar but not necessarily identical; thus man and the guinea pig require vitamin C, or ascorbic acid, whereas the rat does not.

That plants differ from animals in requiring no preformed organic material was appreciated soon after the plant studies of the late 1700s. The ability of green plants to make all their cellular material from simple substances—carbon dioxide, water, salts, and a source of nitrogen such as ammonia or nitrate—was termed photosynthesis. As the name implies, light is required as an energy source, and it is generally furnished by sunlight. The process itself is primarily concerned with the manufacture of carbohydrate, from which fat can be made by animals that eat plant carbohydrates. Protein can also be formed from carbohydrate, provided ammonia is furnished.

Similarity of chemical changes in living things

In spite of the large apparent differences in nutritional requirements of plants and animals, the patterns of chemical change within the cell are the same. The plant manufactures all the materials it needs, but these materials are essentially similar to those that the animal cell uses and are often handled in the same way once they are formed. Plants could not furnish animals with their nutritional requirements if the cellular constituents in the two forms were not basically similar.

Digestion. The organic food of animals, including man, consists in part of large molecules. In the digestive tracts of higher animals, these molecules are hydrolyzed, or broken down, to their component building blocks. Proteins are converted to mixtures of amino acids, and polysaccharides are converted to monosaccharides. In general, all living forms use the same small molecules, but many of the large complex molecules are different in each species. An animal, therefore, cannot use the protein of a plant or of another animal directly but must first break it down to amino acids and then recombine the amino acids into its own characteristic proteins. The hydrolysis of food material is necessary also to convert solid material into soluble substances suitable for absorption. The liquefaction of stomach contents aroused the early interest of observers, long before the birth of modern chemistry, and the hydrolytic enzymes secreted into the digestive tract were among the first enzymes to be studied in detail. Pepsin and trypsin, the proteolytic enzymes of gastric and pancreatic juice, respectively, continue to be intensively investigated.

The products of enzymatic action on the food of an animal are absorbed through the walls of the intestines and distributed to the body by blood and lymph. In organisms without digestive tracts, substances must also be absorbed in some way from the environment. In some instances simple diffusion appears to be sufficient to explain the transfer of a substance across a cell membrane. In other cases, however (*e.g.,* in the case of the transfer of glucose from the lumen of the intestine to the blood), transfer occurs against a concentration gradient. That is, the glucose may move from a place of lower concentration to a place of higher concentration.

In the case of the secretion of hydrochloric acid into gastric juice, it has been shown that active secretion is dependent on an adequate oxygen supply (*i.e.,* on the respiratory metabolism of the tissue), and the same holds for absorption of salts by plant roots. The energy released during the tissue oxidation must be harnessed in some way to provide the energy necessary for the absorption or secretion. This harnessing is achieved by a special chemical coupling system. The elucidation of the nature of such coupling systems has been an objective of the biochemist.

Extent of knowledge about blood

Blood. One of the animal tissues that has always excited special curiosity is blood. Blood has been investigated intensively from the early days of biochemistry, and its chemical composition is known with greater accuracy and in more detail than that of any other tissue in the body. The physician takes blood samples to determine such things as the sugar content, the urea content, or the inorganic-ion composition of the blood, since these show characteristic changes in disease.

The blood pigment hemoglobin has been intensively studied. Hemoglobin is confined within the blood corpuscles and carries oxygen from the lungs to the tissues. It combines with oxygen in the lungs, where the oxygen concentration is high, and releases the oxygen in the tissues, where the oxygen concentration is low. The hemoglobins of higher animals are related but not identical. In invertebrates, other pigments may take the place and function of hemoglobin. The comparative study of these compounds constitutes a fascinating chapter in biochemical investigation.

The proteins of blood plasma also have been extensively investigated. The gamma-globulin fraction of the plasma proteins contains the antibodies of the blood and is of practical value as an immunizing agent. An animal develops resistance to disease largely by antibody production. Antibodies are proteins with the ability to combine with an antigen (*i.e.,* an agent that induces their formation). When this agent is a component of a disease-causing bacterium, the antibody can protect an organism from infection by that bacterium. The chemical study of antigens and antibodies and their interrelationship is known as immunochemistry.

Metabolism and hormones. The cell is the site of a constant, complex, and orderly set of chemical changes collectively called metabolism. Metabolism is associated with a release of heat. The heat released is the same as that obtained if the same chemical change is brought about outside the living organism. This confirms the fact that the laws of thermodynamics apply to living systems just as they apply to the inanimate world. The pattern of chemical change in a living cell, however, is distinctive and different from anything encountered in nonliving systems. This difference does not mean that any chemical laws are invalidated. It instead reflects the extraordinary complexity of the interrelations of cellular reactions.

Hormones, which may be regarded as regulators of metabolism, are investigated at three levels, to determine (1) their physiological effects, (2) their chemical structure, and (3) the chemical mechanisms whereby they operate. The study of the physiological effects of hormones is properly regarded as the province of the physiologist. Such investigations obviously had to precede the more analytical chemical studies. The chemical structures of thyroxine and adrenaline are known. The chemistry of the sex and adrenal hormones, which are steroids, has also been thoroughly investigated. The hormones of the pancreas—insulin and glucagon—and the hormones of the hypophysis (pituitary gland) are peptides (*i.e.,* compounds composed of chains of amino acids). The structures of most of these hormones has been determined. The chemical structures of the plant hormones, auxin and gibberellic acid, which act as growth-controlling agents in plants, are also known.

tudy

The first and second phases of the hormone problem thus have been well, though not completely, explored, but the third phase is still in its infancy. It seems likely that different hormones exert their effects in different ways. Some may act by affecting the permeability of membranes; others appear to control the synthesis of certain enzymes. Evidently some hormones also control the activity of certain genes.

Genes. Genetic studies have shown that the hereditary characteristics of a species are maintained and transmitted by the self-duplicating units known as genes, which are composed of nucleic acids and located in the chromosomes of the nucleus. One of the most fascinating chapters in the history of the biological sciences contains the story of the elucidation, in the mid-20th century, of the chemical structure of the genes, their mode of self-duplication, and the manner in which the deoxyribonucleic acid (DNA) of the nucleus causes the synthesis of ribonucleic acid (RNA), which, among its other activites, causes the synthesis of protein. Thus, the capacity of a protein to behave as an enzyme is determined by the chemical constitution of the gene (DNA) that directs the synthesis of the protein. The relationship of genes to enzymes has been demonstrated in several ways. The first successful experiments, devised by the Nobel Prize winners George W. Beadle and Edward L. Tatum, involved the bread mold *Neurospora crassa;* the two men were able to collect a variety of strains that differed from the parent strain in nutritional requirements. Such strains had undergone a mutation (change) in the genetic makeup of the parent strain. The mutant strains required a particular amino acid not required for growth by the parent strain. It was then shown that such a mutant had lost an enzyme essential for the synthesis of the amino acid in question. The subsequent development of techniques for the isolation of mutants with specific nutritional requirements led to a special procedure for studying intermediary metabolism.

Evolution and origin of life. The exploration of space beginning in the mid-20th century intensified speculation about the possibility of life on other planets. At the same time, man was beginning to understand some of the intimate chemical mechanisms used for the transmission of hereditary characteristics. It was possible, by studying protein structure in different species, to see how the amino acid sequences of functional proteins (*e.g.,* hemoglobin and cytochrome) have been altered during phylogeny (the development of species). It was natural, therefore, that biochemists should look upon the problem of the origin of life as a practical one. The synthesis of a living cell from inanimate material was not regarded as an impossible task for the future.

The coming of space biochemistry

Applied biochemistry. An early objective in biochemistry was to provide analytical methods for the determination of various blood constituents because it was felt that abnormal levels might indicate the presence of metabolic diseases. The clinical chemistry laboratory now has become a major investigative arm of the physician in the diagnosis and treatment of disease and is an indispensable unit of every hospital. Some of the older analytical methods directed toward diagnosis of common diseases are still the most commonly used—for example, tests for determining the levels of blood glucose, in diabetes; urea, in kidney disease; uric acid, in gout; and bilirubin, in liver and gallbladder disease. With development of the knowledge of enzymes, determination of certain enzymes in blood plasma has assumed diagnostic value, such as alkaline phosphatase, in bone and liver disease; acid phosphatase, in prostatic cancer; amylase, in pancreatitis; and lactate dehydrogenase and transaminase, in cardiac infarct. Electrophoresis of plasma proteins is commonly employed to aid in the diagnosis of various liver diseases and forms of cancer. Both electrophoresis and ultracentrifugation of serum constituents (lipoproteins) are used increasingly in the diagnosis and examination of therapy of atherosclerosis and heart disease. Many specialized and sophisticated methods have been introduced, and machines have been developed for the simultaneous automated analysis of many different blood constituents in order to cope with increasing medical needs.

Diagnostic tests

Analytical biochemical methods have also been applied in the food industry to develop crops superior in nutritive value and capable of retaining nutrients during the processing and preservation of food. Research in this area is directed particularly to preserving vitamins as well as colour and taste, all of which may suffer loss if oxidative enzymes remain in the preserved food. Tests for enzymes are used for monitoring various stages in food processing.

Biochemical techniques have been fundamental in the development of new drugs. The testing of potentially useful drugs includes studies on experimental animals and man to observe the desired effects and also to detect possible toxic manifestations; such studies depend heavily on many of the clinical biochemistry techniques already described. Although many of the commonly used drugs have been developed on a rather empirical (trial-and-error) basis, an increasing number of therapeutic agents have been designed specifically as enzyme inhibitors to interfere with the metabolism of a host or invasive agent. Biochemical advances in the knowledge of the action of natural hormones and antibiotics promise to aid further in the development of specific pharmaceuticals.

Methods in biochemistry. Like other sciences, biochemistry aims at quantifying, or measuring, results, sometimes with sophisticated instrumentation. The earliest approach to a study of the events in a living organism was an analysis of the materials entering an organism (foods, oxygen) and those leaving (excretion products, carbon dioxide). This is still the basis of so-called balance experiments conducted on animals, in which, for example, both foods and excreta are thoroughly analyzed. For this purpose many chemical methods involving specific colour reactions have been developed, requiring spectrum-analyzing instruments (spectrophotometers) for quantitative measurement. Gasometric techniques are those commonly used for measurements of oxygen and carbon dioxide, yielding respiratory quotients (the ratio of carbon dioxide to oxygen). Some-

what more detail has been gained by determining the quantities of substances entering and leaving a given organ and also by incubating slices of a tissue in a physiological medium outside the body and analyzing the changes that occur in the medium. Because these techniques yield an overall picture of metabolic capacities, it became necessary to disrupt cellular structure (homogenization) and to isolate the individual parts of the cell—nuclei, mitochondria, lysosomes, ribosomes, membranes—and finally the various enzymes and discrete chemical substances of the cell in an attempt to understand the chemistry of life more fully.

Centrifugation and electrophoresis. An important tool in biochemical research is the centrifuge, which through rapid spinning imposes high centrifugal forces on suspended particles, or even molecules in solution, and causes separations of such matter on the basis of differences in weight. Thus, red cells may be separated from plasma of blood, nuclei from mitochondria in cell homogenates, and one protein from another in complex mixtures. Proteins are separated by ultracentrifugation—very high speed spinning; with appropriate photography of the protein layers as they form in the centrifugal field, it is possible to determine the molecular weights of proteins.

Exploiting electrical charges of molecules

Another property of biological molecules that has been exploited for separation and analysis is their electrical charge. Amino acids and proteins possess net positive or negative charges according to the acidity of the solution in which they are dissolved. In an electric field, such molecules adopt different rates of migration toward positively (anode) or negatively (cathode) charged poles and permit separation. Such separations can be effected in solutions or when the proteins saturate a stationary medium such as cellulose (filter paper), starch, or acrylamide gels. By appropriate colour reactions of the proteins and scanning of colour intensities, a number of proteins in a mixture may be measured. Separate proteins may be isolated and identified by electrophoresis, and the purity of a given protein may be determined. (Electrophoresis of human hemoglobin revealed the abnormal hemoglobin in sickle-cell anemia, the first definitive example of a "molecular disease.")

Chromatography and isotopes. The different solubilities of substances in aqueous and organic solvents provide another basis for analysis. In its earlier form, a separation was conducted in complex apparatus by partition of substances in various solvents. A simplified form of the same principle evolved as "paper chromatography," in which small amounts of substances could be separated on filter paper and identified by appropriate colour reactions. In contrast to electrophoresis, this method has been applied to a wide variety of biological compounds and has contributed enormously to research in biochemistry.

The general principle has been extended from filter paper strips to columns of other relatively inert media, permitting larger scale separation and identification of closely related biological substances. Particularly noteworthy has been the separation of amino acids by chromatography in columns of ion-exchange resins, permitting the determination of exact amino acid composition of proteins. Following such determination, other techniques of organic chemistry have been used to elucidate the actual sequence of amino acids in complex proteins. Another technique of column chromatography is based on the relative rates of penetration of molecules into beads of a complex carbohydrate according to size of the molecules. Larger molecules are excluded relative to smaller molecules and emerge first from a column of such beads. This technique not only permits separation of biological substances but also provides estimates of molecular weights.

Perhaps the single most important technique in unravelling the complexities of metabolism has been the use of isotopes (heavy or radioactive elements) in labelling biological compounds and "tracing" their fate in metabolism. Measurement of the isotope-labelled compounds has required considerable technology in mass spectroscopy and radioactive detection devices.

A variety of other physical techniques, such as nuclear magnetic resonance, electron spin spectroscopy, circular dichroism, and X-ray crystallography, have become prominent tools in revealing the relation of chemical structure to biological function. (E.H.St./B.V.)

GENETICS

Genetics is the branch of biology concerned with heredity. Since prehistoric times, man has recognized the influence of heredity and has applied its principles to the improvement of cultivated crops and domestic animals. A Babylonian tablet more than 6,000 years old, for example, shows pedigrees of horses and indicates possible inherited characteristics; other old carvings show cross-pollination of date palm trees. Most of the mechanisms of heredity, however, remained a mystery until the 20th century, when scientifically supported information became available.

Genetics may be defined as the study of the way in which genes operate and the way in which they are transmitted from parents to offspring. Modern genetics involves study of the mechanism of gene action—the way in which the genetic material (deoxyribonucleic acid, or DNA) affects physiological reactions within the cell. Although genes determine the features an individual may develop, the features that actually develop depend upon the complex interaction between genes and their environment. Normal green plants, for example, have genes containing the information necessary to synthesize the chlorophyll that gives them their green colour, and chlorophyll is synthesized in an environment containing light; *i.e.,* the gene for chlorophyll is expressed. If the plant is placed in a dark environment, chlorophyll synthesis stops; *i.e.,* the gene is no longer expressed.

The study of gene action

Genetics overlaps many different branches of biology and many other sciences; *e.g.,* chemistry, physics, mathematics, sociology, psychology, and medicine. Microbiologists who study inheritance in microorganisms are called microbial geneticists; cytologists who study the genetics of cells are called cytogeneticists. Biochemical, or molecular, geneticists investigate the chemical nature of the gene and its methods of action. Some physicists have applied their techniques to molecular genetics, and mathematicians may specialize in population genetics. Behavioral scientists also look to genetics to solve certain problems of human and animal behaviour. Specialists in medical genetics or genetic counselling act on the knowledge that many of man's afflictions are hereditary.

Historical background. The Greek philosopher Pythagoras speculated around 500 BC that human life begins with a blend of male and female fluids, or semens, originating in body parts. Aristotle later postulated that the semens are purified blood and that blood, therefore, is the element of heredity. That this later concept persisted in the Western world is indicated by such common phrases as blue blood, blood-will-tell, blood relative, bad blood, and royal blood.

About 1651, William Harvey disproved the Greek concept; his discovery that deer embryos have the appearance of a tiny ball during early developmental stages and resemble a deer only later in development led him to conclude that the origin of the tiny ball was a small egg. Before the end of the 17th century, it had been suggested that the female structures called ovaries are the source of eggs and that sperm might carry the hereditary material of the male.

Early in the 19th century, Jean-Baptiste Lamarck suggested that acquired characteristics are inherited. Around 1865 Gregor Mendel reported his discoveries on inheritance in garden peas. A few years later, the DNA component of genes was isolated from pus cells, and it was discovered that salmon sperm also contain considerable amounts of DNA. Late in the 19th century, a German physician, August Weismann, showed that reproductive cells (germ plasm) are independent of other body cells (somatoplasm), thus refuting earlier hypotheses of inheritance of acquired characteristics.

20th-century discoveries

The concept of sudden changes in heredity (mutations) was introduced in the beginning of the 20th century. Discoveries concerning sex determination in insect chromosomes and gene linkage on a chromosome of sweet peas were made soon afterward in the United States and England. In 1908 an English mathematician and a German

physician formulated the so-called Hardy–Weinberg principle, which provided the foundation for population genetics. The study of biochemical genetics was begun in 1909 in England with an effort to discover the way by which gene-induced enzyme deficiencies cause abnormalities.

Hermann J. Muller, a U.S. geneticist, induced mutations in the fruit fly with X-rays in 1927. Experiments on the mold *Neurospora* by George W. Beadle and Edward L. Tatum proved that the function of most genes is to direct the synthesis of enzymes, which thus are the expression of many hereditary traits. By 1944 DNA had been proved to be the substance of heredity, and in 1953 James D. Watson and F.H.C. Crick reported a structure of DNA compatible with the capability for self-duplication. Two French Nobel Prize winners, François Jacob and Jacques Monod, discovered the mechanism by which hereditary information is transferred from genes to the site of protein (enzyme) synthesis. Their work resulted in the discovery of the genetic code, by which DNA is translated into protein. Barbara McClintock, who received a Nobel Prize in 1983, was cited for her discovery of mobile genetic elements—some of the mechanisms that account for mutation.

Areas of study. *Classical genetics.* Classical genetics, which remains a basis for all other topics in genetics, is concerned primarily with the method by which genetic traits classified as dominant (always expressed), recessive (subordinate to a dominant trait), intermediate (partially expressed), or polygenic (due to multiple genes) are transmitted in plants and animals. These traits may be sex-linked (result from the action of a gene on the sex, or X, chromosome) or autosomal (result from the action of a gene on a chromosome other than a sex chromosome). Classical genetics began with Mendel's study of inheritance in garden peas and continues with studies of inheritance in many different plants and animals.

Cytogenetics. Cytogenetics blends the skills of cytologists, who study the structure and activities of cells, with those of geneticists, who study the relationship between the mechanism of heredity and cellular activities. Cytologists discovered chromosomes and the way in which they duplicate and separate during cell division at about the same time that geneticists began to understand the behaviour of genes at the cellular level. The close correlation between the two disciplines led to their combination.

Plant and animal cytogenetics

Plant cytogenetics early became an important subdivision of cytogenetics because, as a general rule, plant chromosomes are larger than those of animals. Animal cytogenetics became important after the development of the so-called squash technique in which entire cells are pressed flat on a piece of glass and observed through a microscope; the human chromosomes were numbered using this technique.

Microbial genetics. Microorganisms were generally ignored by the early geneticists because they are small in size and were thought to lack variable traits and the sexual reproduction necessary for a mixing of genes from different organisms. After it was discovered that microorganisms can have different physiological characteristics and also are able to reproduce sexually, they became objects of great interest to geneticists because they reproduce more rapidly than larger organisms; *i.e.,* a mutation, or change, occurs in a gene about one time in 10,000,000 gene duplications, and one bacterium may produce 10,000,000,000 offspring, among which are numerous mutants, in 48 hours.

Many discoveries in microbial genetics have been applied to other areas of genetics; for example, the way in which genes produce enzymes that function in turn to produce genetic traits has important applications to human genetics. Much of microbial genetics also applies to the study of the genetics of viruses.

Molecular genetics. Molecular genetics includes the study of the molecular nature of the gene and the method by which genes control the activities of the cell. Molecular geneticists have studied the molecular structure of a gene (*e.g.,* that involved in the synthesis of the human blood pigment, hemoglobin) and determined the exact sequence of its components; in addition, they have created a synthetic gene by joining the components comprising a known gene in the correct sequence. Genetic engineering had become a commercial enterprise by the early 1980s.

Synthetic genes

Population genetics. A study of genes in populations of animals provides information on past migrations, evolutionary relationships and extents of mixing among different varieties and species, and methods of adaptation to the environment. Statistical methods are used to analyze gene distributions and chromosomal variations in populations.

Human population geneticists have traced migration and invasion routes of man; genetic studies of present-day Europeans, for example, reveal routes of human migrations that occurred hundreds or thousands of years ago. The origin of the people inhabiting South Pacific islands and the degree of intermingling among mixed races also are studied by human population geneticists.

Behavioral genetics. Another aspect of genetics is the study of the influence of heredity on behaviour. Many characteristics once considered to be acquired behavioral patterns actually are of a hereditary nature. The role of heredity in instinctive patterns of behaviour among animals has long been recognized, but many of man's actions also have a hereditary explanation. The effect of various drugs (*e.g.,* the hallucinogenic drug lysergic acid diethylamide, or LSD) on behavioral patterns in animals, including man, is of particular interest.

Human genetics. Some geneticists specialize in human genetics. When classical geneticists first determined the principles of heredity in plants, fruit flies, mice, and other forms of life, they tried to interpret man's heredity in a similar way but found many traits that did not fit the patterns. As techniques improved, it was found that the method of inheritance of human characteristics is the same as that for other living things.

Some human geneticists, called genetic counsellors, advise individuals concerning the probabilities for the appearance of serious hereditary defects in their children. The counsellors usually have medical training because many traits are recognizable only after special diagnostic procedures. Medical genetics is another important application of human genetics. Many medical schools devote entire departments to medical genetics, which is the study of the treatment and prevention of inherited afflictions in man.

It is possible that man may someday control his heredity; even now functional genes can be transferred from one organism to another, and certain treatments are able to cause specific kinds of mutations. Such manipulation of genes eventually may be useful in solving many human hereditary diseases; *e.g.,* stopping the function of genes that are out of control, starting the function of nonfunctioning ones. Activation of nonfunctioning genes in some types of tissue may enable them to replace body parts that have been injured or destroyed. It is conceivable that man may someday learn how to change harmful genes into normal ones.

Methods in genetics. *Experimental breeding.* When animals that differ with respect to *one* primary trait are bred, and their offspring then are bred among themselves to give a second generation, the method of inheritance of the trait can be determined; the process is known as a monohybrid cross. A dihybrid cross involves breeding individuals that differ with respect to *two* traits; the results of such crosses show whether the genes are linked on the same chromosome or are on different chromosomes. If the genes are linked, the distance between them can be determined by the number of recombinations of traits obtained, an indication of the amount of crossing over between genes. By such crosses, geneticists have established elaborate chromosome maps of many organisms showing the location of many genes on the chromosomes.

Hybrids

A test cross may be used to determine if animals carry recessive genes; *e.g.,* cocker spaniel dogs may be of solid colours or parti-coloured (spotted). Since the gene for parti-coloured is recessive, it may be carried (but not expressed) by some solid-coloured dogs. If a solid-coloured dog is suspected of carrying a recessive gene for parti-coloured, it is bred to a parti-coloured dog. Parti-coloured offspring indicate that the solid-coloured dog carries the recessive gene. This technique is used by animal breeders to eliminate undesirable recessive genes.

Experimental breeding is most successful in organisms

with large numbers of offspring, a relatively short life cycle, and a number of variable characteristics. The fruit fly, *Drosophila,* meets these requirements and has been used extensively in breeding experiments; mice also have been used extensively.

Cytogenetic techniques. Cytogenetic techniques are closely associated with experimental breeding. Older cytogenetic techniques involve placing cells in paraffin wax, slicing thin sections, and preparing them for microscopic study. The newer and faster squash technique involves squashing entire cells and studying their chromosomes. Dyes that selectively stain various parts of the cell are used; the genes, for example, may be located by selectively staining the DNA of which they are composed. Radioactive compounds also are valuable in determining the location of various components of the cell. Tissue-culture techniques may be used to grow cells before squashing; white blood cells can be grown from samples of human blood and studied with the squash technique.

Biochemical techniques. Biochemical techniques are used to determine the activities of genes within cells. Radioactive compounds are valuable in studies involving gene duplication and cell metabolism. Thymine is a compound found only in genes; if radioactive thymine is placed in a tissue-culture medium in which cells are growing, genes use it to duplicate themselves. When cells containing radioactive thymine are analyzed, the results show that, during duplication, genes split in half, and each half synthesizes its missing components. When radioactive uracil, a compound found only in the RNA component of cells, is incorporated into the RNA messengers of genes, their pathway from the chromosomes to the site of protein synthesis in the cytoplasm (ribosomes) is revealed.

Radioactive thymine

Chemical tests are used to distinguish certain inherited characteristics of man; *e.g.,* urinalysis and blood analysis reveal the presence of certain inherited abnormalities—phenylketonuria (PKU), cystinuria, alkaptonuria, gout, and galactosemia. Special techniques (*e.g.,* chromatography, electrophoresis) are used to separate the components of proteins, so that inherited differences in their structures can be revealed; for example, more than 100 different kinds of human hemoglobin molecules have been identified.

Physiological techniques. Physiological techniques also are used in genetic investigations. In microorganisms, most genetic variations involve some important cell function. Some strains of one bacterium (*Escherichia coli*), for example, are able to synthesize the vitamin thiamine from simple compounds; others, which lack an enzyme necessary for this synthesis, cannot survive unless thiamine is present. The two strains can be distinguished by placing them on a thiamine-free mixture; those that grow have the gene for the enzyme, those that fail to grow do not. The technique also is applied to human cells since many inherited human abnormalities are caused by a faulty gene that fails to produce a vital enzyme; albinism, which results from an inability to produce the pigment melanin in the skin, hair, or iris of the eyes, is an example of an enzyme deficiency in man.

Immunological techniques. Many substances (*e.g.,* proteins) are antigenic; *i.e.,* when introduced into a vertebrate body, they stimulate the production of specific proteins called antibodies. Various antigens exist in red blood cells, including those that comprise the major blood groups of man (A, B, AB, O). Blood antigens of man include inherited variations, and the particular combination of antigens in an individual is almost as unique as fingerprints. Immunological techniques are used in the blood-group determinations that precede blood transfusions and in determining Rh incompatibility in childbirth.

Evolutionary relationships can be determined by immunological techniques. If protein from a fruit fly is injected into a guinea pig, and the guinea pig produces antibodies and its blood serum is then mixed with proteins from the fly, antigens and antibodies react to produce a cloudy mixture. Mixtures of guinea pig blood serum and proteins from other fruit-fly species cause various degrees of cloudiness, depending on their evolutionary relationship to the original species; *e.g.,* the closer the relationship, the greater degree of cloudiness.

Mathematical techniques. Mathematical techniques are used extensively in genetics. The laws of probability are applicable to crossbreeding and are used to predict ratios concerning the appearance of specific traits in offspring. Geneticists also use statistical methods to determine the significance of deviations from expected results. In investigations involving possible mutagenic effects of factors such as high-energy radiation and drugs, statistical tests are used to establish the validity of conclusions; statistics are used in studies of the possible effects of LSD in producing chromosome aberrations in man, for example, to show whether differences found in cells of users and nonusers of the drug are significant.

Statistical methods

Mathematics is used by population geneticists to evaluate the distribution of genes in populations. The Hardy–Weinberg principle, for example, is important in studying animals that carry a recessive gene; when the actual number of carriers is much greater than that calculated, it is concluded that some environmental factor favours the carriers. The gene for sickle-cell anemia in black Africans, for instance, is found in more people than the frequency of those who have the anemia would indicate because people who carry the gene are more resistant to malaria than noncarriers and, therefore, have a better chance of survival.

Applied genetics. *Medicine.* Genetic techniques are used in medicine to diagnose and treat inherited human disorders. Knowledge of a family history of cancer or tuberculosis may indicate a hereditary tendency to develop these afflictions. Cells from embryonic membranes reveal certain genetic abnormalities, including enzyme deficiencies, that may be present in newborn babies, and thus permit early treatment. Many countries require a blood test of newborn babies to determine the presence of an enzyme necessary to convert an amino acid, phenylalanine, into simpler products. Phenylketonuria, which results from lack of the enzyme, causes permanent brain damage if not treated soon after birth. The presence of approximately 100 different types of human genetic diseases can be detected in embryos as young as 12 weeks; the procedure, called amniocentesis, involves removal and testing of a small amount of fluid from around the embryo.

Agriculture and animal husbandry. Agriculture and animal husbandry apply genetic techniques to improve plants and animals. Plant geneticists produce new species by special treatment; *e.g.,* a hybrid grain has been produced from wheat and rye, and plants resistant to destruction by insect pests have been developed.

Plant breeders use the techniques of budding and grafting to maintain desirable gene combinations originally obtained from crossbreeding. The use of the chemical compound colchicine, which causes chromosomes to double in number, has resulted in many new varieties of fruits, vegetables, and flowers.

Budding and grafting

Animal breeders use artificial insemination to propagate the genes of prize bulls. Prize cows can transmit their genes to hundreds of offspring by hormone treatment, which stimulates the release of many eggs that are collected, fertilized, and transplanted to foster mothers.

Industry. Various industries employ geneticists; the brewing industry, for example, may use geneticists to obtain strains of yeast that produce large quantities of alcohol. The pharmaceutical industry has developed strains of molds, bacteria, and other microorganisms high in antibiotic yield. (A.M.W.)

EUGENICS

Eugenics is the study of human improvement in all aspects by genetic means. Its goal is to increase the proportion of persons with better than average genetic endowment. It draws from the science of genetics for an understanding of the processes of heredity; from psychology for analysis of the part played by differences in heredity and environment in the development of personality, intelligence, and character; from medicine and medical genetics for information on hereditary defects and susceptibility to disease; and from sociology, and more particularly demography, for the rates of births and deaths, the mating habits, and the social and physical factors that determine the relative

increase or decline of persons with different characteristics. In its scientific aspect it is essentially the study of trends and causal factors in human evolution.

A companion science, euthenics, is also concerned with the improvement of mankind, but by adjustment of the environment. Obviously both concerns are essential to the well-being of man, and since neither science can stand alone, the term "humanics" has been suggested to embrace both aspects of human improvement.

Historical background. The idea of applying knowledge of heredity to the improvement of the human race goes back to earliest times. References to eugenic ideals appear in the Old Testament, and Plato's *Republic* idealizes a society in which there is constant selection for the improvement of the human stock. Thomas Robert Malthus noted the struggle for existence; Charles Darwin saw in it the means of evolution. It remained for Francis Galton, a scientist of many talents and a cousin of Darwin, to see that the theory of evolution implied that man might in part direct his own evolutionary future. Galton's first important work, *Hereditary Genius* (1869), contained the results of his studies of the families of eminent men as evidence for his belief that "it would be quite practical to produce a highly gifted race of men by judicious marriages during several consecutive generations." In 1883 he published *Inquiries into Human Faculty,* in which he coined the term eugenics. In *Natural Inheritance* (1889), Galton pioneered the development and application of advanced statistical methods to the study of man.

While Galton's thinking was much ahead of his time, he retained some of the prejudices of an English gentleman in regard to social class and race. In his studies of the families of eminent men Galton underestimated the effects of a favourable environment. But his faults in this respect were far less than those of many of his followers. He developed and used many statistical methods for the study of populations and was the first to recognize the value of the study of twins for research in heredity. He repudiated the Lamarckian view, then widely held, that acquired characteristics were inherited. Although Galton attached religious significance to the eugenic movement, he did not think of it in revolutionary terms, but rather as ". . . the new duty which is supposed to be exercised concurrently with and not in opposition to, the old ones upon which the social fabric depends."

he slow
ceptance
f eugeni-
al ideas

For all his wisdom and high ability, Galton was not able to gain any wide acceptance for eugenics, largely because much of the scientific and technical foundation was lacking. Psychology was not sufficiently advanced to help him in his studies of individual differences or in assessing the importance of the environment; there was no cultural anthropology to provide an outline of the growth of civilizations; and birth control was so little recognized or accepted that he did not take it into account as a possible factor in the control and distribution of births.

From Galton to World War II. Galton had endowed a research fellowship in eugenics in 1904 and, in his will, provided funds for a chair of eugenics at University College, London University. The fellowship and later the chair at University College were both occupied by Karl Pearson, a brilliant mathematician who helped to create the science of biometry, the statistical aspects of biology. Pearson was a controversial figure who believed that environment had little to do with the development of mental or emotional qualities. He felt that the high birth rate of the poor was a threat to civilization and that the "higher" races must supplant the "lower." His views gave countenance to those who believed in racial and class superiorities. Thus, Pearson shares the blame for the discredit later brought on eugenics in the United States and for making possible the dreadful misuse of the word eugenics in Hitler's propaganda. The English Eugenics Society, founded by Galton in 1907 as the Eugenics Education Society, opposed Pearson's views, but was itself slow in throwing off the prevalent biases of that time.

ugenics
liscredited
y early
acist views

In the United States the American Eugenics Society was founded in 1926 by men whose views were coloured by the times in which they lived. They believed that the white race was superior to other races, and, further, that the "Nordic" white was superior to other whites. They thought of races as "pure" groups, quite separate from each other. They did not know that all races are mixtures of many types, the distribution of genes among the races varying in proportions rather than in kind, as evidenced by the distribution of the various blood groups among all of the races. They did not realize that environments are so uncontrollable that scientists cannot reasonably put forward views on the genetic differences in the performance of different races. Furthermore, they believed that the upper classes had superior hereditary qualities that justified their being the ruling class.

The science of that day supported extreme views on feeblemindedness and "criminal types." Intelligence tests, introduced in the early 1900s by a French psychologist, Alfred Binet, were thought, contrary to Binet's views, to be measures of innate, genetic intelligence. People whose test performance (*e.g.,* intelligence quotient, or IQ) gave them a mental age of 12 or less could be classified as feebleminded or morons, even though the term would then include most of those brought up in deprived environments, such as the southern Appalachian highlands or the blighted rural and urban slums occupied by the descendants of slaves. Criminality was generally considered a concomitant of feeblemindedness. Studies on degenerate family stocks were taken to prove that hundreds of persons in each of these families were feebleminded or criminal types because of the inheritance they received from a single ancestor five or six generations back. Claims were made that immigrants from southern and eastern Europe, besides being socially inferior, included a remarkable number of criminal and defective stocks. There was much in the intellectual atmosphere of the United States. that fostered an extreme hereditarian racist view.

Even before 1905 eugenists had been active in the effort to restrict immigration. Their arguments, along with those of others who advocated restrictions for different reasons, culminated with the passage of the Immigration Act of 1924, which limited quota immigrants to about 150,000 annually, with no more than 2 percent of each nationality according to the number of persons of their national origin in the United States as of 1890, and providing that beginning July 1, 1929, the quota of any country shall have the same ratio to 150,000 as the number of persons of that national origin living in the United States had to the total population of the United States, as determined from the 1920 census. In later years it became clear that the material the eugenists had presented to congressional hearings had little scientific foundation.

Movement to sterilize defectives

Eugenists at this time laid great stress on the importance of sterilizing defective persons. By 1931 sterilization laws had been enacted by 27 states in the United States, and by 1935 sterilization laws had been passed in Denmark, Switzerland, Germany, Norway, and Sweden. Most of these laws provided for the voluntary or compulsory sterilization of certain classes of people thought to be insane, idiotic, imbecilic, feebleminded, or epileptic; some applied equally to habitual criminals, moral perverts, or the feebleminded. In most cases the purpose was clearly eugenic, though some laws tacitly permitted sterilization for social rather than genetic reasons. In the United States most states did not generally enforce these rather extreme measures, and the number of sterilizations was seldom over 100 per year. Exceptions were California, where sterilizations averaged over 350 cases per year, with a total of 9,931 by 1935, and some of the southern states, with fairly high sterilization rates relative to their populations.

With the advance of science the background for these laws began to be questioned. In 1935 a committee of the American Neurological Association reported on an extensive investigation and evaluation of the "facts and theories which constitute the subject matter of the inheritance of the mental diseases, feeblemindedness, epilepsy and crime." The committee concluded that there was a serious question whether "many of the eugenic proposals now current take into account the newer genetic data" and that "though the avowed purpose of such sterilization invariably starts out by being a eugenic one, it often ends by becoming a social one." They exposed many fallacies

in the reasoning behind the sterilization laws and concluded that there was no sound basis for sterilization on the basis of immorality or character defect. They recommended sterilization only with the consent of the patient, or those responsible for him, and only in the case of certain specified diseases or defects, namely: (1) Huntington's chorea, hereditary optic atrophy, familial cases of Friedreich's ataxia, and a few other rare hereditary defects; (2) feeblemindedness common in a family; (3) schizophrenia; (4) extreme cases of manic depressive psychosis; and (5) epilepsy, mainly on the ground of its social aspects. Their recommendation for concerted, coordinated, and planned long-term research was not followed seriously until after 1945, when medical schools began active research into medical genetics.

In Europe the studies of criminal types were discredited, and serious work in eugenics continued in the form of family studies by government institutes. Only in Nazi Germany did eugenics serve racial and political purposes. There, Hitler, exploiting the concepts of the master race and the superman as expounded by some German scholars, developed racism into a powerful political weapon.

Eugenics after 1945. With the development of atomic weapons, the general public and physicians alike became educated to the dangers of genetic mutations produced by radioactive fallout from nuclear explosions. Medical X-rays came under new scrutiny, and the findings of studies on hereditary factors in diabetes and other diseases received new attention. Medicine and public health, professions previously little interested in heredity, recognized a new responsibility. By the 1960s the major medical schools in the United States had included geneticists on their research staffs, and a number had set up departments of medical genetics. Couples planning marriage became more aware of their responsibility to potential offspring, and heredity clinics associated with medical schools began to provide genetic counselling.

Still other factors arose to increase public interest in heredity. The great increase in births that took place in the United States and most European countries after World War II aroused interest in the type of children being born and the kind of homes they were being brought up in. Birth control, given worldwide publicity as a solution to the problem of too rapid growth of populations, raised questions as to the type of people who would use it, and the kind of children they would have. Medical solutions to the problems of male and female infertility—such as artificial insemination, in vitro fertilization, and surrogate mothering—have raised questions about such issues as the heredity as well as the legal status of children so conceived, and about the effect of the psychological environment on the marriage relationship and on the child. New scientific findings were widely disseminated, and the public has begun to take a more balanced view of the contributions made by both heredity and environment to good health, intelligence, and character.

Scientific basis of eugenics broadened

Genetics made unparalleled advances after 1950, opening up a whole new field of the biochemistry of gene structure and gene behaviour. At the same time, the scientific basis for the new eugenics was being further broadened by advances in psychology and in the field of demography. The Institut National d'Études Démographiques in France sponsored important investigations of human populations. In England the Royal Commission on Population made its report in 1949, and the Population Investigating Committee at the London School of Economics gave attention to quantitative and qualitative aspects of population trends in its publication *Population Studies.* In the United States a number of the larger universities established facilities for training and research in demography, and several nationwide surveys on factors affecting fertility were taken. The atmosphere was appropriate to a balanced reconsideration of eugenic problems.

Modern trends. Recent trends in the distribution of births suggest the possibility of the development in modern industrial societies of eugenic selection of a wholly voluntary and unselfconscious sort, in which the only controls might be certain moderate changes in social institutions, most of which changes are already desired for other than genetic reasons. Eugenic thinking seems to be developing along these lines, but the public and many scientists are still disturbed by the older conception of a controlled or authoritarian eugenics that would threaten other social and ethical values.

The most immediate and most publicized procedure that can be eugenically applied is the use of insemination techniques. The insemination of women whose husbands are infertile is quite frequently practiced in the United States and Europe. A proposal was made by Herman Muller that the sperm for insemination be collected from men of high attainment, of family stocks as free as possible from defective strains, and that it be kept, frozen and stored, for as long as possible, perhaps beyond the lifetime of the donor. It would then be available for women who desired to assure themselves of superior children. It was Muller's belief that the advantages of this procedure would result in its rapid and widespread adoption, and an organization was formed to carry on his work.

The "sperm bank"

Other scientific possibilities, not yet in the stage of application, are already being discussed by scientists for their possible effect on the genetic qualities of human beings. Changing hereditary factors in the human cell by chemical means is not an impossibility, but it lies in the future. Another possibility is the implanting of a specified segment of genes into a chromosome. Preliminary experiments have been performed on mice, but it will be a long time indeed before such methods can be used for the improvement of human germ cells. A nearer possibility is vegetative, or clonal, reproduction, similar to the reproduction of cuttings from plants. If this not improbable technique becomes practicable with humans, the way would be open for the reproduction, in any number desired, of individuals as similar genetically as are identical twins. Human beings could then be propagated for diverse valuable characteristics of every sort. Few persons would regard this proposal as desirable or even thinkable. The technical difficulties and social and moral objections to the "mass production" of such twin types make its application unrealistic even in the remote future.

For all practical purposes the measures discussed above are premature. They are just beyond the realm of theory, but far short of general acceptance even as theories. They would violate many established social attitudes. They raise many moral and legal questions. The population at large generally regards such proposals with suspicion. Their fears cannot be dismissed lightly. Who can assure them that eugenical procedures will not be used ulteriorly? Who can promise that there is no danger?

The public's fear of eugenics

Authoritarian controls would have to be employed and extremely difficult value judgments would have to be made. Who, for example, would determine a superior quality in man? Who would make the decisions whether certain qualities should be preserved or extinguished? Modern eugenics is little interested in authoritarian controls. Rather, it believes that the social and economic environment can be shaped so as to influence a eugenic distribution of births throughout entire populations in a voluntary and largely unconscious process of selection.

Areas of study. *Genetic defects.* It is generally accepted that genes causing defects originate in mutations that occasionally take place in one or another of the many thousands of genes present in pairs in every human cell. Usually the mutated gene is recessive; that is, it does not have a harmful effect unless the other gene in the pair has the same characteristics. The chances of two such genes meeting as a pair depend on the number of such genes distributed throughout the intermarrying population. Thus under random mating, if a particular deleterious gene is carried by one person in a hundred, the chances of the mating of persons with such genes are one in 10,000. While the chances of such an unfortunate mating seem slim, in a large population such a ratio results in a considerable number of persons with defects.

With an increase in the proportion of carriers of a particular defective gene, there is an even greater increase in the likelihood of a mating in which two such genes will be paired in the same fertilized cell. When this happens, there will be a defect. If the defect is lethal (*i.e.*, results in

stillbirth or infant death), the two deleterious genes will be removed from the population. If the defect is minor, but of a sort to make marriage or reproduction less likely, the genes are to that extent less likely to survive. Thus at some point nature establishes a balance in which, for every new deleterious gene brought into circulation, a similar gene is lost from circulation.

Geneticists believe that most people carry at least a few deleterious genes; some estimate the average to be as high as 8 percent, and at least 2 percent of the babies born carry some genetic defect, major or minor.

Most scientists believe that the proportion of carriers of deleterious genes may now be increasing, though the results in the form of an increase in defect would not be apparent for a number of generations. Greater exposure to X-rays and to fallout from atomic explosions is currently accelerating the rate of mutations, while medicine is making it possible for an increasing number of persons with some kind of genetic defect to live long enough to rear children unfortunate in having that parental defect. Diabetics, for instance, formerly died at an early age, and the genes for diabetes were lost with them. After an insulin treatment was found, these people led longer useful lives, but were not generally able to have children. Now safe delivery of the children of diabetic mothers is commonplace. The deleterious genes remain in circulation, while new ones are constantly added by mutations. Thus, with good medical care, diabetics live normally and often bear diabetic children of their own. The accumulation of certain severe types of deleterious genes could conceivably reach a point that might seriously threaten man's future.

he genetic urden

To support and maintain defective members in the population is not at odds with the goal of genetic improvement of mankind so long as such persons do not reproduce defective offspring.

While present social and medical conditions favour the increase of many genes that cause physical defects and susceptibility to certain diseases, other genes that affect mental disease and mental defect are probably diminishing as a result of the low reproductive rate and the institutionalization of the carriers. It is probable that efforts at control will be strengthened by increased use of sterilization in some areas, by increased use of more effective means of birth control, and by a more eugenic use of heredity counselling clinics. Each year increasing numbers of defects are being defined, the type of transmission understood, and, in many cases, means found for spotting carriers. The immediate solution to the dilemma seems to lie in educating those persons known to be carrying a seriously defective gene to their societal responsibility, and thereby, hopefully, to convince them to surrender their right to bear children who might be defective and burden them as well as society. The possibility of "correcting" nature's mistakes at their source, the deoxyribonucleic acid molecule (DNA) of the gene, is a hope for the future. Such genetic engineering has been proposed by several prominent scientists and termed "algeny."

Psychological traits. With responsibility for work on mental and physical defects transferred to the professions of medicine and public health, eugenists are now giving major attention to the genetic factors that provide the base for the development of such complexly inherited traits as intelligence, character, and personality. The genetic base for these psychological traits is provided by multiple genes in various combinations. They may be broken up and recombined with other genes from one generation to another, making them difficult to trace in family lines. It takes time to locate these genes and trace the processes involved in their transmission. Fortunately, the efficacy of selection does not depend on a full knowledge of the genetic mechanism. For the present, at least, eugenists will be guided by familial incidence of intelligence and personality and by the survival of family stocks of different types.

Massive evidence from studies on identical and fraternal twins, nontwin siblings, and adopted children reared away from their natural parents indicates that differences in genetic factors play an important part in psychological differences between individuals. These were Galton's findings, and they have been confirmed by larger and more carefully controlled studies. Identical twins are extremely similar; even when reared apart from infancy, they resemble each other in physical as well as mental characteristics to a degree greater than that shown by fraternal twins reared together.

Children tend to be like their parents in intelligence not only because of their common heredity, but also because they usually share a common environment. The evidence on differences in personality is not so clear, largely because these traits are more difficult to measure. All studies indicate, however, that personality, like intelligence, is the product of interaction between environment and the genetic base. This is shown in the extremes of personality, like schizophrenia, which can often be measured.

Environmental and socioeconomic factors. As work in the field of individual differences has progressed, scientists have come to feel that the old distinction between heredity and environment is no longer useful; both are a part of the processes that begin when the cell is fertilized and starts its separate life; both operate throughout the individual's life; and both contribute to making each individual different from every other individual. Genetic factors can be given value only in relation to specific environments; some qualities that are socially valuable in one environment may be harmful in another.

Apparent racial differences in intelligence

Racial groups differ in their average response to intelligence tests, but these tests invariably involve environmental factors that favour those culturally more fortunate. Even when differences in such factors as place of residence, income, or length of schooling can be controlled, the results may still be influenced by factors affecting motivation and behaviour.

In studies of socioeconomic, or other, groups, there is no evidence of genetic differences, except perhaps in the case of comparisons between certain of the professional classes and the rest of the population, in which there is some indication that the genetic factors for response to intelligence tests may be slightly superior. Differences between socioeconomic classes in intelligence-test response are obviously strongly influenced by differences in environment in much the same way as occurs among racial groups. It is as yet impossible to measure the relative genetic potentialities of any large population groups. But differences between individuals within each group can be measured, and it is these differences that are the proper concern of eugenists today.

Until very recently, from 30 to 50 percent of all children died before maturity, and death was an important factor in the survival of particular stocks. The evidence from some areas where people are still living under primitive conditions seems to favour the belief that under conditions of life as it was everywhere before the mid-18th century, the general tendency was toward the survival of more competent stocks. If so, this situation changed in the industrialized countries, when the death rate began an accelerated decline, dropping to 12 or less per 1,000 by 1940. In the mid-20th century, about 95 percent of all children lived to age 30, and differential deaths had little effect on differential survival.

Social-class differences in family size

While this change was taking place, social-class differences in births were widening with the introduction of birth-control measures, which reached first into the more educated and wealthy classes. With differential births greatly favouring the less educated, who made little effective use of birth control, the inverse relation between births and education or socioeconomic status widened rapidly. In the United States this inverse relationship reached its peak with the postponement of births and marriages in the last years of the Great Depression. For the period 1935–40 women with one to three years of college education had a net reproduction rate 33 percent below that required for replacement of their numbers, and women with four years of high school had a rate 26 percent below replacement, while women at the elementary school level had a rate twice that of the college women and well above that required for replacement.

The upsurge of births after World War II and the spread of birth control among the less educated changed this trend. By 1960, among women 35 to 40 years old who had prac-

tically completed their childbearing, high-school women and women with one to three years of college had borne more children than the number needed for replacement. Women with less than eight years of elementary school education had had about the same number of children as those who had completed their childbearing during the Depression. This trend seems likely to continue. Extensive studies made about 1960 on national samples of the U.S. population indicate that the number of children actually desired by couples in the "blue collar" (factory or industrial) group is less than the number desired by couples in the "white collar" (office or business) group. When both the husband and the wife were college graduates, only 7 percent of the last pregnancies were unwanted, while among the couples at grade school level 33 percent had not wanted their last pregnancy. Of the college couples, 92 percent effectively used contraception, while only 69 percent of the grade school couples used contraception, and they used it less effectively.

It is expected that birth control may soon be used as widely and as effectively at the lowest educational levels as at the highest. Should that occur, present trends suggest that educational and social class differentials in births may soon bear a direct relation to size of family. The public generally, and many scientists, have assumed that an inverse relation between size of family and education or socioeconomic class must represent an unfavourable, or dysgenic, trend, even though there is little evidence for genetic differences between classes. If the relation between size of family and educational level becomes direct, with the more educated groups having the greater proportion of children, the trend would be generally taken as favourable, or eugenic. But its greatest significance would be an increase in the proportion of children brought up in above-average home surroundings. The major opportunity for genetic improvement will be found in selection of individuals within each group.

There is some limited evidence that at the present time in the United States the abler and the more intelligent members of any group tend to have the most children. In studies made as early as 1927 on graduates of Yale and Harvard universities, and again on Princeton University graduates in 1939, the men were rated by a committee of classmates for degree of success some years after graduation. In each group the highest-rated married men averaged over two children apiece, while the lowest-rated married men averaged less than one and one-half children. Many studies have indicated that the probability of being childless increases as IQ decreases. There is thus some evidence that in attempting to increase the comparative fertility of the more intelligent and successful individuals, eugenists are working with and not against present trends, as has been claimed by some.

Individual voluntary selection on the increase

A number of changes taking place in industrial societies today are favourable to individual selection. There are more opportunities for finding work appropriate to one's genetic capacities. There is a wider choice of mates in a highly mobile society, which favours the production of novel types and offers greater possibilities if there is selection. The trend toward more education for all classes would help make birth control selective within each class. Also, the continuing improvement of birth control methods should improve voluntary forms of selection at all levels of education. To further these trends, eugenists urge better training for choice of mate and for marriage, a more general individual and community sense of responsibility for the parents who have more than one or two children, and continuing study of all the psychological, social, and economic pressures and rewards that would tend toward a voluntary and favourable selection of births within every occupational group.

(F.H.O.)

ECOLOGY

Long unfamiliar to the public, and relegated to a second-class status by many in the world of science, ecology emerged in the late 20th century as one of the most popular and most important aspects of biology. It has become painfully evident that the most pressing problems in the affairs of men—expanding populations, food scarcities, environmental pollution, and all the attendant sociological and political problems—are to a great degree ecological.

The word ecology was coined by a German zoologist, Ernst Haeckel, who applied the term *oekologie* to the "relation of the animal both to its organic as well as its inorganic environment." The word comes from the Greek *oikos,* meaning "household, home, or place to live." Thus ecology deals with the organism and its environment. The word environment includes both other organisms and physical surroundings. It involves relationships between individuals within a population and between individuals of different populations. These interactions between individuals, between populations, and between organisms and their environment form ecological systems, or ecosystems. Ecology has been defined variously as "the study of the interrelationships of organisms with their environment and each other," as "the economy of nature," and as "the biology of ecosystems."

Historical background. Ecology had no firm beginnings. It evolved from the natural history of the Greeks, particularly Theophrastus, a friend and associate of Aristotle. He first described the interrelationships between organisms and between organisms and their nonliving environment. Later foundations for modern ecology were laid in the early work of plant and animal physiologists.

In the early and mid-1900s two groups of botanists, one in Europe and the other in America, studied plant communities from two different points of view. The European botanists concerned themselves with the study of the composition, structure, and distribution of plant communities. The American botanists studied the development of plant communities, or succession. Both plant and animal ecology developed separately until American biologists emphasized the interrelation of both plant and animal communities as a biotic whole.

During the same period interest in population dynamics developed. The study of population dynamics received special impetus in the early 19th century, after Thomas Malthus called attention to the conflict between expanding populations and the capability of the earth to supply food. R. Pearl (1920), A.J. Lotka (1925), and V. Volterra (1926) developed mathematical foundations for the study of populations, and these studies led to experiments on the interaction of predators and prey, competitive relationships between species, and the regulation of populations. Investigations of the influence of behaviour on populations was stimulated by the recognition in 1920 of territoriality in nesting birds. Concepts of instinctive and aggressive behaviour were developed by K. Lorenz and N. Tinbergen, and the role of social behaviour in the regulation of populations was explored by V.C. Wynne-Edwards.

While some ecologists were studying the dynamics of communities and populations, others were concerned with energy-budgets. In 1920, August Thienemann, a German freshwater biologist, introduced the concept of trophic, or feeding, levels, by which the energy of food is transferred through a series of organisms, from green plants (the producers) up to several levels of animals (the consumers). An English animal ecologist, C.E. Elton (1927), further developed this approach with the concept of ecological niches and pyramids of numbers. Two American freshwater biologists, E. Birge and C. Juday, in the 1930s, in measuring the energy budgets of lakes, developed the idea of primary production, *i.e.,* the rate at which food energy is generated, or fixed, by photosynthesis. Modern ecology came of age in 1942 with the development, by R.L. Lindeman of the United States, of the trophic-dynamic concept of ecology, which details the flow of energy through the ecosystem. Quantified field studies of energy flow through ecosystems were further developed by Eugene and Howard Odum of the United States; similar early work on the cycling of nutrients was done by J.D. Ovington of England and Australia.

The study of both energy flow and nutrient cycling was stimulated by the development of new techniques—radioisotopes, microcalorimetry, computer science, and applied mathematics—that enabled ecologists to label, trace, and measure the movement of particular nutrients and

energy through the ecosystems. These modern methods encouraged a new stage in the development of ecology—systems ecology, which is concerned with the structure and function of ecosystems.

he unifying concept f ecology

Until the late 20th century ecology lacked a strong conceptual base. Modern ecology, however, is now focussed on the concept of the ecosystem, a functional unit consisting of interacting organisms and all aspects of the environment in any specific area. It contains both the nonliving (abiotic) and living (biotic) components through which nutrients are cycled and energy flows. To accomplish this cycling and flow, ecosystems must possess a number of structured interrelationships between soil, water, and nutrients, on the one hand, and producers, consumers, and decomposers on the other. Ecosystems function by maintaining a flow of energy and a cycling of materials through a series of steps of eating and being eaten, of utilization and conversion, called the food chain. Ecosystems tend toward maturity, or stability, and in doing so they pass from a less complex to a more complex state. This directional change is called succession. Whenever an ecosystem is used, and that exploitation is maintained—as when a pond is kept clear of encroaching plants or a woodland is grazed by domestic cattle—the maturity of the ecosystem is effectively postponed. The major functional unit of the ecosystem is the population. It occupies a certain functional niche, related to its role in energy flow and nutrient cycling. Both the environment and the amount of energy fixation in any given ecosystem are limited. When a population reaches the limits imposed by the ecosystem, its numbers must stabilize or, failing this, decline from disease, starvation, strife, low reproduction, or other behavioral and physiological reactions. Changes and fluctuations in the environment represent selective pressure upon the population to which it must adjust. The ecosystem has historical aspects: the present is related to the past and the future to the present. Thus the ecosystem is the one concept that unifies plant and animal ecology, population dynamics, behaviour, and evolution.

Areas of study. Of necessity, ecology is a multidisciplinary science. It involves plant and animal biology, taxonomy, physiology, genetics, behaviour, meteorology, pedology, geology, sociology, anthropology, physics, chemistry, mathematics, and electronics. Often it is difficult to draw a sharp line between ecology and any of these, for all impinge on it. The same situation exists also within ecology. In understanding the interactions between the organism and the environment or between organisms, it is often difficult to separate behaviour from population dynamics, behaviour from physiology, adaptation from evolution and genetics, animal ecology from plant ecology.

Ecology developed along two lines: the study of plants and the study of animals. Plant ecology concerns the relationships of plants to other plants and their environment. The approach is largely descriptive of the vegetational and floristic composition of an area and usually ignores the influence of animals on the plants. Animal ecology concerns the study of population dynamics, distribution, behaviour, and the interrelationships of animals and their environment. Because animals depend upon plants for food and shelter, animal ecology cannot be fully understood without a considerable background of plant ecology. This is particularly true in applied areas of ecology—wildlife and range management.

Both plant and animal ecology may be approached as the study of the interrelations of an individual organism with its environment, called autecology, or as the study of groups of organisms, called synecology.

Autecology and synecology

Autecology, in many ways the classical study of ecology, is experimental and inductive. Because it is usually concerned with the relationship of an organism to one or more variables such as humidity, light, salinity, or nutrient levels, it is easily quantified and lends itself to experimental design both in the field and the laboratory. It has borrowed techniques from chemistry, physics, and physiology. Autecology has contributed at least two important concepts: the constancy of interaction between an organism and its environment, and the genetic adaptability of local populations to local environmental conditions.

Synecology, on the other hand, is philosophical and deductive. It is largely descriptive and not easily quantified and contains a bewildering array of terminology. Only recently, since the advent of the electronic and atomic ages, has synecology developed the tools to study complex systems and enter an experimental phase. Important concepts developed by synecology are those concerned with nutrient cycling, energy budgets, and ecosystem development. Synecology has strong ties with pedology, geology, meteorology, and cultural anthropology.

Synecology may be subdivided according to environmental types, as terrestrial or aquatic. Terrestrial ecology, which may be further subdivided into forest, grassland, arctic, and desert ecology, concerns such aspects of terrestrial ecosystems as microclimate, soil chemistry, soil fauna, hydrologic cycles, ecogenetics, and productivity. Terrestrial ecosystems are more influenced by organisms and subject to much wider environmental fluctuations than are aquatic ecosystems. Aquatic ecosystems are affected more by the condition of the water and resist such environmental variables as temperature. Because the physical environment is so important in controlling aquatic ecosystems, considerable attention is paid to the chemical and physical characteristics of the ecosystem, such as the currents and the chemical composition of the water. By convention, aquatic ecology, called limnology, is limited to freshwater stream ecology and lake ecology. The former concerns life in flowing waters; the latter, life in relatively still water. Marine ecology deals with life in the open sea and in estuaries.

Other ecological approaches concern specialized areas. The study of the geographic distribution of plants and animals is ecological plant and animal geography. The study of population growth, mortality, natality, competition, and predator–prey relations is population ecology. The study of the genetics and ecology of local races and distinct species is ecological genetics. The study of the behavioral responses of animals to their environment, and of social interactions as they affect population dynamics, is behavioral ecology. Investigations of interactions between the physical environment and the organism fall under ecoclimatology and physiological ecology. The study of groups of organisms is community ecology (though it is difficult to separate it from studies of bioenergetics, biogeochemical cycles, and trophic-dynamic aspects of the community or ecosystem ecology). That part of ecosystem ecology concerned with the analysis and understanding of the structure and function of ecosystems by the use of applied mathematics, mathematical models, and computer programs is systems ecology. Systems ecology, concentrating on input and output analysis, has stimulated the rapid development of applied ecology, concerned with the application of ecological principles to the management of natural resources, agricultural production, and problems of environmental pollution.

Systems ecology

Methods in ecology. Because ecologists work with living systems possessing numerous variables, the techniques used by physicists and chemists, mathematicians and engineers, require modification; they are not easily applied nor are the results as precise as those obtained in other sciences. It is relatively simple, for example, for a physicist to measure gain and loss of heat from metals or other inanimate objects, which possess certain constants of conductivity, expansion, surface features, and the like. To determine the heat exchange between an animal and its environment, however, a physiological ecologist is confronted with an array of almost unquantifiable variables and has the formidable task of both gathering the numerous data and analyzing them. Ecological measurements probably never will be as precise or as subject to the same ease of analysis as measurements in physics, chemistry, or certain quantifiable areas of biology.

In spite of these problems, various aspects of the environment can be determined by physical and chemical means, ranging from simple chemical identifications and physical measurements to the use of sophisticated mechanical apparatus. The development of biostatistics and proper experimental design, and the improvements in methods of sampling, permit a quantified statistical approach to

the study of ecology. Because of the extreme difficulties of controlling environmental variables in the field, studies involving the use of experimental design are largely confined to the laboratory and to controlled field experiments designed to test the effects of only one variable or several variables. The use of statistical procedures, and the application of computer science to mathematical models based on data obtained from the field, are providing new insights into population interactions and ecosystem function. Mathematical programming is becoming increasingly important in applied ecology, especially in the management of natural resources and agricultural problems having an ecological basis.

Controlled environmental chambers enable experimenters to maintain plants and animals under known conditions of light, temperature, humidity, and daylength so that the effects of each variable (or combination of variables) on the organism can be studied. Biotelemetry and other electronic tracking equipment, products of the space age, permit the rapid and nondestructive sampling of plant and animal populations. Such tools enable ecologists to follow from a distance the movements and behaviour of a free-ranging animal by radio signals beamed from a sender attached to the organism. Radioisotopes are used for tracing the pathways of nutrients through ecosystems, for determining the time and extent of transfer of energy and nutrients through the different components of the ecosystem, and for the determination of food chains. The use of laboratory microcosms—aquatic and soil microecosystems, consisting of biotic and nonbiotic material from natural ecosystems, held under conditions similar to those found in the field—are useful in determining rates of nutrient cycling, ecosystem development, and other functional aspects of ecosystems. Microcosms enable the ecologist to duplicate experiments and to perform experimental manipulation on them.

(R.L.Sm.)

The study of types of living organisms

ZOOLOGY

Zoology, the study of animals, includes both the inquiry into individual animals and their constituent parts, even to the molecular level, and the inquiry into animal populations, entire faunas, and the relationships of animals to each other, to plants, and to the nonliving environment. Though this wide range of studies results in some isolation of specialties within zoology, the conceptual integration in the contemporary study of living things that has occurred in recent years emphasizes the structural and functional unity of life rather than its diversity.

Historical background. Prehistoric man's survival as a hunter defined his relation to other animals, which were a source of food and danger. As man's cultural heritage developed, animals were variously incorporated into man's folklore and philosophical awareness as fellow living creatures. Domestication of animals forced man to take a systematic and measured view of animal life, especially after urbanization necessitated a constant and large supply of animal products.

The role of the Greeks

Study of animal life by the ancient Greeks became more rational, if not yet scientific, in the modern sense, after the cause of disease—until then thought to be demons—was postulated by Hippocrates to result from a lack of harmonious functioning of body parts. The systematic study of animals was encouraged by Aristotle's extensive descriptions of living things, his work reflecting the Greek concept of order in nature and attributing to nature an idealized rigidity.

In Roman times Pliny brought together in 37 volumes a treatise, *Historia naturalis,* that was an encyclopaedic compilation of both myth and fact regarding celestial bodies, geography, animals and plants, metals, and stone. Volumes VII to XI concern zoology; volume VIII, which deals with the land animals, begins with the largest one, the elephant. Although Pliny's approach was naïve, his scholarly effort had a profound and lasting influence as an authoritative work.

Zoology continued in the Aristotelian tradition for many centuries in the Mediterranean region and by the Middle Ages, in Europe, it had accumulated considerable folklore, superstition, and moral symbolisms, which were added to otherwise objective information about animals. Gradually, much of this misinformation was sifted out: naturalists became more critical as they compared directly observed animal life in Europe with that described in ancient texts. The use of the printing press in the 15th century made possible an accurate transmission of information. Moreover, mechanistic views of life processes (*i.e.,* that physical processes depending on cause and effect can apply to animate forms) provided a hopeful method for analyzing animal functions; for example, the mechanics of hydraulic systems were part of William Harvey's argument for the circulation of the blood—although Harvey remained thoroughly Aristotelian in outlook. In the 18th century, zoology passed through reforms provided by both the system of nomenclature of Carolus Linnaeus and the comprehensive works on natural history by Georges-Louis Leclerc de Buffon; to these were added the contributions to comparative anatomy by Georges Cuvier in the early 19th century.

Physiological functions, such as digestion, excretion, and respiration, were easily observed in many animals, though they were not as critically analyzed as was blood circulation.

Following the introduction of the word cell in the 17th century and microscopic observation of these structures throughout the 18th century, the cell was incisively defined as the common structural unit of living things in 1839 by two Germans: Matthias Schleiden and Theodor Schwann. In the meanwhile, as the science of chemistry developed, it was inevitably extended to an analysis of animate systems. In the middle of the 18th century the French physicist René Antoine Ferchault de Réaumer demonstrated that the fermenting action of stomach juices is a chemical process. And in the mid-19th century the French physician and physiologist Claude Bernard drew upon both the cell theory and knowledge of chemistry to develop the concept of the stability of the internal bodily environment, now called homeostasis.

The cell concept influenced many biological disciplines, including that of embryology, in which cells are important in determining the way in which a fertilized egg develops into a new organism. The unfolding of these events—called epigenesis by Harvey—was described by various workers, notably the German-trained comparative embryologist Karl von Baer, who was the first to observe a mammalian egg within an ovary. Another German-trained embryologist, Christian Heinrich Pander, introduced in 1817 the concept of germ, or primordial, tissue layers into embryology.

In the latter part of the 19th century, improved microscopy and better staining techniques using aniline dyes, such as hematoxylin, provided further impetus to the study of internal cellular structure.

Darwin and the theory of evolution

By this time Darwin had made necessary a complete revision of man's view of nature with his theory that biological changes in species occur through the process of natural selection. The theory of evolution—that organisms are continuously evolving into highly adapted forms—required the rejection of the static view that all species are especially created and upset the Linnaean concept of species types. Darwin recognized that the principles of heredity must be known to understand how evolution works; but, even though the concept of hereditary factors had by then been formulated by Mendel, Darwin never heard of his work, which was essentially lost until its rediscovery in 1900.

Genetics has developed in the 20th century and now is essential to many diverse biological disciplines. The discovery of the gene as a controlling hereditary factor for all forms of life has been a major accomplishment of modern biology. There has also emerged clearer understanding of the interaction of organisms with their environment. Such ecological studies help not only to show the interdependence of the three great groups of organisms—plants, as producers; animals, as consumers; and fungi and many bacteria, as decomposers—but they also provide informa-

tion essential to man's control of the environment and, ultimately, to his survival on Earth. Closely related to this study of ecology are inquiries into animal behaviour, or ethology. Such studies are often cross disciplinary in that ecology, physiology, genetics, development, and evolution are combined as man attempts to understand why an organism behaves as it does. This approach now receives substantial attention because it seems to provide useful insight into man's biological heritage—that is, the historical origin of man from nonhuman forms.

The emergence of animal biology has had two particular effects on classical zoology. First, and somewhat paradoxically, there has been a reduced emphasis on zoology as a distinct subject of scientific study; for example, workers think of themselves as geneticists, ecologists, or physiologists who study animal rather than plant material. They often choose a problem congenial to their intellectual tastes, regarding the organism used as important only to the extent that it provides favourable experimental material. Current emphasis is, therefore, slanted toward the solution of general biological problems; contemporary zoology thus is to a great extent the sum total of that work done by biologists pursuing research on animal material.

Second, there is an increasing emphasis on a conceptual approach to the life sciences. This has resulted from the concepts that emerged in the late 19th and early 20th centuries: the cell theory; natural selection and evolution; the constancy of the internal environment; the basic similarity of genetic material in all living organisms; and the flow of matter and energy through ecosystems. The lives of microbes, plants, and animals now are approached using theoretical models as guides rather than by following the often restricted empiricism of earlier times. This is particularly true in molecular studies, in which the integration of biology with chemistry allows the techniques and quantitative emphases of the physical sciences to be used effectively to analyze living systems.

Areas of study. Although it is still useful to recognize many disciplines in animal biology—*e.g.,* anatomy or morphology; biochemistry and molecular biology; cell biology; developmental studies (embryology); ecology; ethology; evolution; genetics; physiology; and systematics—the research frontiers occur as often at the interfaces of two or more of these areas as within any given one.

Anatomy or morphology. Descriptions of external form and internal organization are among the earliest records available regarding the systematic study of animals. Aristotle was an indefatigable collector and dissector of animals. He found differing degrees of structural complexity, which he described with regard to ways of living, habits, and body parts. Although Aristotle had no formal system of classification, it is apparent that he viewed animals as arranged from the simplest to the most complex in an ascending series. Since man was even more complex than animals and, moreover, possessed a rational faculty, he therefore occupied the highest position and a special category. This hierarchical perception of the animate world proved to be useful in every century to the present, except that in the modern view there is no such "scale of nature," and there is change in time by evolution from the simple to the complex.

Aristotle's attempt at classification

After the time of Aristotle, Mediterranean science was centred at Alexandria, where the study of anatomy, particularly the central nervous system, flourished and, in fact, first became recognized as a discipline. Galen studied anatomy at Alexandria in the 2nd century and later dissected many animals. Much later, the contributions of the Renaissance anatomist Andreas Vesalius, though made in the context of medicine, as were those of Galen, stimulated to a great extent the rise of comparative anatomy. During the latter part of the 15th century and throughout the 16th century, there was a strong tradition in anatomy; important similarities were observed in the anatomy of different animals, and many illustrated books were published to record these observations.

But anatomy remained a purely descriptive science until the advent of functional considerations in which the correlation between structure and function was consciously investigated; as by French biologists Buffon and Cuvier. Cuvier cogently argued that a trained naturalist could deduce from one suitably chosen part of an animal's body the complete set of adaptations that characterized the organism. Because it was obvious that organisms with similar parts pursue similar habits, they were placed together in a system of classification. Cuvier pursued this viewpoint, which he called the theory of correlations, in a somewhat dogmatic manner and placed himself in opposition to the romantic natural philosophers, such as the German intellectual Johann Wolfgang von Goethe, who saw a tendency to ideal types in animal form. The tension between these schools of thought—adaptation as the consequence of necessary bodily functions and adaptation as an expression of a perfecting principle in nature—runs as a leitmotiv through much of biology, with overtones extending into the early 20th century.

The twin concepts of homology (similarity of origin) and analogy (similarity of appearance), in relation to structure, are the creation of the 19th-century British anatomist Richard Owen. Although they antedate the Darwinian view of evolution, the anatomical data on which they were based became, largely as a result of the work of the German comparative anatomist Carl Gegenbaur, important evidence in favour of evolutionary change, despite Owen's steady unwillingness to accept the view of diversification of life from a common origin.

In summary, anatomy moved from a purely descriptive phase as an adjunct to classificatory studies, into a partnership with studies of function and became, in the 19th century, a major contributor to the concept of evolution.

Taxonomy or systematics. Not until the work of Carolus Linnaeus did the variety of life receive a widely accepted systematic treatment. Linnaeus strove for a "natural method of arrangement," one that is now recognizable as an intuitive grasp of homologous relationships, reflecting evolutionary descent from a common ancestor; however, the natural method of arrangement sought by Linnaeus was more akin to the tenets of idealized morphology because he wanted to define a "type" form as epitomizing a species.

The binomial nomenclature of Linnaeus

It was in the nomenclatorial aspect of classification that Linnaeus created a revolutionary advance with the introduction of a Latin binomial system: each species received a Latin name, which was not influenced by local names and which invoked the authority of Latin as a language common to the learned people of that day. The Latin name has two parts. The first word in the Latin name for the dog, *Canis familiaris,* for example, indicates the larger category, or genus, to which dogs belong; the second word is the name of the species within the genus. In addition to species and genera, Linnaeus also recognized other classificatory groups, or taxa (singular taxon), which are still used; namely, order, class, and kingdom, to which have been added family (between genus and order) and phylum (between class and kingdom). Each of these can be divided further by the appropriate prefix of sub- or super-, as in subfamily or superclass. Linnaeus' great work, the *Systema naturae,* went through 12 editions during his lifetime; the 13th, and final, edition appeared posthumously. Although his treatment of the diversity of living things has been expanded in detail, revised in terms of taxonomic categories, and corrected in the light of continuing work—for example, Linnaeus treated whales as fish—it still sets the style and method, even to the use of Latin names, for contemporary nomenclatorial work.

Linnaeus sought a natural method of arrangement, but he actually defined types of species on the basis of idealized morphology. The greatest change from Linnaeus' outlook is reflected in the phrase "the new systematics," which was introduced in the 20th century and through which an explicit effort is made to have taxonomic schemes reflect evolutionary history. The basic unit of classification, the species, is also the basic unit of evolution—*i.e.,* a population of actually or potentially interbreeding individuals. Such a population shares, through interbreeding, its genetic resources. In so doing, it creates the gene pool—its total genetic material—that determines the biological resources of the species and on which natural selection continuously acts. This approach has guided work on

classifying animals away from somewhat arbitrary categorization of new species to that of recreating evolutionary history (phylogeny) and incorporating it in the system of classification. Modern taxonomists or systematists, therefore, are among the foremost students of evolution.

Physiology. The practical consequences of physiology have always been an unavoidable human concern, in both medicine and animal husbandry. Inevitably, from Hippocrates to the present, practical knowledge of human bodily function has accumulated along with that of domestic animals and plants. This knowledge has been expanded, especially since the early 1800s, by experimental work on animals in general, a study known as comparative physiology. The experimental dimension had wide applications following Harvey's demonstration of the circulation of blood. From then on, medical physiology developed rapidly; notable texts appeared, such as Albrecht von Haller's eight-volume work *Elementa Physiologiae Corporis Humani* (*Elements of Human Physiology*), which had a medical emphasis. Toward the end of the 18th century the influence of chemistry on physiology became pronounced through Antoine Lavoisier's brilliant analysis of respiration as a form of combustion. This French chemist not only determined that oxygen was consumed by living systems but also opened the way to further inquiry into the energetics of living systems. His studies further strengthened the mechanistic view, which holds that the same natural laws govern both the inanimate and the animate realms.

Physiological principles achieved new levels of sophistication and comprehensiveness with Bernard's concept of constancy of the internal environment, the point being that only under certain constantly maintained conditions is there optimal bodily function. His rational and incisive insights were augmented by concurrent developments in Germany, where Johannes Müller explored the comparative aspects of animal function and anatomy, and Justus von Liebig and Carl Ludwig applied chemical and physical methods, respectively, to the solution of physiological problems. As a result, many useful techniques were advanced—*e.g.*, means for precise measurement of muscular action and changes in blood pressure and means for defining the nature of body fluids.

The study of organ systems

By this time the organ systems—circulatory, digestive, endocrine, excretory, integumentary, muscular, nervous, reproductive, respiratory, and skeletal—had been defined, both anatomically and functionally, and research efforts were focussed on understanding these systems in cellular and chemical terms, an emphasis that continues to the present and has resulted in specialties in cell physiology and physiological chemistry. General categories of research now deal with the transportation of materials across membranes; the metabolism of cells, including synthesis and breakdown of molecules; and the regulation of these processes.

Interest has also increased in the most complex of physiological systems, the nervous system. Much comparative work has been done by utilizing animals with structures especially amenable to various experimental techniques; for example, the large nerves in squids have been extensively studied in terms of the transmission of nerve impulses, and insect and crustacean eyes have yielded significant information on patterns of sensory inputs. Most of this work is closely associated with studies on animal orientation and behaviour. Although the contemporary physiologist often studies functional problems at the molecular and cellular levels, he is also aware of the need to integrate cellular studies into the many-faceted functions of the total organism.

Embryology, or developmental studies. Embryonic growth and differentiation of parts have been major biological problems since ancient times. A 17th-century explanation of development assumed that the adult existed as a miniature—a homunculus—in the microscopic material that initiates the embryo. But in 1759 the German physician Caspar Friedrick Wolff firmly introduced into biology the interpretation that undifferentiated materials gradually become specialized, in an orderly way, into adult structures. Although this epigenetic process is now accepted as characterizing the general nature of development in both plants and animals, many questions remain to be solved. The French physician Marie François Xavier Bichat declared in 1801 that differentiating parts consist of various components called tissues; with the subsequent statement of the cell theory, tissues were resolved into their cellular constituents. The idea of epigenetic change and the identification of structural components made possible a new interpretation of differentiation. It was demonstrated that the egg gives rise to three essential germ layers out of which specialized organs, with their tissues, subsequently emerge. Then, following his own discovery of the mammalian ovum, von Baer in 1828 usefully applied this information when he surveyed the development of various members of the vertebrate groups. At this point, embryology, as it is now recognized, emerged as a distinct subject.

The concept of cellular organization had an effect on embryology that continues to the present day. In the 19th century, cellular mechanisms were considered essentially to be the basis for growth, differentiation, and morphogenesis, or molding of parts. The distribution of the newly formed cells of the rapidly dividing zygote (fertilized egg) was precisely followed to provide detailed accounts not only of the time and mode of germ layer formation but also of the contribution of these layers to the differentiation of tissues and organs. Such descriptive information provided the background for experimental work aimed at elucidating the role of chromosomes and other cellular constituents in differentiation. About 1895, before the formulation of the chromosomal theory of heredity, Theodor Boveri demonstrated that chromosomes show continuity from one cell generation to the next. In fact, biologists soon concluded that in all cells arising from a fertilized egg, half the chromosomes are of maternal and half of paternal origin. The discovery of the constant transmission of the original chromosomal endowment to all cells of the body served to deepen the mystery surrounding the factors that determine cellular differentiation.

The present view is that differential activity of genes is the basis for cellular and tissue differentiation; that is, although the cells of a multicellular body contain the same genetic information, different genes are active in different cells. The result is the formation of various gene products, which regulate the functional and structural differentiation of cells. The actual mechanism involved in the inactivation of certain genes and the activation of others, however, has not yet been established. That cells can move extensively throughout the embryo and selectively adhere to other cells, thus starting tissue aggregations, also contributes to development as does the fate of cells—*i.e.*, certain ones continue to multiply, others stop, and some die.

Research methods in embryology now exploit many experimental situations: both unicellular and multicellular forms; regeneration (replacement of lost parts) and normal development; and growth of tissues outside and inside the host. Hence, the processes of development can be studied with material other than embryos; and the study of embryology has become incorporated into the more inclusive subdiscipline of developmental biology.

Evolutionism. Darwin was not the first to speculate that organisms can change from generation to generation and so evolve, but he was the first to propose a mechanism by which the changes are accumulated. He proposed that heritable variations occur in conjunction with a never-ending competition for survival and that the variations favouring survival are automatically preserved. In time, therefore, the continued accumulation of variations results in the emergence of new forms. Because the variations that are preserved relate to survival, the survivors are highly adapted to their environment. To this process Darwin gave the apt name natural selection.

Natural selection

Many of Darwin's predecessors, notably Jean-Baptiste Lamarck, were willing to accept the idea of species variation, even though to do so meant denying the doctrine of special creation and the static-type species of Linnaeus. But they argued that some idealized perfecting principle, expressed through the habits of an organism, was the basis of variation. The contrast between the romanticism of Lamarck and the objective analysis of Darwin clearly

reveals the type of revolution provoked by the concept of natural selection. Although mechanistic explanations had long been available to biologists—forming, for example, part of Harvey's explanation of blood circulation—they did not pervade the total structure of biological thinking until the advent of Darwinism.

There were two immediate consequences of Darwin's viewpoints. One has involved a reappraisal of all subject areas of biology; reinterpretations of morphology and embryology are good examples. The comparative anatomy of the British anatomist Owen became a cornerstone of the evidence for evolution, and German anatomists provided the basis for the comment that evolutionary thinking was born in England but gained its home in Germany. The reinterpretation of morphology carried over into the study of fossil forms, as paleontologists sought and found evidence of gradual change in their study of fossils. But some workers, although accepting evolution in principle, could not easily interpret the changes in terms of natural selection. The German paleontologist Otto Schindewolf, for example, found in shelled mollusks called ammonites evidence of progressive complexity and subsequent simplification of forms. The American paleontologist George Gaylord Simpson, however, has been a consistent interpreter of vertebrate fossils by Darwinian selection. Embryology was seen in an evolutionary light when the German zoologist Ernst Haeckel proposed that the epigenetic sequence of embryonic development (ontogeny) repeated its evolutionary history (phylogeny). Thus, the presence of gill clefts in the mammalian embryo and also in less highly evolved vertebrates can be understood as a remnant of a common ancestor.

The other consequence of Darwinism—to make more explicit the origin and nature of heritable variations and the action of natural selection on them—depended on the emergence of the following: genetics and the elucidation of the rules of Mendelian inheritance; the concept of the gene as the unit of inheritance; and the nature of gene mutation. The development of these ideas provided the basis for the genetics of natural populations.

The subject of population genetics began with the Mendelian laws of inheritance and now takes into account selection, mutation, migration (movement into and out of a given population), breeding patterns, and population size. These factors affect the genetic makeup of a group of organisms that either interbreed or have the potential to do so; *i.e.*, a species. Accurate appraisal of these factors allows precise predictions regarding the content of a given gene pool over significant periods of evolutionary time. From work involving population genetics has come the realization, eloquently documented by two contemporary American evolutionists, Theodosius Dobzhansky and Ernst Mayer, that the species is the basic unit of evolution. The process of speciation occurs as a gene pool breaks up to form isolated gene pools. When selection pressures similar to those of the original gene pool persist in the new gene pools, similar functions and the similar structures on which they depend also persist. When selection pressures differ, however, differences arise. Thus, the process of speciation through natural selection preserves the evolutionary history of a species. The record may be discerned not only in the gross, or macroscopic, anatomy of organisms but also in their cellular structure and molecular organization. Significant work now is carried out, for example, on the homologies of the nucleic acids and proteins of different species.

The process of speciation

Genetics. The problem of heredity had been the subject of careful study before its definitive analysis by Mendel. As with Darwin's predecessors, those of Mendel tended to idealize and interpret all inherited traits as being transmitted through the blood or as determined by various "humors" or other vague entities in animal organisms. When studying plants, Mendel was able to free himself of anthropomorphic and holistic explanations. By studying seven carefully defined pairs of characteristics—*e.g.*, tall and short plants; red and white flowers, etc.—as they were transmitted through as many as three successive generations, he was able to establish patterns of inheritance that apply to all sexually reproducing forms. Darwin, who was searching for an explanation of inheritance, apparently never saw Mendel's work, which was published in 1866 in the obscure journal of his local natural history society; it was simultaneously rediscovered in 1900 by three different European geneticists.

Further progress in genetics was made early in the 20th century, when it was realized that heredity factors are found on chromosomes. The term gene was coined for these factors. Studies by the American geneticist Thomas Hunt Morgan on the fruit fly (*Drosophila*), moved animal genetics to the forefront of genetic research. The work of Morgan and his students established such major concepts as the linear array of genes on chromosomes; the exchange of parts between chromosomes; and the interaction of genes in determining traits, including sexual differences. In 1927 one of Morgan's former students, Hermann Muller, used X-rays to induce the mutations (changes in genes) in the fruit fly, thereby opening the door to major studies on the nature of variation.

Meanwhile, other organisms were being used for genetic studies, most notably fungi and bacteria. The results of this work provided insights into animal genetics just as principles initially obtained from animal genetics provided insight into botanical and microbial forms. Work continues not only on the genetics of humans, domestic animals, and plants but also on the control of development through the orderly regulation of gene action in different cells and tissues.

Cellular and molecular biology. Although the cell was recognized as the basic unit of life early in the 19th century, its most exciting period of inquiry has probably occurred since the 1940s. The new techniques developed since that time, notably the perfection of the electron microscope and the tools of biochemistry, have changed the cytological studies of the 19th and early 20th centuries from a largely descriptive inquiry, dependent on the light microscope, into a dynamic, molecularly oriented inquiry into fundamental life processes.

The so-called cell theory, which was enunciated about 1838, was never actually a theory. As Edmund Beecher Wilson, the noted American cytologist, stated in his great work, *The Cell,*

> By force of habit we still continue to speak of the cell 'theory' but it is a theory only in name. In substance it is a comprehensive general statement of fact and as such stands today beside the evolution theory among the foundationstones of modern biology.

More precisely, the cell doctrine was an inductive generalization based on the microscopial examination of certain plant and animal species.

Rudolf Virchow, a German medical officer specializing in cellular pathology, first expressed the fundamental dictum regarding cells in his phrase *omnis cellula e cellula* (all cells from cells). For cellular reproduction is the ultimate basis of the continuity of life; the cell is not only the basic structural unit of life but also the basic physiological and reproductive unit. All areas of biology were affected by the new perspective afforded by the principle of cellular organization. Especially in conjunction with embryology was the study of the cell most prominent in animal biology. The continuity of cellular generations by reproduction also had implications for genetics. It is little wonder, then, that the full title of Wilson's survey of cytology at the turn of the century was *The Cell: Its Role in Development and Heredity.*

Cells as the units of life

The study of the cell nucleus, its chromosomes, and their behaviour served as the basis for understanding the regular distribution of genetic material during both sexual and asexual reproduction. This orderly behaviour of the nucleus made it appear to dominate the life of the cell, for by contrast the components of the rest of the cell appeared to be randomly distributed.

The biochemical study of life had helped in the characterization of the major molecules of living systems—proteins, nucleic acids, fats, and carbohydrates—and in the understanding of metabolic processes. That nucleic acids are a distinctive feature of the nucleus was recognized after their discovery by the Swiss biochemist Johann Friedrich Miescher in 1869. In 1944 a group of American bacteri-

ologists, led by Oswald T. Avery, published work on the causative agent of pneumonia in mice (a bacterium) that culminated in the demonstration that deoxyribonucleic acid (DNA) is the chemical basis of heredity. Discrete segments of DNA correspond to genes, or Mendel's hereditary factors. Proteins were discovered to be especially important for their role in determining cell structure and in controlling chemical reactions.

The advent of techniques for isolating and characterizing proteins and nucleic acids now allows a molecular approach to essentially all biological problems—from the appearance of new gene products in normal development or under pathological conditions to a monitoring of changes in and between nerve cells during the transmission of nerve impulses.

Ecology. The harmony that Linnaeus found in nature, which redounded to the glory and wisdom of a Judaeo-Christian god, was the 18th-century counterpart of the balanced interaction now studied by ecologists. Linnaeus recognized that plants are adapted to the regions in which they grow, that insects play a role in flower pollination, and that certain birds prey on insects and are in turn eaten by other birds. This realization implies, in contemporary terms, the flow of matter and energy in a definable direction through any natural assemblage of plants, animals, and microorganisms. Such an assemblage, termed an ecosystem, starts with the plants, which are designated as producers because they maintain and reproduce themselves at the expense of energy from sunlight and inorganic materials taken from the nonliving environment around them (earth, air, and water). Animals are called consumers because they ingest plant material or other animals that feed on plants, using the energy stored in this food to sustain themselves. Lastly, the organisms known as decomposers, mostly fungi and bacteria, break down plant and animal material and return it to the environment in a form that can be used again by plants in a constantly renewed cycle.

Components of an ecosystem

The term ecology, first formulated by Haeckel in the latter part of the 19th century as "oecology" (from the Greek word for house, *oikos*), referred to the dwelling place of organisms in nature. In the 1890s various European and U.S. scientists laid the foundations for modern work through studies of natural ecosystems and the populations of organisms contained within them.

Animal ecology, the study of consumers and their interactions with the environment, is very complex; attempts to study it usually focus on one particular aspect. Some studies, for example, involve the challenge of the environment to individuals with special adaptations (*e.g.,* water conservation in desert animals); others may involve the role of one species in its ecosystem or the ecosystem itself. Food-chain sequences have been determined for various ecosystems, and the efficiency of the transfer of energy and matter within them has been calculated so that their capacity is known; that is, productivity in terms of numbers of organisms or weight of living matter at a specific level in the food chain can be accurately determined (see ECOSYSTEMS; BIOSPHERE).

In spite of advances in understanding animal ecology, this subject area of zoology does not yet have the major unifying theoretical principles found in genetics (gene theory) or evolution (natural selection).

Ethology. The study of animal behaviour (ethology) is largely a 20th-century phenomenon and is exclusively a zoological discipline. Only animals have nervous systems with their implications for perception, coordination, orientation, learning, and memory. Not until the end of the 19th century did animal behaviour become free from anthropocentric interests and assume an importance in its own right. The British behaviorist C. Lloyd Morgan was probably most influential with his emphasis on parsimonious explanations—*i.e.,* that the explanation "which stands lower in the psychological scale" must be invoked first. This principle is exemplified in the American Herbert Spencer Jennings' pioneering work in 1906 on *The Behavior of Lower Organisms.*

The study of animal behaviour now includes many diverse topics, ranging from swimming patterns of protozoans to socialization and communication among the great apes. Many disparate hypotheses have been proposed in an attempt to explain the variety of behavioral patterns found in animals. They focus on the mechanisms that stimulate courtship in reproductive behaviour of such diverse groups as spiders, crabs, and domestic fowl; and on whole life histories, starting from the special attachment of newly born ducks and goats to their actual mothers or to surrogate (substitute) mothers. The latter phenomenon, called imprinting, has been intensively studied by the Austrian ethologist Konrad Lorenz. Physiologically oriented behaviour now receives much attention; studies range from work on conditioned reflexes to the orientation of crustaceans and the location and communication of food among bees; such diversity of material is one measure of the somewhat diffuse but exciting current state of these studies.

General trends. Zoology has become animal biology—that is, the life sciences display a new unity, one that is founded on the common basis of all life; on the gene pool-species organization of organisms; and on the obligatory interacting of the components of ecosystems. Even as regards the specialized features of animals—involving physiology, development, or behaviour—the current emphasis is on elucidating the broad biological principles that identify animals as one aspect of nature. Zoology has thus given up its exclusive emphasis on animals—an emphasis maintained from Aristotle's time well into the 19th century—in favour of a broader view of life. The successes in applying physical and chemical ideas and techniques to life processes have not only unified the life sciences but have also created bridges to other sciences in a way only dimly foreseen by earlier workers. The practical and theoretical consequences of this trend have just begun to be realized.

Zoology as animal biology

Methods in zoology. Because the study of animals may be concentrated on widely different topics, such as ecosystems and their constituent populations, organisms, cells, and chemical reactions, specific techniques are needed for each kind of investigation. The emphasis on the molecular basis of genetics, development, physiology, behaviour, and ecology has placed increasing importance on those techniques involving cells and their many components. Microscopy, therefore, is a necessary technique in zoology, as are certain physicochemical methods for isolating and characterizing molecules. Computer technology also has a special role in the analysis of animal life. These newer techniques are used in addition to the many classical ones—measurement and experimentation at the tissue, organ, organ system, and organismic levels.

Microscopy. In addition to continuous improvements in the techniques of staining cells, so that their components can be seen clearly, the light used in microscopy can now be manipulated to make visible certain structures in living cells that are otherwise undetectable. The ability to observe living cells is an advantage of light microscopes over electron microscopes; the latter require the cells to be in an environment that kills them. The particular advantage of the electron microscope, however, is its great powers of magnification. Theoretically, it can resolve single atoms; in biology, however, magnifications of lesser magnitude are most useful in determining the nature of structures lying between whole cells and their constituent molecules.

Separation and purification techniques. The characterization of components of cellular systems is necessary for biochemical studies. The specific molecular composition of cellular organelles, for example, affects their shape and density (mass per unit volume); as a result, cellular components settle at different rates (and thus can be separated) when they are spun in a centrifuge.

Other methods of purification rely on other physical properties. Molecules vary in their affinity for the positive or negative pole of an electrical field. Migration to or away from these poles, therefore, occurs at different rates for different molecules and allows their separation; the process is called electrophoresis. The separation of molecules by liquid solvents exploits the fact that the molecules differ in their solubility, and hence they migrate to various degrees as a solvent flows past them. This process, known as chromatography because of the colour used to identify

the position of the migrating materials, yields samples of extraordinarily high purity.

Radioactive tracers. Radioactive compounds are especially useful in biochemical studies involving metabolic pathways of synthesis and degradation. Radioactive compounds are incorporated into cells in the same way as their nonradioactive counterparts. These compounds provide information on the sites of specific metabolic activities within cells and insights into the fates of these compounds in both organisms and the ecosystem.

Computers. Computers process information using their own general language, which is able to complete calculations as complex and diverse as statistical analyses and determinations of enzymatically controlled reaction rates. Computers with access to extensive data files can select information associated with a specific problem and display it to aid the researcher in formulating possible solutions. They help perform routine examinations such as scanning chromosome preparations in order to identify abnormalities in number or shape. Test organisms can be electronically monitored with computers, so that adjustments can be made during experiments; this procedure improves the quality of the data and allows experimental situations to be fully exploited. Computer simulation is important in analyzing complex problems; as many as 100 variables, for example, are involved in the management of salmon fisheries. Simulation makes possible the development of models that approach the complexities of conditions in nature, a procedure of great value in studying wildlife management and related ecological problems.

Importance of computers in research

Applied zoology. Animal-related industries produce food (meats and dairy products), hides, furs, wool, organic fertilizers, and miscellaneous chemical byproducts. There has been a dramatic increase in the productivity of animal husbandry since the 1870s, largely as a consequence of selective breeding and improved animal nutrition. The purpose of selective breeding is to develop livestock whose desirable traits have strong heritable components and can therefore be propagated. Heritable components are distinguished from environmental factors by determining the coefficient of heritability, which is defined as the ratio of variance in a gene-controlled character to total variance.

Another aspect of food production is the control of pests. The serious side effects of some chemical pesticides make extremely important the development of effective and safe control mechanisms. Animal food resources include commercial fishing. The development of shellfish resources and fisheries management (*e.g.*, growth of fish in rice paddies in Asia) are important aspects of this industry. (E.D.H.)

BOTANY

Botany is the study of plants. Plants were of paramount importance to early man; he depended upon them as sources of food, shelter, clothing, medicine, ornament, tools, and magic. Today it is known that, in addition to their practical and economic values, green plants are indispensable to all life on Earth: through the process of photosynthesis, plants transform energy from the sun into the chemical energy of food, which makes all life possible. A second unique and important capacity of green plants is the formation and release of oxygen as a by-product of photosynthesis. The oxygen of the atmosphere, so absolutely essential to many forms of life, represents the accumulation of over 3,500,000,000 years of photosynthesis by green plants.

Although the many steps in the process of photosynthesis have become fully understood only in recent years, even in prehistoric times man somehow recognized intuitively that some important relation existed between the sun and plants. Such recognition is suggested by the fact that, in primitive tribes and early civilizations, worship of the sun was often combined with the worship of plants.

Earliest man, like the other anthropoid mammals (*e.g.*, apes, monkeys), depended totally upon the natural resources of his environment, which, until he developed methods for hunting, consisted almost completely of plants. The behaviour of pre-Stone Age man can be inferred by studying the botany of aboriginal peoples in various parts of the world. Isolated tribal groups in South America, Africa, and New Guinea, for example, have extensive knowledge about plants and distinguish hundreds of kinds according to their utility, as edible, poisonous, or otherwise important in their culture. They have developed surprisingly sophisticated systems of nomenclature and classification, which approximate the binomial system (*i.e.*, generic and specific names) found in modern biology. The urge to recognize different kinds of plants and to give them names thus seems to be as old as the human race.

In time plants were not only collected by primitive man but also grown by him. This domestication resulted not only in the development of agriculture but also in a greater stability of human populations that had previously been nomadic. From the settling down of agricultural peoples in places where they could depend upon adequate food supplies came the first villages and the earliest civilizations.

Because of the long preoccupation of man with plants, a large body of folklore, general information, and actual scientific data has accumulated, which has become the basis for the science of botany.

The basis of botany

Historical background. Theophrastus, a Greek philosopher who studied first with Plato and then became a disciple of Aristotle, is credited with founding botany. Only two of an estimated 200 botanical treatises written by him are known to science: originally written in Greek about 300 BC, they have survived in the form of Latin manuscripts, *De causis plantarum* and *De historia plantarum.* His basic concepts of morphology, classification, and the natural history of plants, accepted without question for many centuries, are now of interest primarily because of Theophrastus' independent and philosophical viewpoint.

Pedanius Dioscorides, a Greek botanist of the 1st century AD, was the most important botanical writer after Theophrastus. In his major work, an herbal in Greek, he described some 600 kinds of plants, with comments on their habit of growth and form as well as on their medicinal properties. Unlike Theophrastus, who classified plants as trees, shrubs, and herbs, Dioscorides grouped his plants under three headings: as aromatic, culinary, and medicinal. His herbal, unique in that it was the first treatment of medicinal plants to be illustrated, remained for about 15 centuries the last word on medical botany in Europe.

From the 2nd century BC to the 1st century AD, a succession of Roman writers—Cato, Varro, Virgil, and Columella—prepared Latin manuscripts on farming, gardening, and fruit growing but showed little evidence of the spirit of scientific inquiry for its own sake that was so characteristic of Theophrastus. In the 1st century AD, Pliny the Elder, though no more original than his Roman predecessors, seemed more industrious as a compiler. His *Historia naturalis*—an encyclopaedia of 37 volumes, compiled from some 2,000 works representing 146 Roman and 327 Greek authors—has 16 volumes devoted to plants. Although uncritical and containing much misinformation, this work contains much information otherwise unavailable, since most of the volumes to which he referred have been destroyed.

The printing press revolutionized the availability of all types of literature, including that of plants. In the 15th and 16th centuries, many herbals were published with the purpose of describing plants useful in medicine. Written by physicians and medically oriented botanists, the earliest herbals were based largely on the work of Dioscorides and to a lesser extent on Theophrastus, but gradually they became the product of original observation. The increasing objectivity and originality of herbals through the decades is clearly reflected in the improved quality of the woodcuts prepared to illustrate these books.

The significance of herbals

In 1552 an illustrated manuscript on Mexican plants, written in Aztec, was translated into Latin by Badianus; other similar manuscripts known to have existed seem to have disappeared. Whereas herbals in China date back much further than those in Europe, they have become known only recently and so have contributed little to the progress of Western botany.

The invention of the optical lens during the 16th century and the development of the compound microscope about 1590 opened an era of rich discovery about plants; prior to that time, all observations by necessity had been made

with the unaided eye. The botanists of the 17th century turned away from the earlier emphasis on medical botany and began to describe all plants, including the many new ones that were being introduced in large numbers from Asia, Africa, and America. Among the most prominent botanists of this era was Gaspard Bauhin, who for the first time developed, in a tentative way, many botanical concepts still held as valid. In 1665 Robert Hooke published, under the title *Micrographia,* the results of his microscopic observations on several plant tissues. He is remembered as the coiner of the word cell, referring to the cavities he observed in thin slices of cork; his observation that living cells contain sap and other materials too often has been forgotten. In the following decade, Nehemiah Grew and Marcello Malpighi founded plant anatomy; in 1671 they communicated the results of microscopic studies simultaneously to the Royal Society of London, and both later published major treatises.

The founding of plant anatomy

Experimental plant physiology began with the brilliant work of Stephen Hales, who published his observations on the movements of water in plants under the title *Vegetable Staticks* (1727). His conclusions on the mechanics of water transpiration in plants are still valid, as is his discovery—at the time a startling one—that air contributes something to the materials produced by plants. In 1774, Joseph Priestley showed that plants exposed to sunlight give off oxygen, and Jan Ingenhousz demonstrated, in 1779, that plants in the dark give off carbon dioxide. In 1804 Nicolas de Saussure demonstrated convincingly that plants in sunlight absorb water and carbon dioxide and increase in weight, as had been reported by Hales nearly a century earlier.

The widespread use of the microscope by plant morphologists provided a turning point in the 18th century—botany became largely a laboratory science. Until the invention of simple lenses and the compound microscope, the recognition and classification of plants were, for the most part, based on such large morphological aspects of the plant as size, shape, and external structure of leaves, roots, and stems. Such information was also supplemented by observations on more subjective qualities of plants, such as edibility and medicinal uses.

In 1753 Linnaeus published his master work, *Species Plantarum,* which contains careful descriptions of 6,000 species of plants from all of the parts of the world known at the time. In this work, which is still the basic reference work for modern plant taxonomy, Linnaeus established the practice of binomial nomenclature—that is, the denomination of each kind of plant by two words, the genus name and the specific name, as *Rosa canina,* the dog rose. Binomial nomenclature had been introduced much earlier by some of the herbalists, but it was not generally accepted; most botanists continued to use cumbersome formal descriptions, consisting of many words, to name a plant. Linnaeus for the first time put the contemporary knowledge of plants into an orderly system, with full acknowledgment to past authors, and produced a nomenclatural methodology so useful that it has not been greatly improved upon. Linnaeus also introduced a "sexual system" of plants, by which the numbers of flower parts—especially stamens, which produce male sex cells, and styles, which are prolongations of plant ovaries that receive pollen grains—became useful tools for easy identification of plants. This simple system, though effective, had many imperfections. Other classification systems, in which as many characters as possible were considered in order to determine the degree of relationship, were developed by other botanists; indeed, some appeared before the time of Linnaeus. The application of the concepts of Charles Darwin (on evolution) and Gregor Mendel (on genetics) to plant taxonomy has provided insights into the process of evolution and the production of new species.

Binomial nomenclature

Systematic botany now uses information and techniques from all the subdisciplines of botany, incorporating them into one body of knowledge. Phytogeography (the biogeography of plants), plant ecology, population genetics, and various techniques applicable to cells—cytotaxonomy and cytogenetics—have contributed greatly to the current status of systematic botany and have to some degree become part of it. More recently, phytochemistry, computerized statistics, and fine-structure morphology have been added to the activities of systematic botany.

The 20th century has seen an enormous increase in the rate of growth of research in botany and the results derived therefrom. The combination of more botanists, better facilities, and new technologies, all with the benefit of experience from the past, has resulted in a series of new discoveries, new concepts, and new fields of botanical endeavour. Some important examples are mentioned below.

New and more precise information is being accumulated concerning the process of photosynthesis, especially with reference to energy-transfer mechanisms.

The discovery of the pigment phytochrome, which constitutes a previously unknown light-detecting system in plants, has greatly increased knowledge of the influence of both internal and external environment on the germination of seeds and the time of flowering.

The discovery of phytochrome

Several types of plant hormones (internal regulatory substances) have been discovered—among them auxin, gibberellin, and kinetin—whose interactions provide a new concept of the way in which the plant functions as a unit.

The discovery that plants need certain trace elements usually found in the soil has made it possible to cultivate areas lacking some essential element by adding it to the deficient soil.

The development of genetical methods for the control of plant heredity has made possible the generation of improved and enormously productive crop plants.

The development of radioactive-carbon dating of plant materials as old as 50,000 years is useful to the paleobotanist, the ecologist, the archaeologist, and especially to the climatologist, who now has a better basis on which to predict climates of future centuries.

The discovery of alga-like and bacteria-like fossils in Precambrian rocks has pushed the estimated origin of plants on Earth to 3,500,000,000 years ago.

The isolation of antibiotic substances from fungi and bacteria-like organisms has provided control over many bacterial diseases and has contributed biochemical information of basic scientific importance as well.

Areas of study. For convenience, but not on any mutually exclusive basis, several major areas or approaches are recognized commonly as disciplines of botany; these are morphology, physiology, ecology, and systematics.

Morphology. Morphology deals with the structure and form of plants and includes such subdivisions as: cytology, the study of the cell; histology, the study of tissues; anatomy, the study of the organization of tissues into the organs of the plant; reproductive morphology, the study of life cycles; and experimental morphology, or morphogenesis, the study of development.

Physiology. Physiology deals with the functions of plants. Its development as a subdiscipline has been closely interwoven with the development of other aspects of botany, especially morphology. In fact, structure and function are sometimes so closely related that it is impossible to consider one independently of the other. The study of function is indispensable for the interpretation of the incredibly diverse nature of plant structures. In other words, around the functions of the plant, structure and form have evolved. Physiology also blends imperceptibly into the fields of biochemistry and biophysics, as the research methods of these fields are used to solve problems in plant physiology.

The close relationship of plant form and function

Ecology. Ecology deals with the mutual relationships and interactions between organisms and their physical environment. The physical factors of the atmosphere, the climate, and the soil affect the physiological functions of the plant in all its manifestations, so that, to a large degree, plant ecology is a phase of plant physiology under natural and uncontrolled conditions; in fact, it has been called "outdoor physiology." Plants are intensely sensitive to the forces of the environment, and both their association into communities and their geographical distribution are determined largely by the character of climate and soil. Moreover, the pressures of the environment and of organisms upon each other are potent forces, which lead to new species and the continuing evolution of larger groups.

Systematics. Systematics deals with the identification and ranking of all plants; it includes classification and nomenclature (naming) and enables the botanist to comprehend the broad range of plant diversity and evolution.

Other subdisciplines. In addition to the major subdisciplines, several specialized branches of botany have developed as a matter of custom or convenience. Among them are bacteriology, the study of bacteria; mycology, the study of fungi; algology or phycology, the study of algae; bryology, the study of mosses and liverworts; pteridology, the study of ferns and their relatives; and paleobotany, the study of fossil plants. Palynology is the study of modern and fossil pollen and spores, with particular reference to their identification; plant pathology deals with the diseases of plants; economic botany deals with plants of practical use to man; and ethnobotany covers the use of plants by aboriginal peoples, now and in the distant past.

Botany also relates to other scientific disciplines in many ways, especially to zoology, medicine, microbiology, agriculture, chemistry, forestry, and horticulture, and specialized areas of botanical information may relate closely to such humanistic fields as art, literature, history, religion, archaeology, sociology, and psychology.

Fundamentally, botany remains a pure science, including any research into the life of plants and limited only by man's technical means of satisfying his curiosity. It has often been considered an important part of a liberal education, not only because it is necessary for an understanding of agriculture, horticulture, forestry, pharmacology, and other applied arts and sciences, but also because an understanding of plant life is related to life in general.

The aesthetic influence of plants

Because man has always been dependent upon plants and surrounded by them, he has woven them into his designs, into the ornamentation of his life, even into his religious symbolism. A Persian carpet and a bedspread from a New England loom both employ conventional designs derived from the forms of flowers. Medieval painters and great masters of the Renaissance represented various revered figures surrounded by roses, lilies, violets, and other flowers, which symbolized chastity, martyrdom, humility, and other Christian attributes.

Methods in botany. *Morphological aspects.* The invention of the compound microscope provided a valuable and durable instrument for the investigation of the inner structure of plants. Early plant morphologists, especially those studying cell structure, were handicapped as much by the lack of adequate knowledge of how to prepare specimens as they were by the imperfect microscopes of the time. A revolution in the effectiveness of microscopy occurred in the second half of the 19th century with the introduction of techniques for fixing cells and for staining their component parts. Before the development of these techniques, the cell, viewed with the microscope, appeared as a minute container with a dense portion called the nucleus. The discovery that parts of the cell respond to certain stains made observation easier. The development of techniques for preparing tissues of plants for microscopic examination was continued in the 1870s and 1880s and resulted in the gradual refinement of the field of nuclear cytology, or karyology. Chromosomes were recognized as constant structures in the life cycle of cells, and the nature and meaning of meiosis, a type of cell division in which the daughter cells have half the number of chromosomes of the parent, was discovered; without this discovery, the significance of Mendel's laws of heredity might have gone unrecognized. Vital stains, dyes that can be used on living material, were first used in 1886 and have been greatly refined since then.

Improvement of the methodology of morphology has not been particularly rapid, even though satisfactory techniques for histology, anatomy, and cytology have been developed. The embedding of material in paraffin wax, the development of the rotary microtome for slicing very thin sections of tissue for microscope viewing, and the development of stain techniques are refinements of previously known methods. The invention of the phase microscope made possible the study of unfixed and unstained living material—hopefully nearer its natural state. The development of the electron microscope, however, has provided the plant morphologist with a new dimension of magnification of the structure of plant cells and tissues. The fine structure of the cell and of its components, such as mitochondria and the Golgi apparatus, have come under intensive study. Knowledge of the fine structure of plant cells has enabled investigators to determine the sites of important biochemical activities, especially those involved in the transfer of energy during photosynthesis and respiration. The scanning electron microscope, a relatively recent development, provides a three-dimensional image of surface structures at very great magnifications.

Fine structure a clue to biochemical activities

For experimental research on the morphogenesis of plants, isolated organs in their embryonic stage, clumps of cells, or even individual cells are grown. One of the most interesting techniques developed thus far permits the growing of plant tissue of higher plants as single cells; aeration and continuous agitation keep the cells suspended in the liquid culture medium.

Physiological aspects. Plant physiology and plant biochemistry are the most technical areas of botany; most major advances in physiology also reflect the development of either a new technique or the dramatic refinement of an earlier one to give a new degree of precision. Fortunately, the methodology of measurement has been vastly improved in recent decades, largely through the development of various electronic devices. The phytotron at the California Institute of Technology represents the first serious attempt to control the environment of living plants on a relatively large scale; much important information has been gained concerning the effects on plants of day length and night length and the effects on growth, flowering, and fruiting of varying night temperatures. Critical measurements of other plant functions have also been obtained.

Certain complex biochemical processes, such as photosynthesis and respiration, have been studied stepwise by immobilizing the process through the use of extreme cold or biochemical inhibitors and by analyzing the enzymatic activity of specific cell contents after spinning cells at very high speeds in a centrifuge. The pathways of energy transfer from molecule to molecule during photosynthesis and respiration have been determined by biophysical methods, especially those utilizing radioactive isotopes.

An investigation of the natural metabolic products of plants requires, in general, certain standard biochemical techniques—*e.g.*, gas and paper chromatography, electrophoresis, and various kinds of spectroscopy, including infrared, ultraviolet, and nuclear magnetic resonance. Useful information on the structure of the extremely large cellulose molecule has been provided by X-ray crystallography.

Ecological aspects. When plant ecology first emerged as a subscience of botany, it was largely descriptive; today, however, it has become a common meeting ground for all the plant sciences, as well as for other sciences. In addition, it has become much more quantitative. As a result, the tools and methods of plant ecologists are those available for measuring the intensity of the environmental factors that impinge on the plant and the reaction of the plant to these factors. The extent of the variability of many physical factors must be measured. The integration and reporting of such measurements, which cannot be regarded as constant, may therefore conceal some of the most dynamic and significant aspects of the environment and the responses of the plant to them. Because the physical environment is a complex of biological and physical components, it is measured by biophysical tools. The development of electronic measuring and recording devices has been crucial for a better understanding of the dynamics of the environment. Such devices, however, produce so much information that computer techniques must be used to reduce the data to meaningful results.

The ecologist, concerned primarily with measuring the effect of the external environment on a plant, adapts the methodology of the plant physiologist to field conditions.

The plant sociologist

The plant sociologist, on the other hand, is concerned with both the relation of different kinds of plants to each other and the nature and constitution of their association into natural communities. One widely used technique in this respect is to count the various kinds of plants within a standard area in order to determine such factors as the

percentage of ground cover, dominance of species, aggressiveness, and other characteristics of the community. In general, the plant sociologist has relatively few quantitative factors to measure and must therefore take a subjective and intuitive approach, which, nevertheless, gives extremely useful results and some degree of predictability.

Some ecologists are most concerned with the inner environment of the plant and the way in which it reacts to the external environment. This approach, which is essentially physiological and biochemical, is useful for determining energy flow in ecosystems. The physiological ecologist is also concerned with evaluating the adaptations that certain plants have made toward survival in a hostile environment.

In summary, the techniques and methodology of plant ecology are as diverse and as varied as the large number of sciences that are drawn upon by ecologists. Completely new techniques, although few, are important; among them are techniques for measuring the amount of radioactive carbon-14 in plant deposits up to 50,000 years old. The most important new method in plant ecology is the rapidly growing use of computer techniques for handling vast amounts of data. Furthermore, modern digital computers can be used to simulate simple ecosystems and to analyze real ones.

Taxonomic aspects. Experimental research under controlled conditions, made possible by botanical gardens and their ranges of greenhouses and controlled environmental chambers, has become an integral part of the methodology of modern plant taxonomy.

A second major tool of the taxonomist is the herbarium, a reference collection consisting of carefully selected and dried plants attached to paper sheets of a standard size and filed in a systematic way so that they may be easily retrieved for examination. Each specimen is a reference point representing the features of one plant of a certain species; it lasts indefinitely if properly cared for, and, if the species becomes extinct in nature—as hundreds have—it remains the only record of the plant's former existence. The library is also an essential reference resource for descriptions and illustrations of plants that may not be represented in a particular herbarium.

One of the earliest methods of the taxonomist, the study of living plants in the field, has benefitted greatly by fast and easy methods of transportation; botanists may carry on fieldwork in any part of the world and make detailed studies of the exact environmental conditions under which each species grows.

New approaches in systematic botany

During the present century, many new approaches have been applied to the elucidation of problems in systematic botany. The transmission electron microscope and the scanning electron microscope have added to the knowledge of plant morphology, upon which classical taxonomy so much depends.

Refined methods for cytological and genetical studies of plants have given the taxonomist new insights into the origin of the great diversity among plants, especially the mechanisms by which new species arise and by which they then maintain their individuality in nature. From such studies have arisen further methods and also the subdisciplines of cytotaxonomy, cytogenetics, and population genetics.

Phytochemistry, or the chemistry of plants, one of the early subdivisions of organic chemistry, has been of great importance in the identification of plant substances of medicinal importance. With the development of new phytochemical methods, new information has become available for use in conjunction with plant taxonomy; thus has arisen the modern field of chemotaxonomy, or biochemical systematics. Each species tends to differ to some degree from every other species, even in the same genus, in the biochemistry of its natural metabolic products. Sometimes the difference is subtle and difficult to determine; sometimes it is obvious and easily perceptible. With new analytical techniques, a large number of individual compounds from one plant can be identified quickly and with certainty. Such information is extremely useful in adding confirmatory or supplemental evidence of an objective and quantitative nature. An interesting by-product of chemical plant taxonomy has resulted in understanding better the restriction of certain insects to specific plants.

Computer techniques have recently been applied to plant taxonomy to develop a new field, numerical taxonomy, or taximetrics, by which relationships between plant species or those within groups of species are determined quantitatively and depicted graphically. Another method measures the degree of molecular similarity of deoxyribonucleic acid (DNA) molecules in different plants. By this procedure it should be possible to determine the natural taxonomic relationships among different plants and plant groups by determining the extent of the relationship of their DNA's: closely related plants will have more similarities in their DNA's than will unrelated ones. (W.C.St.)

The use of nucleic acids in taxonomy

MICROBIOLOGY

The 17th-century discovery that living forms exist that are invisible to the naked eye was a dramatic one in man's history, for, from the 13th century onward, it had been postulated that "invisible" organisms were responsible for decay and disease. The word microbe was coined in the latter quarter of the 19th century to describe these organisms, all of which were thought to be related. As microbiology eventually developed into a separate science, it was found that microbes comprise a very large group of extremely diverse organisms; thus, microbiology became subdivided into various disciplines—*e.g.*, bacteriology, protozoology, and virology. The diversity of microbes, or microorganisms as they are now commonly called, has meant that it is almost impossible for one person to be knowledgeable in all of the disciplines grouped under microbiology.

Microbiology involves the identification of microorganisms and the study of their structure and function. It encompasses the study of bacteria, rickettsiae, small fungi (*e.g.*, yeasts and molds), algae, and protozoans, as well as problematical forms of life such as viruses. Because of the difficulty of assigning plant or animal status to microorganisms—some are plantlike, others animal-like—they are sometimes considered a separate group called protists. Microbes can also be divided into procaryotes, which have a primitive and dispersed kind of nuclear material—*i.e.*, the blue-green algae, bacteria, and rickettsiae—and eucaryotes, which display a distinct nucleus bounded by a membrane. Such are small algae other than the blue-greens, yeasts and molds, and protozoans. (All higher organisms are eucaryotes.)

The biological status of microorganisms

Man's daily life is interwoven inextricably with microorganisms. They abound in the soil, in the seas, and in the air. Everywhere abundant, although usually unnoticed, microorganisms provide ample evidence of their presence, sometimes unfavourably, as when they cause decay of objects valued by man or generate disease, and sometimes favourably, as when they ferment alcohol to wine and beer, raise bread, flavour cheeses, and create other dairy products from milk. Microorganisms are of incalculable value in nature, causing the disintegration of animal and plant remains and converting them to gases and minerals that can be recycled in other organisms.

Historical background. Microbiology can be said to have begun with the development of the microscope. Although others may have seen microbes before him, Antonie van Leeuwenhoek, a Dutch draper whose hobby was lens grinding and microscope making, was the first to provide proper descriptions of his observations, which included protozoans from the guts of animals and bacteria from teeth scrapings. His descriptions and drawings were excellent because his lenses were of an exceptional quality. Leeuwenhoek conveyed his findings in a series of letters to the British Royal Society during the mid-1670s. Although his observations stimulated much interest, no one made a serious attempt either to repeat or to extend them. Leeuwenhoek's "animalcules," as he called them, thus remained mere oddities of nature to the scientists of his day, and enthusiasm for the study of microbes gained ground slowly. It was only later, during the 18th-century revival of a long-standing controversy about whether or not life can develop out of nonliving material, that the significance of microorganisms in the scheme of nature and in the health and welfare of man became evident.

The early Greeks believed that living things could originate from nonliving matter; the goddess Gea was credited with creating life from stones. Although Aristotle discarded this notion, he still held that animals could arise spontaneously from other unlike organisms or from soil. His influence regarding this concept of spontaneous generation was still felt as late as the 17th century. Toward the end of the 17th century, a chain of observations, experiments, and arguments began that dealt a deathblow to the idea that life could be generated from nonlife. It was an involved series of events, with the forces of personality and strong wills often obscuring the facts.

Although Francesco Redi, an Italian naturalist, disproved that higher forms of life could originate spontaneously, proponents of the concept claimed that microbes were different and did indeed arise in this way. Such illustrious names as John Needham, Lazzaro Spallanzani, Franz Schultze, and Theodor Schwann figured in the debates.

It remained for Louis Pasteur to settle the matter. He proved in a series of masterful experiments that only preexisting microbes could give rise to other microbes—at least under current earthly conditions (that life arose spontaneously from nonlife at some earlier time, under appropriate physical and chemical conditions, is an undisputed postulate of chemical evolution).

Microbes and disease

Regarding microbes and disease, Girolamo Fracastoro, an Italian scholar, advanced the notion as early as the mid-1500s that contagion is an infection that passes from one thing to another. The "thing" that is passed along eluded discovery until the late 1800s, when the work of many scientists, Pasteur foremost among them, determined the role of bacteria in fermentation and disease. Robert Koch, a German physician, defined the procedure for proving that a specific organism causes a specific disease.

The foundation of microbiology was securely laid during the period from about 1880 to 1900. The students of Pasteur, Koch, and others discovered in rapid succession a host of bacteria capable of causing specific diseases (pathogens) and elaborated an extensive armamentarium of techniques and laboratory procedures for revealing the ubiquity, diversity, and power of microbes.

All of these developments occurred in Europe. Not until the early 1900s did microbiology become established in America. Many of the microbiologists who worked in America at this time either had studied under Koch or at the Pasteur Institute, in Paris. All microbiologists of the early 20th century, however, were influenced by such men as Koch. Once established in America, microbiology flourished, especially with regard to such related disciplines as biochemistry and genetics.

Since the 1940s, microbiology has experienced an extremely productive period, during which many disease-causing microbes have been identified and methods to control them have been developed. Microorganisms have also been effectively utilized in industry; their activities have been channelled so that valuable products of commerce and agricultural benefits result.

The study of microorganisms has also advanced man's knowledge of living things. Microbes provide easy-to-work-with material for studying the complex processes of life; *e.g.*, metabolism. Correlated with the intensive probing into the functions of microbes have been numerous, and often unexpected, dividends that can be applied to solving existing problems. Knowledge of the basic metabolism of a pathogenic bacterium, for example, often leads to a means for controlling the pathogen. Nutritional requirements of bacteria thus may be of value in combatting an infection.

Areas of study. The study of bacteria, which were among the first objects of microbiological study, is called bacteriology. Various subdisciplines deal exclusively with particular microorganisms.

From another standpoint microbiology can be subdivided into theoretical, or pure, microbiology, and practical, or applied, microbiology. The latter can be further subdivided according to specialties, such as medical, industrial, agricultural, food, and dairy microbiology (see below *Applied microbiology*).

Interdisciplinary work. The science of microbiology has been influenced by, and in turn has influenced, other sciences. Microorganisms are no longer the exclusive concern of microbiologists. Biochemists, geneticists, cytologists, and molecular biologists have discovered the value of microbes as experimental tools in the study of such fundamental biological processes as metabolism, photosynthesis, enzyme action, gene action, and population dynamics. Microorganisms are well suited to such uses; they represent a vast range of metabolic types, and genetic changes are correlated with their rapid proliferation. In addition, they can subsist on relatively simple inorganic nutrients and, because they multiply rapidly, are available in extremely large numbers in a relatively short period of time. They are also relatively easy to maintain and handle under laboratory conditions.

Bacteriology. Modern and accurate knowledge of the forms of bacteria dates from the researches of the German botanist F.J. Cohn, the chief results of which were published at various periods between 1853 and 1892. Cohn's classification of bacteria, published in 1872 and extended in 1875, dominated the study of these organisms thereafter. While various observers added to the knowledge of the structure of bacteria, others laid the foundation of what is known about the relations of bacteria to fermentation and disease. When Pasteur showed in 1857 that lactic acid fermentation depends upon the presence of an organism, it was already known that fermentation and putrefaction are intimately connected with the presence of organisms in the air. In 1862 Pasteur placed beyond reasonable doubt the fact that production of ammonia by the fermentation of urea is caused by the action of a minute bacterium, named in 1874 *Micrococcus ureae.*

Isolation of disease-causing bacteria

After the introduction of bacteriological techniques (see below *The study of microbiology: Cultivation of microorganisms*) came the isolation of many bacteria. It was discovered in 1882, for example, that a bacillus (a rod-shaped bacterium) is the cause of glanders, a disease of horses. In 1883 Koch isolated the organism of Asiatic cholera, and the same year that of diphtheria was found. In 1885 the tetanus bacillus was observed in pus produced in mice and rabbits inoculated with soil; only in 1889, however, did the Japanese bacteriologist S. Kitasato discover the way in which the organisms could be cultivated (they grow only in the absence of oxygen). W.D. Miller, a U.S. dentist, studied the microorganisms of the human mouth in the 1880s, noting their possible relationship to the decay of teeth.

Pasteur and his associates found that animals vaccinated with a specially cultivated anthrax bacillus showed immunity to disease when reinoculated with the deadly wild form. These findings were destined to lead to a study of the principles of immunity, which underlie the prevention and treatment of disease by vaccines and immune serum. Questions relating to causes and to the nature of changes occurring both in the bacteria and in the host, as well as the development of immunity in the latter, continue to be subjects of great interest and importance.

While investigations on infectious diseases and immunity were under way, it became apparent that other activities of bacteria also are of importance to man. In 1878, only two years after Koch announced the discovery of the anthrax bacillus, the U.S. botanist T.J. Burrill discovered the bacterial cause of fire blight in pears, thereby establishing that certain plant diseases are caused by bacteria. The importance of some bacteria in soil and their contribution to soil fertility was recognized in the 1880s and 1890s. The significance of bacterial activities in many aspects of the dairy industry was recognized at about the same time.

The further application of bacterial activities to industrial processes, other than early studies on alcoholic and lactic acid fermentations, began later. Thus, within the span of a few decades the study of bacteria had progressed enormously, and by the early 20th century it was recognized that the activities of bacteria bear an intimate relation to many aspects of human activity.

The original interest of bacteriologists centred upon what bacteria do. This interest has broadened to include the study of the bacteria themselves: what they are, their relationships to each other, and their relationships to other organisms.

Protozoology and others. The name Protozoa is derived from the Greek words meaning "first animal," and, indeed, protozoans are sometimes considered the most simple of all animals. First observed by Leeuwenhoek in the 17th century, protozoans are almost as ubiquitous as bacteria. The study of protozoans at one time centred on the parasites that cause malaria and sleeping sickness, thereby stimulating research in tropical medicine. Improved laboratory techniques for cultivating this diverse group of organisms have made them valuable tools in many types of investigations—from physiological studies, such as cytoplasmic motion in *Amoeba,* to ecological studies involving their role in the food chain of the oceans.

The term fungi, Latin for "mushroom," applies not only to mushrooms but to all of the large and diverse group of plantlike organisms to which the mushrooms belong. The fungi of most interest in microbiology are the yeasts and molds. Many molds are studied because of their economic importance. *Mucor,* for example, not only causes spoilage of foods such as vegetables and fruits but also is used to manufacture some cheeses.

Lichens and slime molds

Some molds form unique relationships with other organisms; lichens, for instance, are composed of both algae and fungi. The unusual nature of lichens was not discovered until after the invention of the microscope. The name lichen appeared long before, however, in the writings of Theophrastus, a disciple of Aristotle, about the 4th century BC. At that time, and for many centuries thereafter, lichens were confused with mosses and the hepatics. Early students thought that the green cells, now known to be an alga, were specialized fungal structures. Not until 1867 were the green cells in lichens indentified as algae; at the same time it was announced that the fungal cells were parasitic upon them. The introduction of pure culture techniques permitted the lichen constituents to be isolated and grown apart from each other. In 1873 the German botanist H.A. De Bary suggested the name symbiosis to describe the mutual benefit between the components of lichens.

Once objects of interest for their curious form, slime molds—as their individual nutritional, environmental, and genetic characteristics have become better understood—have become objects useful in teaching and research. The creeping sheet (plasmodium), or vegetative stage of a slime mold, has the characteristics of a primitive animal and resembles a primitive amoeba. The reproductive stage (sporangium) has the characteristics of a mold. The double life of these organisms is reflected in the name Mycetozoa, meaning fungus animals, which was coined by De Bary in 1858.

Algae, a heterogeneous group of primitive organisms, are of great interest to all biologists because they are capable of photosynthesis and are of evolutionary interest as well. Intensive research is currently directed toward the small forms making up much of the free-floating microscopic life in water (phytoplankton) because they provide food for aquatic animals and thus are of great importance. Many freshwater algae produce undesirable tastes and odours, and studies have been aimed at eliminating them from domestic water supplies. Although algae occasionally form mats on water surfaces, sometimes causing suffocation of aquatic life, heavy growth of certain species also has been found to reduce water hardness and to remove the salts found in brackish water, thereby making the water more suitable for human consumption. Algae are also being studied for their potential value as a food source for man.

Virology and others. Viruses comprise a heterogeneous assemblage of self-reproducing agents, smaller than the microscopically visible bacteria, that multiply only within living susceptible cells. Certain diseases caused by viruses have been known since the late 1700s, when the British physician Edward Jenner developed a vaccine from material isolated from cowpox lesions. He did not see the causative agent. Pasteur, in the mid-1850s, developed an attenuated strain (*i.e.,* one made less virulent) of the virus that causes rabies, but he was not then aware of the viral nature of the disease. An associate of Pasteur, Charles Chamberland, discovered that bacteria would not pass through a porcelain filter but that the causative agent of rabies did. The term filter-passing, or filterable, virus was used to describe these agents.

The Russian bacteriologist D. Ivanovski in 1892 found that a filtrate of sap from tobacco plants infected with mosaic disease could be used to transfer infection to healthy plants; the Dutch microbiologist M.W. Beirjerinck later confirmed the work. The further finding in 1902 that the agent of foot-and-mouth disease of cattle is also filterable made clear the fact that the agents cause disease in animals as well as plants. By 1930 the term filterable had been dropped, and virus is routinely used by microbiologists as a name for these agents.

The study of viruses

Nobel Prize winner Max Theiler found in 1951 a method for attenuating virulent yellow fever virus; the technique has since been modified to produce vaccines against other viral diseases. Thus, viruses have been studied intensively in recent years not only because they provide important information about life processes but also because vaccines against them are constantly sought.

The study of rickettsiae, which resemble very small bacteria but grow only in susceptible cells, is intimately associated with those forms causing human disease. Elucidation of the microbes causing such diseases as epidemic typhus, Rocky Mountain spotted fever, and scrub typhus began in 1906 with the work of Howard Taylor Ricketts, for whom the organisms are named; he described the organism of spotted fever. In 1910 Ricketts and an associate described the organism of typhus fever, which in 1916, was named *Rickettsia prowazekii* in honour of Ricketts and Stanislas von Prowazek, both of whom died of the disease. Research continues as better methods for prevention, control, and treatment of rickettsial diseases are sought.

General trends. One of the more current studies involving microorganisms is their possible occurrence in outer space and on planets other than Earth. A branch of exobiology, space microbiology, includes the investigation of microbes as providers of food and oxygen in the closed environment of spaceships.

A less positive development of microbiology has been biological warfare—the selection and cultivation of microbes as weapons of war, to cause disease or injury to domestic plants, animals, and man.

Although most of the subdisciplines of microbiology are directed at the occurrence of microbes in specific environments, the study of gnotobiotics is concerned with the exclusion of microbes except those involved in any given experiment. Such germfree organisms are important research tools in investigating parasitic diseases, immunological processes, nutrition, stress, shock, and aging.

Methods in microbiology. The study of microbiology is channelled in two major directions. Pure microbiology—that is, the study of a particular group of microorganisms in order to learn about their morphology, physiology, taxonomy, occurrence, variation, heredity, and evolution—seeks to understand the nature of microbes. Applied microbiology, on the other hand, is motivated by the desire to exploit the effects of microorganisms that are of benefit to man and to control the activities of those that are harmful.

Bacteriology as a synonym for microbiology

The methods used to study bacteria have been widely adapted to the study of other microorganisms; indeed, the techniques employed in the microbiological sciences probably have more in common than do the origin and evolution of the organisms themselves. For this reason, the term microbiology is often considered to be synonymous with bacteriology. Similarly, the term microorganism no longer refers only to microscopic organisms. With the adoption of bacteriological methods for the study of many types of organisms, the meaning of the term microorganism has gradually been extended to include any organism that can grow and be studied using the methods originally developed for bacteria. The study of microbiology, therefore, encompasses many organisms that are not microscopic (*e.g.,* molds) but usually does not include some that are (*e.g.,* rotifers).

Microscopy. That invisibly small organisms exist was believed from early times. Lucretius, who expressed an atomic view of matter, wrote about AD 75 that even the plague must be caused by a kind of atom. He considered

the atoms, or seeds, as lifeless, however. The writings of Lucretius influenced 16th-century scientists, but the means for actually observing microorganisms—a magnifying lens—was not developed until the 17th century by Galileo.

The convex lens of Leeuwenhoek allowed a greatly enlarged image to be seen, enabling him to see protozoans, filamentous fungi, and yeasts. In 1676, using his simple lens, which was capable of magnifying 280 times, he first saw bacteria. A few years before Leeuwenhoek's observation of bacteria, Robert Hooke, the father of the cell theory, had observed filamentous fungi (1667) through a compound microscope—one with two lenses, which gives a larger image than that given by a simple lens.

By 1786 various microorganisms, including bacteria, had been viewed through the compound microscope. The compound microscope of today is widely used; it differs from those of the 18th century mainly in the addition of a device, called a condenser, for lighting the object being viewed with a wide cone of light. A condenser is necessary to provide sufficient light when large magnifications are used.

Types of light microscopy used in microbiology

Of the types of microscopy now used in microbiology, most utilize light microscopes; magnification is obtained by a system of optical lenses. The types of light microscopes include the commonly used bright field, in which the background is brightly lighted, the objects studied are dark, and the power of magnification is about 1,000; the dark field, in which the background is dark and the objects studied are bright, a phenomenon particularly useful for examining unstained organisms suspended in fluid; the ultraviolet, the greatest advantage of which is that magnifications two to three times greater than those obtained with the light microscope can be achieved because ultraviolet light has a shorter wavelength than visible light; and phase contrast, in which controlled illumination is obtained by the use of special equipment that enables the refraction, or bending, of light passing from one material to another to be seen, thereby revealing differences in cells not discernible with other microscopic methods. Fluorescence microscopy utilizes the ultraviolet microscope; a chemical substance with the property to absorb ultraviolet waves and emit visible ones is used with a mixture of microorganisms, some of which take up the substance, and thus can be distinguished from those that do not. Still another type of microscopy, electron microscopy, allows very great magnification; waves of electrons (negatively charged particles), rather than light, and magnetic fields, rather than lenses, are used to achieve an image. Although electron microscopy has the advantage of great magnification, it also has several limitations, most important of which is that the material must be dry. This not only eliminates the possibility of studying living specimens but also raises the possibility that the drying process may alter the characteristics of the specimen.

Cultivation of microorganisms. Microorganisms growing on a nutrient medium are referred to as a culture. Early experiments (1776) by Spallanzani, begun as the result of the previously mentioned controversy over whether or not life could develop out of lifeless matter, laid the foundation for the technique of sterile culture. This involves first freeing a suitable medium of microorganisms by heating and, second, keeping the medium sterile—*i.e.,* keeping microorganisms out of the medium. In his experiments, Spallanzani boiled various kinds of seeds in a flask and stoppered it. After a few days, many organisms could be found in the flask; Spallanzani distinguished the larger ones, which were destroyed by boiling for one-half minute, and microbes, which survived boiling and developed even after the flask had been sealed. Eventually, he discovered that, after boiling sealed flasks for as long as 45 minutes, no microorganisms developed.

The objection then voiced to Spallanzani's work—that the quality of the air in the flasks had, by heating, been rendered unable to support life—was overcome later (1836) when air was passed into the flask after having been slowly drawn through solutions containing sulfuric acid. The meat extract in the flask remained uncontaminated because the microorganisms in the air were killed by its passage through the solutions. In 1853 it was discovered that flasks did not have to be sealed after boiling but could be closed with a plug of cotton, which effectively filtered the incoming air; this procedure is still used. Because many microorganisms can produce bodies (spores) that are extremely heat-resistant, mediums for the growth of microorganisms are usually sterilized by heating under pressure to 120° C (250° F) for 15 or 20 minutes.

Simplification of the method for sealing flasks

The Scottish surgeon Joseph Lister contributed to culture methods in microbiology with the introduction in 1878 of the dilution method. During studies probably concerning the souring of milk, he used sterile water to dilute a small amount of milk, then diluted some of this mixture with more sterile water. He continued the dilution process until a sample of the milk and sterile water mixture no longer caused the milk to sour. The last dilution that resulted in souring thus contained a minimum number of organisms, and Lister considered it a pure culture—that is, containing only one species of organism. The dilution method has become an essential part of pure-culture methods.

The dilution method was modified in 1896 by a Danish microbiologist, Emil Hansen, who studied yeasts. He added one drop of a yeast culture to the first of a series of small drops of sterile water, then removed a drop of the culture and added it to the second drop of water. Eventually, he obtained a drop containing just one yeast cell.

Koch also made a significant contribution to culture techniques with his development of a simple method for obtaining pure cultures of bacteria. He added a solidifying agent (gelatin) to a nutrient medium. After the medium had been heat sterilized and partially cooled, he added some microorganisms. By cooling the solution further and spreading the organisms before the gelatin solidified, he was able to isolate the microorganisms from each other, with the result that each organism gave rise to a separate colony, or crop of cells.

The introduction of agar-agar

In 1883 a woman in Koch's laboratory, Frau Hesse, further improved the technique by substituting agar-agar for the gelatin. Unlike gelatin, agar-agar can be liquefied by only a few microorganisms and does not provide a food source, thus allowing better control of the nutrient content of the medium. Silica gel also has been used as a solidifying agent.

One final advance in culture technique was developed in the 1890s by M.W. Beirjerinck and by the Russian microbiologist Sergei Winogradsky. They selected a medium that favours the growth of one organism over another. If an organism, one from the soil, for example, is capable of utilizing a certain substance (*e.g.,* a specific sugar), growth of the organism can be induced by using the substance in the medium. Only the organisms capable of attacking the substance will grow in great numbers. Successive transfers of a relatively small number of organisms (inoculum) to a fresh medium eventually will result in a culture strongly enriched with the organism that utilizes the desired substance.

After a species of microorganism has been obtained as a pure culture, it is necessary to maintain it alive and as a pure culture. Microbiology laboratories in schools, universities, and industry usually maintain collections of pure cultures of the particular species they use. Various organizations throughout the world maintain pure cultures of microorganisms; such collections are important in that they make available pure cultures of species when needed.

The Kral Collection in Prague, established in 1900, was the first known culture collection. The names and locations of a few of the other collections are: the American Type Culture Collection (Rockville, Maryland), the Japanese Type Culture Collection (Tokyo), and the (British) National Collection of Type Cultures (London). Other collections also exist worldwide to serve particular needs. A section on culture collections was established in 1966 by the International Association of Microbiological Societies in order to promote the exchange of information among culture collections.

Whenever a microbiologist proposes a new species, he provides one or more of the national culture collections with a pure culture of the species.

Staining techniques. Until the latter third of the 19th

century, microorganisms were observed only in the natural state; the similarity of their refractive index to water and their small size, however, made them difficult to see when viewed through a microscope. Thus, the discovery of a method that would allow them to be seen more easily was an important development.

By 1875 the German pathologist Carl Weigert, using techniques developed more than a decade earlier for staining animal tissues with dyes, had found that dead ("fixed") bacteria would become heavily stained with the dye picrocarmine. Other dyes were then introduced—*e.g.,* methylene blue, fuchsin, and crystal violet. Hans Christian Gram, a Danish bacteriologist, discovered in 1884 a simple procedure for placing bacteria into either a gram-negative class or a gram-positive class, depending on whether or not the organisms retained crystal violet when treated in a specific way. Although the gram stain is used mostly with bacteria, other microorganisms also show a reaction. Yeasts and actinomycetes, for example, are gram-positive; rickettsiae are gram-negative. Stained preparations now are used particularly to observe structural features of microorganisms.

Other methods. Twentieth-century developments in microbiological methods have depended largely upon the techniques of other disciplines—namely, biochemistry, physiology, organic chemistry, and physics.

The gas exchange of respiring microorganisms, called the respiratory quotient (the ratio of carbon dioxide produced to oxygen consumed), is measured by following the pressure change of respiring organisms in a closed vessel. Other processes—*e.g.,* fermentation—can also be studied using this method.

The transfer of hydrogen ions (positively charged atoms) in microorganisms has been studied by adding to the organisms or extracts prepared from them a substance (*e.g.,* the dye methylene blue) the colour of which changes when hydrogenated. Many other dyes behave in this way.

Techniques for breaking apart microorganisms

The techniques used to break up microorganisms include such biochemical techniques as alternate freezing and thawing, prolonged grinding, vigorous shaking with glass beads, and exposure to supersonic vibration; certain microorganisms (*e.g.,* yeast) are especially difficult to disrupt because of their resistant cell walls.

The apparatus of modern physics has greatly aided the advance of virology. Around 1930 the steady development of new technical methods for studying the physical, chemical, and biological properties of microorganisms completely changed the outlook of biologists toward viruses. An important advance in this new approach was the development of graded filter membranes of known pore size. This created for the first time the opportunity to assess the actual size of virus particles.

Another important advance of the 1930s was the growth of the virus of fowl pox in the tissues of a developing chick embryo. Methods for the growth in the laboratory of rickettsiae are similar in that living host cells are necessary. In 1949, tissue culture methods, long used in half-hearted fashion for the cultivation of viruses, were shown to be suitable for the growth of poliomyelitis viruses. This not only opened the way to immunization against polio but supplied a method by which many new types of virus could be isolated.

PHYSICAL ANTHROPOLOGY

Physical anthropology is that branch of natural science that is concerned with the origin and evolution of man. Both the course that human evolution has taken and the causes or processes that have brought it about are of equal concern. In order to interpret the diversity within races and between races, physical anthropologists have had to search for the meaning of these differences by including as objects of study past races of fossil man as well as such nonhuman primates as anthropoid apes, monkeys, tarsiers, and lemurs. Much light has been thrown upon man's relation to other primates and upon the nature of the transformation of his skeleton in the course of evolution from early man to modern man, a span of at least 2,000,000 years. Discoveries of the South African man apes, the first in 1924, and of other forms in East Africa beginning in 1959 have revealed unanticipated data concerning the diverse combinations of traits that can coexist and the singularly illuminating fact that erect posture preceded the great expansion of the brain in human evolution.

Many of the processes responsible for the differentiation of man into different races, although he still remained a single species, *Homo sapiens,* are known: selection, genetic drift, migration, and mutation. Objective methods of isolating various kinds of traits and dealing mathematically with their frequencies, as well as their functional or phylogenetic significance, make it possible to understand the composition of human populations and to formulate hypotheses concerning their future. The resulting information accumulated by physical anthropologists makes available facts about the groups inhabiting the world as well as the individuals composing these groups. Thus, it is possible for a person to learn about his own genetic constitution with reference to traits ranging from blood types to the fissural patterns of his molar teeth and to know the frequency and distribution of these traits in the various races about the world. He is also able to secure some estimate of the probability with which his children will inherit these features.

Historical background. Inasmuch as the history of physical anthropology is, in large part, a history of man's attempt to determine his place in nature, to compare himself with other primates, and to interpret the physical differences, more is to be gained from examining the kinds of problems that have been studied and the nature of the evidence that has been used than from reviewing the succession of great names. Twentieth-century familiarity with primates tends to obscure the fact that the precise distinction between man and the apes, based on evidence secured from actual dissection, had not been made before 1699. At that time Edward Tyson published the comparative anatomy of a chimpanzee and correctly deduced that the chimpanzee was not a human being. Succeeding Tyson is a distinguished series of men who launched into the formidable task of describing and classifying human beings as well as the other primates. Georges-Louis Leclerc de Buffon, Immanuel Kant, Johann Friedrich Blumenbach, Jean-Baptiste Lamarck, and Georges Cuvier in the 18th century all made notable contribution. Of these, Blumenbach (1752–1840) is recognized as the father of physical anthropology. Although many early classifications of human races failed to distinguish between physical and cultural characteristics and leaned heavily upon the concept of primordial types with a corresponding minimization of variability, it is noteworthy that Blumenbach as early as 1775 observed that the "innumerable varieties of mankind run into each other by insensible degrees." He also initiated use of the term Causasian to describe members of the white race, basing the choice of his term upon the race of men of Georgia on the southern slope of the Caucasus Mountains who at the time enjoyed a remarkable reputation for beauty. Blumenbach anticipated 20th-century analyses of locomotion in his critical observation that the chimpanzee was essentially quadrupedal in spite of occasionally erect posture, and he cited as evidence the receding heel bones and the elongated pelvis.

Tyson's comparative anatomy

Great chain of being and the "missing link." A basic concept that constituted the organizing assumption of primate taxonomy, from its inception to well after the formal appearance of a theory of evolution in 1859, is the idea of the "great chain of being" or the hierarchical arrangement of nature. This great explanatory theory made necessary a correlative concept, that of the famous "missing link." The missing link proved to be of less value to scientists than to P.T. Barnum, who entertained the public with specimens of every conceivable link between groups of animals, including for good measure a mermaid. One useful result of this belief in unilinear gradation was the search for previously unknown forms that would complete man's knowledge of the chain of being. With this inclusive charter, the scientists of western Europe were ordained to take an inventory of nature and to determine the appropriate place of each newly described form. In practice, it of course supplied the theory for understanding not only man's place in nature but that of all other organisms and

was extended to cultures as well. In the absence of genetics and a concept of culture, personality traits as well as skin colour were used for classification. The period between Tyson and the later study by Thomas Huxley, *Man's Place in Nature* (1863), is filled with works devoted to the positioning of the anthropoid apes, monkeys, and newly discovered "races." While some persons investigated the anthropoids, others were impressed with the possibility that various groups of unknown aborigines might be the missing link or links. Thus, the "savage Hottentot" or the "stupid native of Nova Zembla" (Novaya Zemlya) was pressed into service to fill the gap between anthropoid apes and man.

Darwin's theory of evolution. Publication of *On the Origin of Species* by Charles Darwin in 1859 provided the outstanding theoretical contribution of the 19th century. The essential concept for the evolution of man was that of natural selection, though many more decades were to pass before its implications were either appreciated or employed. Darwin not only showed that evolution took place in the different organisms but he also provided an explanation that was sound in its major outline and that subsequently was given more precise meaning. The idea that nature selects those forms which are better adapted to a particular geographic zone and way of life laid the basis for understanding the adaptive radiations of the primates. Anthropologists were slow to appreciate the implications of adaptation and continued to measure and to observe traits that were felt to be nonadaptive. Linnaean species, the hypothetical prototypes of which individual specimens were copies in varying degrees of perfection, continued to be described. The weight of attention remained on classification rather than on processes of evolution, and research continued to focus on description without a corresponding concern for understanding the functional significance of traits or the role that they might play in the adaptation of a species to its ecological zone.

Natural selection

The idea of evolution was slowly accepted, accompanied by many rancorous disputes. The chief accomplishment of the period between 1859 and 1900 lay in the recognition of a considerable time depth for man. The system of arranging the primates remained unilinear, but it was extended far back into the geological past. Both fossil races of man and contemporary races were arranged according to their assumed degree of morphological primitiveness. The findings of extinct forms of animals by paleontologists, the excavation of older cultures by archaeologists, and the discovery of Neanderthal skulls all contributed to questioning the scriptural authorities who credited the world with being only approximately 6,000 years old. Combined researches of geologists, paleontologists, archaeologists, and physical anthropologists finally established the antiquity of man as well as of other forms of organic life; and thus the evolutionary sequence became of foremost interest. The first recognized discovery of the extinct race of Neanderthal man was made in 1856 in northwestern Germany and was disputed by many persons, including Rudolf Virchow. An earlier discovery of the Neanderthal skull in Gibraltar in 1848 had been largely ignored. The continuing search for more primitive specimens of fossil man was richly rewarded when in 1891–92 Eugène Dubois discovered the Java ape man, now classified as *Pithecanthropus erectus*, considered one of the earliest known races of man.

New approach. By the end of the 19th century several useful classifications of all the races of the world had been completed. Many of the differences between the races were quite well known. Similarly, differences between man and the anthropoid apes had been inventoried and also between modern man and fossil man. A great deal of attention was paid to the number of differences, and it was assumed that the degree of relatedness was adequately indicated by the degree of morphological similarity.

The year 1900 may be taken as a turning point in the development of a new conceptual approach, though no single date can fully comprehend a shift in such an exceedingly complex continuum. Two major events took place which were to have far-reaching consequences: (1) the rediscovery of Gregor Mendel's two genetic principles by several investigators and (2) Karl Landsteiner's discovery of the ABO blood groups. Mendel had formulated the basic principles of heredity in 1865, but these had passed unnoticed. The inheritance of the blood groups was not at first appreciated, but within 10 years became a focus of research and thus a building stone in modern racial studies. Many new concepts came into use with the increasing influence of genetic theory, such as the breeding population, genetic equilibrium, genetic drift, and the gene frequency method of differentiating populations or races. Attention was immediately directed to the processes of change, those ways in which gene frequencies are modified. At the same time increasing attention was paid to the significance of traits and to the ways in which they were interrelated. Experimental studies were devised to demonstrate the functional significance of differences in morphology. The concept of straight-line evolution (orthogenesis) was qualified, and examples of reversals or major shifts in the direction of evolution were objectively examined. The concept of the missing link went into discard.

Effect of Mendel and Landsteiner

It was recognized that a change in way of life which introduced a species to a new "adaptive plateau" and brought about many radical changes in its structure obviated the need for a belief in so-called missing links. The techniques of anthropometry were reinforced by many other techniques, such as blood typing, so that the physical anthropologists had a much more versatile set of research tools.

Statistical methods. Spanning both the pre-evolutionary and the evolutionary periods of physical anthropology was the development of statistics and their application to the measurement of man, included under biometry. As early as 1835, L.A.J. Quételet (1796–1874) had applied the statistical concept of the normal probability curve to human beings. He demonstrated that most of the statures in a population will cluster about a mean and that the frequency of both taller and shorter statures will diminish in frequency at opposite ends of the curve. Sir Francis Galton (1822–1911) succeeded in constructing new measures of variability, correlation, and regression. Galton also investigated certain aspects of human heredity. Karl Pearson (1857–1936) classified the types of distribution, perfected the coefficient of correlation, developed chi-square, and was a founder of the journal *Biometrika*. Not the least of his many contributions consisted in separating the sample from the population it represented and indicating the necessary restrictions for interpreting a population in the light of information drawn from the sample. Sir Ronald Fisher, continuing the development of modern statistical theory initiated by Pearson, made extensive contributions in the design of experiments and to the field of genetics. One of the trends in the anthropological use of statistics is toward those kinds that preserve the description of the organism as a whole. Analysis of variance, multiple regressions, discriminate functions, generalized distance, and factor analysis all share the criterion of treating different variates as a single coherent vector. Unfortunately, the finest statistical treatment will not compensate for poorly selected units of observation or measurement.

The measurement of man

Areas of study. Insight into the field of physical anthropology may be obtained by reviewing the general fields of investigation in which particular researchers are actively engaged.

Human ecology. The relationship of the human organism to its environment, or human ecology, is a bridge between the biological and social sciences. Problems of population, size, and stability are important in many ways. A very immediate aspect is the varying rate of change that may occur in populations of different sizes. Theoretically, a small population is more susceptible to chance fluctuations than a large one. Both the natural environment and the economy of a particular society affect the population size.

Studies of evolution. Human evolution is another area that serves as a focus for research. The essential problems are not only the complete description of fossil forms but the evaluation of the significance of particular traits. Old concepts of orthogenesis, or evolution in a straight line, have had to be abandoned, and radiant and parallel evolution have come to the fore. It is clear that the course

of human evolution may swing about so that what were formerly considered relatively modern forms may actually precede morphologically earlier ones, as in the case of the more modern kind of Neanderthal man who apparently preceded the more primitive or early form. Fossil man of considerable antiquity has been found in Europe, Asia, and Africa. No area in the world is without skeletal remains, so that researchers may everywhere engage in skeletal studies.

Primatology. Primatology is an area in which man's place in nature is no longer the major point of focus. Researchers are concerned with experimental, medical, and ecological aspects of primates, and it is from these studies that much of the functional significance of various bone and muscle complexes has been derived. The different kinds of adaptations that groups of monkeys have made to life in the trees or to life on the ground have had many consequences in the proportions of their limbs or in the elaboration of various groups of muscles. Similarly, the mode of progression through trees by the use of the arms, known as brachiation, is accompanied by the elongation of the arms, reduced size of the thumb, and many other structural arrangements in the anthropoid apes. Thus the primates provide a natural laboratory of many kinds of experiments in physical adaptation to fundamentally different ways of life or adaptive zones.

Genetics. Genetics is a fourth major area of research. The study of inherited traits in individuals and the behaviour of the genes responsible for these traits in populations is essential to understanding human variability. Although the blood groups have provided the bulk of the data, many other traits are being analyzed and theories of their inheritance tested. As a result of research in this area it is possible to describe races in terms of gene frequencies and to calculate amounts of race mixture.

Growth studies. Growth studies, both of human beings and other primates, engage the attention of many physical anthropologists in medical and dental schools as well as in independent clinics and universities. Methods of assessing rates of growth, skeletal age compared with chronological age, and the genetic, endocrinological, and nutritional factors are some of the aspects involved in these studies. The relation between growth and socioeconomic status and other cultural features receives considerable attention. Dentitions have been frequently studied, often because the emergence of the teeth is of great practical importance and serves as an index of development. As a result of research in this area it is possible to describe races in terms of gene frequencies and to calculate amounts of race mixture.

Anthropometry. Measurement, or anthropometry, has been a mainstay of anthropological research for well over a century. More attention is being given to the judicious selection of measurements than to the simple techniques with which calipers are handled. Many traditional measurements cannot be analyzed, and the addition of multivariate statistics does not make them any more intelligible. Statistical considerations are especially important in genetic and anthropometric research, and part of the history of statistics is identical with the history of the development of these two research interests. Quite certainly the end results of growth can only be studied by measurement. Newer growth studies have followed children through their morphological and biochemical changes with the aim of discerning why children grow.

Applications of physical anthropology

Many of the applications of physical anthropology lie in the field of measurement. Thus the problems involved in providing military and civilian clothing for large numbers of people depend on measurement and statistical treatment. Substantial savings have been made possible by measuring the people of a particular area and adjusting the clothing tariffs to these known distributions of body sizes. There is sufficient variation within most countries so that the geographical variations in size of the body and intermembral proportions are of practical importance. Human constitution is another area of research interest. Several descriptive systems exist for classifying persons who vary from a lateral or relatively squat body build through a relatively muscular to a linear body build. The components of body build, the different tissues and dimensions, were being studied in the late 20th century by means of factor analysis and comparisons of siblings and twins, and their actual mode of inheritance and response to environmental conditions were slowly being specified. The various areas of interest referred to above are, of course, not mutually exclusive; ideally they should all form part of the training of researchers in the origin and evolution of man. (Ed.)

BIBLIOGRAPHY. The following publications deal with fundamental biological concepts as well as with the structure and functions of living things: JEFFREY J.W. BAKER, *Cell* (1966), a paperback that presents the structure of the cell as seen by the electron microscope; and, with GARLAND E. ALLEN, *Matter, Energy, and Life,* 2nd ed. (1970), a fundamental and easily understood basic chemistry of living systems, and *The Study of Biology,* 2nd ed. (1971), a general college-level survey of biological principles; GEORGE W. and MURIEL BEADLE, *The Language of Life* (1966), the chemistry of the gene explained in an easily understood manner; PETER R. BELL and C.L.F. WOODCOCK, *The Diversity of Green Plants* (1968), a compact survey of the multiformity of green plants; ERNEST BOREK, *The Atoms Within Us* (1961), a nontechnical paperback explaining the chemical processes involved in living matter; A.J. CARLSON, V. JOHNSON, and H.M. CAVERT, *The Machinery of the Body,* 5th ed. rev. (1961), metabolism, digestion, and other human physiological processes clearly explained in this excellent text; RACHEL CARSON, *The Sea Around Us,* rev. ed. (1966), a beautifully written book that discusses food chains and ecological problems of the sea in an almost poetic fashion; T. DOBZHANSKY, *Evolution, Genetics, and Man* (1955), an excellent textbook on the relationship of the evolutionary theory to man; L.C. DUNN, *Heredity and Evolution in Human Populations,* rev. ed. (1967), a nontechnical and interesting explanation of genetics and the evolution of man; JAMES D. EBERT and IAN M. SUSSEX, *Interacting Systems in Development,* 2nd ed. (1970), one of an excellent series of books, each developed around a different biological concept; PAUL R. and ANNE H. EHRLICH, *Population, Resources, Environment: Issues in Human Ecology* (1970), a general textbook of ecological problems written for the layman; LOREN EISELEY, *The Immense Journey* (1957), a well-written and most interesting story of man's development as an organism; DONALD KENNEDY, *The Living Cell* (1965), a collection of articles from *Scientific American* with good photographs of cell structure; H.R. MAHLER and E.H. CORDES, *Biological Chemistry,* 2nd ed. (1971), a standard college-level text of biochemistry; A.I. OPARIN, *The Chemical Origin of Life* (1964; originally published in Russian, 1936), an updated version of Oparin's theory of the origin of life; E.P. ODUM, *Fundamentals of Ecology,* 3rd ed. (1971), a standard college-level text on ecology with an excellent discussion of the cycles in nature; JAMES A. PETERS (ed.), *Classic Papers in Genetics* (1959), original papers by outstanding geneticists; A.E. ROMER, *Man and the Vertebrates* (1941; rev. as *The Vertebrate Story,* 1959), a comparative study of the anatomy of man and other vertebrates with emphasis on evolutionary significance; M.W. STRICKBERGER, *Genetics* (1968), a standard college text with a clearly written section on population genetics; N. TINBERGEN, *Social Behavior in Animals,* 2nd ed. (1965), an introductory, well-written book about animal behaviour; FRITS WENT *et al., The Plants* (1963), presents the structure, evolution, and function of plants in a nontechnical and well-illustrated fashion.

History of biology: Publications concerned with the history and philosophy of biology include: ISAAC ASIMOV, *A Short History of Biology* (1964), a book written for the layman, emphasizing accomplishments of the 19th and 20th centuries; SIR GAVIN DE BEER, *Charles Darwin* (1963), a biography of Darwin by an eminent biologist; M. BERGER, *Famous Men of Modern Biology* (1968), brief biographies of 19th- and 20th-century biologists; F.S. BODENHEIMER, *The History of Biology: An Introduction* (1958), contains a short history, but also a source reader from 130 authors, beginning with the Egyptians; MORDECAI L. GABRIEL and SEYMOUR FOGEL (eds.), *Great Experiments in Biology* (1955), a presentation of scientific writings in the original, from Robert Hooke to the 20th century; ELDON J. GARDNER, *History of Biology,* 2nd ed. (1965), a college-level text, and *History of Life Science* (1960), an outline of biological history written for the biology student; PHILIP GOLDSTEIN, *Triumphs of Biology* (1965), a survey of selected aspects of biology, written for college level; URLESS LANHAM, *Origins of Modern Biology* (1968), a survey of biology from Greece to the present; RUTH MOORE, *The Coil of Life* (1961), a clearly written description of the development of molecular biology for the general reader; CHARLES SINGER, *A History of Biology,* rev. ed. (1950), a highly readable classic that surveys the historical development of biological problems; M.J. SIRKS and CONWAY ZIRKLE, *The Evolution of Biology* (1964), a college-level survey of the history of biology from prehistory to the present; HENRY OSBORN TAYLOR, *Greek Biology and Medicine* (1922, reprinted

1963), a sketch for the layman of the scientific method of Greece and Rome.

Morphology: B.I. BALINSKY, *An Introduction to Embryology,* 3rd ed. (1970), an excellent general college-level text that includes details of organogenesis in each of the vertebrate types, plus a synthesis of the experimental analysis of cellular differentiation; R.D. BARNES, *Invertebrate Zoology,* 2nd ed. (1968), an excellent modern treatment of invertebrate morphology; E.D.P. DE ROBERTIS, W.W. NOWINSKI, and F.A. SAEZ, *Cell Biology,* 5th ed. (1970), an excellent text describing the cytological features of animal and plant cells; KATHERINE ESAU, *Plant Anatomy,* 2nd ed. (1965), a beautifully illustrated text with an excellent treatment of plant anatomy; DON FAWCETT, *The Cell* (1966), a collection of superb electron micrographs of several kinds of cells and cell organelles, with a brief description of each; LIBBIE H. HYMAN, *The Invertebrates,* 6 vol. (1940–67), the definitive treatise of the invertebrates, covering morphology, development, and evolution; A.S. ROMER, *The Vertebrate Body,* 4th ed. (1969), a standard college-level text of comparative anatomy of the vertebrates; C.A. VILLEE, W.F. WALKER, and R.D. BARNES, *General Zoology,* 4th ed. (1973), a standard college-level text of vertebrate and invertebrate morphology and its relation to function.

Physiology: K.J. FRANKLIN, *A Short History of Physiology,* 2nd ed. (1949), through the 19th century; J.F. FULTON (ed.), *Selected Readings in the History of Physiology* (1930), excerpts from classical publications; T.S. HALL, *Ideas of Life and Matter* (1969), on concepts of physiology and related fields; K.E. ROTHSCHUH, *Geschichte der Physiologie* (1953), a detailed account in German, with emphasis on German physiologists; J. BARCROFT, *Features in the Architecture of Physiological Function* (1934), broad interpretations of physiology; W.B. CANNON, *The Wisdom of the Body* (1932), on regulatory physiology; A.V. HILL, *Adventures in Biophysics* (1931), studies on the biophysics of muscle; M. FOSTER, *Lectures on the History of Physiology During the 16th, 17th, and 18th Centuries* (1901, reissued 1970), a classic by one of the founders of modern physiology; C.S. SHERRINGTON, *Man on his Nature,* 2nd ed. (1951), a summary of and reflections on classical work in neurophysiology; E.F. ADOLPH, *Origins of Physiological Regulation* (1968), a broad survey of regulatory physiology; AMERICAN PHYSIOLOGICAL SOCIETY, *Handbook of Physiology* (1959–), a series of volumes summarizing in detail the status of research in specialized areas of physiology; H. DAVSON, *A Textbook of General Physiology,* 3rd ed. (1964), a revision of a classical English text by SIR WILLIAM BAYLISS; A.C. GIESE, *Cell Physiology,* 3rd ed. (1968), a standard text; B.T. SCHEER, (ed.), *Comparative Physiology* (1968), a collection of recent research papers.

Taxonomy: GEOFFREY C. AINSWORTH, and P.H.A. SNEATH (eds.), *Microbial Classification* (1962), a symposium of the Society of General Microbiology, with discussion of the principles of classification and their application to microbial groups; GUY R. BISBY, *An Introduction to the Taxonomy and Nomenclature of Fungi,* 2nd ed. (1953); ARTHUR J. CAIN (ed.), *Function and Taxonomic Importance* (1959), a symposium of the Systematics Association on the relevance of function to classification, especially to convergence; OLOV HEDBERG (ed.), *Systematics of Today* (1958), symposium held at the University of Uppsala to commemorate the 250th anniversary of Linnaeus's birth; JOHN G. HAWKES (ed.), *Symposium on Chemotaxonomy and Serotaxonomy* (1968); WILLI HENNIG, *Phylogenetic Systematics* (1966), a statement of phylogenetic "principles"; VERNON H. HEYWOOD and J. MCNEILL (eds.), *Phenetic and Phylogenetic Classification* (1964); ROBERT R. SOKAL and P.H.A. SNEATH, *Principles of Numerical Taxonomy* (1963), an important introduction to numerical taxonomy. General texts include RICHARD E. BLACKWELDER, *Taxonomy* (1967); VERNON H. HEYWOOD and PETER H. DAVIS, *Principles of Angiosperm Taxonomy* (1963); JULIAN S. HUXLEY (ed.), *The New Systematics* (1940); ERNST MAYR, *Principles of Systematic Zoology* (1969); GEORGE G. SIMPSON, *Principles of Animal Taxonomy* (1961). Also consult INTERNATIONAL ASSOCIATION OF MICROBIOLOGICAL SOCIETIES, *International Code of Nomenclature of Bacteria and Viruses* (1958); JOSEPH LANJOUW (ed.), *International Code of Botanical Nomenclature* (1966); INTERNATIONAL COMMISSION ON ZOOLOGICAL NOMENCLATURE, *International Code of Zoological Nomenclature* (1961).

Biophysics: LUIGI GALVANI, *De viribus electricitatis in motu musculari commentarius* (1791; Eng. trans., *Commentary on the Effect of Electricity on Muscular Motion,* 1953), Galvani's own account of the discovery of animal electricity; H. BENCE JONES (ed.), *On Animal Electricity, Being an Abstract of the Discoveries of Emil Du Bois-Reymond* (1852), an English abstract of the work of this great 19th-century German scientist; A.V. HILL, "Why Biophysics?" *Science,* 124: 1233–1237 (1956), probably the best concise statement of the attributes of a biophysicist and the qualities needed to make important scientific contributions in the field; NOBEL FOUNDATION, *Les Prix Nobel en 1962* (1963), contains the lectures delivered by Crick, Wilkins, Watson, Kendrew, and Perutz when they received the Nobel Prize; R. OLBY, "Francis Crick, DNA and the Central Dogma," *Daedalus,* 99:938–987 (1970), a good historical account of the discovery of DNA and the subsequent events; J.D. WATSON, *The Double Helix* (1968), a fascinating first-person account of the discovery of the molecular conformation of DNA; A.L. HODGKIN, "The Ionic Basis of Nervous Conduction," *Science,* 145:1148–1153 (1964), his Nobel prize lecture; A.F. HUXLEY, "Excitation and Conduction in Nerve: Quantitative Analysis," *Science,* 145:1154–1159 (1964), his Nobel prize lecture; H.E. HUXLEY, "The Mechanism of Muscular Contraction," *Sci. Am.,* 213:18–27 (1965), a definitive semipopular exposition of the mechanism of muscular contraction; A.K. SOLOMON, "A Short History of the Foundation of the International Union for Pure and Applied Biophysics," *Q. Rev. Biophys.,* 1:107–124 (1968).

Biochemistry: JOSEPH NEEDHAM (ed.), *The Chemistry of Life: Eight Lectures on the History of Biochemistry* (1970), provides brief development of the important areas of photosynthesis, enzymes, microbiology, neurology, hormones, vitamins, and other topics. Two selected biographical treatments that couple human interest with development of biochemical areas are FRITZ A. LIPMANN, *Wanderings of a Biochemist* (1971); and DAVID KEILIN, *The History of Cell Respiration and Cytochrome* (1966). Two monographs that describe areas in the forefront of biochemistry are JAMES D. WATSON, *Molecular Biology of the Gene,* 2nd ed. (1970); and THOMAS H. JUKES, *Molecules and Evolution* (1966). Two attractively illustrated textbooks are ALBERT L. LEHNINGER, *Biochemistry: The Molecular Basis of Cell Structure and Function* (1970); and ROBERT W. MCGILVERY, *Biochemistry: A Functional Approach* (1970). Other standard and somewhat more comprehensive texts are ABRAHAM WHITE, PHILIP HANDLER, and EMIL L. SMITH, *Principles of Biochemistry,* 5th ed. (1973); and EDWARD S. WEST *et al., Textbook of Biochemistry,* 4th ed. (1966). A useful set of paperbacks is *Essays in Biochemistry,* published for the Biochemical Society (1965–). More comprehensive survey treatises are MARCEL FLORKIN and ELMER H. STOTZ (eds.), *Comprehensive Biochemistry* (1962–); and MARCEL FLORKIN and HOWARD S. MASON (eds.), *Comparative Biochemistry,* 7 vol. (1960–64).

Genetics: A.G. DEBUSK, *Molecular Genetics* (1968), a paperback providing concise coverage of this subject; L.C. DUNN, *A Short History of Genetics* (1965), a paperback outlining the major features of the development of genetics; I.M. LERNER, *Heredity, Evolution and Society* (1968), a discussion of the problems of society as related to genetic discoveries; J.A. PETERS (ed.), *Classic Papers in Genetics* (1959), reprints of reports of important genetic discoveries; CURT STERN, *Principles of Human Genetics,* 3rd ed. (1971), a classic work in the field, thorough coverage; M.W. STRICKBERGER, *Genetics* (1968), a college-level treatment of modern genetics; R.P. WAGNER and H.K. MITCHELL, *Genetics and Metabolism,* 2nd ed. (1964), a comprehensive account of the relationship between genes and cellular activities; A.M. WINCHESTER, *Genetics* (1971), an introductory genetics text, including all principles of the subject, but slanted toward human genetics, and *Heredity: An Introduction to Genetics,* 2nd ed. (1966), providing concise coverage of the subject in terms understandable to the general reader.

Eugenics: Classic works include C.P. BLACKER, *Eugenics: Galton and After* (1952); THEODOSIUS G. DOBZHANSKY, *Mankind Evolving: The Evolution of the Human Species* (1962); FRANCIS GALTON, *Hereditary Genius: An Enquiry into Its Laws and Consequences* (1869); THOMAS HUNT MORGAN, *The Theory of the Gene* (1926); and J. SUTTER, *L'Eugénique* (1950). See also R. FREEDMAN, P.K. WHELPTON, and A.A. CAMPBELL, *Family Planning, Sterility, and Population Growth* (1959); FREDERICK H. OSBORN, *Preface to Eugenics,* rev. ed. (1951); C.F. WESTOFF *et al., Family Growth in Metropolitan America* (1961); C.F. WESTOFF, R.G. POTTER, JR., and P.C. SAGI, *The Third Child: A Study in the Prediction of Fertility* (1963); P.K. WHELPTON, A.A. CAMPBELL, and J.E. PATTERSON, *Fertility and Family Planning in the United States* (1966); P.K. WHELPTON and CLYDE V. KISER (eds.), *Social and Psychological Factors Affecting Fertility,* 4 vol. (1946–54); and ROGER J. WILLIAMS, *Biochemical Individuality: The Basis for the Genetotrophic Concept* (1956).

Ecology: W.C. ALLEE *et al., Principles of Animal Ecology* (1949), a somewhat dated but still important source book in animal ecology, with an excellent early history of ecology; H.G. ANDREWARTHA, *Introduction to the Study of Animal Populations* (1961), a concise summary of an important and controversial earlier text, *The Distribution and Abundance of Animals,* by Andrewartha and L.C. BIRCH (1954); PETER FARB, *Ecology* (1963), an enjoyable introduction to ecology, heavily illustrated with outstanding photographs; E.B. FORD, *Ecological Genetics* (1964), a basic reference on adaptation and adjustments of wild populations to their environment; E.J. KORMONDY, *Concepts*

of Ecology (1969), a short, interesting introduction to major concepts of ecology, and (ed.), *Readings in Ecology* (1965), a collection of annotated research papers that illustrate many important concepts of ecology, and, ed. with R.S. LEISNER, *Ecology* (1971), a collection of essays; G.K. REID, *Ecology of Inland Waters and Estuaries* (1961), a good summary of ecological principles as applied to freshwater and estuarine ecosystems; P. SHEPARD and D. MCKINLEY (eds.), *The Subversive Science: Essays Toward an Ecology of Man* (1969), a collection of thoughtful and provocative papers written by contemporary students of the ecology of human populations; R.L. SMITH, *Ecology and Field Biology* (1966), a comprehensive survey of all aspects of ecology; T.R.E. SOUTHWOOD, *Ecological Methods* (1966), an advanced book on the study of populations, with emphasis on insects and quantitative analysis; G.M. VANDYNE (ed.), *The Ecosystem Concept in Resource Management* (1969), a technical review of the application of ecological theory to forest range, watershed, and wildlife management; K.E. WATT, *Ecology and Resource Management* (1968), a highly technical but important text relating mathematical models and computer programming to resource management; C.B. WILLIAMS, *Patterns in the Balance of Nature and Related Problems in Quantitative Ecology* (1964), an advanced treatise.

Zoology: P.R. and A.H. EHRLICH, *Population Resources Environment: Issues in Human Ecology* (1970), vigorous documentation of our misuse of the environment, P.P. GRASSE (ed.), *Traité de zoologie,* 23 vol. (1948–), in French, the most recent encyclopaedic survey of animal biology; P. HANDLER (ed.), *Biology and the Future of Man* (1970), a brilliant survey of the current status of biological knowledge and its relation to human life with an excellent chapter on computer technology; L.H. HYMAN, *The Invertebrates,* 6 vol. (1940–68), a technical but lucid survey of animal biology, exclusive of the vertebrates; W. LEY, *The Dawn of Zoology* (1968), a fascinating account of certain historical aspects of zoology; E. NORDENSKIOELD, *Biologins historia,* 3 vol. (1920–24; Eng. trans., *The History of Biology,* 1928), a basic source for tracing the major ideas and personalities in the life sciences, although occasionally presenting interpretations that have been replaced.

Botany: H.S. REED, *A Short History of the Plant Sciences* (1942), an interesting and thought-provoking account with many useful insights; K.V. THIMANN, *The Plant Sciences, Now and in the Coming Decade* (1966), a thoughtful and persuasive statement, well-written and readable; J. REYNOLDS GREEN, *A History of Botany, 1860–1900* (1909, reprinted 1967), a scholarly treatment designed to supplement the classic work of JULIUS VON SACHS, *History of Botany, 1530–1860,* trans. by HENRY E.F. GARNSEY, rev. by ISAAC BAYLEY BALFOUR (1890, reprinted 1967), arranged by botanical structure and function; AGNES ARBER, *Herbals, Their Origin and Evolution: A Chapter in the History of Botany, 1470–1670,* 2nd ed. rev. (1938, reprinted 1970), a readable and authoritative work; ELLISON HAWKS and G.S. BOULGER, *Pioneers of Plant Study* (1928, reprinted 1969), an interesting account of major historical figures.

Microbiology: G.C. AINSWORTH, and P.H.A. SNEATH (eds.), *Microbial Classification* (1962), a series of essays about the problems of classifying microorganisms, includes names and addresses of institutions maintaining culture collections; T.D. BROCK (ed. and trans.), *Milestones in Microbiology* (1961), a collection of original papers important in the history of microbiology; ALBERT DELAUNAY *et al.* (eds.), *The World of Microbes,* vol. 4 of the *Encyclopedia of the Life Sciences* (1965), a well-illustrated account of microbial activities in relation to man; C.L. DUDDINGTON, *Micro-organisms As Allies* (1961), an interesting account of the industrial uses of bacteria and fungi; R.K. JENNINGS and R.F. ACKER, *The Protistan Kingdom* (1970), an informative and entertaining account of protists and viruses; H.A. LECHEVALIER and MORRIS SOLOTOROVSKY, *Three Centuries of Microbiology* (1965), a reconstruction of the main aspects of the development of microbiology; JOHN POSTGATE, *Microbes and Man* (1969), an introduction to the importance of microorganisms to life on Earth; THEODOR ROSEBURY, *Life on Man* (1969), a witty and informative book.

Physical anthropology: P. TOPINARD, *Eléments d'anthropologie générale* (1885), is the oldest of the treaties; A.E. MOURANT, *The Distribution of the Human Blood Groups* (1954); W.C. BOYD, *Genetics and the Races of Man: An Introduction to Modern Physical Anthropology* (1950); R. KHERUMIAN, *Génétique et anthropologie des groupes sanguins* (1951); G. HEBERER, G. KURTH, and I. The Biosphere

Before the coming of life, the Earth was a bleak place, a rocky globe with shallow seas and a thin band of gases—largely carbon dioxide, carbon monoxide, molecular nitrogen, hydrogen sulfide, and water vapour. It was a hostile and barren planet. This strictly inorganic state of the Earth is called the geosphere; it consists of the lithosphere (the rock and soil), the hydrosphere (the water), and the atmosphere (the air). Energy from the Sun relentlessly bombarded the surface of the primitive Earth and in time—millions of years—chemical and physical actions produced the first evidence of life, formless, jelly-like blobs that could collect energy from the environment and produce more of their own kind. This generation of life in the thin outer layer of the geosphere established what is called the biosphere, the "zone of life," an energy-diverting skin that uses the matter of the Earth to make living substance.

The biosphere is a system characterized by the continuous cycling of matter and an accompanying flow of solar energy in which certain large molecules and cells are self-reproducing. Water is a major predisposing factor, for all life depends on it. The elements carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur, when combined as proteins, lipids, carbohydrates, and nucleic acids, provide the building blocks, the fuel, and the direction for the creation of life. Energy flow is required to maintain the structure of organisms by the formation and splitting of phosphate bonds. Organisms are cellular in nature and always contain some sort of enclosing membrane structure, and all have nucleic acids that store and transmit genetic information.

All life on Earth depends ultimately upon green plants, as well as upon water. Plants utilize sunlight in a process called photosynthesis to produce the food upon which animals feed and to provide, as a by-product, oxygen, which most animals require for respiration. At first, the oceans and the lands were teeming with large numbers of a few kinds of simple single-celled organisms, but slowly plants and animals of increasing complexity evolved. Interrelationships developed so that certain plants grew in association with certain other plants, and animals associated with the plants and with one another to form communities of organisms, including those of forests, grasslands, deserts, dunes, bogs, rivers, and lakes. Living (biotic) communities and their nonliving (abiotic) environment are inseparably interrelated and constantly interact upon each other. For convenience, any segment of the landscape that includes the biotic and abiotic components is called an ecosystem. A lake is an ecosystem when considered in totality as water, nutrients, climate, and all of the life contained within it. A given forest, meadow, or river is likewise an ecosystem. One ecosystem grades into another along zones termed ecotones, where a mixture of plant and animal species from the two ecosystems occurs. A forest considered as an ecosystem is not simply a stand of trees but is a complex of soil, air, and water, of climate and minerals, of bacteria, viruses, fungi, grasses, herbs, and trees, of insects, reptiles, amphibians, birds, and mammals.

Stated another way, the abiotic, or nonliving, portion of each ecosystem in the biosphere includes the flow of energy, nutrients, water, and gases and the concentrations of organic and inorganic substances in the environment. The biotic, or living, portion includes three general categories of organisms based on their methods of acquiring energy: the primary producers, largely green plants; the consumers, which include all the animals; and the decomposers, which include the microorganisms that break down the remains of plants and animals into simpler components for recycling in the biosphere. Aquatic ecosystems are those involving marine environments and freshwater environments on the land. Terrestrial ecosystems are those based on major vegetational types, such as forest, grassland, desert, and tundra. Particular kinds of animals are associated with each such plant province.

Ecosystems may be further subdivided into smaller biotic units called communities. Examples are the organisms in a stand of pine trees, on a coral reef, in a cave, a valley, a lake, or a stream. The major consideration in the community is the living component, the organisms; the abiotic factors of the environment are excluded.

A community is a collection of species populations. In a stand of pines, there may be many species of insects, of birds, of mammals, each a separate breeding unit but each dependent on the others for its continued existence. A species, furthermore, is composed of individuals, single functioning units identifiable as organisms. Beyond this level, the units of the biosphere are those of the organism: organ systems composed of organs, organs of tissues, tissues of cells, cells of molecules, and molecules of atomic elements and energy. The progression, therefore, proceeding upward from atoms and energy, is toward fewer units, larger and more complex in pattern, at each successive level (see Figure 1).

This article focuses on the makeup of the biosphere and examines the relationships between its principal components, including man. The characteristics and dynamics of biological populations and communities are dealt with, as are the interactions that constitute the primary stabilizing links among the constituent organisms. Due attention is also given to the distribution patterns of these biotic units and to the processes that produced such patterns. The major aquatic and terrestrial ecosystems of the Earth are treated in some detail. Other points include energy transformations and transfers within the biosphere and the cyclic flow of materials needed for life. For the development, methodology, and applications of the study of interrelations of organisms with their environment and each other, see BIOLOGICAL SCIENCES, THE: *The study of biological structure and function: Ecology.* Further treatment of the various aquatic and terrestrial environments is provided in OCEANS; LAKES; RIVERS; and CONTINENTAL LANDFORMS. For a discussion of the origin of life on Earth and the varieties of and commonalities among organisms, see LIFE.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 351, 352, 354, and 355, and the *Index.* (D.M.G./Ed.)

The article is divided into the following sections:

THE ZONE OF LIFE: AN OVERVIEW

Energy flow and material cycling

THE FLOW OF ENERGY IN THE BIOSPHERE

Energy and organization. A unique characteristic of life is that it is an organized system capable of creating more order from less order. This seems contrary to the general trend of the universe, in which there is a tendency to move toward maximum disorder (entropy) as expressed in the second law of thermodynamics. Life results from the steady-state, or balanced, situation in which there is a flow of energy from the Sun to the Earth and then to the cosmic cold of outer space. The first law of thermodynamics, the conservation of energy, states that energy is neither created nor destroyed but remains constant for the universe. It does not indicate how energy is transformed but only that all the energy within the system must be accounted for.

The constancy of energy in the universe

In order for sunlight to organize life on Earth, it must irradiate the surface with electromagnetic frequencies harmonious with the peculiar chemical bonds of organic molecules. Whereas the short-wave ultraviolet rays, gamma rays, and X rays are destructive to organic molecules, and the long-wave infrared radiation is absorbed and dissipated as heat, the near-ultraviolet and visible wavelengths interact well with matter to stimulate the formation of bonds and the arrangement of organic molecules.

The single most important photochemical reaction in the world is photosynthesis, the union of carbon dioxide and water in plants through the interaction of sunlight and chlorophyll molecules. In the photosynthetic process, light energy is absorbed by chlorophyll to convert carbon dioxide and water into carbohydrate and oxygen. This photochemical event is a stepwise process by which electrons are energized within the chlorophyll molecule and raised to higher energy levels with the formation of carbohydrate. In the process, which is complex, high-energy phosphate bonds are formed, and adenosine triphosphate (ATP) results. The end products within green plants are carbohydrates and energy-rich compounds that become food for plant-eating (herbivorous) organisms and a succession of animal-eating (carnivorous) organisms. The food web of ecosystems is provisioned in this way.

The universal fuel within all organisms is ATP, in which high-energy phosphate bonds store energy and release it when the bonds are broken. The complex reactions within a cell that lead to the formation of ATP combine at least one phosphorus atom per adenosine molecule. Without phosphorus no life could exist, since the entire linkage between photosynthesis and cellular activity would be missing. One process by which the energy stored in ATP is utilized is in the transformation of glucose sugar to sucrose, or ordinary sugar.

Phosphorous

Efficiency of utilization of solar energy. The intensity, as well as the composition, of the sunlight irradiating the Earth's surface is important to life. The tremendous amount of solar energy incident upon the Earth's outer atmosphere each day is distributed unevenly over the world, with the greatest amount of solar radiation reaching the desert regions and the least amount reaching the polar regions, where the slanted rays of the sunlight through the atmosphere are long. Temperate regions of the world, where food crops are grown, receive an intermediate amount of solar radiation, but a substantial fraction of this sunlight is received during the winter, when temperatures are too low for maximum plant growth. When intense winter cold grips the Arctic landscape, there is little light and no plant growth; only higher members of the food chain, birds and mammals, move about the land. In the tropics, temperatures are warm and constant throughout the year; the land is irradiated by sunlight more evenly throughout the seasons and plant growth is abundant. Although desert regions receive by far the greatest amount of sunlight, the lack of water limits plant productivity.

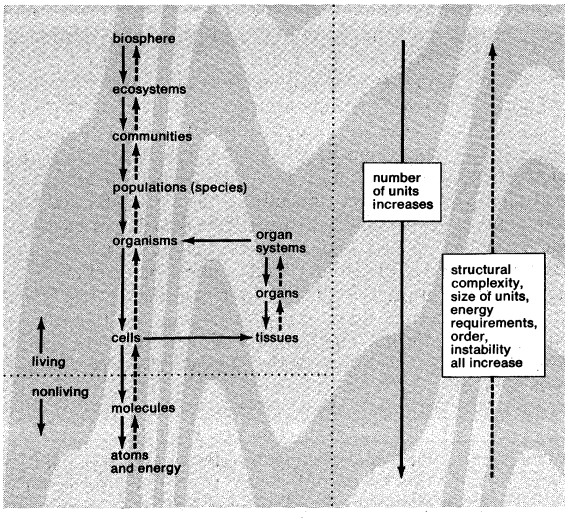

Figure 1: Hierarchy of levels in the biosphere.

The conversion of energy into matter

Only about 25 percent of the sunlight reaching the ground is in wavelengths useful for photosynthesis, and only a fraction of useful light is available to green plants. An understanding of the performance of the biosphere requires an appreciation of the efficiency of the primary production process. The efficiency of energy conversion from incident sunlight into organic matter (net primary productivity) seldom is as large as 3 percent and usually is 1 percent or less. Estimates for a cornfield, for example, show that only slightly more than 1 percent of the total sunlight striking it ends up as part of the corn plants; about 44 percent is used in the evaporation of water from soil and plants, 54 percent is reflected or dissipated as heat, and a fraction of a percent is consumed by the respiration of plants and animals in the field. This is not to say that all these other processes are not important, for indeed they are necessary to the proper functioning of the biosphere, but only a little more than 1 percent of the total incident energy ends up in new plant material. Other estimates of the net productivity of various vegetation types are:

	percent productivity
Tropical rain forest	1.4
Perennial grass–herb field	1.05
Coniferous forest	0.9
Deciduous temperate forest	0.4
Temperate lake	0.3
Desert	0.03

Animals grazing on the primary production convert only about 10 to 15 percent of the energy stored in plant material into animal tissue, and humans eating the animals convert only about 1 percent of this energy stored in animal tissue into human tissue. The total conversion process from sunlight to plants to animals to humans operates at an overall efficiency of about 0.001 percent. For a discussion of productivity in terms of the function of biological communities, see below *Biological communities, biomes, and ecosystems: Community function.*

Energy balance of organisms. Organisms utilize heat energy as well as light. All plants and animals must remain in reasonable energy balance. A plant leaf has a temperature that depends upon the amount of radiation absorbed, the flow of air over its surface, and its rate of transpiration, or gas exchange. The temperature a plant leaf assumes for any set of environmental conditions is of great importance to the plant, since all chemical reactions, including photosynthesis, are influenced by temperatures. A plant is coupled to its environment through the exchange of energy, gases, and nutrients.

A warm-blooded (homeothermic) animal remains in energy balance with approximately a constant body temperature. It moves about in its environment in such a manner that the amount of radiation it absorbs, the amount of energy it exchanges by convectional heating or cooling, and the quantity of energy it consumes by respirational water loss and evaporative cooling are such that its body temperature remains within a narrow range. A cold-blooded (poikilothermic) animal, on the other hand, has much less control over its body temperature. It nevertheless seeks the combination of radiation, air temperature, wind speed, and humidity that will result in an energy flow that is compatible with its body-temperature limits. Each and every animal in the world, depending upon its coloration, body size, shape, quantity of thermal insulation (fat, fur, or feathers), metabolic and water loss rates, and preferred body-temperature range and limits, has a well-defined climate space within which it must live in order to survive. Each species is restricted to its particular climate space as defined by its physiology and general body characteristics. Many animals will live in a somewhat restricted climate space, but none can live beyond its maximum climate space limits. The animals of the world are therefore distributed accordingly (see below *The distribution of organisms*).

Climate space

THE CYCLING OF MATTER IN THE BIOSPHERE

The general pattern of chemical cycles in nature. All life depends upon the cycling of matter (nutrients and water), as well as upon the flow of energy. Clearly, no organism can grow, propagate, and continue its kind for millions of generations without replenishing the elements that support it. Like birth and growth, death and decay are rules of the living landscape. Even the purely physical world has its cyclic processes of evaporation and condensation of water and the rise and erosion of rocks. In contrast to the unidirectional flow of energy through the ecosystem, whereby sunlight is absorbed by plants and heat is emitted to space at every conversion of energy from the eaten to the eater, any living and most nonliving entities emerge from the surface of the Earth only to return to their original point of origin in one form or another. Such a movement is called a biogeochemical cycle, in reference to the biological and geologic phases of chemical substances, impelled by the Sun's energy (see Figure 3).

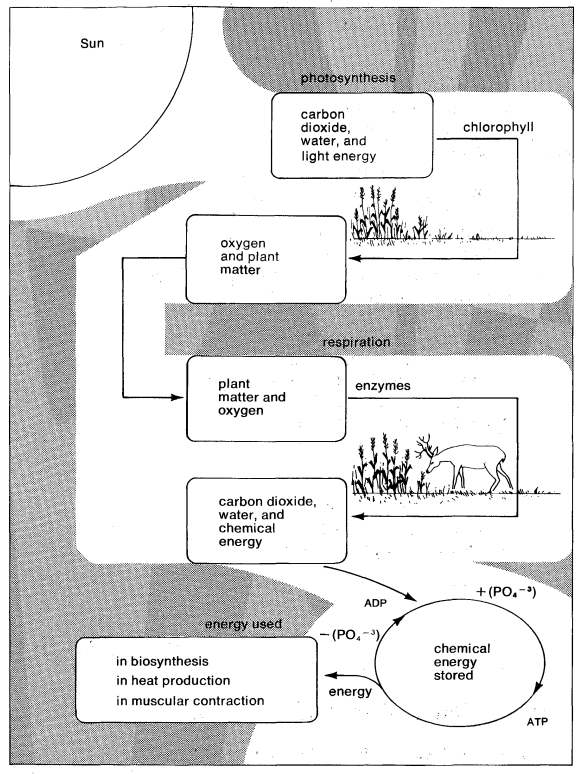

Figure 2: Energy relationships in the biosphere.

Elementary composition of organisms

All organisms contain water and utilize carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur in order to form carbohydrates, proteins, fats, lipids, and other structural materials. Most elements are obtained by plants through molecules such as water, H_2O; and carbon dioxide, CO_2; and compounds such as nitrate, NO_3^-; ammonia, NH_3; sulfate, SO_4^{2-}; and hydrogen sulfide, H_2S. Oxygen is taken in by animals through respiration, bound up in organic products, and converted to water, in which form it is eventually returned to the environment. Plants utilize soil and water and, through photosynthesis, return oxygen to the air. Phosphorus, which is so desperately needed by organisms that its abundance or lack often limits populations, does not cycle easily in the ecosystem. Eutrophication is a condition of lakes that results from phosphorus enrichment of the water. Much phosphorus is lost from soils by erosion, and the sediment deposits in the bottom of the ocean keep phosphorus out of circulation for extended periods. Nitrogen, the most abundant of atmospheric constituents, is a relatively inert gas that most organisms cannot use directly but that is essential to life. Fortunately, certain species of bacteria and some blue-green algae are able to utilize gaseous nitrogen that diffuses into the soil from the atmosphere. These soil organisms convert nitrogen (N_2) into ammonia (NH_3). Some plants utilize the ammonia directly, but most depend upon the oxidation of ammonia to nitrite (NO_2^-) and then to nitrate (NO_3^-) by other soil bacteria before it is absorbed by plant roots. This process is known as nitrification.

Mineral elements such as calcium, sulfur, magnesium, potassium, and boron are taken up in solution from soils by the roots of plants and are returned to the soil by decomposers, organisms that promote breakdown and decay of the dead litter of forests or fields. Although rainwater slowly washes out, or leaches, some minerals from an ecosystem, it also brings in with it some nutrients during the precipitation process. As rainwater runs down mountains and hills it gradually picks up nutrients and makes them available to green valleys below. When humans cut the forest and expose the soils to sun and rain, they accelerate the leaching process, often with disastrous consequences. In order to maintain high agricultural productivity it becomes necessary to apply increasing quantities of synthetic fertilizers to replace those nutrients washed away.

The carbon and oxygen cycles. The total biosphere contains approximately 20 quadrillion (2×10^{16}) tons of carbon, mostly in the form of inorganic carbonates in the rocks and oceans, and in organic fossil fuel deposits such as coal, oil, and natural gas. The atmosphere contains 7×10^{11} tons of carbon in the form of carbon dioxide, and the green plants of the world contain 4.5×10^{11} tons as carbohydrates and other organic compounds. The exchange of carbon dioxide with the atmosphere by means of photosynthesis and respiration in plants results in a net annual productivity of the land of about 2.5×10^{10} tons per year and of the oceans of about 2×10^{10} tons per year. During the daytime, photosynthesis often produces a 12 percent drop in atmospheric carbon dioxide in the vicinity of plants, but at night, respiration by soil bacteria, plants, and animals often produces a 25 percent increase in carbon dioxide concentration near the ground.

Fossil fuels combustion, deforestation, and decay accounted for a CO_2 atmospheric concentration of about 340 parts per million in the late 20th century. Much of this output may cycle into the oceans, and it is possible that a considerable fraction is bound up in new plant growth. But the increasing concentration of atmospheric carbon dioxide appears to be sufficient to accelerate the so-called greenhouse effect, the means by which the atmosphere retains sun-heat. This acceleration poses the threat of global warming, which would disturb weather patterns and diminish the polar ice caps, thus causing a potentially devastating rise in the sea level. These possibilities have made the greenhouse effect and its causes major public policy concerns in the late 20th century.

Greenhouse effect

Carbon dioxide is relatively soluble in water. It is not surprising, therefore, that the oceans play a significant role in the global distribution of carbon dioxide and that rainfall sometimes contains about 0.3 cubic centimetre of CO_2 per litre of water. Carbon dioxide combines with water to form carbonic acid (H_2CO_3), which dissociates into hydrogen ions (H^+) and bicarbonate ions (HCO_3^-); the bicarbonate ions, in turn, dissociate into hydrogen and carbonate ions (CO_3^{2-}). These reactions can be expressed:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{2-}.$$

These reactions are readily reversible, the direction depending upon the concentration of the components. The amount of carbon present as bicarbonate or carbonate depends upon the alkalinity or acidity (pH) of the water. If the water is alkaline, more carbon is present as carbonate than if the water is acid. High amounts of dissolved carbon dioxide in water produce high plant productivity (*e.g.*, algal blooms), but often this results in higher respiration, depleted oxygen, and subsequent fish kills. Acidic waters usually have low productivity.

Another gas of enormous significance to life is oxygen, which is cycled between the lithosphere, the atmosphere, and the biosphere. Plants are primarily responsible for the presence of atmospheric oxygen through the photosynthetic process. Oxygen in metabolism and in the production of energy-rich phosphorus bonds provides the power for all higher forms of life. Although oxygen is utilized within cell constituents such as mitochondria for the release of energy and the synthesis of ATP, other cellular bodies called peroxisomes appear to protect the cell from too much oxygen, which would result in destruction of the cell. Hence, in the oxygen cycle some organisms utilize the gas, some must be protected against it, and some generate it, all at the same time.

The nitrogen cycle. The atmosphere contains nearly 80 percent nitrogen. Ironically, most green plants are unable to use free nitrogen and must have it converted to soluble compounds of nitrogen, such as ammonia (NH_3), nitrite (NO_2), or nitrate (NO_3), which can then be taken up by their roots and the nitrogen converted into amino acids and plant proteins. The Earth's primitive atmosphere apparently contained ammonia, so the necessity

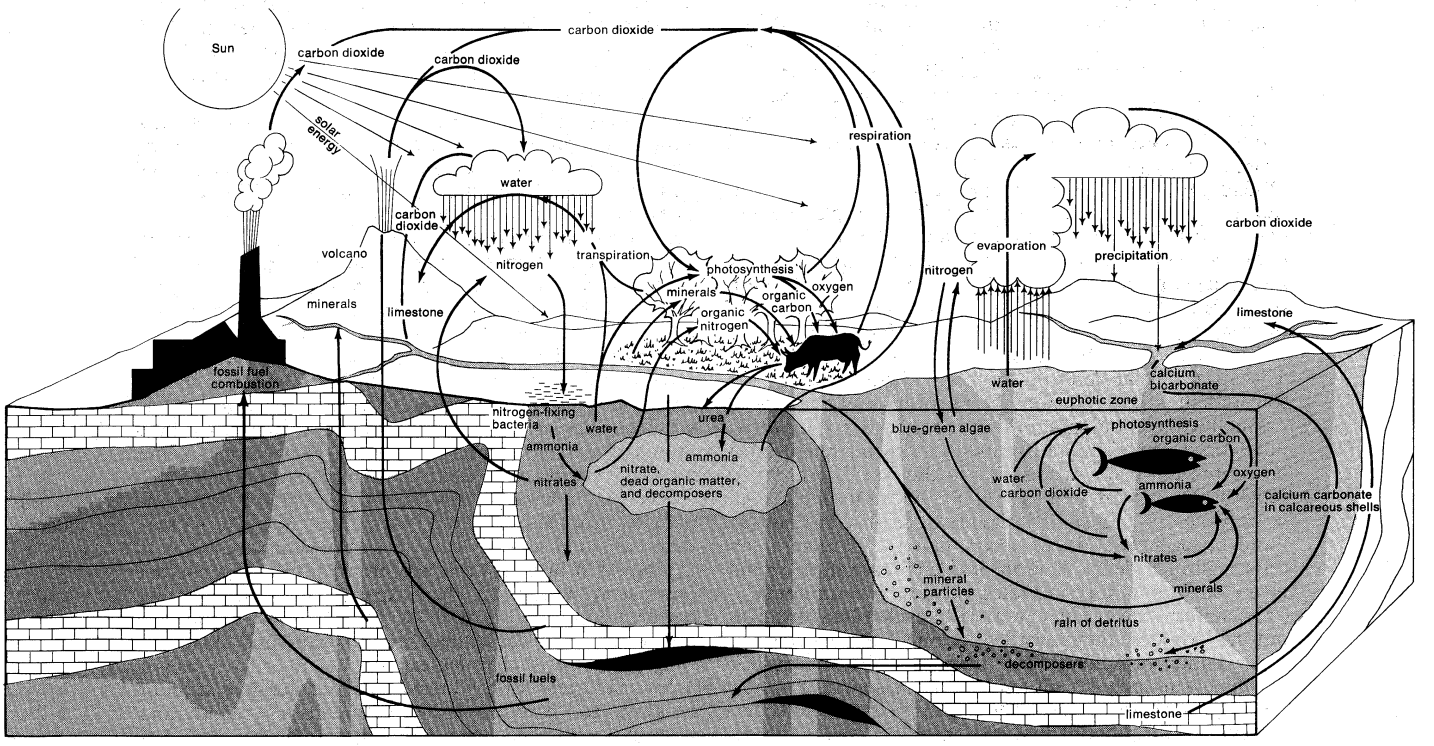

Figure 3: Major cycles of the biosphere.

for conversion of nitrogen into soluble products (nitrogen fixation) did not arise until more recently. Nitrogen fixation, or nitrification, is performed by a few species of microorganisms. The reverse process—by which soluble compounds of nitrogen are reduced to molecular nitrogen (N_2)—is called denitrification and is accomplished by other microorganisms. Microorganisms that decompose the remains of dead plants and animals reduce amino acids containing nitrogen to ammonium ions and other products. This process is known as ammonification. The rate at which nitrogen fixation removes nitrogen from the atmosphere is almost balanced by the rate at which denitrification returns nitrogen to the atmosphere. (The large-scale and widespread use of fertilizers by humans may be upsetting this balance, however.)

The indispensability of microorganisms in the movement of nitrogen

Nitrogen is present in proteins and nucleic acids. It is a versatile element in living processes because of its ability to form many different kinds of compounds and to release energy when moving from one compound to another. Nitrogen is cycled in nature from reduced inorganic compounds to oxidized compounds by atmospheric oxygen, with the release of energy; when oxygen is unavailable, oxidized nitrogen compounds can in turn oxidize organic compounds. Two main types of bacteria and algae participate in nitrogen fixation. One lives in a mutualistic partnership (symbiosis) with higher plants; the other is a free-living form that derives energy directly from sunlight and indirectly from plant materials. Rhizobia, the most abundant of the root-nodule symbiotic bacteria, are found on the roots of legumes, alders, and buckthorns. Legumes, which include peas, soybeans, and alfalfa, are often used in agriculture to increase the productivity of the land. Symbiotic nitrogen fixers normally contain certain trace elements such as molybdenum and cobalt. When these are absent, the bacteria do not function effectively, and the rate of nitrogen fixation is reduced.

Symbiotic microorganisms occur only in terrestrial ecosystems as far as is known. Among the nonsymbiotic nitrogen fixers are aerobic soil bacteria such as azotobacters, which supply fixed nitrogen in grasslands and in marine and other ecosystems where symbiotic microorganisms are absent. Blue-green algae (cyanophyceans) are an important source of fixed nitrogen in rice paddies and in aquatic systems. One free-living nitrogen-fixing bacterial genus that lives only without oxygen *(i.e.,* anaerobically) is *Clostridium.*

Autotrophs

A group of microorganisms known as autotrophs functions without an organic source of energy by oxidizing various forms of soluble nitrogen compounds. Nitrosomonads oxidize ammonium to nitrite with the release of water and energy. Nitrobacters, in turn, oxidize nitrites to nitrates with the release of energy. Nitrates are highly soluble in water and are easily taken up by roots and assimilated by plants.

Pseudomonads and some fungi use nitrate as an oxygen source; they draw on the energy available in glucose and phosphate to convert the nitrate to nitrous oxide and nitric oxide. Some denitrifiers reverse the process only partway by reducing nitrate to nitrite or ammonia. Denitrification proceeds best under anaerobic conditions, since whenever oxygen is present it is more efficient for organisms to use it than to use the oxygen bound up in nitrate ions. This suggests that denitrification would occur best in the soil and in deeper portions of the waters of the world. From the enormous amount of nitrogen fixed annually, however, about 92 million tons, it is obvious there must be enormous anaerobic reserves in the world in order to return this amount of nitrogen to the atmosphere each year. It is entirely likely that the use of fertilizers is causing more nitrogen fixation to occur than the biosphere can return through denitrification, in which case there would be a gradual buildup of nitrates, nitrites, and ammonia.

The sulfur cycle. For materials to cycle easily throughout the biosphere they must be not only water-soluble but also volatile. In addition to carbon and nitrogen, sulfur is a highly mobile constituent of the biosphere. Furthermore, all proteins incorporate sulfur in their molecular structure to form bonds that give them well-defined three-dimensional shapes. Just as carbon and nitrogen are reduced during the formation of proteins, so also is sulfur. In distinction to carbon, however, which requires green plants and sunlight for reduction, nitrogen and sulfur reductions are most often accomplished anaerobically by microorganisms. Most of this activity occurs in oxygen-deficient soils, bogs, and swamps.

When an organism dies and decays, much of its incorporated sulfur is returned to a mineralized state by bacteria and fungi, but some is reduced under anaerobic conditions directly to sulfides, such as the evil-smelling hydrogen sulfide (H_2S), some of which escapes to the atmosphere. Burning of fossil fuels sends massive quantities of sulfur dioxide into the atmosphere as a pollutant. When the sulfur dioxide combines with water in rainfall it forms dilute sulfuric acid (H_2SO_4), a form of acid rain. Inorganic sulfate (SO_4), formed by the decomposition of organic matter, is readily soluble in water and serves as a further source of sulfur to plants and animals. Sulfate is reduced under anaerobic conditions to elemental sulfur or to sulfides by bacteria. Large quantities of hydrogen sulfide occur in the anaerobic (deeper) portions of aquatic ecosystems. The anaerobic bacteria utilize the sulfate in metabolic oxidation much as bacteria denitrify nitrate and nitrite.

Acid rain

There are sulfur-utilizing bacteria that play the same role with sulfur compounds as nitrifying bacteria do with nitrogen compounds. These include the green and purple photosynthetic bacteria; the green bacteria oxidize sulfide to sulfur and the purple bacteria generate sulfate.

Sulfur precipitates in lake waters as sulfides in the presence of iron under anaerobic conditions. Some sulfide is insolubly bound with iron in the bottom muds of lakes, bogs, swamps, etc., where other elemental metals, such as copper, cobalt, cadmium, and zinc, also become bound as precipitates.

The water cycle. Water is a ubiquitous and unique substance necessary for life on Earth. Water in liquid and vapour states in the atmosphere regulates and ameliorates the climates of the Earth. Strictly speaking, water conforms to a gaseous cycle, but because of its great importance in the biosphere it is here discussed separately. Life began in the oceans, evolved in the waters of the world, and spread upon the land; yet life has always remained dependent upon the availability of water. The relative distribution and availability of water on the land determines the vegetative character of the landscape. Water erodes and sculpts the rocky surface of the Earth, transports nutrients and sediments, and forms the lakes, swamps, rivers, and seas. Sun-heat evaporates water from land and sea into the atmosphere, where it is transported with the global circulation of air and precipitated onto the surface as rain or snow.

The topography of continents and islands affects very strongly the precipitation pattern of the Earth. Windward mountain slopes are wet, as warm moist air rising cools and condenses its moisture as rain or snow. The leeward sides of mountains are dry, since the moisture has already been wrung from the air on the other side of the divide, and the air moving down the leeward face warms, thereby retaining whatever moisture it still has. Semiarid regions with sparse vegetation often occur to the leeside of mountain ranges. Cold polar ice caps have relatively low precipitation since very cold air can contain little moisture. Deserts generally occur where the air is stable. The trade winds move toward the equator from cooler latitudes, picking up moisture and heat as they go; hence the coastlines of southern California, Mexico, and Chile are relatively dry, and the equatorial regions are wet.

Properties of water

Water has amazing properties, particularly when compared with most other forms of matter known in nature, that make it chemically and physically suitable for life. It is a liquid at ordinary temperatures, contracts on cooling down to 4° C (39° F), then expands on further cooling to the freezing point at 0° C (32° F). Solid water, or ice, is thus less dense than liquid water and floats on water. The fact that water expands on freezing makes it a powerful agent for the breakdown and fragmentation of rock into soil particles. Water warms up less rapidly and in turn cools more slowly than other substances. Lakes and oceans, therefore, have a different temperature from

the adjoining landmasses, with a seasonal lag. Water tends to hold dissolved material in solution and also has the greatest surface tension of any known liquid. Moist air is less dense than dry air and rises above it, contributing to the weather dynamics of the atmosphere.

Taken over the world as a whole, the horizontal distribution of moisture must always add up to zero—the amount of water falling as precipitation is equal to the amount of water vapour taken up by evaporation. For any single region of the world, however, there may be a water surplus or a water deficit, differences that are theoretically balanced by ocean currents or river runoff. The Northern Hemisphere, for example, has an excess precipitation over the Southern Hemisphere, and the difference is redistributed by means of ocean currents. The drier the continent, the smaller the fraction of the annual precipitation that runs off. Australia and Africa, as a whole, are relatively dry continents in which large areas are covered by deserts and more than 75 percent of the annual precipitation is lost through evaporation.

In order for evaporation to occur, two conditions must exist. There must be energy available, which is derived largely from sunlight, and there must be a water vapour gradient from a moist surface to air that is less moist. In other words, heat and dryness aid evaporation.

Interrupting this cycle of simple precipitation and evaporation are the organisms of the world, which divert water for their own use. Water relationships are most dramatic in land situations. Soils hold considerable amounts of water. On the average, worldwide, this may be a reserve of about 10 centimetres (4 inches) in depth. In some parts of the world, such as North Carolina, where soils are thin, the total amount of water held in the soil may not exceed 5 centimetres (2 inches), but in the deep volcanic soils of east Africa as much as 50 centimetres (20 inches) is held in the soil.

Plants take up water largely through their roots and evaporate water through the leaves in a process known as transpiration. A green plant may transpire 3 to 5 millimetres (about 1/8 to 1/5 inch) of water a day, depending upon the amount of energy available. Maximum rates in sunny, hot, irrigated regions may reach 8 millimetres (1/3 inch) a day.

Transpiration ratio

An important ratio for plants, known as the transpiration ratio, is the amount of water used to the weight of accumulation of dry matter in the plants. For corn (maize) it is 317 grams of water per gram of dry weight, for cotton 568, deciduous trees 825, and evergreen trees 140. Taken over a whole growing season, although it is highly variable among crops, one can estimate that a production of 20 fresh-weight tons of crop will require 2,000 tons of water from the soil. Of the 20 tons of crop only about three tons consist of water molecules utilized in photosynthesis, the remainder being evaporated as transpiration.

In addition to their physiological need for water, large numbers of terrestrial animals use bodies of water as sanctuaries. The eggs of many insects are laid in water, larvae live in water, and the adults emerge from ponds or rivers to spend their adult lives on the land. Amphibians occupy a narrow zone between land and water, in which they can move from the harsher, more variable climate of land into the milder, more comfortable conditions of water. All land animals give off moisture when they exhale, and some animals pant or sweat to evaporate moisture and thus cool themselves.

The sedimentary cycles of essential minerals. While many elements give rise to gaseous compounds that are significant parts of biogeochemical cycles, some elements in the biosphere cycle primarily through water transport and sedimentation in bodies of water. For any soluble but nonvolatile compound a natural cycle is only possible when life is involved, since otherwise the compounds wash from the land to the rivers and oceans, where they remain in the sediments. Green plants pick up the compounds in the nutrient-rich soil water and convert them into plant cells where they may be passed to animals in the food chain; they eventually return to the soil through death and decay of plants and animals. Some compounds soluble in water are carried into the atmosphere by water evaporation and returned to the surface in rain.

The elements calcium, potassium, silicon, and magnesium each have important biological roles in the biosphere. Magnesium, for instance, is an essential element in the chlorophyll molecule, and calcium and silicon help form the hard parts of shells, bones, and teeth of animals. Iron, manganese, and sodium are present in organisms in minute, or trace, amounts, but nevertheless are vitally important. As mentioned earlier, phosphorus is probably the most important element among those that form nonvolatile compounds. A deficiency of phosphorus is most often responsible for poor crop production. Free phosphorus as such is not found in the atmosphere. If it were not for green plants absorbing its salts from the soil and transporting it to the leaves, phosphorus would not rise above the surface of the ground. So it is also for trace elements such as iron and manganese. Some trace elements such as vanadium, cobalt, nickel, and molybdenum are found primarily in aquatic plants, since they accumulate in bottom sediments.

The problem of phosphate enrichment

Phosphorus is soluble in acidic waters; under special environmental conditions it is bound up as calcium phosphate or iron (ferric) phosphate. Phosphorus is extremely scarce in the lithosphere, concentration normally being 1,050 parts per million. But great supplies of phosphorus are found in bird guano, the excrement of fish-eating gulls, cormorants, pelicans, and penguins, on the islands and in the ocean sediments off the coast of Peru. Artificial, or chemical, fertilizers are made from phosphate rocks and marine phosphates. Great quantities of these phosphates are used in detergents and wash into lakes and streams. Such phosphate enrichment creates rapid and excessive growth of algae, especially the blue-green algae. Increased decay and respiration result in oxygen depletion of the water and the suffocation of more sensitive species of fish, usually the game fish. This enrichment process, called eutrophication, usually results in a simpler animal and plant community, a shortening of the food web, and a less stable ecosystem. (D.M.G./Ed.)

The distribution of organisms

The subject of distribution embraces the individual organism as a unit of study as well as the highest taxonomic unit. As far as scale is concerned, the range is equally great, from a drop of water to the largest ocean. Not surprisingly, the study of distribution encompasses several overlapping disciplines. Ecology is concerned with the numbers and distribution of organisms on a local scale, and biogeography is concerned with distribution on a regional or even worldwide scale. Other disciplines contribute much to the study of distribution and are in turn helped by it. The two most prominent of these are systematics and the study of evolution. Systematics, the study of the relationships between organisms, in the widest sense embraces classifying and naming organisms, information essential to biology in general and to the study of distribution in particular. Systematists, in turn, use distribution information in reaching decisions on the relationships between organisms. The study of evolution has benefited considerably from distribution information, as the best-known pioneers in the field, Charles Darwin and Alfred Russel Wallace, freely acknowledged. In return, a knowledge of the processes of natural selection has made large contributions to the understanding of the reasons for changes in distribution with time.

PATTERNS AND PROCESSES OF DISTRIBUTION

It is convenient to distinguish two closely related modes of distribution that are, in fact, inseparable in nature: (1) the local arrangement—on a small scale—of members of a population to ensure their survival by maximizing the use of the environment, often in accordance with the time of day, week, month, or year, and (2) the large-scale geographic spread—on a regional, or even global, scale—of a species over a long span of time. Obviously, the distribution of organisms on a local scale eventually affects the geographic arrangement of the species.

Local distribution. Just as the body of an organism has

a structure, so does a population of organisms. The structure that results from the distributions of organisms is termed a pattern. Patterns may be characterized either by the forces that produced them (physical, social, or other) or, as in this discussion, by the ability of the organisms themselves to adjust their distribution.

Spatial and temporal arrangements. In a homogeneous environment—one that varies little from place to place—all parts of the environment may be occupied or visited by organisms. Protozoans may be distributed throughout a small pool of water, and all available space on a rock in the intertidal zone of a shore may be covered by mussels or barnacles. In a heterogeneous environment, the total volume occupied or visited by a population may contain parts that are not exploited. In the pelagic, or open water, realm of an ocean, minute plantlike organisms may occur patchily, and the animals that feed upon them may be distributed in the same manner. These extremes of distribution are difficult to characterize because of the problems of measurement and representation in three dimensions. If the third dimension is not occupied, or unimportant enough to ignore, then distribution in a single plane, such as a flat piece of ground, is easy to characterize.

The three patterns of dispersion

There are three patterns of internal distribution (or dispersion) of a population in a single plane (Figure 4). Organisms are distributed at random when individuals are free to choose a place to settle. But individuals often influence each other. When they attract each other, an aggregation, or clump, tends to form; when they repel each other, an overdispersion, or uniform spacing of the individuals, results. In the soil or in the leaf litter of a forest floor, almost all arthropod species are distributed in a clumped or aggregated fashion, with only a few species randomly distributed. Territorial animals, such as birds, and some plants, such as certain cacti, repel each other at a certain distance and thereby assume a uniform pattern of distribution.

The importance of scale is illustrated in Figure 4. It shows that, on a small scale, members of a population are uniformly distributed, but on a large scale they are aggregated in clumps. This happens, for example, when many flocks of birds occur in a large area but retain their discreteness. A certain minimum distance is maintained between individuals in each flock by mutual avoidance, yielding uniform spacing within the flock. But the flocks themselves may be randomly distributed or clumped.

For many species, distribution is a function of time. The members of a population make regular movements, so that their distribution is different from one hour to the next; one day, week, or month to the next. Short-term shifts in distribution are best exemplified by plankton, small, often microscopic, organisms that float in the surface waters of lakes and seas. They move vertically in response to daily changes in light intensity, so that they are at greatest depth at midday and are at the surface or close to it at dawn and dusk.

More striking, perhaps, are the regular annual movements of some animals, which bring them to one region at the time of breeding and to another region in the nonreproductive season. Such movements are known as migrations (see below *Biological populations: Changes in population characteristics: Movements*).

Environmental influences. Organisms cannot exist outside a certain range of environmental conditions. There is an upper temperature limit to the activities of protoplasm, beyond which proteins are denatured, and a lower limit, which for many organisms corresponds with the temperature at which water freezes. Many organisms, however, are capable of existing, at least for a short time, under inclement conditions. They can survive long enough to move out of the area (by migrating) or to become physiologically inactive and, thus, protected against adverse conditions (by hibernating, estivating, or encysting). Some "cold-blooded" animals have the ability to adjust or acclimate physiologically by altering their metabolic activities in such a way as to operate best under the prevailing temperatures. Physiological adjustments of this sort are possible only when the environmental conditions change relatively slowly and by a relatively small amount.

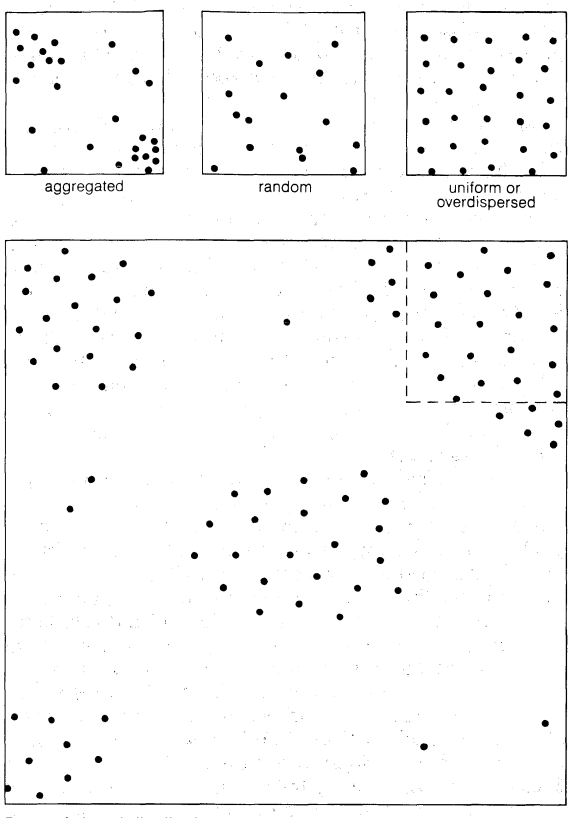

Figure 4: *Local distribution of organisms.*
(Top) The three basic dispersion patterns. (Bottom) The relativity of dispersion to scale. On a local scale (inset) the individuals are uniformly distributed (overdispersed), but, on a larger scale, they are aggregated.

Within this framework, many processes operate in the establishment of a pattern of distribution of a species on a local scale. Perhaps the easiest to envisage is a distribution determined largely by the characteristics of reproduction. In many plants, and some lower animals, the reproductive products (seeds, spores, etc.) remain close to the parents because their dispersal capabilities are poorly developed, thus creating an aggregated distribution. In contrast are the intertidal organisms, many of which, although themselves fixed firmly to the substrate, shed their reproductive products into the water at high tide. The larvae develop in the pelagic realm of the sea and are carried to shore at the time they are metamorphosing to the adult stage.

Directional versus random forces

The distribution pattern of adults that results from this combination of dispersal and settlement is determined by two kinds of processes, which are termed vectorial and stochastic. The vectorial process refers to directional dispersal caused by environmental motion, as in wind and water currents. The stochastic process refers to essentially random forces whose operation does not allow a prediction to be made as to where organisms will be carried and will settle.

As was mentioned earlier, the pattern of distribution may be determined also by the influence of one organism upon another. The social process that gives rise to the pattern is one of signaling. The messages are either "come here," leading to aggregation, or "go away," leading to uniform spacing. Alternatively, these two patterns, as well as a random one, may be produced by each organism responding individually to environmental features such as nutrients, which are themselves distributed in random, clumped, or uniform fashion.

Interactions with other organisms. Finally, the distribution of organisms of a species may be determined by interactive processes with other species. Heavy grazing by animals in a certain area often leads to a sparseness of plant species in the grazed area. Similarly, competitor species may influence each other, the one causing the other to be either rare or absent in one part of a local area. Throughout Europe, North Africa, and some of

the Canary Islands, for example, the chaffinch (*Fringilla coelebs*) occurs in both deciduous and coniferous forests, but on two of the Canary Islands, Tenerife and Gran Canaria, it occurs only in deciduous forests, a closely related species, the blue chaffinch (*Fringilla teydea*), occupying the coniferous areas. The distribution of the chaffinch on Tenerife and Gran Canaria appears to be influenced, in a restrictive way, by the blue chaffinch, with which it could compete for space and food. This type of influence, while not easy to recognize, is probably exercised commonly between species that live in the same habitat as well (see also below *Biotic interactions*).

Differences in the way in which the three basic patterns of distribution—random, clumped, or uniformly spaced—are set up have been emphasized, but a single mechanism could be responsible for any one. Consider plants, for example. If the spatial pattern of germinating seeds is random, if they thrive only in space not occupied by other root systems, and if they grow to a size that depends upon the space available, then the resulting distribution will depend solely upon the density, or numbers of seeds. Going from low to medium to high density, the distribution changes from clumped to random to uniformly spaced. Thus, the factors that govern the abundance of a species within a local area indirectly determine the distribution of the species in that area. It is possible that the factors that govern the abundance of a species also limit the distribution of that species. The processes leading to the establishment of a distribution range (area or volume), as opposed to the pattern of distribution within that range, are discussed in the next section.

Large-scale distribution. More is known about distribution on a large scale than on a local scale. The reasons are partly practical and partly historical; it is easier to collect a few isolated specimens of plants or animals over a wide area than to study in detail their distribution in a clearly circumscribed area such as a field or a grove. In the past taxonomists and students of evolution have spent much energy trying to determine the extent of geographic variation in morphological characters of organisms, for which purpose collected specimens are sufficient.

The shape and extent of spread. Most species occupy areas of irregular shape. The irregularities are often determined by obvious environmental features. The irregular pattern of distribution in North America of the pika (*Ochotona princeps*), a small rabbitlike animal, for example, corresponds with the irregular pattern of distribution of its habitat—rock slides and talus slopes at high altitude in the Rocky Mountains. When the distribution of certain habitat features is essentially linear, so too is the distribution of the species; the emergent vegetation at the edge of a lake and the intertidal mollusks in a narrow band along a rocky seacoast are cases in point.

Continuous versus discontinuous distribution

Viewed on a local scale, the distribution of organisms may be continuous, or without interruption, but when viewed on an intermediate regional scale, the distribution may be discontinuous, or spotty, because of unsuitable habitat intervening between areas of suitable habitat. Viewed on a large scale, a continental or worldwide scale, the distribution may appear continuous once again, as the narrow bands of unsuitable habitat that produce the discontinuities slip out of focus.

Discontinuities on a worldwide scale are evident for some species. Horseshoe crabs (family Limulidae) are found on the Atlantic coast of North America from the state of Maine to Mexico. These crabs are not found on the west coast of that continent, however, but on Asian coasts, from India to Japan, thousands of kilometres away.

Few species—of which man is one—have a worldwide distribution. Of those that do, several are associated closely with man and have achieved their present distribution as a result of this relationship. Nevertheless, there are cosmopolitan species that have achieved worldwide distribution by their own efforts. Such are the short-eared owl (*Asio flammeus*) and the osprey (*Pandion haliaetus*), two birds, both predators, conspicuous on all continents excluding Antarctica.

Restricted distribution

It is much more common to find species with restricted distributions. In addition to the numerous species confined to single, small islands, there are continental species found in extremely small areas on large landmasses. The dusky seaside sparrow (*Ammospiza nigrescens*), for example, occurs only in the salt marshes around Merritt Island, Fla., and on the adjacent peninsula.

Another form of restriction is indicated by the distribution of small carrion (*Catops*) beetles (Figure 5): restriction to a climatic zone, in this case the north temperate zone. The booby (*Sula leucogaster*), a seabird, has a pantropical distribution, breeding only—but extensively—within the tropical zones. Two closely related species of the marine wormlike priapulids are restricted to the polar regions, one in the Arctic, the other in the Antarctic.

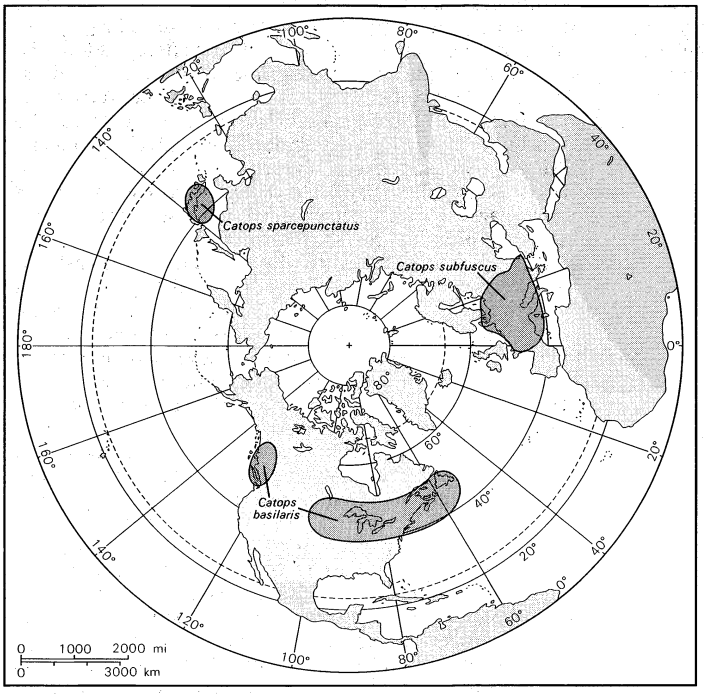

Figure 5: Discontinuous distribution of three beetles of the genus *Catops* in the north temperate zone.

In all these instances, and in their variations, the restriction is the result of the inability of the organisms to exist beyond a range of certain environmental conditions. This is contrasted with restriction caused by the inability of organisms to travel over barriers, which has led to regional differentiation of faunas and floras.

The factors limiting spread. Although more is known about the gross distribution of species than about their distribution within local areas, little has been established with certainty concerning the determination of the limits of an area occupied. In some cases the reasons for limitation of geographic range are obvious: the distribution of terrestrial organisms stops at the edge of sea, lake, or river; freshwater organisms occupy the length of a river, but extend no farther than its estuary. But within the major environments the reasons for the observed distributions are not always so easy to discern.

At the outer edge of a distribution range the continued existence of organisms depends upon either reproduction or immigration from more central regions. The requirements of the individual for existence and reproduction must be met. One obvious way in which the distribution is limited is by insufficiency of the supply, or rate of supply, of these requirements. Any number of environmental factors, acting singly or in combination, can act in this limiting way.

The northernmost limit of distribution of the wood frog (*Rana sylvatica*), in North America, is almost certainly set by a combination of temperature and time. Complete development of the tadpole stage in one summer is the rule. At their northern limit, these frogs have just enough time in the short Arctic summer, at the prevailing low temperatures, to complete development. Temperature has

also been implicated as a factor in limiting the southern distribution of introduced pheasants (*Phasianus*) in North America. If the environmental temperature is high before incubation of the eggs, the eggs will not hatch. The southern limit to the distribution of the pheasant in North America corresponds approximately with those spring temperatures that are critically high.

In Scandinavia, the distribution of a carabid beetle (*Bembidion aeneum*) corresponds well with the distribution of soil that was lightly salted when the land was covered by the sea about 9,000 years ago. The beetle appears to depend upon the salt, either directly or, perhaps more likely, indirectly, through plants or other animals that require the salt and that themselves serve as food for the beetle.

Relationship between plant and animal distribution

In general, gross climatic and soil conditions determine the distribution of plants, singly and as assemblages; animals, being dependent upon plants for energy, follow the plant distribution. There are some highly specialized associations between plants and animals, as between some pollinators and the plants they pollinate; the edges of the distributions of the two interdependent species coincide.

Many animal species, however, are not so much limited in distribution by a single plant species as by an assemblage of plant species, such as those constituting a savannah or a tidal marsh, for example.

Factors limiting the distribution of a species are easier to recognize when they are discrete rather than graded, as is temperature. The side-blotched lizard (*Uta stansburiana*), for example, which occurs in the deserts of southwestern North America, breeds only in the abandoned nests of the pack rat (*Neotoma micropus*); the number of such nests thus sets an upper limit to the number and the distribution of breeding pairs of lizards.

The Australian ecologists H.G. Andrewartha and L.C. Birch have suggested that the factor or factors that limit the abundance of an animal species within its distribution range also limit the range itself. Exceptions to this are easy to find, particularly where the limit of distribution is set, at least in part, by a physical barrier, such as a mountain range. Nevertheless, the statement is likely to be widely true, especially for arthropods, and it is easy to appreciate when the species fluctuates in numbers markedly from one year to the next. A fine example is provided by the cutworm moth (*Porosagrotis orthogonia*), a pest species in North America, whose larvae feed on the roots of wheat. In Montana, for instance, in years of great abundance the species occurs throughout most of the state, but in years of scarcity it is either rare or absent from some parts.

Not only are distributional limits at one point set by an interaction of factors, but different boundaries are set by different factors. The saguaro cactus (*Cereus giganteus*) occurs in the Sonoran Desert of the United States and Mexico, but is not found either at the highest or lowest altitude within its area of distribution. The upper limit appears to be set by low winter temperatures, and the lower limit is set by a variety of factors, most important among which seems to be the fineness of the soil; this in turn probably affects the plants in a complex way through its properties of stability and of retention of nutrients and water.

One species can prevent the spread of another by virtue of competitive superiority in the range that it occupies, thereby setting the limit to the distribution of the other species. The distribution of two species of western pocket gophers (*Thomomys*) in North America is representative. The northern pocket gopher (*T. talpoides*) occurs in northern states and the valley pocket gopher (*T. bottae*) in southern ones. An outline of their distributions shows that there is little overlap and that their boundaries are often complementary (Figure 6). No conspicuous environmental feature coincides with the highly distinctive boundaries, so it appears that the species have set them themselves by interacting.

THE NATURE OF DISPERSAL

The requirements of an organism are a place to live, food, and, for sexually reproducing organisms, a mate. The requirement of space is not easily met in a densely populated area. Animals, of course, possess the ability to seek out unoccupied space, but for plants there is a strong element of chance in the finding of suitable space. In both, however, the dispersal characteristics of the organisms are of fundamental significance and, as such, are strongly under the influence of natural selection. These characteristics partly determine whether a species is widely or narrowly distributed and whether it can establish itself in isolated areas. Dispersal characteristics also influence the evolutionary process. Since the evolution of two populations from a single ancestral population usually requires spatial isolation, the dispersal frequency of members of the populations determines whether the degree of isolation is sufficient for evolution to take place.

The role of natural selection

Mechanisms of dispersal can be considered both active and passive. Some seeds are actively dispersed by mechanical means, as when a seed pod dries out, splits open, and sends a shower of seeds to the ground in the vicinity of the parent plant. Generally, however, plants rely on passive means of dispersing, whereas both passive and active means are used widely by animals.

Active dispersal. The conditions under which active dispersal occurs are not uniform throughout the life of organisms. Dispersal usually occurs at the time of reproduction, when the individual seeks a mate or, in the case of many vertebrates, seeks a place in which it can attract a potential mate. The first patch of suitable terrain or water is chosen by the dispersing individual, and this may be close to the place where it was born. If all the space in the vicinity of home is already occupied by other individuals, however, then that individual will be forced to disperse more widely, to increase its chances of securing a mate and food. It is these far-dispersing individuals that are likely to significantly alter the distribution range of the species. The rule is almost certainly that most of these individuals perish as they encounter unsuitable conditions beyond the limit of distribution of the species. Still, some reach suitable pockets of habitat beyond and somewhat isolated from the original distribution range, and occasionally these give rise to new populations.

The most spectacular of dispersal movements, however, are the so-called irruptions of birds. These movements are not the result of a search for a place to breed, but are induced by a combination of poor food supply and possibly other adverse environmental conditions coupled with

unusually high density at the end of the breeding season. An example of such an irruption is observed in Great Britain, which is beyond the breeding range of Pallas's sand grouse (*Syrrhaptes paradoxus*) but which has been visited irregularly by sizable numbers of this species. As far as vertebrates are concerned, it seems that all individuals in a population have an approximately equal ability to disperse. Whether they do disperse, and how far, is dependent upon density in relation to the required resources of food and water and upon the availability of mates.

Somewhat distinctive dispersal abilities are exhibited by members of many insect populations. Perhaps the best-known examples are found among locusts, ants, and termites. In central and eastern Africa the desert locust (*Schistocerca gregaria*) occasionally swarms and consumes all green plant material in its path. The species actually occurs in two forms of quite different behaviour. The bright green form is solitary and sluggish, while the darker form, the one observed in the plagues, is highly mobile and gregarious. If the young produced by the green form are raised at high density with frequent physical contact between individuals, they develop into adults of the dark form and not the green form. This phenomenon, known as phase polymorphism, is admirably suited to the species. As the population increases and depletes its food supply, a developmental and behavioral mechanism comes into play, resulting in the production of individuals that are predisposed to dispersing.

Polymorphism: forms to fit the need for dispersal

The caste polymorphism of ants and termites serves a similar function. In these highly social insects, in which different members of the society are structurally and behaviorally specialized to perform different tasks, dispersal to new areas and the founding of new colonies is the task of the winged forms.

A third form of polymorphism exhibited by insects is life-history polymorphism, as exhibited among butterflies, dragonflies, and wasps. In all of these insects the wingless larvae are the feeding phase and disperse little, whereas the adults are the dispersal phase and feed little. In fact, the adults of some insects, such as mayflies, do not feed at all, but disperse, mate, lay eggs, and die.

There are exceptions to the statement that larval insects disperse little, which introduces a fourth kind of polymorphism, termed behavioral polymorphism. In a population of the larch budmoth (*Zeiraphera griseana*) in Switzerland, there are at least two types of larva that differ in structure and behaviour. One is intolerant of crowding; it disperses readily and is usually the first to appear on the principal food plant, larch trees (*Larix*). The other is tolerant of crowding and disperses little. The proportion of these two types in the population varies from time to time in accordance with the overall density. A balance of advantages and disadvantages allows the two forms to persist together without one replacing the other.

As indicated by the above example, natural selection does not always favour the individuals that disperse the most. If the chances of dispersing and finding a new, suitable, and unexploited environment are very low, selection will act against the strong dispersers. Such seems to be the case in highly restricted and well-isolated environments such as oceanic islands and mountaintops. In these environments the number of flightless birds and insects is striking and is much greater than in continental regions. Charles Darwin pointed out that the possession of large wings and well-developed powers of flight could be a disadvantage to animals on oceanic islands, particularly small ones, because an occasional strong wind might carry an already airborne animal away from the island and out to sea. The zoogeographer P.J. Darlington has emphasized that wings are also used in flight from predators, but predators are scarce or absent on these islands, so the need for dispersal powers within the island environment is not as great as within continental environments.

Passive dispersal. Organisms are dispersed passively by three principal agents: wind, water, and other organisms.

Dispersal by wind and by water. The capability of wind to transport organisms is well known, but the extent and the scale of such transportation is only now becoming clear. Microscopic organisms, such as viruses and protozoa, are readily carried by the wind, but even some of the smaller vertebrate animals such as frogs can be carried along on strong winds. Spiders, mites, and insects have been collected on airplane flights across the Pacific Ocean at distances up to 3,000 kilometres from land. Because of the method of capture, specimens are dead, so there is no means of distinguishing whether they were or were not living when they were collected. Nevertheless, in view of these remarkable results, it is no longer surprising that even the most isolated islands have an extensive insect fauna. There are, for example, close to 4,000 insect species native to the geographically rather remote Hawaiian Islands. It has been suggested that these species evolved from 250 ancestral types that could have been windborne from continents.

In a similar way, winds carry insects from lowland regions to mountaintops, where they may be deposited in the snow. Those incapable of existing in this climatically rigorous environment (probably almost all) are eaten by the native arthropod fauna. In fact, the native arthropods may be dependent upon this wind-drifted food, just as some stream-dwelling insects are dependent for food upon the organic matter drifting down from upper levels of the stream.

A study of the spotted alfalfa aphid (*Therioaphis maculata*) in California indicates that an amazingly large number of organisms are passively transported by wind. Millions of these winged aphids alone float passively with the current in the spring months.

Structural adaptations facilitating dispersal by wind are strongly developed in some groups of spiders (class Arachnida). Gossamer, the silk secreted by the spider, is blown by the wind, and the spider, attached to it, is carried along, assisted sometimes by rising air currents.

Adaptations for dispersal

Water currents carry organisms in the same manner as wind. In the aquatic environment, however, the terrestrial organisms must stay afloat, avoid becoming saturated with water, and maintain their internal salt balance. Some outstanding examples of long-distance passive dispersal by ocean currents are known. Marine invertebrates are carried from West Africa to South and Central America on the main equatorial current of the Atlantic. Some water in this current comes from the Niger and Congo rivers, so it is possible for estuarine and freshwater animals to be transported to another continent by this means as well.

The distribution of several species of terrestrial animals is evidence that long-distance dispersal has been achieved by major ocean currents. One dramatic example is the distribution of a flightless staphylinid beetle (*Micralymma marinum*) believed to have been carried passively from the Western Hemisphere to the Eastern by means of the Gulf Stream.

The odds are considerable against terrestrial organisms surviving the ordeal of a prolonged journey in the surface waters of the sea. Some vertebrates may actively participate in the travel by swimming, thereby increasing their chances of survival. Others may cling to floating debris or natural rafts of land or ice. Pieces of river banks or fringing swamp vegetation and soil break off and are carried out to sea, particularly when flood conditions prevail, and with the rafts go the animals that were stranded on them. Pack ice, breaking loose, can similarly function as a raft for polar animals, such as polar bears, foxes, etc. A remarkable floating island was observed in the Atlantic off the coast of North America in 1892. It was estimated to be 30 metres square, with trees 9 metres high, and to have drifted at least 1,600 kilometres. Whether it reached land and its plant and animal passengers were able to colonize the new land is not known, but this example at least demonstrates the feasibility of distribution of organisms on rafts.

The distinction between airborne and waterborne means of dispersal is easy to make, but the two are not alternatives, because many organisms that start a journey on air complete it by water. Insects cross the Baltic Sea from Estonia in the Soviet Union to Finland, originally participating in mass flights, but reaching the other side in the water, many of them alive.

Dispersal by other organisms. The third means of dis-

persal—by other organisms—may be regular, as in the case of a host transporting a parasite, or irregular, as in the chance attachment of one organism to another. For parasites, finding a host is a major problem, and an efficient means of dispersal from one host to another, or to the environment in which another can be found, is essential. Consequently, parasites have developed remarkable specializations to the life history characteristics of the host that enable the parasite to disperse at the most favourable time. Dispersal is often assisted by the use of an additional species as a transporting agent, or carrier, from one host to another. A case in point is the myxoma virus, which parasitizes rabbits and uses mosquitoes as carriers. When aided by wind, an individual mosquito can carry the virus as far as 65 kilometres before infecting a rabbit; by this process of transporting and infecting, the mosquito population can disperse the virus rapidly over a large area.

Many organisms are distributed by attachment to mobile organisms. Small invertebrates such as snails and flatworms, for example, are accidentally transported on the legs of migrating birds. Undigested food items, such as the seeds of some plants, can be widely dispersed by their consumers in excrement deposited far from the source. There are numerous cases of mutualistic associations between animals and plants in which the plants are dispersed. One example is provided by flightless weevils of the genus *Gymnopholus,* which carry fungi, lichens, algae, or liverworts in depressions on their backs. From this association the plants gain a place to grow and a vehicle of dispersal. Plant dispersal is also carried out by mites that live for part of the time in the plant association growing in the weevils' backs. The advantage gained by the weevils is that of camouflage; to a predator they appear to be part of the vegetation-covered tree bark on which they occur (see also below *Biotic interactions*).

Introductions by humans

Probably the most effective agents of dispersal are humans, by virtue of their numbers, widespread distribution, and long-distance travel and shipping and of the objects they use. It is not surprising to find, for example, that ports of entry are the centres of distribution of some arthropod groups newly introduced to a continent. The arthropods, other small animals, and plant seeds are transported in boats with cargo. It used to be the custom for vessels to take on soil as ballast in England and unload it in Newfoundland, which resulted in the introduction to Newfoundland of a number of soil organisms not previously found there. These examples might be termed adventitious transport through the agency of humans. By contrast, there are also numerous instances of deliberate introduction of "exotic" species of plants and animals to new areas. In many cases, the newly introduced species perishes or simply does not spread from the point of introduction, as has happened with the skylark (*Alauda arvensis*), introduced from Great Britain to southern Vancouver Island, Canada. In other instances, the introduced species has exploited the new environment and spread rapidly. It took only 50 years for the Old World rabbit (*Oryctolagus cuniculus*), exported from Great Britain, to spread the length and breadth of Australia from a single farm, even in the face of efforts to prevent the spread.

The dispersal of plants depends largely on their exploitation of animals as carriers. Their structural specializations to being carried and dispersed exhibit great variety. These include a variety of hooks, barbs, bristles, and sticky secretions to aid attachment to animals; fleshy palatable fruit for consumption by animals (but enzyme-resistant seed walls); very small seeds light in weight but large in area to facilitate wind dispersal; and resistance to saltwater to facilitate dispersal by ocean currents.

The means of transport determine the type of environment to which the plant part (seed, fruit, spore, etc.) will be carried. In a study of flowering plants on various islands and island groups, it has been found that different types of island situations receive dispersing plant species by different means. Atolls, for example, receive most of their plant colonists by oceanic drift. Plants have colonized high islands most frequently by bird transport. Adherence of bristly seeds to the feathers of migratory birds is responsible for the extensive plant populations of dry volcanic islands. Air transport, whether aided by birds or not, is most effective for carrying plants to islands near the mainland.

Reduction in dispersal powers

Both plants and animals exhibit a loss or reduction of dispersal powers on islands. Examples include an increase in fruit size without concomitant increase in appendages such as hooks that serve in dissemination, a diminution or actual loss of those appendages, and an alteration of the mechanism of the release of fruits. These evolutionary shifts prevent the loss of reproductive products to unsuitable neighbouring environments in which they may not survive. There also tends to be a corresponding reduction in the number of seeds or fruits produced. And, in the case of increases in fruit size, there is the additional advantage of a greater volume of stored food, of particular help to seedlings growing under shady forest conditions. There are probably other less conspicuous changes in the dispersal abilities of plants, affecting such attributes as resistance to seawater, resistance to the digestive enzymes of animals, and the length of viability of seeds.

COLONIZATION OF NEW AREAS

From what has been said about the dispersal powers of organisms, it is a wonder that all taxonomic groups are not found everywhere. They are not, for two principal reasons. Different groups have different dispersal abilities, and environments have a limited capacity for supporting organisms, in terms of both number of individuals and number of species.

Effects of dispersal abilities. The probability that an organism will successfully colonize a new area is lessened by the distance it must travel and increased by the suitability of the new area. The most rapidly successful colonizing species are those with well-developed dispersal powers and a wide tolerance for environmental conditions. Plants referred to as weeds have these properties, and in addition they have the ability to exploit recently disturbed terrain. As a community of plants and animals undergoes a natural successional change toward greater complexity and stability, these pioneer organisms are replaced by organisms inferior in dispersal abilities but superior in competitive abilities. Such pioneer species, both plants and animals, tend to be found in ecologically marginal and geographically peripheral regions, from which position they are well suited to disperse to new areas. Many of them have other advanced biological properties that relate to their role of ecological opportunism, including the ability to reproduce without fertilization.

The future of initial colonists is partly determined by the ability of other competing species to reach the new area. The barrier to be crossed in reaching the new area—be it mountain, sea, river, or climatic zone—is not to be considered an insuperable one; it simply presents an obstacle that reduces the probability of transgression by some organism. There may be what has been termed a filter route across the barrier; that is, a route suitable for only some members of a fauna or flora, those with the most well-developed dispersal powers (Figure 7). An island 30 kilometres from the mainland can be colonized by birds flying across the water barrier, a route suitable only for the more dispersive members of the mainland bird life. Alternatively, the barrier may be almost impenetrable. For some organisms, the Sahara must be such a formidable barrier. The route across it is a "sweepstakes route"—to use the term coined by the American paleontologist George Gaylord Simpson—for the probability of any organism crossing the barrier is very low indeed, and yet some do cross it. Chance plays the major role in determining which ones get across, and when.

Chance in dispersal

The most strongly isolated environments may be so difficult to reach that the initial colonists have the opportunity to undergo evolutionary changes, unaffected by immigration of members of the same species or members of different species. In both plants and animals, these changes involve the relinquishing of their opportunistic characteristics.

Effects of the new environment. On the other hand, an organism arriving in a new area may have little chance of establishing itself, either because the habitat is unsuitable

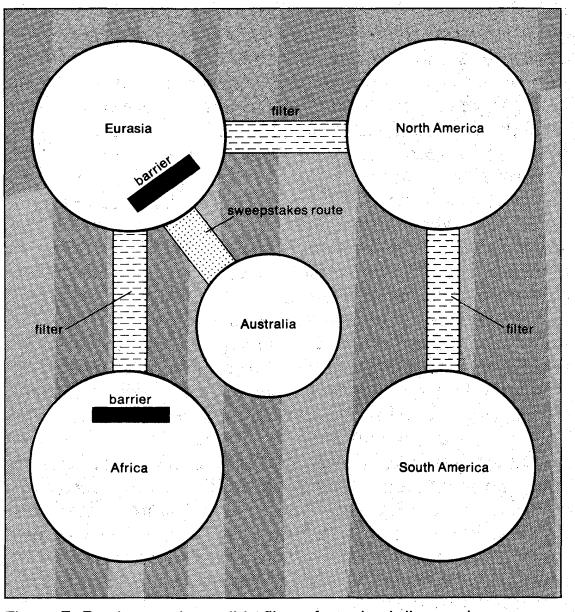

Figure 7: Barriers and possible filters for animal dispersal.

or because numerous other species already occupy the area. There appears to be a maximum number of species that can be supported in a given area (or volume) of environment. Size of the environment itself is one determinant of this maximum; the larger the area, the larger the number of species (and individuals) present. Climatic and related physicochemical factors are other determinants; these are responsible for the gradual change in species from the equator to the poles. This variation in species number with latitude is well illustrated for the mammals. It is equally well illustrated by mollusks, snakes, birds, ants, or corals. In contrast, variation in species number with longitude is less pronounced and less predictable. The number of species at any point along the latitudinal gradient is more or less the maximum possible, given present-day physicochemical conditions and the total number of species in the world today. In other words, most areas are saturated with species; if a new species arrives in an area, it can establish itself usually only by displacing a resident species.

Species saturation

The process by which an area becomes saturated with species can be expressed in a simple model (Figure 8). Immigration and successful establishment of new species depends on the number of species already present. The rate of establishment of new species declines and the rate of extinction of older species rises until a point is reached when these two processes are equal and no further change in number of species takes place; the area is then saturated. There are interesting variations of this model that allow

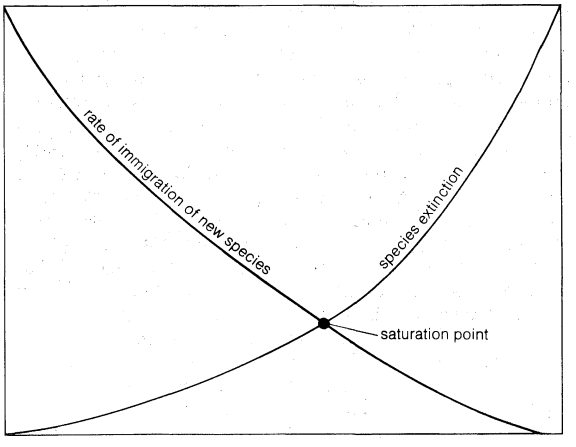

Figure 8: Model of species equilibrium on a single island (see text).

assessment of the importance of size of area and degree of isolation upon the two processes and upon the equilibrium number of species. Large size and weak isolation, for instance, are conditions conducive to a large equilibrium number (many species), and small size and large isolation yield a small equilibrium number (fewer species).

If the environment changes, however, the equilibrium number is subject to change. The shifting of average temperature over a long period of time in water, for example, may enable more species to exist at a given position in that body of water. In the terrestrial environment, the geographic distribution of climate has changed frequently in the past, which has caused a change in the distributions of organisms.

CHANGES IN DISTRIBUTION WITH TIME

Interpretation of past biological events will always remain a challenge because the necessary information will never be complete. The determination of past distributions of organisms, and changes in them, is biological detective work with generally few clues at hand. It is first of all dependent upon fossils that can be identified and located as to place and time of occurrence. Attention is focused less on individual species than on large groups (such as a family or order) or an ecological assemblage (such as a community or population). It is, secondly, based upon the principle that biological and ecological processes operating today are the same as those that operated in the past.

Centres of evolutionary origin. A survey of many groups of organisms shows a common pattern. It is characterized by evolution and proliferation (adaptive radiation) into a diversity of types adapted to performing a variety of ecological roles. The adaptive radiation of marsupial mammals in Australia from a primitive insectivore is a good example. The evolutionary processes are accompanied by expansion of distribution ranges and a geographic radiation. There follows recession or contraction of distribution ranges, of the group as a whole or of individual species, as new groups arise and partly supplant their predecessors. Superimposed upon this pattern are large-scale shifts in distribution, without necessarily any expansion or contraction, as environmental conditions change; for instance, there was a steady southward shift of northern vegetation zones during much of the Tertiary period (66.4 million to 1.6 million years ago), evidently caused by a cooling of northern climates. The distribution of organisms in the past can be viewed as an ever-changing kaleidoscope, the result of movements, countermovements, spreadings, competitions, extinctions, and replacements of a diversity of plants and animals over the whole of the diverse surface of the world.

An examination of the distribution of fossil material and the distribution of present-day organisms suggests that there were regular aspects to the kaleidoscope. It has been recognized, for example, that there were major centres of origin and evolution of terrestrial vertebrates, although the identification of these centres has not met with unanimous approval because the fossil evidence by itself is not convincing. Some biologists have suggested that the north temperate zone was the centre of origin because its variable climate continually presented challenges to vertebrates, to which the vertebrates responded evolutionarily by diversifying. Others have argued instead for the tropics as a centre of origin and evolution, in view of the greater number and variety of species in the tropics than in either temperate zone today. Furthermore, north temperate forms are not usually peculiar to the north, but are representatives of groups also present, often more abundantly, in the tropics; among birds, the hawks, owls, and finches may be cited as among these forms. Finally, many groups present in the tropics are absent in the north.

The tropics as the evolutionary centre

There are other reasons for considering the tropics to be an evolutionary centre, and here historical clues play a large part. It seems reasonable to expect that (1) the region in which the largest number of species and genera existed in the past is where the majority of them originated, (2) the region of greatest degree of differentiation might be the place of origin of a group, and, finally, (3) the region of largest area would have been occupied longest.

The fossil evidence interpreted in the light of these three statements points strongly to the Old World tropics as the main origin of terrestrial vertebrates.

The subsequent spread of organisms. *Environmental influences.* Major shifts in the distribution of whole faunal and floral assemblages can usually be correlated with inferred environmental change. At different times in the history of the Earth there have been different patterns of climate and, more particularly, the average temperature has been higher or lower than at present. Climatic changes have had profound effects upon animal and plant distribution, both directly and indirectly. In colder periods, for example, the Earth was covered with more ice and less water, and the sea level was sufficiently depressed that landmasses now separated by a water barrier were connected.

The best-known of these climatic changes is the most recent Ice Age, comprising several glacial (cold) and interglacial (warm) periods. The sea level was as much as 120 metres lower than at present during glacial periods, and as much as 50 metres higher than at present during interglacial periods. These fluctuations affected organisms most profoundly in polar and temperate regions, least in the tropics.

At the start of the Tertiary (Paleocene epoch), there were great differences between the faunas and floras of North America and Eurasia. There then occurred, according to the geologic and fossil evidence, an interchange of faunas across a land bridge in what is now the Bering Sea. Initially, the interchange involved large parts of the continental faunas and many major groups, most noticeably among the mammals. Subsequently, exchanges were increasingly selective and tended to involve smaller fractions of faunas, progressively less distinctive types of animals, lower taxonomic categories only, and ecological types less novel in the invaded regions. This has been interpreted to mean that the land bridge was increasingly difficult to cross, perhaps the result of an increasingly effective climatic barrier; additionally, each continent may have become increasingly saturated with the major types of animals, making it progressively more difficult for a potential colonist to establish itself. This whole process, extending down through the Tertiary period and up to the recent Ice Age (Pleistocene epoch), was evidently interrupted three or more times by submergence and subsequent elevation of the land bridge.

The dispersal of man

One of the species of mammals taking advantage of the land bridge across the Bering Sea was man himself. By late Pleistocene times man had become a dominant species throughout the Old World. In several waves of dispersal, man entered North America, probably at the last continental glaciation. Dispersal and changing (mainly expanding) distribution have continued to be characteristic of the species.

In contrast to the events in the far north, North and South America were separated during most of the Tertiary period. They were connected by land possibly at the beginning of and then again late in the Pliocene epoch. The effect of this Pliocene connection upon the distribution of organisms can be illustrated with mammals, of which many fossils are available. Before the connection was made, North America had about 27 families of terrestrial mammals, and South America had 29 families. Only one or two families were common to both continents. After the connection, the number of families in common rose to a maximum of 22. Incursions, withdrawals, and extinctions led to the stabilization of 23 families in North America and in South America, as before, 29. North America benefited by the arrival of opossums, three families of ground sloth, two stocks of armadillos, and many others. South America benefited by the arrival of several species or genera of cats (including saber-toothed cats), horses, camels, elephants, tapirs, and rabbits. Most have survived to the present day, although tapirs, camels, elephants, horses, and sabre-toothed cats have since disappeared from North America, and South America has lost a portion of its rich fauna also.

The recurring expansion and contraction of distribution ranges have produced some patterns exhibited by contemporary organisms that at first sight seem inexplicable. Continuous distributions are not difficult to understand; but what past events led to the highly discontinuous or disrupted distributions evident today, such as the distribution of horseshoe crabs in North America and Southeast Asia? Migration from one area to another is possible but unlikely; it is more likely that the distribution was once more widespread and either continuous or moderately discontinuous and that a shrinking of distribution range has occurred. The distribution of fossils indicates that horseshoe crabs were widespread and abundant in the Paleozoic era and that a restriction of range occurred in the Mesozoic, possibly as a result of competition with newly evolved marine invertebrates.

Other species were profoundly affected by climatic disturbances, such as the recent Ice Age, surviving partly in relatively small areas of suitable habitat, or refuges, and partly in larger areas farther away, to which they dispersed when the climatic change rendered the previously occupied area unsuitable. The evidence for this consists of numerous instances of much differentiated forms isolated from the main range of the group. These are referred to as relicts. Examples are Arctic plants found isolated on mountaintops in north and middle Europe. Even before Darwin's time, their occurrence was explained as due to survival in refugia, areas untouched by glaciers but once surrounded by them.

Relicts

Certain groups of coastal plants still may be confined to their glacial refugia because they are not evolutionarily versatile enough to break out from them; their variability became restricted during the past glaciation when new variants would have been at a disadvantage owing to the harsh conditions. In contrast, there are some species, termed disharmonious relicts, which occur in unusual and isolated habitats where they are thought to have survived because of broad ecological tolerance in the past.

Relict patterns of distribution are found on islands as well. These are in irregular and unpredictable patterns interpreted as having been formed by partial extinction of an old fauna or flora formerly common to all the islands. They are most pronounced on oceanic islands. An example is the distribution of frogs on islands in the Indian Ocean. The pattern is replete with discontinuities and mixed relationships, which indicates that the fauna is partly a relict one and that existing geographic relationships are partly the result of extinction and survival rather than of direct dispersal. The relict pattern of distribution contrasts with an immigrant pattern, characteristic of continental islands, in which the number of species in a taxonomic group decreases in more or less orderly fashion with distance from the continent, although modified by island area.

Geologic influences. Much has been said about the distribution of terrestrial organisms, as if the organisms have moved and the land has stood still. But, in fact, a large body of geologic and fossil evidence suggests that the continents have not always been in their present positions. In view of this evidence, the distributions of organisms, in relation to the Earth's axis, have undergone even more change than has been referred to so far.

Continental drift

The theory of continental drift holds that the continents were once connected but that they split apart during or after the Triassic period (245 million to 208 million years ago) and gradually drifted apart. In conjunction with seafloor spreading and mountain building, continental drift conforms to a broader theory according to which large plates making up the Earth's crust "float" on the molten mantle, variously colliding and separating (see PLATE TECTONICS). The earliest proponents of a once-unified landmass cited as evidence the present shapes of continents. The outline of West Africa, for example, is complementary to that of eastern South America. In fact, if the two continents are fitted together like a jigsaw puzzle, the Paleozoic and early Mesozoic rocks of the continents in the vicinity of their (present) coasts show remarkable correspondence in structure as well as magnetic orientation. The paleontological evidence is that the flora and fauna of the two continents showed a great degree of resemblance in those early times, and this resemblance may have diminished progressively thereafter.

Human influence. The agricultural, industrial, and commercial activities of humans have had an enormous impact upon the distribution of organisms. In the last 10,000 years human beings have replaced the climate as the most important agents of change.

Some organisms are more widely distributed now as a result of human activities, many more are more restricted, and a sizable number have disappeared altogether. Since 1600, almost 100 species of birds and 40 species of mammals are known to have become extinct, and it is probable that humans exercised an important, if not decisive, influence in these extinctions. Moreover, many species are now on the verge of extinction, again largely because of human activities.

Human influence upon the distribution of organisms has been, and continues to be, needlessly destructive. Admittedly, some destruction is probably inevitable, since species like man, with novel ecological features, spread and cause a reduction in numbers of other species. But this process leads to a state of dynamic equilibrium, to something approaching stability. Unfortunately, modern man shows no sign of approaching an equilibrial relationship with his environment in the immediate future. (P.R.G./Ed.)

Biotic interactions

As previously noted, no species lives in isolation from other species. Plants grow together in spatial patterns determined in part by competition and are fed upon by characteristic herbivorous animals, which in turn serve as food for carnivorous animals. Both plants and animals are attacked by parasites. Animals interact with each other competitively and sometimes beneficially. Some of these interactions are temporary, casual, and of minor importance, whereas others are permanent, vital, and of major significance.

Intraspecific and interspecific interactions

Biotic interactions may occur between members of the same species (intraspecific interactions) or between two or more species (interspecific interactions). They may involve nutritional benefits, space in which to live, shelter or protection, transport, or reproductive capability. Many interactions are highly specialized and complicated, involving adaptive changes in structure, function, behaviour, and ecology. Some create negative effects upon the interactants, reducing survival or reproductive success; other interactions produce positive effects, increasing survival or reproductive success. In some cases, members of an interaction are apparently unaffected.

Biotic interactions are significant not only because they influence individual species but also because they constitute the principal stabilizing, connective linkages among the various species contained in a biological community. In a general sense, species in a biological community persist in relative harmony because of biotic interactions, despite individual gains and losses. As a consequence of this web of interactions, the community as a whole persists, with all species ultimately contributing to its continuation.

INTERACTIONS WITHIN A SPECIES

Negative interactions. Intraspecific competition provides the ultimate force limiting the abundance of a species in a community. Natural enemies may be present or absent, but others of the same species are always present, providing the competition that insures against overexploitation of available resources and the irreversible destruction of a community due to overpopulation.

Cannibalism

Cannibalism, fighting, and territorial defense are some of the overt methods by which competition manifests itself. Many animals, both herbivores and carnivores, exhibit cannibalism when overcrowded, and some are cannibalistic whenever they contact another of their own species. The codling moth caterpillar (*Cydia pomonella*) in the apple is of the latter sort; hence, there is never more than one worm per apple. Mice and rats, when crowded, undergo psychological disturbances leading to excessive fighting and litter destruction. Territoriality, the dividing up of resources, mostly space, is a common means of defense against overcrowding. It differs from simple aggression in that, instead of involving individuals against individuals, it involves groups of individuals, breeding pairs, families, or herds. Migration away from overcrowded conditions is another common intraspecific response. It may be individualistic, with each member of a population going its own way, or it may involve mass flight, such as occurs with locusts, butterflies, and birds.

Positive interactions. On the positive side, numerous interactions among individuals of the same species lead to clustering, aggregation, swarming, herding, and, ultimately, development of social groups. Tent caterpillars (*Malacosoma*) live together in large colonies, foraging together in masses and resting at night in communally spun silk tents. Isolated caterpillars are unable to survive; only the aggregation thrives. Parental care provides the basis for many aggregations of like individuals. Parental protection of the egg, as occurs in birds, some insects, and some fish, is the simplest form of care. Feeding and protection of the young is a more advanced level of care. Insect societies, in which one reproductive adult, the queen, is served by her own progeny, represent a still more highly developed custodial configuration. In such cases the offspring remain with the parent, providing protection for the colony, care of younger members, nest building and cleaning services, and food gathering and storage. Division of labour to attend to these services is common.

Some species live in habitats where—because of small size and weak flight ability, limited and scattered resources, and relatively low population densities—the chances of the mature sexes meeting for reproductive purposes are low. One method for overcoming this hazard is the phenomenon of autoparasitization, in which one sex lives as a virtual parasite on the other, an unusual form of intraspecific interaction. Certain insects exhibit this mode of life: the males of scale-insect parasites develop as hyperparasites on their own females. Some deep-sea angler fish also employ this habit, with the very small adult male living in permanent attachment to the body of the larger female. In such situations the association of the sexes is facilitated, and reproduction in hazardous environments is ensured.

THE RANGE OF INTERSPECIES ASSOCIATIONS

Positive, negative, and neutral effects

One system of analyzing two-species interactions assigns positive (+), negative (−), or neutral (0) value to the interactants on the basis of how they affect each other. If the survival or reproduction of a species is enhanced, it is a gain and given a plus value. If survival or reproduction is reduced, it is a loss and given a minus value. If survival or reproduction is unaltered and the species unaffected, it rates a zero value. From such a rating scheme, a two-species (A, B), three-effect (+, 0, −) table can be constructed in which the bases for association (symbiosis) of all biotic interactions can be defined (see Figure 9).

species A (large, strong) \ species B (small, weak)	+	0	−
+	+, + interdependence (obligative mutualism) protocooperation (facultative mutualism)	+, 0 commensalism	+, − herbivory predation
0	0, + commensalism	0, 0 neutralism	0, − amensalism (competition)
−	−, + parasitism parasitoidism	−, 0 amensalism (antibiosis)	−, − mutual antagonism

Figure 9: Bases for association of all biotic interactions.

Mutualism (+, +) is an association of two different species that results in mutual benefit or gain. Obligative mutualism requires that both members interact together, or neither survives. Facultative mutualism, or protocooperation (+, +), refers to a less-rigid association in which one or both members can survive in the absence of the other. In commensalism (0, +) one member benefits while the other remains unaffected. A case in which the small or weak species is unaffected while the larger or stronger

benefits, especially in nutritional relations, is sometimes called allotrophy (+, 0).

In parasitism (−, +) the smaller organism benefits at the expense of the larger. Many parasites are microorganisms that cause disease, but not usually the death, of the host. A special case of parasitism, which involves insects that do kill their hosts, is called parasitoidism. Predation (+, −) refers to an association in which a large or strong animal consumes a small or weak animal. Herbivory (+, −), the consumption of plants by animals, is generally comparable to predation. Amensalism (0, −) occurs when one organism loses while the other organism is unaffected. Unilateral competition, to which the term competitive exclusion refers, and antibiosis, in which one species remains unaffected while a competitor is deprived, are examples of amensalism. In antagonism (−, −) both species lose or are harmed. Neutralism (0, 0) is an association in which neither species is affected by the presence of the other, the two species sharing a localized resource or habitat.

The following sections will provide selected examples of the various forms of biotic interactions, based on the definitions above. The emphasis rests on the pattern of the interactions rather than the symbiotic associations themselves.

CONSUMPTION: ORGANISMS EATING ORGANISMS

The basis of community food webs

Herbivory: animals eating plants. Herbivory constitutes one of the most important classes of biotic interactions. It serves as the main connection between all plant and animal life, the basic food association (trophic link) through which the composition, dynamics, and variation of community structure takes place. All higher organisms, primary and secondary carnivores and scavengers—essentially all the remaining links in the community food chains and food webs—are more or less dependent on this basic link (see Figure 10).

Herbivory is encountered at all levels of animal life, from the smallest to the largest animal, and in all habitats. No plant species is exempt, whether in the Arctic tundra, the tropical forest, or the desert and whether on the highest mountain, along the seashore, or in mid-ocean. It is a reciprocal interaction, or coaction, wherein the number or quantity of plants is altered by the number and consumption rates of the herbivores and in which, conversely, the number of herbivores is limited by the quantity of plants. This coaction, therefore, may approach a state of balance in which the amount of plant material is just sufficient to sustain the number of herbivores associated with it, and the herbivores collectively remove only the surplus plant material produced. The manner in which specific herbivores respond to the results of this interaction is dependent on their food habits. Species that require one kind of plant material are very sensitive to changes in abundance of their preferred food, whereas less-specialized species simply shift their attentions to other plants when the quantity of a given one fluctuates.

The degree of herbivory is rather wide. A plant may be totally consumed, as it is when a protozoan or a fish consumes unicellular planktonic algae. Vital parts of a plant may be eaten, leading to the eventual death of the individual, as occurs when bark beetles girdle a pine tree or when birds eat the tender tips of germinating plants. When only nonvital parts of a plant are eaten—including leaves, twigs, and roots—the plant may be stunted or not affected at all. In the latter case, which is quite common, the herbivore is truly living on "surplus" plant life.

Herbivory is one factor responsible for limiting the amount of plant life in a community and, therefore, influencing the composition of communities. It serves as an important means of recycling plant tissues back into the nutrient minerals, carbon dioxide, and water from which they were derived and enters into the determination of the numbers and kinds of animals associated with the community.

Herbivores to control weeds

Plant pests can drastically reduce the growth or productivity of crop plants. Successful attempts to use specific herbivorous insects to control certain weed species (*e.g.*, cactus in Australia or the poisonous Klamath weed in California) and the remarkable recovery of plant populations when an adverse factor is removed (*e.g.*, a pest) or a stimulating factor is added (*e.g.*, nutrients) suggest that herbivore–plant interactions are of critical importance to community composition. Plant–animal interactions are also illustrated in the overgrazing that occurs when deer, protected against predators, increase to such numbers that a plant community is threatened by excessive browsing. Grazing by stock animals, sheep, and cattle is an important factor in the composition of range and pasture lands; if excessive, grazing can actually destroy such communities. A rapid increase in plant growth brought about by excessive nutrient deposition (eutrophication) in bodies of water through runoff of soil fertilizers and discharge of municipal and industrial wastes results in "blooms" of aquatic algae and the disruption of the normal trophic balance between algae and algal feeders.

The concentration of a few plant species into large areas, as is the general practice in agriculture, provides a potential for excessive herbivory. Such large tracts of single crops (monocultures) concentrate and augment the numbers of herbivores (when insects, they are usually called phytophages) to the point that massive population outbreaks commonly occur. By contrast, natural communities, which are diverse in species, are much less prone to support pest outbreaks: an expression of the ecological principle of stability in diversity in community life.

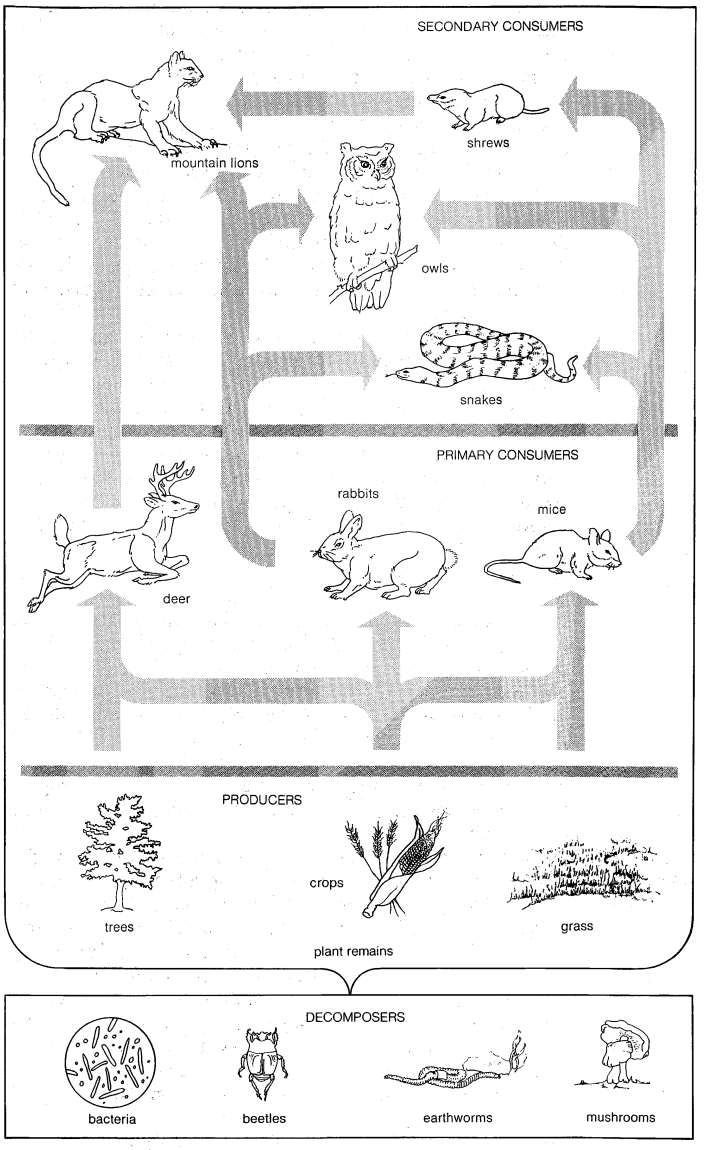

Figure 10: A representative food web comprising several interacting food chains.

From *Biological Science: An Inquiry into Life*, 2nd ed. (1968); Harcourt Brace Jovanovich, Inc., New York; by permission of the Biological Sciences Curriculum Study

Predation: animals eating animals. Just as most plant species are fed on by herbivores, so are most animal species subject to predation by other animals. By feeding upon and reducing the numbers of both herbivores and other carnivores, predators constitute the higher links in the nutritional pathways characteristic of communities. Predators substantially affect the numbers of herbivores and thus influence their impact on plants. When the numbers of predators fluctuate, their effects upon prey and plants vary accordingly (see below *Biological populations: Changes in population characteristics: Fluctuations in stable populations*).

Because of the obvious importance of and interest in the mechanics of predation, predator–prey interactions have been the subject of much scientific research. Laboratory and theoretical studies have been made of isolated predator–prey "systems" and of predator–prey "models." The degree to which such systems and models simulate natural predator–prey population fluctuations has been used as a basis for judging the "soundness and realism" of the scientific methods and for "explaining" the process of predation. Simple mathematical expressions have been devised that represent predator and prey numbers and indicate that predators vary in numbers in a smooth, oscillatory manner purely as a result of prey abundance changes, and vice versa. This latter result, that prey oscillate because of predation, is the important new "evidence" that prey–predator interactions are, indeed, reciprocally coupled.

The importance of predation in determining prey abundance and community stability can be illustrated by several examples. When man (a predator) overexploits his animal resources (in effect, prey), they decline in numbers sufficiently to affect subsequent utilization (consumption). Such is the result when fish, whales, sea otters, buffalo, and other animals are excessively hunted. Whales and sea otters have declined drastically; buffalo became exterminated as a wild animal, and grizzly bears, mountain lions, and elks similarly are threatened with extinction.

Predators to control pests

An illustration approaching the point from the opposite side is the employment by humans of predators to control pests, a technique called biological pest control. The effective suppression of the cottony-cushion scale (*Icerya purchasi*) pest of citrus in California in the late 1800s by use of the Australian ladybird beetle (*Rodolia cardinalis*) is a classic example. Since that time more than 100 successful cases of biological control, leading to permanent suppression of pests, have been accomplished.

The unintentional unleashing of new pests through the use of pesticides, which cause the destruction of natural enemy predators, illustrates the delicate balance between predator and prey that exists in most communities.

Occasionally, outbreaks of predators occur, with resultant drastic impact on prey populations. An example is in the Great Barrier Reef, Australia, and near Guam, in the western Pacific, where the crown-of-thorns starfish (*Acanthaster planci*), a predatory species, has increased in numbers that have seriously reduced the abundance of many corals. Sometimes the predator attacks a valuable resource of humans. The whelk, a marine snail, attacks oysters. An American whelk, the oyster drill (*Urosalpinx cinerea*), has invaded oyster beds off southern England, causing severe reductions in harvest since the late 1950s. And humans have always been uneasy about both bird and mammal predators—such as hawks, eagles, coyotes, wolves, and foxes—that attack their domesticated animals.

PARASITIC INTERACTIONS

Parasitism. In practically every community, plant and animal populations are burdened with parasites, which include viruses, fungi, protozoans, nematodes, many marine and freshwater coelenterates, flukes and tapeworms, leeches, some insects, certain birds, and higher plants such as dodder, mistletoe, and broomrape. A parasite usually does not kill its host (if it does, the parasite itself may die before reaching a new host), but it generally reduces the growth rate, survival ability, and reproductive capacity of the host. From an ecological standpoint, therefore, parasitism does constitute a considerable burden on a host population.

Parasites that live on the body surface of the host are called ectoparasites. They do not commonly cause disease in their hosts but rather suck blood or create superficial damage to the skin; examples include leeches, fleas, lice, and ticks. Other parasites live inside the host's body—either in cells or in spaces lined by cells (*e.g.*, intestine, blood vessels, mouth, etc.). Parasites that live within host cells—such as many bacteria and viruses—are called intracellular endoparasites; those that inhabit spaces within the host's body are called intercellular endoparasites.

Many disease-causing organisms, or pathogens, are endoparasites carried from host to host by some other organism; malaria, for example, is caused by a protozoan endoparasite transmitted by mosquitoes. In such situations, the biotic interaction involves three necessarily coexisting species: the pathogen, the carrier (or vector), and the host. A number of plant diseases transmitted by insects are dependent on carrier density, pathogen abundance and virulence (disease-producing power), and host density. Host susceptibility is also a significant factor in influencing the outcome of host–parasite interactions. In Europe the Dutch elm disease fungus (*Ceratocystis ulmi*) is a minor pest of elm trees (*Ulmus*). When this pathogen established itself in North America, however, it severely infected native American elms (*U. americana*), which were more highly susceptible than their European counterparts. A similar event occurred when the chestnut blight (*Endothia parasitica*), a fungus native to chestnuts in China and Japan, invaded North America and devastated stands of native chestnuts (*Castanea dentata*).

Not all invading parasites are microorganisms, however. The sea lamprey (*Petromyzon marinus*), an ectoparasite on fish, attaches itself to its host by means of a suckerlike mouth with which it sucks blood and soft tissues. The sea lamprey is native to the North Atlantic, living in the ocean but breeding in coastal rivers and streams. It was able to move into Lake Ontario but no farther, being blocked by Niagara Falls. After construction of the Welland Canal, however, which bypassed the falls, the lamprey invaded the remaining Great Lakes and began decimating the populations of commercially valuable fishes.

Intermediate hosts

An intermediate host—interposed between the target host and parasite—adds ecological complications to host–parasite interactions: the parasite, host, and intermediate host must all be present in the same community in suitable numbers at the same time. The liver fluke (*Fasciola hepatica*) that attacks sheep and cattle, for example, requires an aquatic snail as an intermediate host; there is no direct transmission of the fluke from sheep to sheep. Sheep, snail, fluke, pasture, and aquatic habitat must all coexist in the same community. Many other common parasites similarly require an intermediate host; *e.g.*, malaria, sleeping sickness, and wheat stem rust. One reason that such complicated three-component interactions are so common is that with at least one of the organisms the reproductive capacity is very high; this increases the likelihood of continuation of the pathogen. Furthermore, in the case of parasites carried by insects, the motility and numerical abundance of the insect carrier facilitates parasite dissemination.

Parasitoidism. Parasitoids—insects that parasitize other insects—differ from true parasites in that, like predators, they always kill their hosts. Most are free-living in the adult stage. In a typical life history, the female parasitoid lays an egg in or on a host; the ensuing larva feeds upon host fluids and tissues, eventually killing the host; and the fully developed larva pupates and later emerges as an adult. Most species of parasitoids have a distinct preference as to the stage of host attacked, whether egg, larva, pupa, or adult.

Parasitoids are among the most important agents in limiting the numbers of other insects. For this reason they, along with true insect predators, are frequently sought and used by humans as control agents for insect pests. Almost all insect species are attacked by one parasitoid or another. Some parasitoids are gregarious, with several living in one host simultaneously; others are solitary, with only one developing in a host. Certain wasp parasitoids exhibit polyembryony, wherein one egg deposited in a host may

give rise to dozens or thousands of parasitoid embryos, and the host is literally overwhelmed by the developing parasitic larvae. In some parasitoid flies the female lays her eggs on leaves, and the host becomes infected by eating the egg-bearing leaves. Other parasitoid flies lay their eggs on the backs of hosts, and the larvae hatch out and bore into the host body.

The parasitoid's life cycle is always well attuned to that of its host. If the host is a leaf-feeder and found only in the foliage of trees, that is where the female parasitoid searches for them. If the host has but one generation a year, so usually does the parasitoid. If the host passes the winter hibernating in the soil, the parasitoid generally does likewise, emerging from the soil in the spring soon after the host does.

Hyperparasitism

A parasitoid may itself sometimes be parasitized. In such cases its parasites are called hyperparasites. The hyperparasitic habit, commonly found in insects, may extend to several levels; for example, an aphid (order Homoptera) can be attacked by a solitary, endoparasitic aphid wasp (family Pemphredoninae), which, in turn, may be parasitized while still within the host's body by an endoparasitic gall wasp (family Cynipoidea). Moreover, the gall wasp can itself be attacked by an ectoparasitic pteromalid wasp. In theory even additional levels of parasitism are possible.

The free-living habit of the adult parasitoid enables it to spread rapidly from host to host throughout a community. Because the host almost always dies as a result of a parasitoid attack, few host-immunity responses have evolved. Only when parasitoids attack unusual hosts—those not in their normal host range—can a host survive and sometimes elicit an immune response to further attacks. The true parasite and the parasitoid can sometimes interact in their association with a host insect. Some parasitoid wasps coincidentally distribute pathogens from host to host when they deposit their eggs.

Brood parasitism. Brood parasitism, the laying of eggs in another animal's nest to be reared therein by the host, occurs in certain birds, including the cuckoo and the cowbird, and in certain insects, including cuckoo wasps. The female cuckoo bird (family Cuculidae) lays an egg in the host's nest, where the hatched cuckoo chick either kills or pushes out the host's brood, so that it is reared alone until it can fly. The cuckoo wasp (family Chrysididae) accomplishes much the same result, except that its host is one of the social wasps or bees. It enters a colony and lays an egg in one of the compartments, or cells. After hatching, the parasitic larva destroys the normal cell occupant and is taken care of by the colony workers.

The cuckoo habit is a balanced one, not being so efficient as to suppress unduly the host population but effective enough to assure perpetuation of the habit. In most cases, the reproductive habits of the host species enable progeny to be produced at times when the brood parasite is not active.

AMENSALISM AND ANTAGONISM

Competition. Competition occurs when two species utilize a common, limited resource (such as food, space, or moisture), and, in so doing, one species interferes with, injures, or deprives the other. When the competitors are of the same species, intraspecific competition occurs (dealt with earlier). Populations of two species cannot persist together for very long in the same community when both compete for and are limited by a common resource. This

Gause's hypothesis

principle, known as Gause's hypothesis, further suggests that the species having the greater competitive advantage—manifested in greater searching ability, more rapid exploitation of the resource, greater numerical growth rate per unit of resource attained, greater aggressive or fighting ability—in time gains more and more of the limited resource. Competitive interactions between species are resolved in either of two ways: (1) the exclusion or displacement of one species by the other or (2) the coexistence of the two competing species as a result of minor differences in habit or because their numbers are limited by factors other than the resource under consideration. When a species invades the habitat or community of another species and both occupy the same niche, either the incumbent will persist and the invader will disappear, illustrating competitive exclusion, or the invader will become established and the incumbent will disappear, resulting in competitive displacement.

Actual competition is difficult to see in nature, since a community usually contains "superior" competitors only, the lesser adapted species having already been ejected from the area. When a species invades a new habitat, however, either through its own dispersive powers (rare) or through human activities (common), competition can be observed in operation. Hence, when settlers established themselves in western North America and brought with them grains and forage grasses for their livestock, they also brought, unwittingly, many weed seeds from Europe. Many of those weeds and foreign forage plants became established, forcing out or eliminating many native plants. The Klamath weed (*Hypericum perforatum*) is a remarkable example of the way in which weedy competitors can succeed in a new habitat. Gaining a foothold in California a few years before 1900, Klamath weed established itself as the dominant perennial on low-elevation rangelands. Several decades later, millions of acres of land were infested. Only when the weed itself was suppressed by biological control agents in the late 1940s were the displaced native species able to return to their old habitats. In England the shrub purple-flowered rhododendron (*Rhododendron ponticum*), an invader from the Continent, has become a pest in wooded areas, displacing holly and preventing regeneration of oaks and other desirable trees.

Insect invaders

Many insect invaders have displaced incumbent species through competition. The Argentine ant (*Iridomyrmex humilis*) and the imported fire ant (*Solenopsis saevissima richteri*), both invaders of North America from South America, have displaced many native ant species. When the Oriental fruit fly (*Dacus dorsalis*), the maggots of which feed on tropical fruits, invaded Hawaii in the mid-1940s, it apparently displaced an earlier invader, the Mediterranean fruit fly (*Ceratitis capitata*), from all the low-elevation habitats that the latter had occupied for so many years. The Mediterranean fruit fly was forced up into higher elevations on volcanic slopes, where coffee remained its major host, leaving the lower slopes and shores to the newer invader.

In aquatic habitats, aggressive fish such as carp and perch commonly displace trout and other game fish. When the long-legged crayfish (*Potamobius leptodactylus*), a native of eastern Europe, was introduced into some central European lakes, it totally displaced the native broad-legged crayfish (*P. astacus*).

Laboratory experiments also show the nature of competition. When two species of the single-celled protozoan paramecia compete for food and space in small glass tubes, one displaces the other, even though both thrive when grown alone. Similar results are obtained when the confused flour beetle and the red flour beetle (*Tribolium confusum* and *T. castaneum*) are cultured together in jars of medium. Either species, living alone, limits its own population numbers (intraspecific competition) through such self-regulatory actions as cannibalism (adults and larvae feed on eggs and pupae), interference with female egg laying, and defilement of the common food supply. When populations of the two species are grown together, one species is eventually eliminated; the other persists. The interesting difference in these experiments is that, possibly because of slight variations in genetic composition of the organisms used, the same species does not always survive in every experiment. Rather, there is an element of probability as to the outcome. The probability of winning the competition can be varied, sometimes substantially, by altering the physical conditions for growth, such as temperature, moisture content, or humidity.

When two species of closely related water fleas, *Daphnia pulicaria* and *D. magna*, are cultured together with algae as food, both species increase in numbers for about three weeks; then the *D. magna* population ceases to grow and instead gradually declines to extinction at the end of the sixth week. The competition for the common food supply, not important while the populations were small, soon becomes severe enough to affect strongly the less adapted

of the two competitors. On a different food supply, yeast cells, *D. magna* actually increases at a greater rate at first, but after about 24 days it reaches a peak and declines to extinction, as in the previous case.

Coexistence of potentially competitive species

It often happens that two species with similar niches occur in adjacent geographic areas and partially overlap. Coexistence in the area of overlap is then possible as a consequence of the continuous migration of the "excluded" species from its area of exclusivity. Displacement takes place, but the dispossessed are constantly being replaced by new immigrants into the "overlap" area. Eventually, if the area of overlap is broad enough, niche separation may occur through the process of evolution. Niche separation, or displacement, is the shifting of one or the other competitor species from the common, limited resource to another resource not competitively limited. This can be a different food, different spatial habitat, or different nesting site. An example of niche displacement is that of the finches on the Galápagos Islands. Some of the 12 or so finch (order Passeriformes) species that have evolved from a mainland insect-eating finch have become vegetarian, whereas others have remained insectivores; some occupy ground-level habitats, others inhabit trees, and one lives on cactus; some eat seeds, others fruit. These are all ways by which the original stock extended into unutilized niches.

Occasionally, niche displacement is reflected in a structural or behavioral change in the species involved, a phenomenon called character displacement. The change in character, or feature, occurs in the region of overlap but not in the regions of exclusive occupancy. A good example is provided by the same Galápagos finches. Two species living on separate islands have approximately the same bill length; when they occur together on other islands, they exhibit altered bill dimensions, which reflect changes in food resources brought about by competitive interactions. A similar displacement of characters is seen in two related ant species—the yellow ant (*Lasius flavus*) and the good ant (*L. nearcticus*)—that coexist in the eastern United States and differ in at least eight features. These differences are not apparent in *L. flavus* in areas where it occurs alone in the western United States.

Antibiosis. Antibiosis occurs when one species interferes with or injures another through the secretion of a chemical substance. This commonly occurs among the bacteria and fungi and to a lesser extent among higher plants and some animals. The observance of such an effect in certain penicillium molds is well known. A bactericidal substance secreted into the growth medium prevented the growth of competing microorganisms and led to the discovery of the antibiotic penicillin. A more complicated example concerns needle, or wire, grass (*Aristida oligantha*), which invades old-field communities. It secretes phenolic acids, which inhibit the development of nitrogen-fixing bacteria and the blue-green algae of the soil. This, in turn, suppresses the production of available nitrogen in the soil, thus slowing the invasion of other competing, nitrate-requiring plants into the grass community.

Plant resistance

Antibiosis is the basis of the resistance exhibited by certain varieties of crop plants to insect attack. Corn varieties resistant to the European corn borer (*Pyrausta nubilalis*), for example, contain benzoxazolinones, chemicals that adversely affect larval growth and survival.

The discovery that many plants and some animals contain or secrete chemicals injurious to competitors or natural enemies has led to development of the study of allelopathy; the chemicals are called allelochemics. This phenomenon—the suppression of some higher plants by chemicals released by another higher plant—has been extended to include chemical defenses of plants against herbivores, phytophagous insects against predators, and the resistance of hosts to parasitoids.

Examples of plant-to-plant antibiosis based on allelochemics include the chaparral plants, whose toxic phenolic secretions are washed by rains into the soil, where they inhibit the germination and growth of herb seeds close enough to provide competition. The milkweed-feeding caterpillar of the monarch butterfly (*Danaus plexippus*) acquires toxic chemicals from its host plant, thereby rendering the adult butterfly distasteful to bird predators.

Antibiosis can take forms other than chemical defense. They include immune responses, whereby hosts defend themselves against invading parasites. Immune responses of a host to an invading organism can involve engulfment (phagocytosis), chemical inactivation (precipitation), dissolution (lysis), or encystment.

Mutual antagonism. Mutual antagonisms occur when a biotic interaction between two species results in harm or death to both. Most mutual antagonisms occur as a result of competition for a limited resource. In some cases two pathogenic species together invade a host and thereby bring about its death, but in the process they destroy themselves; either pathogen alone would normally not destroy the host. An insect parasitoid and a predator occasionally engage in competitive interactions that result in death to both competitors, a phenomenon called synnecrosis.

When more than one insect parasitoid parasitizes a given host, competition for the host results. For example, when the female wasp parasitoids *Praon exsoletum* and *Trioxys complanatus* both attack the same aphid host, usually only one parasitoid survives, but occasionally the competition is so disruptive that the host dies as well, and with it all competitors. A variation of this habit is superparasitism, or the depositing by one species of more eggs into a host than can survive. The usual, adaptive outcome of such a situation is the death of all but one, an example of intraspecific competition. When hosts are in relatively short supply, however, superparasitism to an excessive degree commonly takes place. The result often is the death of both the parasitic larvae and the host itself.

It has been said that the true parasite rarely exploits its host to the point of death, for the death of the host means the death of the parasite. The "prudent" parasite has evolved to avoid such drastic interaction, and the host likewise has evolved a resistance (immunity) to a parasitic species of long-standing association. When the pathogen, however, invades a new host species or subspecies or a previously unparasitized, susceptible host population, the resulting association may be one of extreme virulence, with rapid onset of death of the host.

Another example of mutual antagonism that is clearly harmful to both interacting species is the case in which cattle consume halogeton plants, whose leaves contain a poison that frequently kills the cattle.

COMMENSALISM

In many communities there are species that benefit through interaction with other species, while the latter remain indifferent or unaffected. Such unilateral benefits include attainment of nutrients, space or support, shelter or protection, and transport. The commensal population is, by virtue of the association, increased in numbers through improved survival. If the commensal is obligatorily associated with a host, it cannot live in a community that does not contain the host in question.

Nutritional commensalism. Nutritional commensals, or allotrophs, are well illustrated by the many organisms found in the alimentary tracts of higher animals. Such endosymobiotes use host waste products for food and acquire suitable water supplies and a suitable microclimate in which to live. No harm is done to the hosts. Endosymbiotic bacteria and yeasts are found in most large mammals, particularly cattle, horses, sheep, deer, and buffalo.

Endosymbiotes

Numerous bacterial and yeast colonies grow on the bark, twigs, and leaves of trees and large shrubs, particularly in tropical habitats. These nonparasitic organisms live on the nutritious exudates and the decomposing bits and flakes of dead bark that coat the surfaces of such plants. In the soil many fungi and bacteria live on nutrients derived from the root exudates of higher plants.

Aquatic organisms with poor dispersal powers or poor food-gathering capabilities often attach themselves to species on whom they can depend to provide those qualities. The small crab *Lissocarcinus* lives commensally on the surface of sea cucumbers (class Holothuroidea), being protected by colour camouflage from natural enemies and gaining its food simply by diverting bits of the plankton that is pulled into the sea cucumber's mouth by feeding currents. Clown fish (*Amphiprion*), which habitually swim

among the tentacles of sea anemones (order Actiniaria), are unaffected by the stinging cells (nematocysts) of the host, but they receive protection from small predators and also partake of surplus bits of any food captured by the anemone. The well-known remora (family Echeneidae) and the pilot fish (*Naucrates ductor*) also obtain their food from the activities of such hosts as a shark, marlin, or swordfish. The remora attaches itself to its host by a sucker organ, whereas the pilot fish swims in close association with the host. Both commensals feed on the leftovers of their host's meals.

Numerous birds are food commensals of other animals. Cattle egrets (*Bubulcus ibis*) in Africa follow herds of elephant, buffalo, or antelope, feeding on insects and grubs turned up by the grazing activities of such animals. The cowbird (*Molothrus*) behaves similarly with cattle in the Americas. In northern Europe, ptarmigan (*Lagopus*) travel with caribou in order to get the insects uncovered from the semifrozen sod. Gulls, lapwing plovers, and herons follow the farmer's plow to attain soil organisms turned up to the surface. Gulls and albatrosses follow ships at sea, feeding on garbage tossed overboard or on small fish stirred up by the passing vessel. Vultures follow carnivores such as lions, leopards, jackals, and hyenas and scavenge upon what is left of a killed carcass.

Insects such as biting lice, fleas, and louse flies, commonly categorized as ectoparasites, are more correctly designated ectosymbiotic commensals; they feed on feathers, sloughed-off flakes of skin, or waxy epidermal exudates. Only in the few cases of blood sucking are they regarded as true parasites.

Some insects and spiders closely resemble ants and associate with army ants in their foraging columns. These mimics feed on the booty flushed up by the foraging ant column. Certain ant mimics live within the nests of the host and as such are termed symphiles. Such symphiles include some of the rove beetles, claviger beetles, and certain mirid bugs.

Physical commensalism. The need for living space is a common basis for commensalism. In overcrowded communities, offshore marine habitats, or tropical rain forests, many nonmotile (sessile) microorganisms are unable to find adequate sites on which to become established; hence, many of them attach themselves to the surfaces of other plants or animals. Most sessile or slow-moving marine animals—sponges, corals, bivalves, snails, turtles, and whales—carry ectocommensals such as algae, hydroids, and barnacles about with them. Woody plants physically support numerous orchids, ferns, bromeliads, grasses, and mosses of the tropics in tropical habitats. Trees in the temperate zone provide support for mosses and lichens.

Insects and mites live in birds' nests or rodent burrows, feeding on dead organic litter. Nest inquilines—insects living in the nests of bees, wasps, termites, or ants—subsist on excess food stores, nest materials, or dead hosts. Some inquilines apparently find the internal physical habitat of these social insect nests favourable for their own well-being.

Batesian mimicry

Batesian mimicry, the morphological and colour-pattern resemblance of certain animals to other animals, is a form of protective commensalism. Edible butterflies, through natural selection by predatory birds or toads, come to resemble, or mimic, distasteful butterflies, which are avoided by these same predators. Drone flies (*Eristalis tenax*) gain protection from predatory toads by mimicking bees that sting and hence are avoided. In such situations the mimicking species benefits by avoidance of predation, whereas the model is little affected, being neither harmed nor benefited by the mimicry.

Examples of protective commensalism include the bird species that build their nests near those of aggressive species, such as predatory birds or certain venomous or predacious insects. In Europe, house sparrows (*Passer domesticus*) and starlings (family Sturnidae) often locate their nests at the sides of an eagle's nest. In North America, house sparrows and grackles (family Icteridae) often nest in close contact to nests of ospreys. In both cases the "protector" species are interested in other prey: the eagles usually attack large rodents or larger birds; the osprey preys on fishes. The cordon bleu weaver (*Uraeginthus*), of Africa, nests directly above colonies of the predatory, fiercely stinging papernest wasps, and the Asiatic woodpecker *Micropternus* often builds nests inside the larger nest complexes of pugnacious Texas shed-builder, or acrobat, ants (*Crematogaster*). These weavers and woodpeckers rarely feed on their insect protectors, and the latter appear never to attack the birds in their nests.

MUTUALISM

Facultative mutualism: protocooperation. Many plant and animal species interact facultatively in ways that are general and indirect but beneficial to both species. These relations, called protocooperation, can be considered the first evolutionary step toward mutualism.

The interactions that occur between soil bacteria and fungi and between them and higher plants growing in the soil are protocooperative. No species is dependent on such an association, but collectively all microflora and higher plants, with associated soil fauna, participate in determining soil composition, structure, and fertility. In the zone of plant roots, soil bacteria and fungi interact with each other, some producing nutrients (metabolites) required by others and all obtaining nutrients ultimately from root exudates and decaying organic matter. Plants benefit from the actions of this microflora by acquiring needed mineral nutrients and carbon dioxide.

Plants also interact protocooperatively with grazing herbivores. Although this relationship constitutes herbivory, grazing herbivores such as deer or cattle maintain a characteristic plant association in their habitual grazing habitats. Removal of the grazing herds soon exposes the range or pasture to invasion by aggressive pioneer plants, including woody shrubs, brambles, and trees. If the grazers are returned, the carrying capacity of the range, much reduced at first, is gradually restored as the grasses and browse plants return. The reason for this interaction is that grasses and browse plants grow from their bases rather than from their tips, so grazers rarely injure the growing crowns of such plants. Shrubs and seedling trees, on the other hand, grow from the tips of their stems and hence are usually destroyed by grazing.

Maintenance of pasturage by grazing animals

The natural control of herbivore populations by natural enemies provides an indirect, protocooperative benefit to plants. These natural enemies (predators, parasites, and pathogens), whose direct influence on herbivorous and other animals has already been described, are some of the major factors that keep herbivore numbers in check. At a community level, this interrelatedness of trophic levels, plant–herbivore–carnivore, constitutes a large-scale protocooperative interaction.

Some of the relationships exhibited between ants and aphids are examples of protocooperation. Benefits are provided to both ant and aphid, but the relationship is often quite loose and facultative (a few such ant–aphid associations are obligatory and are treated in the next section). Generally, the ant member forages for food on trees and shrubs infested with such honeydew-secreting species as aphids, mealybugs, and some scales, collecting the sugary material and transporting it to its nest as food for developing young. In some cases the ant actually stimulates the aphid to secrete honeydew directly into its mouth. Some ant species even protect the honeydew producers from natural enemies, the consequences of which are noticeable: ant-attended trees usually bear much heavier infestations of aphids.

Plants whose flowers are pollinated by insects and birds benefit protocooperatively, particularly when the pollinator is a general one and the plant is attended by many different pollinator species. Many plants, particularly those with colourful, showy flowers bearing nectar glands, are the beneficiaries of cross-pollination accomplished for them by insects. The insect, of course, benefits from the supply of food in the form of pollen and nectar. Honeybee (*Apis mellifera*) colonies are used commercially to ensure pollination of many agricultural crops.

An interesting and apparently widespread form of protocooperation, called cleaning symbiosis, appears most noticeably in birds and fish. The Egyptian plover (*Pluvianus*

aegyptius) picks insect pests from the backs of buffalo, antelope, giraffes, and rhinoceroses and even leeches from the open mouths of crocodiles. The cattle egret in America performs the same function. Certain fishes function habitually as cleaners of other fishes, nibbling away at ectoparasites, wounded tissues, and dead flesh. Even predatory fish search out such cleaning symbiotes and remain passive while they are worked over. Such fish cleaners are often concentrated in fixed sites, called cleaning stations, where other fish come to be cleaned.

Müllerian mimicry, the close similarity in appearance of two or more unrelated species in which each species is more or less distasteful to predators, is a form of protocooperation. Such mimicry presumably benefits all participating species.

Obligative mutualism: interdependency. In many communities the most stable, persistent, and interdependent associations between species are those based on obligative mutualism. Since the association is mandatory for the survival of each participant, coexistence in a given habitat is always required. Thus, ways have evolved to assure the perpetuation of the association from one generation to the next. Some of these means are intricate, involving adaptations in structure, behaviour, or life history so as to guarantee the coexistence of the partners. On the other hand, some mutualistic relationships are maintained simply through the high probability of mutual encounters as a result of the population density or great reproductive powers of one or both mutualists, or symbiotes.

How nature assures continuation of interdependencies

A number of bacteria–protozoan associations occur in aquatic environments. In certain cases, endosymbiotic bacteria, which exist in the cytoplasm of protozoan flagellates, are able to digest cellulose in quantities to provide for themselves and their hosts. Associations of fungi and single-celled algae include the well-known lichens, in which the fungal member penetrates algal cells with feeding tubes or haustoria, thus effecting an intimate physical interconnection. The mutual benefits derived from this association are nutrient exchange, maintenance of water and mineral balance, and resistance to drying or to extreme temperatures. Whether the association is truly mutualistic is difficult to resolve on formal grounds; some authorities contend that the fungi parasitize the algae. Ecologically, however, there is no question that the lichen is far better able to cope with its environment and to invade many more habitats than can either partner living alone.

Single-celled algae also enter into symbioses other than lichen formation, particularly in marine habitats where photosynthesis is restricted. Algae are symbiotic with, among other groups, protozoans, sponges, coelenterates, rotifers, flatworms, mollusks, echinoderms, and tunicates. The algal cell provides oxygen and manufactured food to its partner and, in turn, receives physical support, water, minerals, and a proper environment. Some algae are acquired by ingestion (the more primitive mechanism), whereas others are inherited; *i.e.,* transmitted during cell division of the host (the more advanced mechanism).

The association of algae with a motile coral polyp is accompanied by remarkable behavioral alterations in the host, which reinforce the benefits derived. Free-living larvae (planulae) of certain corals that contain yellow-green algae move toward light, whereas planulae lacking such algae are unresponsive to light. Corals endowed with algae grow more rapidly, take on different shapes, and are much denser than corals without algal members. In Caribbean mangrove swamps, certain algae-containing anemones distribute themselves in zones of intermediate light intensity; bleached anemones become indifferent to light or shade.

The important association of nitrifying bacteria with the roots of certain mostly leguminous plants is well known. Nitrogen fixation—the extraction of nitrogen from the environment—occurs only after the bacteria have invaded the plant roots and stimulated the host to form nodules that encapsulate the bacteria (a response of the host to infection). This association is closely related to parasitism. Nevertheless, the mutual benefits to the interactants are substantial: an environment and nutrients for the bacteria and improved fertility of the soil (by addition of nitrogen compounds) for the plant host.

The unusual case of nodule bacteria

Many insect species (perhaps most) contain microbial endosymbiotes, including bacteria, rickettsias, fungi, yeasts, and protozoans. These organisms provide required nutrients for the host—often vitamins, occasionally digestive enzymes, and sometimes simple foodstuffs such as glucose sugar. The host provides the symbiote with a protected microhabitat containing food, water, minerals, and the proper chemical environment. The endosymbiotes are rarely found in the free-living state, and their hosts are unable to survive in their absence. They may be either extracellular—residing in the mouth, gut, rectum, blood spaces, or excretory tubules—or intracellular—living in the cytoplasm of various cells of the host. Because of the intimacy of such symbioses and the dependent nature of the associations, intricate mechanisms have evolved for the transmission of the endosymbiote from one generation of the host to the next. In some conenoses (*Triatoma*) and seed bugs (family Lygaeidae), intestinal symbiotes are deposited as fecal material with the egg, and newly hatched larvae regain the symbiotes by consuming this material. In some stinkbugs (family Pentatomidae) the symbiotes are smeared on the oviposited egg shell, reinfecting the new hatchling as it emerges from the shell. In the olive fly (*Dacus oleae*) the egg is smeared with bacteria as it passes down the ovipositor, the bacteria penetrating the egg and becoming enclosed in the developing embryo. Finally, there are cases where the symbiotes penetrate the female ovary to invade the egg before it is even deposited; this occurs in some roaches, weevils, and ants.

One of the most notable mutualistic associations is that between certain wood-eating insects and cellulose-digesting protozoans. The wood roach (*Cryptocercus punctulatus*) acquires the intestinal cellulose-digesting symbiotes at an early age, retaining them for life. The termite, also a wood-eater, loses its symbiotes at each molt (shedding of skin) during its immature stages. The termites, however, reinfect themselves: newly molted nymphs ingest anal secretions from nonmolting nymphs and thereby obtain the intestinal organisms.

Numerous insects have become adapted to the use of fungi as specific food resources. These include the wood-boring insects that introduce and maintain fungal growths in their nest galleries and termites and ants that cultivate fungal "gardens" in their subterranean colonies. Various wood-boring insects possess this habit: ambrosia beetles (family Platypodidae), bark beetles (family Scolytidae), and sawflies (family Tenthredinoidea). The adult ambrosia and bark beetles introduce the fungus into the brood galleries they make when they invade a tree. The adult timber borers and sawflies lay their eggs on or beneath the surface of the bark of a tree, introducing the fungus along with the eggs. The fungi then grow in the galleries formed in the wood and provide food for the developing insect larvae.

Insects that cultivate fungi

Myrmicine ants and certain tropical termites also are fungal "gardeners." The fungus-raising termites (subfamily Macroterminae) apparently utilize the fungi to control the localized climate of the nest rather than to obtain food. In termite nests where fungal gardens thrive, both the relative humidity and temperature are maintained at relatively constant, high, favourable levels as a result of the metabolic activities of the fungi. Fungus-culturing ants, however, clearly acquire nutrients from their gardens. Leaf-cutting ants (*Atta*) clip off and carry to their nests pieces of fresh leaves on which the fungi grow. The gardens are established usually in enlarged underground cavities, well ventilated, and tended by a class of workers who remove undesirable fungi and bacteria. All members of the colony feed on strands of the cultured fungi.

Certain insects are obligatory mutualists of the plants they pollinate. The California desert yucca (*Yucca*) can be pollinated only by the yucca moth; the moth, in turn, is wholly dependent on the yucca flower ovary as a place to deposit its egg and develop its young. The common Smyrna fig (*Fiscus carica*) can fruit only after pollination by the fig wasp (*Blastophaga psenes*). This is a much more complicated process, since three different kinds of figs are involved in proper sequence: one for maintaining an overwintering population of wasps, one for producing adult wasps during the growing season, and one (the edible fig)

that requires pollination but is otherwise unavailable for wasp reproduction.

Insects also enter into protective relationships with plants. The acacia ant (*Pseudomyrmex ferruginea*), which lives on and derives its food from the bull-horn acacia (*Acacia cornigera*), protects the acacia from intruding vines, competing plants, and herbivorous insects. The ant depends on the acacia, and the acacia cannot survive without the ant. A concomitant development of this mutualism is that this particular acacia has lost the chemical defenses against insect defoliators that other acacias possess.

NEUTRALISTIC INTERACTIONS

The final category of interspecies association commonly encountered in communities is neutralism, the persistent appearance of two or more species together with neither benefit nor harm accruing to any. It is a commonplace that seems self-evident and without significance; thus, it is often ignored in discussions of symbiosis. Indeed, in some cases—perhaps most—this interaction is trivial or accidental, yet in many communities such interspecific associations are characteristic. Most often, neutralistic associations occur when a common resource for several species is highly localized within the community, as when numerous species aggregate about water holes or streams. Insectivorous birds and predatory insects and rodents are persistent followers along foraging columns of army or driver ants, not to prey on the ants but rather upon the organisms stirred up by the mass advance. Neutralistic associations are characteristic in the distribution of trees in forests. The common situation is mixed stands of different species rather than pure stands of single species.

Simple aggregations

POPULATION EFFECTS OF INTERACTION

At the population level the interaction between different species can have two different effects, particularly when the interaction influences the survival or reproductive success of either species (see also below *Biological populations*). One effect is on the numbers of individuals in the interacting populations. The other is on the qualities, or properties, of the individuals in these populations. The first effect—the quantitative one—is the basis for the balance of nature, the state of rareness or commonness of different species. The second effect—the qualitative one—is an aspect of evolution. Biotic interactions, when influencing the survival of a species, tend to produce changes in such aspects as structure, function, behaviour, and colour of the affected species. Since inherited changes in one species can serve as the basis for change in the other, biotic interactions between two species often lead to mutually induced changes in both, or coevolution.

Ecological aspects. The effect of one population on the numbers of another can be either positive or negative. A positive effect occurs when the survival or reproductive success of individuals of one species, or both, is enhanced and leads to an increase in the numbers of one or the other interacting population. Hence, an insect that consumes pollen in seeking a meal will generally bring about the pollination of the flowers of the host plant concerned; the result is an increase in the reproductive success of the host plant. Algae in such hosts as coral polyps stimulate the growth rate of coral colonies, and the enhanced growth of the coral benefits the algae.

A negative effect occurs when the survival or reproductive success of one or both interacting populations is reduced, usually leading to a reduction in numbers of the affected populations. Negative interactions are those resulting from herbivory, predation, or parasitism, in which the food, prey, or host species suffers and may therefore diminish in abundance, or from competition or mutual antagonism, in which both interacting species may suffer, be reduced in numbers, or even be eliminated from the habitat altogether.

In cases in which the biotic interaction is obligatory for one or both participating species, both species must appear together in the same community for the interaction to persist and for one or both participants to survive. A host species that is dependent upon an endosymbiote to provide necessary dietary components will usually not survive in the absence of the symbiote, and vice versa. A predator in consuming prey thereby reduces the numbers of the prey population to a point at which the prey becomes scarce and more difficult for the predator to find. The predator population then comes into balance with the diminished prey population. Any later increase in the prey results in an increase in the predator, and so on.

Interdependence of interactants' populations

Evolutionary aspects. Since all species gradually change in response to selective factors, biotic interactions can serve as the means by which one of the interacting species brings about evolutionary change in the other. Just as predators can alter the numbers of a prey, and vice versa, evolutionary change in one interacting population can result in the evolutionary response of the other. For example, if a prey, through natural selection, becomes swifter or more agile in escape, a predator may develop, also through natural selection, capabilities for better pursuit. Plants, under the selective pressure of herbivory, often evolve a capability to produce toxic poisons that discourage herbivores. Subsequently, however, the herbivore, especially if it is dependent solely on the particular plant group involved, tends to develop tolerance for or resistance to the poisons. These examples of coevolution illustrate the dynamics of the process, the constant influence of each participant upon the other.

Since two interacting species tend to influence each other's evolution, it is not surprising that evolutionary convergence occurs in dissimilar organisms involved in similar biotic interactions. Convergence is the acquisition, through natural selection, of similar structure, function, or behaviour by unlike and totally unrelated species. One interesting example of convergence is a consequence of insect herbivory. A variety of unrelated insect species attack members of the mustard family (Cruciferae or Brassicaceae), the plant family that also includes the cabbage, brussels sprout, and radish. All crucifers contain chemical irritants or poisons that affect many animals and many microorganisms. Such toxins likely were evolved as chemical defenses in response to herbivore pressure. The insect species that now attack crucifers, however, have not only become capable of detoxifying the poisons but in some cases are even able to utilize them, either as attractants or as feeding stimulants.

Through coevolution, interspecific interactions among mutualists have led to mutual adaptations of unusual complexity. The mutualistic associations between the yucca plant and the yucca moth, the Smyrna fig and the fig wasp, and the bull-horn acacia and the acacia ant have already been described. An even more striking example concerns the mimicry developed in the fly orchid, or bee orchid (*Ophrys insectifera*). The flowers of this unusual orchid—pollinated chiefly by a species of bumblebee—simulate very closely the shape and colour of a female bumblebee, so much so that male bumblebees frequently try to mate with it and in that attempt pollinate the flower.

Mutual adaptations

Polymorphism, as mentioned before, is the occurrence in the same species of two or more different forms, distinguishable by colour, pattern, function, body dimensions, shape of the appendages, or behaviour. Often, polymorphism in one species occurs as a consequence of biotic interactions with another species. Character displacement in overlapping competitor species may present a situation in which the taxonomist often wonders whether he is not dealing with three or four different species rather than just two. Similarly, the discovery of noninterbreeding species, identical in every morphological detail but coming from different regions, also poses problems for the taxonomist. Such so-called sibling species often can be recognized only through differences in the nature of their biotic interactions. An example is the two parasitoid species *Trioxys complanatus* and *T. pallidus*. They are virtually identical in structure, yet each attacks and is specific to altogether different aphid hosts. (P.S.M./Ed.)

Biological populations

Animal and plant populations (the numbers of individuals of given species living in a particular area) tend to be stable—that is, their fluctuations are small compared

with what would be theoretically possible if no limits were placed upon their increase. Only a relatively small number of species are either expanding in numbers or decreasing to extinction. Stability is possible only if numbers tend to rise when low and to fall when high, through the action of density-dependent factors. An attempt is made here to summarize what is known about the critical factors concerned.

Human populations

Human populations are currently unstable. More specifically, they are increasing at an unprecedented rate, owing in part to improved food supplies in many regions of the world and to the eradication of diseases. In the course of a few generations, these advances have significantly reduced infant and child mortality as well as increased the life expectancy of adults. In addition, human beings have characteristically insulated themselves from factors such as natural predation and severe weather that serve to regulate other species' numbers. But a population must eventually cease to increase. It can do so in one of two ways, either through higher mortality (from starvation, disease, or war) or lower natality. While a further increase in food supplies may be desirable on humanitarian grounds, it can at best provide only temporary alleviation.

THE CHARACTERISTICS OF BIOLOGICAL POPULATIONS

Populations consist of individuals of different ages, of two sexes, and of varying heredity.

Age distribution. In some animals, the young are similar to the adults except in size; they eat similar types of food and are subject to similar predators, so their numbers and those of the adults may interact with each other. But in other kinds, the young are extremely different in appearance, live in different habitats, eat different types of food, and are subject to different predators, so that adults and young have no direct influence on each other's survival.

In many small invertebrates, notably many insects, the eggs are laid in one short period of the year, hatch into larvae more or less synchronously, pupate synchronously, emerge as adults together, and die after breeding. Hence at any one time, almost all the population consists of animals of the same age, and the breeding stock of one year is derived wholly from eggs laid the previous year. The situation is slightly more complex in species that have a similar life history but raise two successive generations each year, or, alternatively, that take several years to raise one generation. Most sockeye salmon (*Oncorhynchus nerka*), for example, live for four years. Each individual breeds once and dies; its young move from fresh water to the sea to complete their growth and then return to breed. Thus the populations coming up the rivers of British Columbia in four successive years are nearly separate. The point has commercial importance because in some areas one of the annual populations in a four-year period is much larger than the other three, probably because the average chance of survival is greater for a young fish hatched in a peak year, when they are much more numerous—relative to the numbers of predators—than in other years.

Age distribution in salmon populations

The age distribution (*i.e.,* the proportion of individuals in each age group) is much more complex in most other vertebrate animals and in some of the larger invertebrates. In these groups, most adults breed every year until they die, so that the breeding population at any one time consists of individuals of a mixture of ages. In most stable populations the age distribution remains relatively constant. But in certain fish and marine invertebrates, many more young are produced in some years than in others, and the predominance of a particular year class may persist for some years.

Various small plants, like various small animals, are annuals; they winter as seeds, breed once, and then die. Other species are biennials, and many more, including trees and bulbs, are perennials. Some large trees live much longer than any known animal—as long as several hundred or, in rare instances, 1,000 years.

Sex distribution. In most animals the male-female sex ratio is approximately equal. In various animals with an almost equal sex ratio at birth, one sex may become more common than the other later in life. In many monogamous birds, for instance, adult males are more common than adult females. This is probably because the females take the greater part, and in some species the whole part, in incubating and raising the young and thus are subject to heavier predation than the males. On the other hand, in polygynous birds (*i.e.,* those in which each male has several mates), breeding males are much scarcer than breeding females, perhaps in part because their exceptionally conspicuous plumage and behaviour patterns render them more subject to predation than the females. In one such species, the boat-tailed grackle (*Cassidix mexicanus*), the conspicuous males disappear faster than the less-conspicuous females in winter, perhaps through predation. Among humans, about 51 percent of all births are male, but in modern Western civilization, females survive slightly better than males, so that during adolescence the sex ratio becomes equal, and among adults there are slightly more women than men.

In certain arthropods, notably aphids and water fleas, some generations consist solely of females that lay eggs that develop without fertilization by a male (parthenogenesis), though at other times of the year males are present and fertilize the eggs, which are of a different type. In another group of insects, the social bees and wasps (order Hymenoptera), most of the population consists of workers, which are sterile females. In various rotifers, only females are known. The spoonworm (*Bonellia*) is at first undifferentiated, but environmental factors determine sex; while other marine worms change their sex with age. Earthworms and snails, along with a few other animals, are hermaphrodites, with male and female organs on each individual. Hermaphroditism is, of course, common in flowering plants, both sets of organs usually being on the same flower. Asexual reproduction is common in plants, but in nearly all of them sexual reproduction is also the rule, and only a few species have dispensed with it entirely.

Hermaphroditism

Genetic differences. In addition to the differences linked with sex, individuals of the same population differ somewhat in other genetic characteristics. These constitute the subject matter of population genetics, but it should be noted that the extent of genetic variation may vary with the state of the population; in particular, it may be unusually great in an expanding population because selection is temporarily lightened. Some researchers have argued that the regular population cycles discussed later in this article result from the production, in different years, of individuals of different genetic makeup; but there is no positive evidence for this, and it seems unlikely to be an important cause of cycles (though some genetic change is to be expected in populations that alternately increase and decrease in numbers on a big scale).

NUMBERS AND DENSITY

The numbers of large animals can often be counted directly, and aerial photography has been developed as a method for counting both big mammals and large birds. The numbers of various other animals have been assessed by capturing some of the population, marking and releasing them, and in a further series of captures finding the proportion of marked individuals in the new sample. Given large samples and random means of catching the animals, this "capture-recapture" method can provide accurate estimates of numbers. The results can be misleading, however, if the samples caught are biased as to age or sex, particularly if this varies seasonally, and also if previous capture affects the chances of later capture—*e.g.,* if an animal learns to avoid being caught. In the case of some animals, including small but abundant species, total numbers are normally estimated from those counted in sample areas.

Some animals are much more numerous than others. In general, large animals are sparser than small, because the larger the animal, the more food needed to sustain it; but there are so many exceptions that this generalization is of little use. Predators are much scarcer than their normal prey and are usually larger in size. Among the smallest existing populations are those of various land vertebrates on remote islands, though this is partly the result of destruction by humans. Where human destruction is

checked, even a severely reduced population may persist, as shown by the conservation and recent small increase of the whooping crane (*Grus americana*) on the American mainland. The most numerous large animal in the world is man. It would be extremely hard to determine which is the most numerous small animal in the world.

The population density of a species typically varies in different parts of its range. Population biologists have tended to study animals where they are common—in the middle parts of their range and in optimal habitats—but their relation to their environment may be different where they are sparse. In the few cases in which a population has been studied in two areas, it has been found that its density, natality, mortality, main predators, and even main foods may differ from one area to another. Most animal populations have inevitably been studied under conditions affected by humans. This need not affect the validity of the general conclusions reached, but the proportionate importance of various factors influencing birth rates or death rates may be different in human-modified and in natural habitats.

'he quality etween atality nd ıortality

Natality. The reproductive rate—in mammals the birth rate, in plants the rate of seed production—is the rate at which new individuals are produced. It should be distinguished from the recruitment rate, which is the rate at which new adults (not new eggs or new young) enter the breeding population. Most animal populations are not, on the average, either increasing or decreasing markedly, and in such populations the recruitment rate equals the adult mortality, while the natality or reproductive rate equals the total mortality of eggs, young, and adults.

Some biologists have argued that the equality between natality and mortality is an evolutionary mechanism to prevent overpopulation. This suggests that natality is smaller than it might otherwise be, particularly in long-lived animals. A different view holds that the implication of evolution by natural selection is that those hereditary types (genotypes) that leave most offspring must come to predominate over the rest. In other words, the reproductive rate of each species has been evolved through natural selection to correspond with that which gives rise to most surviving young per adult. This does not mean that each species must produce an immense number of eggs or young. In some this may, indeed, be the most efficient means of reproduction, but others are unable to form sufficient food reserves for many eggs, or cannot find food for a large family without serious risk to themselves, or need large food reserves for the young at hatching, and hence produce few (but often large) eggs or seeds. In this view, natality and mortality are roughly equal because mortality rises when the population is high.

Natality differs significantly in different kinds of animals. An oyster can probably lay a hundred million eggs during its life, and even so complex an animal as the Atlantic cod (*Gadus callarias*) produces some four million. In contrast, an elephant matures late, has one offspring at a birth with an interval of several years between births, and may produce only five young in its life. Similarly, the number of seeds produced by a plant differs greatly in different species.

Birds. The average clutches of different species of birds vary from one to fifteen; the largest in a species that feeds its young is ten, in the blue tit (*Parus caeruleus*). Clutch size is characteristic for each species and presumably depends on hereditary factors, although there are also phenotypic (nonhereditary) variations, the same individual laying clutches of different size under different conditions.

Egg ıumbers

In birds that feed their young, clutch size corresponds to the greatest number of young for which the parents can find enough food without serious risk to themselves. For instance, the European common swift (*Apus apus*) usually lays three eggs. If it is experimentally given four, then, as shown in Table 1, so many nestlings starve that each pair raises, on the average, fewer young than pairs starting with three. Hence, any tendency to lay a clutch of four will be eliminated by natural selection. Similarly, the most frequent clutch size in first broods of the European starling (*Sturnus vulgaris*) and the great tit (*Parus major*) corresponds with that brood size from which the most young survive; in these species, however, the young in larger broods do not starve in the nest but leave it underweight and die soon afterward.

Table 1: Number of Young Raised by the European Common Swift (*Apus apus*)

brood size	broods observed	number hatched	number fledged	proportion raised (percent)	number raised per brood
2	72	144	139	97	1.9
3	20	60	51	85	2.6
4	16	64	27	42	1.7

Source: Observations by C.M. Perrins at Oxford in the years 1958–61. Broods of four were not natural but were made up by adding newly hatched young from other broods, which does not disturb the parents. Some broods of two came from clutches of two, but others from clutches of three, either through failure of an egg to hatch or because a nestling was removed to make up a brood of four.

Many phenotypic variations in clutch size are adaptive. The Eurasian nutcracker (*Nucifraga caryocatactes*), which stores the food for its young the previous autumn, lays four after a good and three after a poor season for nuts. Various hawks and owls that prey on lemmings or voles lay unusually large clutches in the occasional years when their prey is extremely abundant. Regular seasonal variations in the clutch size of songbirds in north temperate regions broadly fit the seasonal variations in the availability of their food. Individuals breeding for the first time lay slightly smaller clutches than older individuals and are also known to be less efficient at finding food. If such phenotypic adaptations were perfect, each species would always lay the clutch best suited to its circumstances, but this would require precise prediction of future feeding conditions for the young.

In hawks, storks, and other large birds, incubation starts with the first egg, so that the young hatch at one- or two-day intervals. This is an adaptation, for if food is sparse, the older nestlings are so much stronger than the younger that they get all of it, while if the food is plentiful, the larger nestlings are sated and the younger are fed; hence the brood size comes quickly to correspond with the feeding conditions at the time, and food is not wasted on young that would starve later. Another adaptation is the growth rate of the nestlings, for the same quantity of food per day can be used to raise a larger brood more slowly or a smaller one more quickly. This is probably why hole-nesting songbirds have larger clutches than those with open nests; the latter suffer such heavy predation that there must be strong selection for rapid growth, but fewer young can then be raised together. A slow growth rate may also be advantageous for species that find difficulty in bringing enough food for even one nestling, such as various large raptors and seabirds.

Forms of adaptation

Another general tendency is for clutches to be larger at higher than at lower latitudes. At the higher latitudes, summer days are longer, so the parents can collect more food per day. Many species breed with the flush of insects after the winter dearth in which many adults have starved, so that food becomes plentiful in relation to adult number and large broods can be fed. Similar conditions hold in tropical savannas, where birds breed with the rains after a long dry season. In tropical evergreen forests, however, food may be available in nearly the same quantities throughout the year; hence, the number of adult birds may stay close to the limit set by food, there being only enough extra food for small broods.

Although ducks (family Anatidae), unlike most birds, do not feed their young, there is a broad inverse correlation between the number and size of the eggs in different species. This suggests that the female's food reserves may be used for more and smaller, or fewer but larger, eggs. Presumably, natural selection has favoured the evolution of a larger egg (and therefore a smaller clutch) in those species in which it is advantageous for the young to be larger, or to carry greater food reserves, at hatching. In a few other birds, including the common swift and the red grouse (*Lagopus scoticus*), the clutch is slightly larger

when more food is available for the laying female, but this is a minor factor.

Natality is also affected by the number of broods raised. Most species raise one a year; many songbirds raise two, some even three, and the Senegal fire finch (*Lagonostricta senegalla*) raises four. At the other extreme, probably because their food is sparse, a few large raptors and seabirds take more than one year to raise a nestling; they breed successfully only once every two years.

The young of some finches and doves first breed when two to four months old; most birds when just under a year old; various water birds, raptors, and others not until several years old; and large albatrosses not until about the age of 10. Such "deferred maturity" (like a small clutch) has been seen as an adaptation to reduce natality in long-lived species. But it can as readily be explained in terms of natural selection, provided that those individuals that defer maturity ultimately leave more descendants than those that start breeding when younger. This will hold if (1) younger individuals are unlikely to raise young and (2) the attempt to breed involves a greater chance of death for the adults. It has been found that in pelicans and herons, which have deferred maturity, immature individuals catch food less efficiently than adults and thus might be unable to feed a brood. Again, in the royal penguin (*Eudyptes schlegeli*), subadults weigh less than adults, presumably because they find it harder to obtain food, and only the heaviest birds breed; presumably this is because big food reserves are needed by the female to form eggs and by the male to take the first long incubation stint. Many species with deferred maturity lay only one egg, which suggests that they find it hard to obtain food for their young. In various seabirds, however, deferred maturity may simply result from an insufficient number of safe nesting sites. Finally, deferred maturity is also found in the males but not the females of various polygynous and promiscuous birds, in which there is such intense competition for mates that younger males may well fail to secure them and in which the elaborate plumage displays probably involve extra mortality from predation. One may conclude that, in birds, the age of first breeding may well have been evolved in relation to the maximum number of young that the adults can raise during their lifetime. Still, the alternative view—that breeding age is adapted to mortality—has not been disproved.

Deferred maturity

Mammals. Mammals produce from 1 to about 12 young at a birth, the latter being the figure for the African multimammate rat (*Rattus coucha*). In some species, individuals breeding for the first time have smaller litters than older parents; in others, such as hares and rabbits, there are seasonal variations in litter size; and in some species litter size varies with latitude. These parallels with birds suggest that similar factors operate in both birds and mammals. It has been shown that, in laboratories, infant mortality in the guinea pig (*Cavia porcellus*) rises with increasing litter size, but the extent to which it may do so in the wild is not known. Similarly, in man, the proportion of stillbirths is lowest for single babies, higher for twins, and much higher for triplets; it is likely that, in primitive conditions with poor food supplies, infant mortality also rises with the number of young at a birth.

Many rodents have several litters a year; many other mammals breed once annually and some only once in two or more years. The female meadow vole (*Microtus arvalis*) is fertile when 25 days old, many mammals when one year old, and other mammals not until several years old. As in birds, larger mammals tend to mature later than smaller ones, but there are many exceptions: at least two species of large whales first breed when two years old, whereas elephants and humans mature in their teens.

Phenotypic effects on maturity

Maturity is also influenced by phenotypic factors. Thus a reduced diet delays maturity in various domestic and wild species; this is because it retards the growth rate, and the species concerned breed at a particular size rather than a particular age. Humans are capable of producing young when quite undernourished, but in the near-starvation conditions of some concentration camps in World War II, many women ceased to menstruate and could not have conceived. Conversely, the marked lowering of the average age at which menstruation begins among girls of late-20th-century Western societies has been attributed to improved nutrition.

Fishes. In fishes, as in ducks, there is a broad inverse correlation between the numbers and sizes of the eggs; this implies that egg production is limited by the food reserves of the female and that larger eggs may in some circumstances be sufficiently advantageous to offset the disadvantage of smaller numbers. In general, marine fishes with planktonic larvae have many small eggs, and the larvae hatch with abundant food around them and so do not need large food reserves; on the other hand, various deep-sea fishes and those that breed in polar coastal waters have fewer and larger eggs, because food is less abundant for the young and it is advantageous for them to be larger at hatching. Some species that have only a few large eggs protect them by making a case for them or even by staying beside them, and a few fishes are viviparous (producing their young alive from eggs retained in the body). This has given rise to the idea that, because the eggs are protected, fewer are "needed"; but, as suggested earlier, natural selection must favour those individuals leaving the most offspring. Presumably, the species in question leave the most offspring when they utilize their food reserves to produce a few well-nourished and well-protected eggs rather than many small and unprotected eggs.

Most temperate-zone fishes, once they mature, breed in successive years until they die. A few species living in lakes that dry up each summer breed once and die, their eggs withstanding the drought. More remarkably, various salmon and eels grow for several years and then undertake a long migration from the sea to fresh water (or conversely in the case of eels), where they breed once and die. The long distance between the growing and breeding grounds of salmon and eels doubtless makes it disadvantageous for the female to breed in successive years. If a female can put virtually all her food reserves into eggs, she can produce more at one time than if she has to survive afterward; even so, most species of fishes can probably lay more eggs in a lifetime by breeding in successive years.

The relation between breeding and food supplies

The fishes, like various mammals, first breed at a certain size rather than at a certain age, and they grow faster and mature earlier when food is more plentiful. Each individual also lays more eggs when it is larger. The young of many marine fishes have grown faster and matured earlier after commercial fishing made their food more plentiful by removing many of the larger fishes.

Freshwater crustaceans. The inverse correlation between egg number and egg size is also found in crustaceans. Thus, the "clutch" (retained in a brood pouch) of the freshwater copepod *Eudiaptomus graciloides* consists of 9 to 18 small eggs in spring and of 4 larger eggs in summer, the total volume being in both cases the same. Food is plentiful for the larvae hatching in spring but not for those hatching in summer, for which food reserves in the egg are therefore advantageous. Similar variations have been found in other species. In the water fleas, as in fish, breeding starts at a particular size rather than a particular age, and the number of eggs laid tends to increase as the body size increases. Water fleas also have asexual generations, and the descendants of one female (the members of a single clone) have the same genetic constitution. Individuals of different clones living in the same environment at the same time may differ consistently from each other in egg number, which suggests that there are hereditary differences in the size of the clutch.

Insects. In insects there is also a general tendency for species in which the larvae hatch with abundant food to lay many small eggs and for other species to lay fewer but larger eggs. This reaches its extreme development in the few viviparous species, of which the tsetse flies (*Glossina*) produce only one young at a birth. In some insects, such as the bordered white moth (*Bupalus piniarius*), the number of eggs laid is proportional to the size of the female's body and hence to the amount of nourishment she received as a larva.

In insects that lay their eggs on a limited source of food for the larvae, such as a flow of sap from a tree, a ripe fruit, a cowpat, or a corpse, there is some adjustment of

Adjustment to food source

the number of eggs laid to the duration of the food supply and to the number of eggs or larvae already present. An insect is likely to leave more survivors if it seeks another source of food than if it lays its eggs in a crowded or deteriorating source. Aphids, for instance, lay more eggs on fresh young leaves rich in nutrients than on old leaves poorer in nutrients, and a predominance of old leaves may inhibit breeding. Comparable adaptations are found in parasitoid insects. Those that parasitize species of similar size to themselves lay only one egg in each host and can also detect whether another individual of their species has already laid an egg there. In contrast, species that are much smaller than their host lay many eggs in it (see above *Biotic interactions*). Finally, in the specialized social insects, such as ants and bees, many sterile workers provide food for, and protect, the larvae hatching from eggs laid by the queens. This significantly increases the number of eggs a queen can lay, since egg laying is thus her main or sole duty; the modification reaches an extreme among those termites in which a queen lays 6,000 to 7,000 eggs every 24 hours for a period that may extend over years.

Flatworms. Small animals are often thought of as having more young than large animals. But a freshwater flatworm in the genus *Polycelis,* which is less than 1 centimetre (0.4 inch) long, produces only 2.7 young per cocoon; and the average natality is only 1.0 per adult because many adults do not breed. This low reproduction rate has been shown to be the result of a limited food supply: in one experiment, natality rose by seven times when much extra food was provided in a pond.

Flowering plants. In certain fishes and insects, as already mentioned, the number of eggs laid by different individuals of the same species varies somewhat with their body size. This variation is far greater in flowering plants. In the corn poppy (*Papaver rhoeas*), for example, the number of seeds produced by different individuals of the same genetic constitution, but grown under different conditions, varies between 1 seed capsule with 4 seeds and 400 seed capsules with 2,000 seeds each. In some trees, the number of seeds produced by the same plant varies enormously in different years, depending partly on climatic conditions and partly on a tendency for a good crop to be followed by a small one.

When species of plants are compared, it is found that the size of the seeds tends to be smaller when there are more of them. Small seeds are advantageous, not only because more of them can be produced but also because they are dispersed more readily in the air. They are characteristic of those species that colonize broken ground. Because their seeds disperse so readily, species characteristic of broken ground, such as many of the daisy family (Compositae), are among the first to reach oceanic islands where, in the absence of competitors, some of them have evolved into trees that have larger and much less dispersible seeds. The seeds of forest trees usually have to germinate in deep shade, so it is advantageous for them to have large food reserves to give them a good start. Some plants have two means of reproduction: a seed requires fewer nutrients from the parent plant than a vegetative shoot but has a much smaller chance of survival than a shoot that remains attached to the parent plant until it is viable.

Advantages of small seeds

Mortality. The death rate varies at each stage of the life cycle. In long-lived species, the "potential age" to which survival is possible is much higher than the average age at death. Hence it is useful to calculate the mortality and the expectation of further life separately for each age group.

If an animal population is kept under favourable conditions in the laboratory, with plentiful food and without enemies, the annual adult mortality is much lower, and the expectation of further life much higher, than in a wild population of the same species. In the laboratory, mortality may be fairly high in the small young, but it is low in large young and in young adults, and, while it rises with increasing age, it is high only in the elderly. At the opposite extreme, among wild birds in natural conditions, the losses of young and juveniles are extremely high. Adult mortality is also relatively high but does not rise with increasing age, nor does the expectation of further life decrease, until the individual reaches senility, as in the case of the lapwing. Relatively few individuals reach that age, however. A similar contrast is found in human beings: mortality in Western civilization is similar in pattern to that of a protected laboratory animal, whereas that of Neanderthals and of people living in Roman times seems to have been similar to the pattern of various wild mammals, though not so extreme in its characteristics as that of wild birds.

Birds. Two methods are available for determining the mortality of birds. The whole of a particular breeding population may be marked, and the number returning in each later year recorded; or the age can be determined of all those birds, banded by many different observers, that are later found dead and reported by others. The former method gives a lower figure for the annual mortality than the latter, probably because breeding birds constitute the most successful part of a population.

Death rate variations among birds

In all the birds so far studied, mortality is much higher in juveniles than adults, and it is particularly high soon after the young become independent of their parents. The highest known adult mortality is 70 percent per annum (which means an expectation of further life, at any given time, of only about 11 months), found in the Senegal fire finch. The lowest figure is 3 percent (expectation of further life, 33 years) in a very small population of the royal albatross (*Diomedea epomophora*) in New Zealand. As already mentioned, in a stable population, mortality equals natality; correspondingly, the Senegal fire finch has four broods each year with a mean of 3.4 young per brood, while the royal albatross raises, at most, only 1 young every two years. The mortality of various birds is summarized in Table 2.

Table 2: Annual Adult Mortality in Various Birds

species	average annual mortality (percent)	expectation of further life (years)
Fire finch *Lagnosticta senegalla*	70	nearly 1
Typical songbirds, ducks, gallinaceous birds, and doves shot for sport (northern Europe, North America)	50 (45–55)	1½
Herons, gulls, terns, waders, plovers, and one species of pigeon, in northern Europe and North America	30–40	2–3
Swifts *Apus melba* and *A. apus*	18–20	5
Penguin *Megadyptes antipodes* (New Zealand), kittiwake *Rissa tridactyla* (Britain), manakin *Manacus manacus* (Trinidad)	10	9½
Gannet *Sula bassana* (Britain) and Australasian shearwaters *Puffinus tenuirostris* and *P. griseus*	6	16
Manx shearwater *P. puffinus* (Britain)	4	25
Royal albatross *Diomedea epomophora* (New Zealand)	3	33

Mammals. The age of some mammals can be told from the annual rings on their teeth or horns, and that of a few others has been determined by marking. In all the wild mammals so far studied, adult mortality rises steeply with age after the first few years. In the Himalayan tahr (*Hemitragus jemlahicus*), a goat introduced into New Zealand, about half the young die in their 1st year; in the 2nd year mortality is only 1.3 percent, after which the figure rises steadily to 38 percent in the 12th and 13th years; omitting the 1st year, overall average mortality is 15 percent. In the male waterbuck (*Kobus defassa*), annual mortality in the 2nd to 4th years is only 2 percent, but in the 8th year it is 14 percent; thereafter it increases steeply, and the overall figure is similar to that in the tahr. Because mortality rises with increasing age, the average annual mortality is a less meaningful figure in wild mammals than in wild birds. In young adult mammals, mortality ranges between 50 and 67 percent in various larger rodents and smaller carnivores; it is between 15 and 40 percent in various deer; but it is apparently only 5 percent in the mountain sheep (*Ovis dalli*) and slightly less in the hippopotamus (*Hippopotamus amphibius*).

Fishes. The ages of fishes that live in high latitudes can be determined from the annual rings on the scales, bones, and the otoliths in their ears. Fish fry have a huge mortality. In the few unfished populations so far studied, adult mortality rises with age as it does in mammals. In

High mortality among young fishes and insects

the Lake Superior whitefish (*Coregonus clupeaformis*), for example, the figure rose in one lake from 8 percent in the 12th year to 17 percent in the 20th year and to 45 percent in the 27th year; in another lake it rose from 41 percent in the 7th year to 59 percent in the 13th year. Such figures show that annual mortality may differ greatly in different populations of the same species. In the Queen Charlotte Islands' herring (*Clupea pallasii*), annual mortality increased from 28 percent in the 6th year to 72 percent in the 11th year. With heavy commercial fishing, however, annual mortality becomes much higher and may be almost independent of age.

Insects. In most insects, as already noted, the adults die after breeding; interest therefore centres on the losses in earlier stages. The spruce budworm (*Choristoneura fumiferana*), the larvae of which eat the balsam fir, may be taken as an example. Each female lays about 200 eggs, of which an average of 19 percent are lost (nearly half through insect parasitoids and one-third through predators), leaving 162. Of the newly hatched larvae, 82 percent are lost (mainly through failure to establish on suitable parts of the food plants), leaving an average of 29.2. Of the surviving larvae, 86 percent are lost (nearly half through insect parasitoids and more than one-tenth through predators), leaving 2.7 to emerge as adults. Of the adults, about one-fifth are lost before they breed, leaving one male and one female to repeat the cycle.

CHANGES IN POPULATION CHARACTERISTICS

Growth of populations. If a few fruit flies (*Drosophila*) are put in a milk bottle with banana mash suitable for their larvae, or a few flour beetles are put in a tin of flour, or a few water fleas are put in a jar of pond water, they increase through breeding, first slowly, then rapidly, then slowly again. If their numbers are plotted against time, as in Figure 11, they form an S-shaped curve with the ends flattened. The initial slow, and later rapid, increase may actually represent a constant rate of change. A population that doubles its numbers in each generation seems to increase slowly from 2 to 4 to 8, and much more rapidly from 256 to 512 to 1,024. This type of population growth is called exponential or geometric.

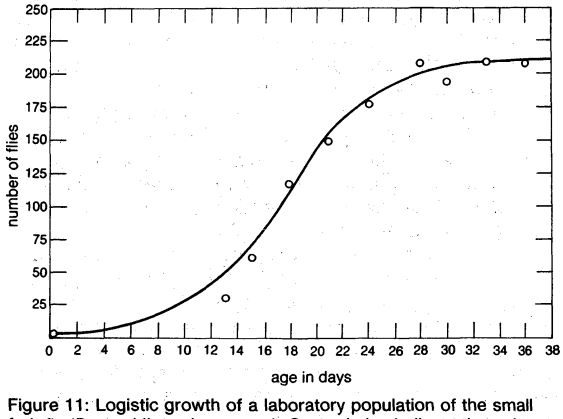

Figure 11: Logistic growth of a laboratory population of the small fruit fly (*Drosophila melanogaster*). Open circles indicate the points resulting from one experiment.

Variable rates of increase

When an animal is introduced by humans to a new region suitable for it, it increases at first slowly and then rapidly, probably in an exponential way. After an animal has become abundant where introduced, its numbers in that area may stabilize while at the same time it is spreading into new areas. In this way the house sparrow (*Passer domesticus*) spread from the Atlantic to the Pacific coasts of the United States in less than 40 years. Similar spectacular increases have been recorded among plants: the water fern (*Salvinia auriculata*) was introduced to Ceylon (Sri Lanka) in 1939 and only 16 years later had put more than 25,000 acres of rice paddy out of production.

Some laboratory populations eventually level off in numbers, but the situation is artificial in that their food supply is constantly renewed. The evidence suggests that, in nature, a successfully introduced population usually declines after a time and does not again reach its first high level, probably because its food supply declines. A few reindeer (*Rangifer tarandus*) introduced to St. George Island in the Pribilovs in 1911 increased to 200 by 1922, fell to 50 in 1926, and fluctuated somewhat below this figure in succeeding years. Another 29 reindeer introduced in 1944 on St. Matthew Island increased to 6,000 by 1963, decreased to less than 50 in the following year, and two years later were practically extinct. They had destroyed their food supply. In the late 19th century the cattle egret crossed from the Old World to the New, where it is increasing and spreading rapidly, but in a habitat (grass pasture with cattle) made by humans. Humans have also caused the rapid increase of various species in their natural habitats by changing their food situation. The herring gull (*Larus argentatus*) has been increasing rapidly on the coasts of Europe and North America; in the latter it has been doubling in numbers every 12 to 15 years since 1900, mainly from feeding on fish waste and on rubbish dumps.

Examples of rapid increase by natural means in natural and undisturbed habitats are far less common because there are usually no ecological niches to be filled. A rapid though temporary natural increase can be observed when numbers have been greatly reduced by a catastrophe, such as a severe winter; the species involved usually attain their former numbers within a few years.

While the rate at which a population can increase is influenced by natality, this is not the main factor determining eventual numbers. Species with a high natality are not likely to be more abundant than those with a low natality. As pointed out by Darwin, the fulmar petrel (*Fulmarus glacialis*) is extremely abundant (and, since he wrote, has greatly increased in western Europe) but has an exceptionally low natality since it lays only one egg a year and requires several years to mature.

Fluctuations in stable populations. All animal populations eventually stabilize at a level around which they fluctuate between relatively narrow limits compared with what is theoretically possible. The extent of the fluctuations, however, does vary significantly; for example, in studies over a period of 40 years of the gray heron (*Ardea cinerea*) in the Thames basin in England, the largest breeding population seen was about double the smallest. At the other extreme, in studies of the bordered white moth (*Bupalus piniarius*) in a German pine forest, the largest population in a period of 60 years was 100,000 times the smallest. But even the largest observed variation is negligible compared with what is theoretically possible. The duckweed (*Lemna minor*) can double in numbers each 2½ days, and at this rate an initial square inch of duckweed would cover one acre in 55 days: yet the waters of the world are not all covered with duckweed. A pair of European robins (*Erithacus rubecula*) producing 10 young a year could theoretically increase to more than 120,000,000 in 10 years. Since even the largest observed fluctuations are negligible compared with what is theoretically possible, animal populations are said to be "stable"; it should be understood, however, that this term allows for fluctuations of the size mentioned, provided that, in the long term, numbers tend to fall when high and to rise when low. The only unstable populations in nature are those recently introduced to a new area and those decreasing to extinction.

Density-dependent factors

Most biologists consider that populations as stable as those found in nature must be regulated by "density-dependent" factors—*i.e.*, factors that tend to reduce numbers when they are high and to allow them to rise when they are low. The contrary view, still advocated by some, is that animal numbers fluctuate irregularly by chance and should not be considered controlled or regulated. The conflict has been partly the result of a difference in interest. Some biologists are interested primarily in annual fluctuations (particularly if a pest is numerous only in occasional years), which may be caused by climatic or other factors acting independently of population density. Others are mainly concerned with the level about which such fluctuations occur, and it is in determining this level that density-dependent factors are important. Density-dependent factors may affect natality, mortality, or movements

of the population; though some populations may be regulated by a single factor, in others two or more factors—for example, food supply and predation—may interact, or the effect of a density-dependent factor may be greatly influenced by that of a density-independent one.

Seasonal fluctuations in numbers. Nearly all animal populations show seasonal changes, often large. In small organisms, some changes of this type are linked with the time needed to complete one generation, or in marine organisms they may be related to tidal cycles; but by far the biggest fluctuations are connected with seasonal change in the environment—from winter to summer at high latitudes, and from the dry to the rainy season in tropical grassland and savanna. This is because nearly all the animals in such places breed at one time of the year, usually in late spring or summer at high latitudes and in the rainy season (or just after it) at low latitudes. They increase significantly in numbers toward the end of the breeding season and thereafter decline until breeding commences the following year. Hence in studying statistics of animal populations based on annual censuses, it should be remembered that between the annual counts there is each year a big and rapid increase in numbers, followed by a corresponding but more gradual decline, and that these seasonal fluctuations in numbers may be much bigger than those between one year and the next.

In a few natural habitats, notably evergreen forests, tropical lakes and oceans, and the deep-sea bottom, seasonal changes are small or almost absent. Even in a rain forest, however, there are small regular differences from month to month in rainfall, vegetation, and the availability of insects; these seem to affect the breeding seasons of many birds. On the other hand, many tropical seabirds that feed on marine organisms on or near the sea surface may breed in any month of the year, which suggests great uniformity in the numbers of their prey and hence also in the food of their prey.

mportance
of the
limatic
actor

Irregular annual fluctuations. All populations fluctuate in numbers to some extent, most fluctuations being irregular. (The few regular cycles are described later.) Large annual fluctuations are usually connected with climatic factors that affect natality or the survival of the young; they are most marked in animals or plants that live for only one year or at least have a high adult mortality, since in such species the young of one year form all, or at least most, of the adult population of the following year. Large annual fluctuations in the production of young (or of seeds) may, however, cause little change in the numbers of a species in which the adults have reached the limit set by space or food supply, especially if the adults have a low mortality. Also, not all annual fluctuations result from variations in the birth and survival of young; in a species living near the northern limit of its range the adult mortality linked with winter cold may vary significantly from year to year.

Irregular fluctuations in numbers have been of special interest to entomologists, particularly in respect to species that remain comparatively scarce for many years and then have a huge outbreak. Examples are the spruce budworm moth, the larvae of which occasionally devastate the forests of balsam fir in northeastern North America, and several other species of moths, the caterpillars of which occasionally strip German pine forests of their needles. It is thought that in most years the numbers of such species are held down by insect parasitoids or predators, but that if climatic factors lead to an exceptionally high production of larvae, especially in two or more consecutive years, the natural enemies do not have time to increase proportionately; thus, the caterpillars then increase rapidly until they are so numerous that they defoliate the trees and eventually die in large numbers of starvation.

Such occasional huge outbreaks are rare. A more usual picture is presented by the annual fluctuations of the red grouse (*Lagopus scoticus*). The adult grouse eat mainly heather. The average clutch is slightly higher and the proportion of surviving young much higher in summers when the heather has a high nutritive value. The actual mechanism of the link between the state of the heather and juvenile survival is not known. In the years when many young survive, the size of the autumn territories is smaller, and the breeding population of the following year is larger. These fluctuations in numbers are proportionately greater in areas of low, rather than high, average density of grouse.

Density-dependent natality. Density-dependent effects may be of two types: direct, in which increasing population exerts a negative effect on factors causing population growth; or indirect, in which increasing population exerts a positive effect, tending to promote further population increase. The latter would not, however, regulate numbers. The natality of many animals is known to be influenced by food supplies, and, since food may be scarcer when the animals are more numerous, it is at least theoretically possible that natality varies inversely with population density. A probable example is the southern elephant seal (*Mirounga leonina*). On the island of South Georgia, where adults are killed in large numbers, cows first have pups at the age of three; bulls first arrive on the breeding ground at the age of four and first hold harems at the age of seven. In contrast, on Macquarie Island, where the animals are protected, cows first have pups at a mean age of six; bulls first arrive at the age of six to eight and breed much later (one marked bull at thirteen or fourteen). The age of first breeding depends on body size, and young seals grow much faster on South Georgia than on Macquarie, presumably because the removal of many adults on South Georgia leaves more food for the young. In the North American mule deer (*Odocoileus hemionus*), the average age of first breeding is also known to vary somewhat with population density. The same is doubtless true of other mammals.

Natality rates of the southern elephant seal

In fish subjected to heavy fishing, the natality of the remainder rises, because with fewer numbers more food is available and the fish grow faster; both the age of first breeding and the number of eggs vary with body size. In the sycamore aphid (*Drepanosiphum platanoides*), and doubtless other species, crowding inhibits breeding; this may reflect reduced food supplies, since breeding is also inhibited by food shortage. The number of eggs produced per female is also density-dependent in the pine beauty moth (*Panolis flammea*), because when the larvae are crowded each forms a smaller pupa and, hence, in the following year a smaller adult, which lays fewer eggs than a larger adult. Again, the number of eggs laid by an insect parasitoid is equal to the number of unparasitized hosts it finds, and the latter number depends in part on the population density of the parasitoid species.

Density-dependent mortality. A simple example of density-dependent mortality was cited earlier for nestling European swifts in which the mortality from starvation is much higher in broods of four than of three. Broods of young are not, however, independent populations. Three examples from such populations follow.

In British Columbia the adults of sockeye salmon come up the rivers to spawn in fresh waters between July and November. The proportion of eggs that fail to hatch rises markedly with an increasing density of adults. Latecomers may expose eggs laid by earlier females; many individuals are forced to lay in suboptimal places susceptible to either drying out or freezing; and crowded eggs may die from fungal infection or shortage of oxygen. These factors are not sufficient to regulate the size of the population, however, since the total number of young that hatch continues to rise, although at a slower rate.

Salmon fry

The small fry suffer heavy predation, chiefly from fishes of other species, on the way from where they hatch to the lake nurseries where they grow. Probably this predation is proportionately less when population density is high. This is evidently because, in years when prey is sparse, the numbers of the predators are held down by the numbers of their prey, and hence in a year with far more fry than usual there are proportionately fewer predators (as their numbers have not yet increased). In such years, small fry have a greater chance of survival than usual, which is probably why, as mentioned earlier, one of the four successive sockeye populations is much larger than the others.

After the fry reach the lake nurseries there is further heavy mortality from predatory fishes, especially in the

first 100 days. This is directly related to population density and therefore affects their numbers. While the immediate cause of their mortality is predation, it is closely linked with food shortage, because when the fry are at higher densities their food is sparser; they grow more slowly than at other times, and because they are smaller they are more vulnerable to predation.

The growth rate of the fry is inversely related to their population density, and so is the average weight of the smolts when they set off for the sea. Moreover, the proportion of smolts returning later to breed is strongly correlated with their weight at departure and hence with their density as fry in the lakes. The population density of the fry is therefore inversely correlated with their subsequent survival at several stages of their life history; its overall effect on the production of adult salmon is summarized in Figure 12. The density-dependent mortality of the salmon fry regulates their numbers, bringing them down when they are high and allowing them to increase when they are low. The causal factors are predation acting in combination with food shortage.

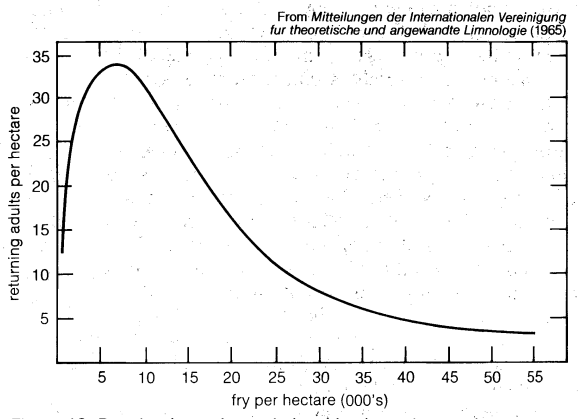

Figure 12: Density-dependent relationships in sockeye salmon (*Oncorhynchus nerka*): relation between density of fry in lakes and that of returning adults.

Food shortage also limits the population density of freshwater flatworms (genera *Polycelis* and *Dugesia*), though in a complex way because these relatively simple animals have the power, when food is short, of feeding from their own tissues. A *Polycelis tenuis* 8 to 9 millimetres (about 0.33 inch) long can survive without food for eight months, during which it shrinks to 1.5 millimetres (0.06 inch). Only the largest individuals of the species breed. Three species studied in North Wales feed on oligochaete worms, one of them also on pond snails. When their food supplies start to increase in spring, the surviving large adults breed. But their numbers are sufficiently close to the food limit to mean that the appearance of many small young produces a shortage, as a result of which many large adults become small and many young fail to grow. A little breeding continues until autumn, at which time the food supply is low and hardly any large individuals remain; the heavy mortality of small individuals from starvation allows the remaining adults to grow larger. As mentioned previously, the experimental removal of two-thirds of the adults from one pond, and the provision of much extra food in another, caused a large increase in natality. In addition, in both ponds the mortality fell and the proportion of big adults increased. In an experiment in which a population was kept without food, the large individuals shrank to medium size, the medium-sized became small, and the small died.

Adult flatworms

Poppies have small seeds with small food reserves. When experimental plots are sown with seeds at different densities, the mortality of the seedlings becomes higher at the higher densities, until it is so high that the addition of further seeds does not produce any further increase in the number of surviving plants and may even cause a decrease. The mortality among densely planted seedlings in this and other species has a number of causes, including higher humidity and hence greater fungal infection, more blanching because the plants partly screen each other from the light, and a great attraction of predators such as wireworms.

In similar experiments involving plants with large seeds, such as the corn cockle (*Agrostemma githago*), each seedling has more food reserves and mortality does not rise with increasing density, so that the greater the density of seeds, the greater the density of plants produced. At the higher densities, however, the rate of growth of each plant is significantly reduced, and above a certain density there is no further increase in the total weight of plant matter per unit of area, or in seed production per unit of area. Corn or maize (*Zea*) is another large-seeded plant in which the rate of growth decreases markedly with increasing density of seedlings; above a certain density, the number of seeds on the plants falls, not merely per individual plant but per unit area, although the total weight of green shoots continues to rise. These findings are of importance in determining the most economic density at which to sow crop seeds.

Predator–prey oscillations. In the examples so far considered, mortality was directly dependent on density, in the sense that the higher the density, the greater the proportion of individuals dying. But in some cases the effect of population density on mortality is delayed, notably when a prey species and its predator (or an insect parasite) each limit the numbers of the other. If, for example, both species are scarce, the prey can increase rapidly through reproduction; but the predator can then also increase in numbers, and the process continues until the predator is so numerous that it begins to reduce the numbers of its prey; this in turn brings down the numbers of the predator, and the cycle starts again (see above *Biotic interactions*). In such a cycle, the relationship between prey numbers and prey mortality is not simple and direct. Instead, the prey mortality is low throughout the phase of increase and high throughout the phase of decrease. A particular density of prey is followed by an increase in numbers at one phase of the cycle and by a decrease at the other. This is because the increase of the predator lags behind the increase of the prey.

Mutual population limitations in predator–prey interactions

Early mathematical analyses suggested that, in a predator–prey interaction of this type, the numbers of both species should oscillate regularly and that the oscillations might increase in amplitude with time. Efforts to test this idea in the laboratory ran into difficulties in achieving ecological balance: the predator tended to increase, exterminate its prey, and then die out. Regular oscillations were finally produced in a closed laboratory population (Figure 13), but only when the situation was complicated by the addition of launching posts to assist the prey to reach undiscovered food sources within the culture and of partial barriers to reduce the movements of the predator between these sources.

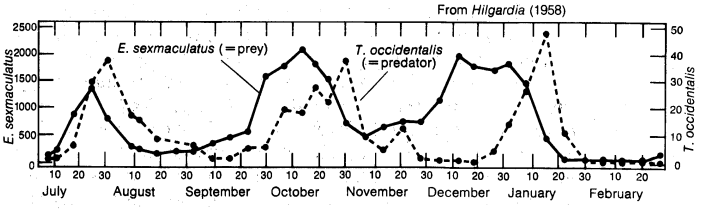

Figure 13: Laboratory study of oscillations in population density of a predator and its prey. The predatory mite (*Typhlodromus occidentalis*) preys upon the orange-feeding, six-spotted mite (*Eotetranychus sexmaculatus*).

Few natural populations of predators and prey oscillate regularly in numbers. In some cases in which a predator has been successfully introduced to control a pest, the predator has at first increased greatly; as a result the prey has decreased greatly, and after it the predator, following which both species have remained extremely scarce. This happened when the Australian ladybird beetle was introduced and successfully controlled the cottony-cushion scale insect in the citrus groves of California. The same result followed when the cactus moth (*Cactoblastis cactorum*) was introduced and successfully controlled the prickly pear (*Opuntia*) in Australia. As of 1971 there were more than 60 cases in which an insect pest had been significantly reduced through the introduction of a

Effects of predators on prey populations

predator or insect parasite and a number of others in which a harmful plant had been similarly controlled by a phytophagous (plant-feeding) insect. These large-scale field experiments show that a single predator is capable of holding the numbers of its prey to a level far below that which prevailed before its arrival. It is generally supposed that the prey continues to survive and to multiply in little pockets, but before it has multiplied far, the pockets are discovered and eliminated by the predator, by which time, however, further pockets have appeared elsewhere. This capacity for movement of both prey and predator can only with difficulty be reproduced in the laboratory.

A phytophagous mite that damaged strawberry plants was maintained by a predator at a level low enough to cause minimal harm. The reverse can occur, however, in populations that lose their predators. An example is the mule deer (*Odocoileus hemionus*) on the Kaibab Plateau in Arizona, following the removal of carnivorous mammals and human hunters. A population of about 4,000 deer in 1906 increased to about 100,000 in 1924 but then fell dramatically to about 20,000 in 1931 and to less than 10,000 in 1939, probably because overgrazing prevented adequate regeneration of the food plants (a delayed density-dependent interaction). Similar effects occurred in other parts of the United States following the removal of the natural enemies of the deer. In parts of Alaska where wolves (*Canis*) are present, mule deer have a light winter mortality from starvation and the range remains in fair condition; but, in parts where wolves are absent, the deer have a heavy winter mortality from starvation and there is marked deterioration in the condition of the range. Thus, the interaction between the wolves and the deer significantly modifies the interaction between the deer and their plant food.

A similar situation is found on Isle Royale in Lake Superior, to which a few moose (*Alces americana*) crossed early in the 20th century. They increased to about 3,000 by 1930, when their food supplies were badly damaged, decreased through starvation to 200 in 1935, rose again to 800 in 1948, and decreased to 500 in 1950. Shortly before 1950, 20 gray wolves (*Canis lupus*) arrived; after that, up to the last published count in 1961, moose numbers stabilized near 600. The wolves tended to take calves or debilitated animals.

Regular, large, and continuing cycles occur in the numbers of some wild mammals. If a cycle is regular, one may be reasonably certain that its cause is simple. The best attested example is that of the lynx (*Felis lynx*), which the records of the Hudson's Bay Company, covering more than a century, show to have a remarkably uniform periodicity of 9 to 10 years. The years of peak numbers are similar in its prey, the varying hare (*Lepus americanus*), and clearly its numbers are determined by those of the hare. This is probably not a simple predator–prey interaction, for there is no evidence that the numbers of the hare are brought down primarily through predation by the lynx. The regularity in the successive declines of the hare suggests a simple interaction with some other factor, and the continuation of each decline for several successive years is characteristic of a delayed density-dependent factor; interaction with plant foods is perhaps involved, but this has not been investigated.

Lemming cycle

The best-known regular fluctuations in numbers are the 4-year cycles of lemmings. The only population so far studied for a long period is that of the brown lemming (*Lemmus trimucronatus*) at Barrow, Alaska. Lemmings are vegetarian, and at the peak in numbers, about every fourth year, there is heavy overgrazing followed by starvation. Grazing transfers most of the nutrient salts from the vegetation to the lemmings, but the nutrients eventually return to the soil and thus, after delay, become available again to the plants, which regenerate only slowly in the cold soil. Once the plants have regenerated, the lemmings increase again, and the cycle is repeated. Removal of the plant cover by the lemmings also exposes them to predatory birds and mammals, but the latter are not the primary cause of their decline.

Several alternative theories of the lemming cycle have been proposed. One is that lemmings regulate their own numbers by emigration. Emigration is particularly characteristic of the Norway lemming (*L. lemmus*), which moves out of areas where food has become sparse to others where food is present. But when all suitable ground has been colonized and overgrazed, emigration is of no further benefit; the lemmings then descend in large numbers from the tundra and may even cross rivers or fjords. Another theory is that physiological stress caused by overcrowding (not starvation) induces metabolic deficiencies in the lemmings, especially in the endocrine system, that reduce fecundity or kill them. A third theory advanced to explain the continuation of the declines after numbers have fallen is that genetic changes occur in the population at different stages of the cycle.

The mammals and birds that prey on lemmings, like the predators of the varying hare, fluctuate in numbers with their prey. The goshawk (*Accipiter gentilis*) and the American red fox (*Vulpes fulva*) are of special interest in this connection because in some areas they prey on lemmings and have a 4-year cycle and in other areas they prey on varying hares and have a 10-year cycle. The numbers of grouse and ptarmigan living in the same areas also fluctuate in parallel, for unknown reasons, but presumably because their numbers are linked with those of the rodents through common foods or common predators.

The examples discussed so far concern simple, or apparently simple, interactions; but most animals, especially those living in natural habitats outside the Arctic, eat diverse foods and have diverse enemies. Because a diversity of factors is involved, their fluctuations are likely to be irregular. The numbers of a species may be regulated in different ways in different parts of its range. For example, much of the mortality of young barnacles (*Balanus*) on the rocks in Scotland is the result of intraspecific crowding, but in San Juan Island in the state of Washington, it is the result of predation by snails (*Thais*); these very different factors govern both the distribution and abundance of the barnacles in the areas concerned.

Movements. Movements often have an important effect on the size of a population, especially in mitigating temporary food shortage or overcrowding, and are of four main types: migration, emigration, dispersion, and dispersal.

Migration. As commonly understood, migration is a regular, seasonal, long-distance, large-scale movement of populations in set directions between two areas, one of which (rarely both) is used for breeding. The term is also used for short movements, in any compass direction, to a special habitat for breeding, such as are found in many types of land, freshwater, and marine animals.

Migratory species

Many birds breed at high latitudes in summer and move for the winter to low latitudes or to coasts or to the sea. Many others have extensive movements between a breeding and a nonbreeding area within the tropics. A few, notably the common redpoll (*Carduelis flammea*) in northern Europe, the Old World quail (*Coturnix coturnix*) around the Mediterranean, and the quelea (*Quelea quelea*) in tropical Africa, almost certainly breed in two areas in succession, but this is not yet fully proved. In mammals, also, certain bats and the caribou (*Rangifer tarandus*) migrate to breed at high latitudes in summer; various whales feed and form fat stores at high latitudes in summer and breed at low latitudes in winter. Various antelope migrate in the grasslands of tropical Africa. Some fishes and at least one squid migrate regularly like birds. In various eels and salmon, each individual moves once in its life from a breeding to a feeding area, returning after several years to the breeding area and then dying. Various northern butterflies breed in the north in summer; their offspring migrate south and breed; and their offspring in turn fly north the following spring, so that, while each individual migrates only once, there is a twice-yearly migration of the population. The monarch butterfly (*Danaus plexippus*), on the other hand, migrates from a northern breeding area to hibernate in the south, the same individuals returning to the northern breeding area the following summer. Other butterflies migrate within the tropics.

The migratory habit enables a species to breed in one area and to survive the winter in another, or to grow large in one area and to breed in another, or even to breed in

two areas at different seasons. Nonmigratory animals may have to survive cold or drought in a resting stage as eggs or pupae, or, if adult, in hibernation or aestivation.

Certain northern birds are partial migrants, some of the population leaving and the rest staying for the winter in the breeding area. In such species, the advantages of leaving or staying must be almost equal; this view is supported by the fact that the proportion migrating increases toward the north of the range, where the winters are more severe. Like other adaptations, migratory movements are anticipatory. If food will become scarce, it is advantageous for an animal to move away before this occurs, and similarly it is advantageous to leave a wintering area so as to arrive on time in the breeding area. Many migrant species have evolved special abilities that enable them to sense time, accumulate fat reserves, and navigate over long distances—strong circumstantial evidence that migration is advantageous to the species concerned (see also BEHAVIOUR, ANIMAL: *Basic behavioral activities of individuals: Migratory behaviour*).

Emigration. Emigration differs from migration in that it occurs at irregular intervals, in a variety of directions, without a set return movement, and in direct response to food shortage or overcrowding. The European red squirrel (*Sciurus vulgaris*) and the Siberian nutcracker emigrate from the taiga in years when they are numerous and coniferous seed crops fail; the common waxwings (*Bombycilla garrulus*) and some other northern birds emigrate when particular berry crops fail; the lemmings, as mentioned earlier, move from the tundra when they have overeaten their vegetable foods; the hawks and owls that prey on lemmings also move when the latter decline; water birds breeding beside shallow lakes in the steppes leave in the occasional summers when the lakes dry out; locusts move when overcrowded, producing a special migratory form; and various aphids, after multiplying significantly on a food plant, produce winged forms that drift away. Some emigrations are combined with migration, in that they may occur at set seasons and in set directions with later return movements, but the numbers participating are much greater in occasional years than in others.

Emigration and natural selection

Emigration is advantageous for any individual that has a greater chance of survival if it moves than if it remains where it is, and hence the habit is explicable in terms of natural selection. It may be specially advantageous in cases of local crowding or local food shortage, when small and inconspicuous movements suffice to take the emigrants to suitable new areas. Even in occasional catastrophic years, when many emigrants die, the chance of survival may be higher for an individual if it moves than if it stays; recoveries of marked birds have shown that some of the emigrants, in fact, survive and return later to their breeding grounds. There is no positive evidence for the alternative idea that the emigrants constitute a doomed surplus that moves out to die in order to save a remnant of the species from starvation; no means are known by which a species can evolve behaviour that benefits unrelated members of the species but is harmful to the participating individuals.

Dispersion. The small and usually inconspicuous movements by which various animals space themselves out, especially for breeding, lead to what is called dispersion. Birds that are solitary breeders tend to be spaced out fairly evenly but with a tendency to be denser where food and other conditions are more favourable; in colonial species, both the spacing and the size of the breeding colonies vary somewhat with the availability of resources. Since adult birds usually breed from year to year in the same place, dispersion is brought about mainly by the younger individuals that are settling for the first time; they first of all seek the preferred habitat of their species, but, if it is densely occupied, they may choose to settle in suboptimal habitats. The latter may give them a better chance of raising young than would otherwise suitable but crowded areas, and therefore suboptimal habitats are occupied chiefly in years of high numbers. Similarly, the young adults of colonial species tend to settle in established breeding colonies but may move elsewhere if these are crowded in relation to resources. In winter, birds join feeding flocks if this helps them to obtain food and leave them if it does not. Similar principles apply to many other kinds of animals.

Dispersal. Dispersal is often used as a general term for animal movements but also in a special sense for the movements of young animals or plant seeds from their birthplace to where they settle down. It has little effect on numbers, although it is an important means by which an increasing species gradually extends its range. In various sedentary or sessile marine animals, however, and in many land plants, specialized larvae or seeds have adaptations for active or passive transport that enable them to settle at long distances from their birthplace (see above *The distribution of organisms: The nature of dispersal*).

(D.L.L./Ed.)

Biological communities, biomes, and ecosystems

A biological, or natural, community consists of two or more interacting and interdependent populations, such as the plant and animal inhabitants of a lake or forest. The major biological communities of the world, such as the Arctic tundra or the Amazon rain forest, are called biomes. Similar biomes considered collectively in terms of predominant vegetation constitute biome types—*e.g.*, tropical rain forest, which comprises biomes in Southeast Asia, Africa, South and Central America, and northeast Australia. A biological community, biome, or biome type considered together with the nonliving components of its environment (*i.e.*, soil and water conditions and climate) is called an ecosystem.

COMMUNITY STRUCTURE

Growth forms and life-forms. The different types of plants represented in a community, in terms of height, form, manner of growth, and kind of foliage, are termed growth forms. Every community includes a number of different growth forms, each represented by a number of plant species. The one or two growth forms that are most important are said to dominate the community. The major growth forms of the community determine its overall appearance or structure. The structure of a plant community on land, as determined by its growth forms, is called its physiognomy.

The plant types, as distinguished in another conceptual system, are termed life-forms. Instead of the many characteristics of plants by which growth forms are distinguished, life-forms are defined by the relationship of the embryonic growing tissues from which new stems and branches will come to the ground surface. The life-forms are (1) phanerophytes—trees and shrubs with growing tissues in buds well above the ground, (2) chamaephytes—low shrubs with buds within 25 centimetres of the ground, (3) hemicryptophytes—perennial herbs with growing tissues at ground level, (4) geophytes—perennial herbs with underground bulbs, buried horizontal stems, etc., (5) therophytes—annual herbs with the growing tissues surviving unfavourable seasons only in seeds, and (6) hydrophytes—aquatic plants. The percentages of the life-forms in a list of plant species for a community or landscape constitute a life-form spectrum. Because the different life-forms represent the ways in which plants are adapted to survive unfavourable seasons, the life-form spectrum expresses aspects of the community's adaptation to its environment. Thus, the phanerophytes predominate in the life-form spectrum of a tropical forest, the hemicryptophytes in temperate forests and grasslands, the therophytes in some deserts, and the hemicryptophytes and chamaephytes in Arctic tundra. Life-form and growth form concepts are most commonly applied to land plants, but similar categories can be defined for animals and aquatic communities.

Stratification of communities

Vertical and horizontal patterns. Growth forms and life-forms relate to stratification—a general characteristic of communities. Plant communities on land show vertical differentiation when the different life-forms and growth forms bear their leaves at different distances above the ground. This stratification is strongly related to light conditions because a given stratum is adapted to the light intensity at its own level and it reduces the light inten-

sity for lower strata. Light intensity in a forest decreases downward; the light reaching leaves of the different strata decreases from full sunlight for the uppermost trees, to approximately 10–50 percent of full sunlight for smaller trees, 5–10 percent for shrubs, and 1–5 percent for herbs. The animal taxocenes of a community also show stratification. In a forest three groups of bird species may be distinguished: those feeding in the tree canopy, those near ground level, and those in foliage of shrubs and low trees between these. Strata involving roots of different plant species, and different animal species, may be recognized from the soil surface downward. Stratification in relation to light and depth occurs also in aquatic communities. Marked vertical differentiation is observed in shore communities and involves water depth and light intensity below tide levels, exposure to air and other factors within the tidal belt.

Many communities also show patterns of horizontal differentiation. On the forest floor scattered patches of different herb species may be observed. In some cases these patches are caused by environmental differences within the forest—differences in light intensity or small undulations in the soil surface, for example, that affect distributions of plant species. In some cases the patches result from growth of plant colonies that spread by underground stems from a common parent; in others, they may result from interactions between species, as in a parasitic plant that forms patches where the roots of its host species occur. Individuals of plant species are not usually scattered at random through the horizontal space of the community; they show clumped or clustered distributions. Many animal populations, both on land and in aquatic communities, also have clumped distributions. A less common condition is spacing that is more regular than a random distribution. Shrubs in some deserts have regular distributions, and singing birds and some other animals appear to occupy definite territories with roughly equal areas, so that individuals or breeding pairs are evenly spaced.

Internal patterning

In the community some species tend to occur together in the same patches, others to occur separately. The tendency to occur together has different causes for different associations of species. Two species may be responding in similar ways to place-to-place differences in light intensity or other environmental factors within the forest; but another pair of species may occur together because one is dependent on the other. The tendency of individuals to occur separately may result because each species responds differently to environmental factors, or because effects produced by one species tend to inhibit or exclude others. Species thus relate differently to environments and to one another within the community, and complex patterns of patchiness and horizontal differentiation of the community can result from these different responses.

Time relations. Communities also show differentiation in time. In plankton different species of algae appear and disappear to give way to other species during the annual cycle of seasons. In a broad-leaved deciduous forest one group of herbs blooms early in spring before leaves are on the trees; other groups bloom in later spring, early or later summer, or fall. Different insect species appear and disappear as the seasons progress, and bird species respond differently to seasons, some migrating and others remaining throughout the year. Organisms also show rhythms of behaviour related to daily time. Some animals are active in the daytime, others at dusk, still others at night. Flowers of different plant species are open at times of day that coincide with the activity of the animals that pollinate them. Many plankton animals migrate upward toward the water surface at night and downward away from intense light in the daytime, but different species have different patterns and extents of vertical migration. The complex rhythms of the tides govern the activities of many shore-dwelling organisms. Plant and animal species of a community thus differ in their relationships to time (see BEHAVIOUR, ANIMAL: *Nature and patterns of animal behaviour: Periodic biological phenomena*).

Interactions. Species within the community also differ in sources of food and ways of interacting. Three major ways of obtaining food may be recognized in a community: photosynthesis, ingestion (eating), and absorption. These three means of nutrition represent major directions of evolution, corresponding, with a few exceptions, to major groups of organisms (plants, animals, and fungi). As treated earlier, animals exhibit a variety of feeding adaptations—*e.g.*, herbivory, carnivorous predation, carnivorous parasitism, and carnivorous scavenging. Many aquatic animals filter a mixture of dead particles and living microorganisms from the water and use some of this organic material as food.

Thus, most species are food specialists, differing from other species in the same community in the source of their food. Species differ in other ways of relating to one another. They may, for example, variously affect one another's environment. An herb growing beneath a tree in a forest must be adapted to the low light intensity of the tree's shade and to the chemical effects produced by the tree in the soil where the herb grows. Some plant species release toxic materials to the soil, preventing some other species from growing nearby. Some species rely on another species for shelter, support, transportation, or concealment. Many plants live as epiphytes (plants not rooted in soil but living among the branches of trees or on other supports) supported by another plant; the lichens on the bark of a tree and the orchids borne on high branches of tropical trees are epiphytes. Many marine animals live on the surface of another animal. A close, sustained living together of two species or kinds of organisms is referred to as symbiosis. Many species, rather than benefiting one another, are competitors. If two species live together and use the same resource, and use of the resource by one limits the growth or population level of the other, the species are in competition. Species may compete for food sources, light, soil nutrients, space, and other resources needed for the support of their populations (see also above *Biotic interactions: Amensalism and antagonism: Competition*).

Symbiosis

Niches and species diversity. Species differ in their positions in a community—in their relation to vertical and horizontal space, time, resource use, and manner of interacting with other species. The position and function of a species in the community in relation to other species is termed its niche. Competition relates to the niche concept. In an experimental culture if two species are in direct competition for the same resources, the population of one species will decline to extinction in the culture. From similar observations on competition and on species positions in communities, the principle of competitive exclusion can be stated: two species cannot occupy the same niche, in direct competition with one another in the same stable community. The species of the community consequently evolve toward niche difference—*i.e.*, different positions in the community by which competition between them will be reduced. A community is, thus, a system of interacting, niche-differentiated species.

Because of niche diversification, many species are able to live together in a community without direct competition. The community's richness in species is referred to as its species diversity, a quality most directly measured in terms of the number of different species found in a sample of standard size taken from a community. Another characteristic of communities is to be recognized, however, in the manner in which relative importances or abundances of species relate to one another. In some communities one species is strongly dominant, and the abundances decrease rapidly in the sequence from the first to the second and third species and beyond. In other communities no species is conspicuously more important than others, and the decline in abundance in the sequence of species is much less pronounced.

Species diversity of communities is affected by evolutionary time (the time during which a community changes and evolves), environmental stability, and favourableness of the habitat. During evolutionary time new species enter a community, each new species adapting itself to a niche different from those of other species in the community. Even though some species become extinct, species tend to accumulate in a community, and diversity tends to increase through evolutionary time. In more rigorous and unfavourable environments, however, fewer species are

able to adapt to the environment itself. Such environments imply that selective forces acting on the species are directed primarily toward adaptation to environmental hazard, rather than toward niche differentiation in relation to other species. Many communities in rigorous environments have low species diversity and high concentration of dominance. In more stable and favourable environments (such as that of the tropical rain forest) selection toward refined niche differences, acting through a long evolutionary time, has made high species diversities possible. Many of the aspects of community structure—*e.g.*, differences among species in vertical and horizontal position, time, food relations, and other interactions—are in part consequences of evolution of niche difference. Complexity of community structure tends to increase through evolutionary time as species of different positions in the community accumulate. Community structure and appearance reflect adaptation to the environment on two levels: (1) the limitations imposed by the environment determine what growth forms can survive in the community, and (2) the niche differentiation among plant species is in part expressed by growth-form differences in stature, form, leaf type, and seasonal relations.

Community structure and niche difference

COMMUNITY FUNCTION

Productivity of organic matter. The existence of the community and of all organisms in it requires energy. Photosynthesis is the source of biological energy for communities, and the creation, through the process of photosynthesis, of organic compounds from inorganic materials by the green plants of a community is termed primary productivity.

Primary productivity. Primary productivity may be measured either in terms of the amount of energy incorporated in organic compounds by photosynthesis or in terms of the dry mass of the organic material produced. In approximate terms 1 dry gram of plant tissue represents 0.4 gram of organic carbon and 4.25 kilocalories of sunlight energy incorporated in organic compounds. The community's gross primary productivity is the total energy captured by green plants (or the mass equivalent of this energy) per unit area and time. The community's net primary productivity is the organic mass (or its energy equivalent) produced by photosynthesis that remains after some of that organic matter has been used in respiration (chemical reactions supporting life processes) by the photosynthesizing plants. In forests 60 to 75 percent of gross productivity may be respired by the plants; the remaining 40 to 25 percent is net productivity. In aquatic communities less than half of gross productivity may be respired by the plants.

Amounts of photosynthesis vary widely in different communities; communities may be grouped in terms of four ranges of net primary productivity as expressed in units of net dry weight in grams per square metre of earth surface area per year ($g/m^2/yr$). The ranges correspond to different environmental and vegetational conditions as shown in Table 3. For a discussion of photosynthetic efficiency in terms of overall energy flow in the biosphere, see above *Energy flow and material cycling.*

The amount of gross primary productivity represents the total energy available to carry on all the biological activities of the community if no organic matter is brought into the community from the outside. The amount of net primary productivity represents the total energy available for use by the community's heterotrophs (nonphotosynthetic organisms that do not manufacture their own food like plants but that must obtain it elsewhere), the animals, bacteria, and fungi. The rate of utilization of net primary production by heterotrophs is important in determining the amount of the community's plant biomass. Biomass (or standing crop) is the amount of organic matter present in a community at a given time potentially available for harvest and use by heterotrophs. In a land community the biomass primarily comprises living and dead tissues of plants. A grassland, for example, might have a stable net primary productivity of 600 grams per square metre per year, and one-third of this plant tissue might be eaten by animals (or decomposed by bacteria or fungi) the first year, one-third of the remainder the second year, and so on. A forest, on the other hand, might produce 1,300 grams per square metre per year and then lose by various means only one-fortieth of it each year. In each case the portion of past production remaining in the community is its biomass. Eventually the grassland biomass will remain steady at about 1,800 grams per square metre and the forest biomass will reach about 52,000 grams per square metre. The forest and grassland differ widely not only in amounts of biomass but in biomass accumulation ratios, the ratios of plant biomass to net annual primary productivity (3 and 40 in this example). Biomass accumulation time and standing biomass are compared for several communities in Table 4.

Biomass

The plant food harvested by herbivores is used for their growth and activity. Herbivores in turn are harvested by a series of carnivores. Such a sequence of organisms along which food is passed—for example from an oak tree (the producer) to a caterpillar (the herbivore) to a warbler (the first carnivore) and finally to a hawk (second carnivore) is called a food chain.

Secondary productivity. When organisms of the community are grouped by position along food chains, the groupings represent trophic levels. Productivities of the trophic levels above the primary level are referred to as secondary productivities. Because many animal species feed upon a number of other species, food chains are linked together into community-wide food webs. A species' place in a food web is an important aspect of its niche. At each trophic level some of the organisms' energy is used in their own life processes, and some organisms die and decompose without being eaten by other animals. The productivity of a given trophic level, therefore, can never be more than a fraction of that of a preceding trophic level. The ratio of energy on a given trophic level to that of the preceding level is known as the efficiency of the given level. For the first and second consumer levels ef-

Food webs

Table 3: Communities Arranged by Net Primary Productivity

net primary productivity*	description and productivity value	some examples of communities with typical productivities in each range
3,000 or more	very high productivity in particularly favourable conditions of water and nutrient availability and temperature	some young tropical forests, salt marshes, coral reefs, rice paddies, sugarcane fields
1,000–3,000	high productivities in generally favourable environments	most forests and some highly productive grassland, some estuaries and nutrient-rich lakes
200–1,000	intermediate productivities in environments in which water or nutrients or temperature are in some respect limiting	many temperate grasslands, semiarid woodlands and shrublands, many lakes and coastal waters of oceans
200 or less	low productivities in environments that are severely limiting in some respect	dry and cold deserts, some nutrient-poor lakes, and many open waters of oceans

*Net dry weight in grams per square metre of earth surface area per year.

Table 4: Comparison of Communities by Biomass

community	accumulation time	standing biomass (kg/m^2)
Forest	10–50	10–70
Shrubland	3–10	2–10
Grassland	2–5	0.2–5
Field of annual herbs	1.0	0.1–1
Plankton	0.01–0.05	0.001–0.04

ficiencies tend to be about 10 percent. Efficiency of producers, comparing their net primary productivity with their energy source in sunlight in the visible range, is much less—*e.g.*, about 1 percent for many forests and even as low as 0.1 percent for some of the open-ocean plankton. Because of the loss of energy on each level, productivity must decrease up the sequence of trophic levels, forming what is known as a pyramid of productivity. In many, though not all, cases, biomasses and numbers of organisms will also decrease up the sequence of trophic levels and for illustrative purposes these can also be visualized as pyramids.

Decomposition of organic matter. Only part of net primary productivity is harvested by animals. The remainder is decomposed by bacteria and fungi, or is transported out of the community, or accumulates as net ecosystem production. In many communities the fraction of net primary production harvested by animals from tissues of living plants is small compared with the fraction utilized after death of the tissues by scavengers, bacteria, and fungi. Less than 10 percent of leaf tissue and less than 1 percent of wood tissue of living trees in a forest may be harvested by animals. The remainder falls to the ground to form the litter covering the soil surface and is utilized by the soil community. The soil community includes animal scavengers that eat dead plant tissue, scavengers on dead animal tissue, bacteria and fungi of decomposition, and animals feeding on these organisms. Although animals contribute to the breakdown of the litter, the bacteria and fungi have the most essential role in reducing dead organic matter to inorganic end products. The major modes of nutrition previously referred to thus appear as the three major trophic parts of the community: producers (photosynthesizing plants), consumers (ingesting animals), and reducers or decomposers (absorbing bacteria and fungi).

The biomass of the reducers may be small compared with that of the consumers and very small compared with that of the producers. The activities of this small mass of reducers are, however, of great importance in community function. The reducers break down almost all remains of dead organisms in the community; food chains normally end in reducers. Decomposition by the reducers in most cases prevents continuing accumulation of dead remains of organisms. When such accumulation does occur, as in the peat formed in bogs, community productivity may be limited by the fact that nutrients are locked up in dead tissues. The reducers thus make possible the steady-state condition of a stable community's biomass. In this steady state the pool of organic matter in the community is relatively constant, while matter is being added to it as net primary production and subtracted from it by animal harvest and decomposition, at equal rates. Decomposition of the dead remains of organisms makes available to the soil or water the nutrients that were contained in those tissues.

Decomposition

Nutrient circulation. The reducers thus make possible the circulation of nutrients in the community. The producers take up inorganic nutrients (including nitrogen, phosphorus, sulfur, calcium, potassium, magnesium, and other elements) from the soil or water. The producers use these for the synthesis of certain organic compounds and to maintain the levels necessary for the composition of protoplasm and the functioning of cells. Animals and reducers obtain these nutrient elements in their food. The nutrients are passed along food chains until released back into the environment by decomposition or excretion. In the nutrient circulation of a forest a nutrient atom or ion may be taken up from the soil into a tree root, transported upward through the tree's conducting tissues to a leaf, taken in by a caterpillar that eats the leaf, consumed then by a bird that eats the caterpillar, until, with the death and decomposition of the bird, it is released back into the soil for renewed uptake by a plant root. Many nutrients are returned from forest trees to the soil by shorter routes—by the fall of dead plant tissues to the litter and decomposition, or by washing down from plant surfaces to the soil in rainwater.

The community's biomass has a marked effect on nutrient circulation. For some elements in some communities, the greater part of the ecosystem's stock of that element is held in the tissues of the plants and a smaller part is free in the soil or water. The amount of phosphate in solution in the water, for example, may be a small fraction of the amount in plankton cells and particles. Tropical forests hold the stocks of some nutrients in relatively "tight" circulation: much of the nutrient stock is held in plant tissues, and nutrients released by leaching or litter decay by fungi are quickly reabsorbed into plants. When a forest is cut or burned, abrupt and extensive loss of nutrients from the ecosystem may occur by erosion or by downward movement of nutrients in soil water. The plankton of the open oceans is low in productivity because the settling of plankton cells and dead particles carries nutrients downward, leaving only low concentrations of critical nutrients in the lighted surface water where photosynthesis occurs. It is thus true both that nutrient resources of the environment affect community function and that community function affects observed nutrient levels in the community and its environment.

Movement of nutrients by water

Water movement transports nutrients between the different communities—plankton, shore, and bottom—of a water body and relates these communities to one another as parts of the water ecosystem. Land ecosystems and lakes and streams receive some nutrients from the outside—by rain, dust, groundwater movement, immigration of organisms, etc.—and lose some nutrients to the outside—by settling, water movement, emigration, erosion, etc. There is, thus, some movement of nutrients between the communities of a given landscape. On a broader scale nutrients are taken up from the ocean surface into the air in the spray from waves, transported over the continents in air currents, and carried downward into land communities in rain. Nutrients from land communities are carried into streams and transported in stream water into the oceans. The ecosystems of the world are linked together by the transfer of nutrients between them into the biosphere.

COMMUNITY SUCCESSION

When gross primary productivity is greater than total community respiration, and net primary productivity is greater than the rate of harvest and decomposition, organic matter accumulates. Coal and petroleum represent surpluses of productivity over respiration accumulated in past geologic time. Such surpluses are bases also of shorter-term growth of communities, as is illustrated in the contrast of a mature, stable forest with a young growing forest shown in Table 5. The accumulating surplus in the young forest may be termed a net ecosystem production. If not exported from the community, net ecosystem production implies growth in the community's biomass. Thus the young forest, with biomass of 10 kilograms per square metre, may in time mature into a forest of 50 kilograms per square metre. The process by which communities grow toward a stable, mature condition is called succession.

Table 5: Contrasts in Productivity and Respiration Between a Mature and Young Forest*

	gross productivity	plant respiration	decomposer respiration	animal respiration	net ecosystem respiration
Young forest	2,650	1,450	580	80	540
Mature forest	3,350	1,950	1,250	150	0

*Net dry weight in grams per square metre of earth surface per year.

Developmental communities. If the forest is destroyed by fire, a new forest is established by developmental communities, which replace one another in sequence (*e.g.*, a field of annual weeds, a meadow of perennial grasses, a community of shrubs, a young forest, a mature forest like the one destroyed). If the soil has not been lost, such a succession replacing a former community is a secondary succession. A succession that develops a new soil in a bare environment is a primary succession. If a forest on a mountain slope is destroyed by an avalanche, a succession on the exposed, bare rock surface may lead back to forest by way of lichens, mosses, grasses, shrubs, and trees as dominants of successive stages. Each stage paves the way for the next stage. Thus the grasses are able to begin growth in the sparse soil formed and collected by the mosses. Growth of the grasses suppresses the mosses and forms a meadow in which a deeper soil develops. This soil permits shrubs to enter the meadow, to grow taller than the grass, and to kill the grass by shading, etc. The soil and shelter of the shrub stage permits trees to enter, grow above, and replace the shrubs. A number of developmental trends—progressive changes in community characteristics—are observed in most successions. During a succession there is usually not only increasing accumulation of biomass but also progressive increase in community height, differentiation into strata of the plant community, and consequent structural complexity, productivity, effect of the community on environment, soil development, stocks of circulating nutrients, species diversity, longevity of dominant organisms, and relative stability of the community. There are exceptions. Productivity and species diversity in particular often decrease during the late stages of a succession and are lower in the stable end community.

Stable communities. The mature, relatively stable community in which a succession finally ends is termed the climax. The climax is characterized not by maximum productivity but by maximum biomass and biomass accumulation ratio and by low or zero net ecosystem production. More broadly, the climax is characterized by steady-state function—that is, a dynamic equilibrium, a condition of relative constancy in an open system. Energy, materials, or individuals may flow through the system, but if the input and output of these are equal, the system can remain stable in its characteristics. Thus in the community steady states may be recognized in these three categories: (1) population balances, (2) energy flow, and (3) materials turnover.

Climax

The individual species populations of the climax are stabilized (relatively, and despite some fluctuation). The rate of addition of individuals by birth (and in some cases immigration) is balanced by rate of loss of individuals by death (and emigration).

Energy intake in photosynthesis is balanced by energy loss in respiration, while the community's pool of energy in organic materials remains relatively constant. Intake of materials by photosynthesis and nutrient uptake is balanced by loss through respiration, decomposition, excretion, and leaching, while the community's biomass and nutrient stock remain relatively constant.

The community is thus (like an individual organism or a cell) an open system through which energy and materials flow. The intimate relation of the community to its environment in this flow provides justification for the concept of ecosystem. Like an individual organism, the community sustains itself by continuing the intake of available free energy in organic compounds. Like the organism, it uses this energy to maintain its function and complex structure. Like the organism, the community grows with increase of mass and structural complexity to a final, mature state. There may, however, be different reasons for growth and maturity. The manner of growth, functional organization, and point of reproductive maturity are determined in the organism by its inherited genetic instructions. There are no corresponding community-wide instructions determining succession and climax. These phenomena are resultants of the manners in which species populations interact and of overall balance of materials and energy flow. The character of the climax is determined by the resources and limitations of environment and by the characteristics of the species that interact and maintain themselves in that environment.

Open system concept

The stability of the climax is suggestive of the homeostasis (the constancy of function and internal conditions) in the organism, but the mechanisms are different. The community has no central regulatory system such as the nervous, circulatory, and endocrine systems provide in higher animals. Yet the community tends to stabilize itself and to return to normal after disturbances. The expression "balance of nature" refers to this condition.

COMMUNITIES IN SPACE

Landscape patterns. Many of the habitats of a landscape are related to one another along environmental gradients (adjacent regions of changing elevation, soil characteristics, surface moisture conditions, etc.). Some of these are interrupted by cliffs or other barriers, but the habitats may be conceived as forming a pattern of environmental gradients. At each habitat, or point in this pattern, a climax natural community may develop. Characteristic species and functions of the community are adapted to the habitat in which they occur. Along a continuous environmental gradient the characteristics of one community change, often smoothly, into those of other communities. The environmental gradient is thus paralleled by a gradient of communities developed in response to the environmental gradient. An environmental gradient comprising many environmental factors that change together along spatial gradients may be termed a complex gradient; its corresponding gradient of communities is a coenocline. The complex gradient and coenocline together form an ecosystem gradient, or ecocline (see Figure 14).

Ecocline

A pattern of climax communities corresponds to the environments of the landscape. Climax communities over much of the area may have been replaced by disturbance and successional communities; but the climax pattern represents the potential maximum development of natural communities in equilibrium with environment for that landscape. A landscape is a pattern of ecosystems related to one another by (1) intergradation as parts of ecoclines, (2) occurrence of populations of the same species in different communities, (3) movements of materials and organisms, and (4) developmental relations of communities to one another (if some are successional).

Climax interpretation. There are three major approaches to interpreting climax communities: (1) monoclimax theory, (2) polyclimax theory, and (3) climax pattern hypothesis.

Monoclimax theory emphasizes the convergence of successions in a given landscape from different beginnings toward similar climaxes. Thus, in a forested area successions on a rocky hillside and a valley bottom will both lead to forests, though these forests may consist of different tree species. Because of this relative convergence, one may consider that in principle all the successional communities of an area could converge on a single (broadly defined) climax community. This hypothetical single climax is termed the climatic climax or monoclimax. If one of the communities of the area is interpreted as the climatic climax, the other stable communities present are termed proclimaxes.

Polyclimax theory recognizes more than one possible climax community. As already observed, the communities of an area form a pattern in which a number of types of stable or climax communities may be distinguished. Many ecologists prefer to grant the occurrence of a number of climax communities in an area, hence they accept a polyclimax interpretation. One of these communities may be considered most typical, or most representative of the general climate of the area, and this community may be regarded as the climatic climax. Other stable communities may be termed topographic climaxes (differing from the climatic climax because of topographic position) or edaphic climaxes (differing because of soil characteristics).

The climax pattern hypothesis allows one to visualize the landscape as a pattern of intergrading communities corresponding to the pattern of environmental gradients. The type of community that forms that largest fraction of the climax pattern and is most widespread in the landscape (if

undisturbed) is then regarded as the prevailing climax or climatic climax.

Community gradients. The appropriateness of the climax-pattern-hypothesis interpretation results from the manner in which species populations and communities relate to environmental gradients. Community samples, including counts of plant populations, can be taken at intervals along an environmental gradient to form a transect (a line along which measurements are taken). The rise and fall of species populations along the gradient can then be observed. Results of interest emerge; especially significant are the symmetrical, bell-shaped form of the majority of such population curves and the scattered positions of the modes or peaks of the species distributions scattered along the gradient. The fact that the curves generally overlap broadly, rather than forming abrupt breaks where one species excludes another, is also apparent. The coenocline, or gradient of communities, may appear as a continuum when species populations are observed along a transect, or when growth forms are observed along a climatic gradient, as in Figure 14.

Sampling communities along transects

Such study supports two principles that are basic to the interpretation of communities. The first is the principle of species individuality, which states that each species is distributed on the basis of its own genetic, physiological, and life-cycle characteristics and ways of relating to environment and other species; consequently no two species will be distributed alike. The second is the principle of community continuity. It states that along continuous environmental gradients, natural communities in general intergrade continuously, rather than appearing as distinct species combinations that give way abruptly, along distinct boundaries, to other species combinations.

Although they are basic, some exceptions to these principles must be noted. Certain pairs of symbiotic species have parallel distributions. Populations of certain animal species exclude one another along a boundary, rather than overlapping broadly. There are some discontinuities between communities that are not produced by soil or topographic changes. The forest edge between forest and grassland is in some areas such a discontinuity, the abruptness of which may be increased by effects of fires that burn the grassland up to the forest edge but do not burn the forest. Steep community transitions, known as ecotones, often show an "edge effect." The transition zone is a distinctive community of high species diversity, combining species of both communities that are bounded by the edge with other species that occur primarily in the edge itself.

Ecotones

Habitat differentiation. Underlying the manner in which species are distributed along a gradient is an evolutionary phenomenon related to the principle of competitive exclusion referred to earlier. Species may escape direct competition either by exploring different niches or by occupying different habitats. Species that are partial competitors (with overlapping niches) evolve toward different locations of their population centres along environmental gradients. Many species that adapt to an environmental gradient and to interaction with one another do so by evolving toward a scattering of population centres along the gradient. Through evolutionary time additional species fit themselves into a gradient of communities (coenocline), with population centres between those of other species. As they do so they tend to narrow the distributions of the other species that are nearest to them along the gradient and that overlap with them in niche. Coenoclines may thus evolve from the condition of relatively few species with broad distributions to that of a larger number of species with narrower distributions.

Gradient analysis. An arrangement of community samples (or species) in relation to one or more environmental gradients or axes, by either direct or indirect means, is an ordination and an essential means of accomplishing gradi-

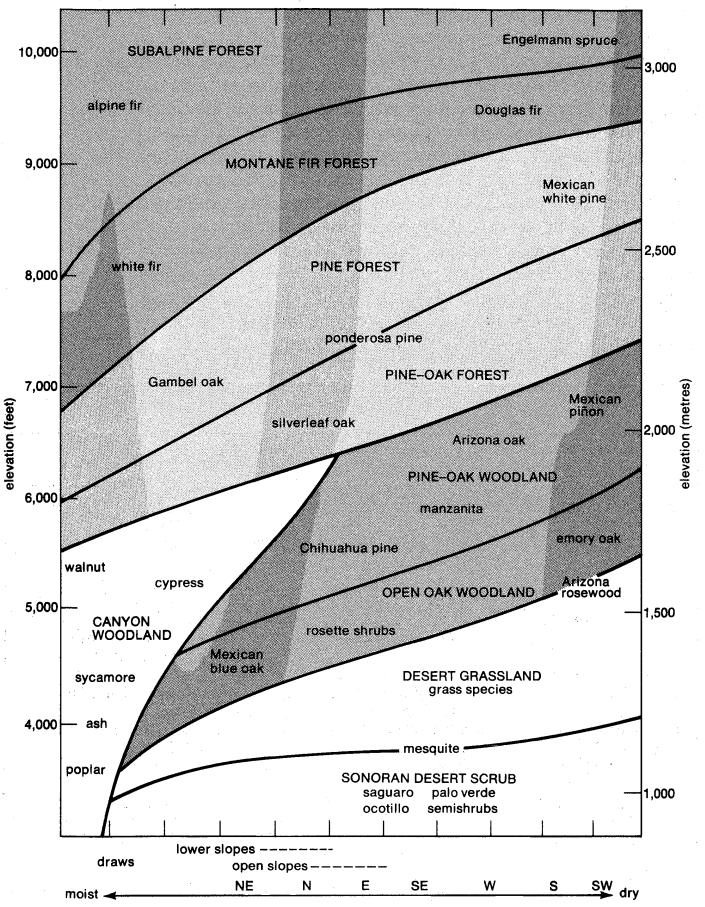

Figure 15: *A mountain vegetation pattern in relation to environment.*
Distributions of major kinds of plant communities are shown in relation to elevation and topographic moisture gradients in the Santa Catalina Mountains of Arizona, U.S. Locations of boundaries are approximate.

ent analysis. Gradient analysis is the study of communities in terms of how gradients of environment, species populations, and community characteristics relate to one another. Through gradient analysis the communities of a landscape may be analyzed and related as a pattern of intergrading communities. In one approach community samples are arranged on a diagram with major environmental gradients as axes as in Figure 15. The samples are classified into types of communities, and boundaries between these may be drawn onto the diagram. Types of communities are then shown in their relations to one another and to the environments of the landscape pattern. The types in Figure 15 have oblique boundaries because of the effects of topography, as well as elevation, on temperature and moisture conditions.

Alternatively, from a set of community samples pairs of end-point samples can be chosen to represent extremes of environmental gradients. Other samples can then be arranged relative to these end-point samples to form what is known as an indirect ordination. This ordination can also be displayed as a diagram that will show the changes in community composition in response to the environment.

Chief aims

Whether direct or indirect, gradient analysis has as its objectives the observation and interpretation of relationships among environments, species, and communities, and the representation of the range of community variation of a landscape as a comprehensible, unified pattern.

COMMUNITY CLASSIFICATION

Bases for classification. In most ecological studies communities are classified, whether or not they are also ordinated. Because of the individuality of species and the continuous intergradation of communities, communities do not form clearly defined natural units of classification. Classification units do not simply emerge from observation; they are created by an ecologist's choice of criteria of classification (*i.e.*, characteristics of communities by which they are to be grouped into classes or units). Application of different criteria of classification to communities of the same landscape will result in the use of different units of classification for those communities. There is consequently no universally accepted "correct" approach to classifying communities, comparable to the system of species and other categories into which organisms are classified.

Table 6: Some Approaches to Community Classification

criteria upon which judgments are based	terms used for the units of classification
Physiognomy	biome or formation
Dominant species of major stratum	dominance type
Dominant species of the different strata	sociation
Species composition using full range of plant species present	association, etc.
Composition of the undergrowth independent of the dominant species of canopy	forest site type
Quantitative comparisons of composition of community samples	nodum
Characteristics of habitats	habitat type
Kinds of communities recognized as belts forming a sequence along a major environmental gradient	life zone, littoral zone
Characteristics of landscapes as patterns rather than particular communities	landscape type

Means of classification

Some of the principal approaches to community classification are given in Table 6. Although these and other approaches are in use, the classifications most widely in use are those that have been based on species composition and on physiognomy, that is to say, the associations and biomes, or formations.

Associations. The system of classification most used for intensive study of particular landscapes has as its basic unit the association. The system considers all plant species

From P. Dansereau, *Biogeography: An Ecological Perspective*, Lieth, *Berichte der deutschen botanischen Gesellschaft*, L.R. Holdridge, *Science*, vol. 105, pp. 367–368 (April 4, 1947) in R.H. Whittaker, *Communities and Ecosystems* (copyright 1970), The Macmillan Company

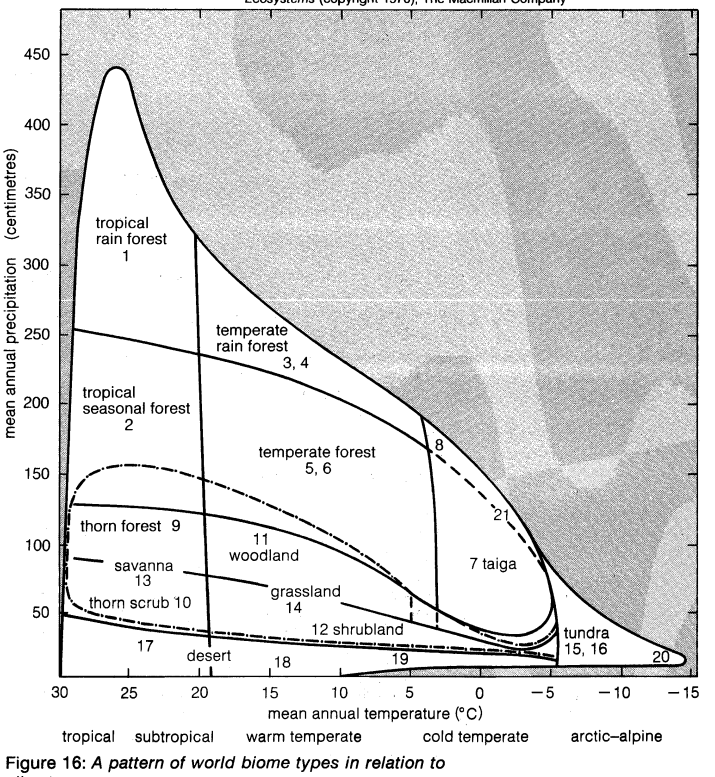

Figure 16: *A pattern of world biome types in relation to climates.*
The numbers refer to biome types listed in Table 7. The dot-and-dash line encloses a wide range of environments in which either grassland or one of the types dominated by woody plants may form the prevailing climax vegetation in different areas.

in community samples as a basis for classifying those samples into units. In grouping samples into associations the ecologist seeks, however, for character species—*i.e.*, those species that are centred in or largely restricted to the communities considered to belong to a given association. These character species are emphasized as means of defining associations, though dominance and other criteria may also be considered. Associations and other units are given latinized names (*e.g.*, the Caricetum curvulae is an association characterized by the sedge, *Carex curvula*). Associations may be grouped into units termed alliances on the next higher level; alliances may be grouped into orders, and orders into classes. These higher-level units may also be defined by character species, which are species that are too broadly distributed to become character species of associations but are centred in or are largely restricted to one of the higher-level units. Vegetation of an area may thus be classified into a formal arrangement in a graded series of units from classes down to associations and lower units. The units below the association (subassociation, variant, and facies) may be defined by differential species and quantitative relations of species. (Differential species are those that tend to be present in one and absent in the other of two units being compared, regardless of their distributions in relation to other units.) The lower-level units make possible effective use of plant communities to indicate habitat properties and the potential of land for agriculture or forestry. This system has been important not only in the development of vegetation mapping but also in the use of vegetation for its indicator value in the

Table 7: Biome Types of the World

biome type	characteristics and environment	distribution
1. Tropical rain forest*	large forests with many tree species, epiphytes (unrooted plants supported on trees), and lianas (vines) in area of abundant rainfall throughout the year	Southeast Asia, Africa, South and Central America, northeast Australia
2. Tropical seasonal forest and monsoon forest	forests adapted to climates with a marked dry season in which some or all leaves are shed	extensive in Southeast Asia; occurs in other tropical areas
3. Giant temperate rain forest	very large forests (trees up to 100 metres tall) in areas of abundant rainfall	northwest coast of the United States, eastern Australia
4. Montane rain forests and thickets	smaller evergreen forests of wet temperate climates of mountains	throughout the tropics and in the Southern Hemisphere
5. Temperate deciduous forests	trees with broad leaves that are shed in winter, mainly in continental, moderately humid climates	Northern Hemisphere mostly, especially in the eastern United States, eastern Asia, and western Europe
6. Temperate evergreen forests	either needle-leaved or broad-leaved evergreen trees or both, in moderately humid temperate climates	all continents (excluding Antarctica)
7. Taiga or boreal forests	needle-leaved forests, mostly evergreen, of cool temperate (subarctic and subalpine) climates	across northern North America and Eurasia and southward at high elevations in mountains
8. Elfin woodlands	dense evergreen thickets with heavy moss and lichen growth in cool subalpine belts of tropical mountains	mountainous tropics
9. Thorn forests and thorn woodlands	communities of acacias and other trees armed with spines, often in open growth, in moderately dry climates	widespread in the tropics
10. Thorn scrub	dense communities of spiny shrubs and small trees, often with succulents, in dry climates of the tropics	widespread in the tropics
11. Temperate woodlands	communities of small trees in open spacing, generally with well-developed undergrowth, in climates too dry or otherwise unfavourable for forests	on all continents
12. Temperate shrublands	diverse shrub communities in temperate climates including as types macchie, or maquis, garigue, chaparral, heath, etc.	on all continents
13. Savannas	tropical grasslands, often with scattered trees, in moderately dry climates or in consequence of soil conditions and fire	extensive in Africa, also in Southeast Asia and South America
14. Temperate grasslands	plains, prairies, steppe, pampas, and veld, moderately dry climates	North America, Eurasia South America, southern Africa, New Zealand
15. Alpine meadows	treeless vegetation above the subalpine forests or thickets in cold mountain climates; sedge or grass meadows, paramo and puna, tussock grasslands	worldwide at high elevations
16. Arctic tundra	treeless vegetation of cold climates north of the taiga, formed by varied combinations of lichens and mosses, grasses and sedges, and dwarf shrubs	northern North America and Eurasia
17. Tropical deserts	sparse vegetation in very dry subtropical climates	North Africa, Asia Minor, southwestern Africa, western South America
18. Warm-temperate deserts	scrub of small-leaved or spiny shrubs or both, in arid climates	south-central Asia, south-western North America, Australia, Argentina
19. Cool-temperate semidesert scrub	shrub communities of sage-brush or other shrubs with grasses in semiarid climates	western United States, interior Asia, Southern Hemisphere
20. Arctic-Alpine deserts	sparse vegetation of widely scattered plants, or lichens only or rock or snow, in extremely cold climates	at high elevations, in the far north in America and Eurasia, and in Greenland and Antarctica
21. Bog†	wet communities with sphagnum moss, mostly in cold climates	worldwide, most extensive in the Northern Hemisphere, especially Ireland and Scotland
22. Tropical fresh-water-swamp forest	evergreen forests of soils seasonally or permanently submerged by water	Amazon basin and other areas of tropical forest
23. Temperate freshwater-swamp forest	cypress swamps and other forests of seasonally or permanently submerged soils	southeastern United States and other humid temperate areas
24. Mangrove swamps	forests of small evergreen broadleaf trees, growing in shallow brackish water or wet soils	tropical coasts and estuaries
25. Marshes	wet soil communities of grasses or grasslike plants	worldwide
26. Marine pelagic‡	plankton (small plants and animals suspended in the water) of the open oceans, fish, marine mammals and birds	worldwide
27. Marine benthos	communities of the ocean bottom, at greater depths limited to microorganisms and animals living on, or rooted in, or burrowing in the bottom mud or ooze	worldwide
28. Marine rocky littoral	animals and algae living on rocky coasts, many of them attached to the rocks and subject to wave action and tidal exposure	marine coasts throughout the world
29. Marine sandy littoral	animals and algae living on or in the sand of beaches and sandy shores in shallow water	marine coasts throughout the world
30. Estuarine and marine mudflat	microscopic algae of the mud surface, animals living in the mud, and plankton of bays and estuaries	marine coasts throughout the world
31. Freshwater lentic	communities of inland lakes and ponds, including in the biome type the plankton, bottom, and shore organisms	on all continents
32. Freshwater lotic	communities of streams and rivers, with organisms of fast-flowing water and rocky bottoms, and of slow-flowing water and sand or mud bottoms, as major subdivisions	on all continents

*Numbers 1–21 refer to biomes shown in Figures 14 and 16. †Numbers 21–25 are biomes determined primarily by wet soils. ‡Numbers 26–32 are aquatic biomes.

intensively used land of the western European continent.

Worldwide classification systems

Biomes or formations. A system of classification is also used for treatment of communities on an extensive scale for whole continents and the world. Treatment of vegetation on a continental scale generally deals primarily with prevailing climax vegetation, uses physiognomy as the criterion of community units and community expression of climate, and employs the formation as its unit of classification. A formation groups together the communities of a given continent that are of similar growth-form structure in response to broadly similar environmental conditions (especially climate). In studies concerned with animals as well as plants, formations are generally termed biomes. Similar formations or biomes occur as convergent responses to similar climates on the different continents. A grouping of convergent formations or biomes of the different continents is a formation type or biome type. Many systems of biome types have been proposed by ecologists and geographers; Table 7 employs one of these many systems for its elaboration of the biome types of the world.

The relations of biome types to climate are represented in Figure 16, which represents the adaptation of world vegetation to world climate. Mean annual temperature and precipitation are considered to be the principal factors determining physiognomy. On the basis of these factors approximate boundaries between major physiognomic types are shown, and the relations of the biome types in Table 7 to these is indicated by their numbers. Community gradients involving some of these formations are illustrated in Figure 14. The pattern of Figure 16 cannot adequately represent (1) the effects of different seasonal relations of temperature and precipitation, notably the contrasts of maritime and continental climates, (2) the effects of fire in determining occurrence of communities dominated by grasses rather than woody plants in many areas, (3) effects of differences in soil, and (4) the continuous intergradations between formations. Despite these simplifications the figure offers, as does Figure 15, a representation of the broad pattern of natural communities on land in relation to climates. (R.H.W./Ed.)

AQUATIC ECOSYSTEMS

An aquatic ecosystem consists of plants and animals interacting with the chemical and physical features of a watery environment from the smallest puddle to the world ocean. And, while conditions in a short-lived puddle differ considerably from those in the ocean deeps, there are many points of similarity imposed upon the communities that inhabit such environments by the unique properties of water. Life forms have adapted to these environmental extremes and to the myriad intermediate aquatic environments available on Earth.

Types of aquatic ecosystems

A common distinction is usually made between seawater and fresh water or between oceans and inland waters. The oceans of the world constitute a deep, interconnecting system of saline water (salty with dissolved minerals) surrounding the continents. This world ocean is characterized by complex circulation and tidal movements. Inland waters, on the other hand, comprise a widely disparate series of bodies of water that tend, generally, to be fresh (*i.e.*, low in dissolved salts) and to drain into the oceans.

Many variations in the aquatic environment are products of organisms themselves; for example, the diatom (one-celled organisms with skeletons composed of silica) population of a lake in May is determined by chemical nutrients, but the chemical composition of the lake, particularly the aspect of it most important to diatoms, is very much the product of diatom activities in the same lake a month earlier. It is impossible to understand the life of waters without taking into account a reasonably large part of the web of circular causality that binds the system together.

Water as a medium for life. Because organisms are themselves aquatic systems, water provides a more kindly environment than does land (and the air above it), the other principal medium of the living world. Yet problems exist that must be overcome. Maintaining the proper internal concentration of water may cost organisms some energy in salty environments. An organism living in a concentrated desert lake or coastal lagoon may be faced with problems of water balance similar to those of its terrestrial neighbours. At the other end of the salinity scale, in freshwater environments, organisms must work to keep an excess of water from flooding in and disrupting their metabolism. In general, though, the problems of gaining and holding an adequate supply of water are very much less in aquatic ecosystems than they are in terrestrial systems.

Water has a high specific heat, which, simply stated, means that water gains or loses a large amount of heat before its temperature changes appreciably. This property of water moderates seasonal, daily, and local extremes of temperature. In even the coldest polar environments, aquatic ecosystems commonly provide refuges beneath the winter ice where the temperature is above the freezing point and far above that of the overlying air. In hot regions, evaporative heat loss rises with increasing temperature under most circumstances and keeps the water relatively cool. As a further consequence of the high specific heat of water, aquatic ecosystems do not show the pronounced microclimatic variability of many terrestrial systems. The contrast between the higher temperatures close to the ground in a sheltered hollow and the lower temperatures a few feet above an exposed ridge—a characteristic of high mountains in summer—is not found in mountain ponds, at least the surface water of which is nearly the same temperature throughout. High specific heat is also an important factor in maintaining the temperature of deep ocean water, even at the equator, always a few degrees above freezing.

The supporting ability of water

Water is much denser than air, so the structural difficulties of maintaining a large organism in it are much less. In water, whales and sharks, much larger than any terrestrial organism—including the dinosaurs—are supported with ease. It is largely this property of water that has permitted the evolution of a style of life—that of the plankton—that has no analogue in air. Plankton is a collective term for all the aquatic free-floating organisms that are buoyant or nearly so. They sink so slowly that normal turbulence keeps most of them in suspension. Birds, bats, insects, and other organisms use the air as a medium of transport, to get from place to place, but typical plankters, by contrast, are completely at home in the water—breeding, feeding, and dying there. Their movements, if any, simply keep them in suspension and do not afford transport.

Water exhibits some important differences from related substances—such as ammonia, hydrogen fluoride, and hydrogen chloride—that theoretically could have provided a fluid medium for the maintenance of life. The hydrogen atoms in the water molecule are on one side, the oxygen atom on the other. The hydrogens being positively charged and the oxygen negatively charged creates a strong polarity and is responsible for the unusual physical and chemical behaviour of water as a solvent for many solids. Some idea of the importance of this capacity in organic evolution can be gained by comparing the relative abundance of the elements in the Earth's crust and in organisms. The elements that accumulate in living things are those that form soluble ions (charged particles) under the conditions of oxidation and acidity normally found in aquatic ecosystems.

The asymmetric arrangement of the hydrogen atoms also creates strong forces of attraction between the molecules of water, so that they tend to clump together. With, on the average, six molecules clumped together, water has much higher values for properties such as viscosity (resistance to flow), surface tension, specific heat (heat required to raise the temperature of one gram of water one degree Celsius), melting point, and boiling point than it would have if its molecules remained separate.

One other important consequence of the asymmetry of

the water molecule is worth particular note. Most substances contract (*i.e.,* become denser) as they become colder. Water is unique in contracting and increasing in density down to about 4° C (39° F), after which it starts to expand again, undergoing a great expansion as it freezes into ice. If it were not for this anomalous thermal expansion of water, ice would form on the bottoms of polar seas and temperate lakes and rivers. Instead of winter water being insulated from further freezing by a surface layer of ice, summer ice would be insulated from melting by a surface layer of water. The ice would gradually increase in volume until all the aquatic ecosystems that are commonly ice-covered in winter became solid ice, and life in them would be impossible.

Physicochemical control of life in water. Water, however, does place limitations on its denizens that air in terrestrial ecosystems does not. Since water is denser and more viscous than air, it is more difficult for an organism to move through water, a matter of consequence to an organism attempting to travel quickly or to move large quantities of water over its gills. Mixing of ingredients occurs slowly in water by comparison with air. Although a productive forest on a clear day or a downtown avenue at rush hour may show departures from the normal levels of carbon dioxide or monoxide, generally the atmosphere is well mixed. In aquatic ecosystems, mixing is so slow that local depletions and excesses of biologically important substances are common.

Mixing of ingredients in water

The mass and metabolic activity of organisms in the water are governed by many physical and chemical factors. For the Earth as a whole, the most important of these is certainly light. If the light intensity throughout the deep ocean water were raised to the level in the upper 10 metres (33 feet), the effects would be to increase the amount of photosynthesis and the activities of plants and animals dependent on it more than any other single change in physical and chemical factors. The fundamental control imposed by the supply of solar energy is so all-pervading that it is usually taken for granted, and investigations are limited to the experimental manipulation of other factors, particularly dissolved chemical substances known to be essential to plant growth. For particular places at particular times, it is possible to enhance photosynthesis by experimental additions of a wide variety of substances. Phosphorus, nitrogen, sulfur, silicon, iron, and other elements may all produce important increases in productivity when used singly and dramatic increases when used in combination; commonly, however, the biggest increase for a single element is obtained with phosphorus. Potassium, a common constituent of agricultural fertilizers, is seldom or never in short supply in aquatic systems.

It is reasonable to expect an enhancement of photosynthesis if the supply of carbon dioxide is increased in a system with a high light intensity. Certain elements required in small amounts and vitamins, known to be essential to the nutrition of many aquatic plants, are occasionally scarce in aquatic ecosystems, but for the most part these substances seem to be available in adequate supply. This is undoubtedly because nutrients are more readily circulated through the water than they are on land.

Animals are affected by anything that influences the plants on which they depend for food. In many aquatic situations, they also must contend with a shortage of oxygen. Many plants and animals are excluded by the extremely acid or extremely alkaline waters of a few lakes in volcanic regions or by the extreme salinity of coastal lagoons or lakes in arid lands saturated with sodium chloride. Whereas the entire range from salt-saturated lakes to fresh snow meltwater provides living space for communities of organisms, the constituent species are seldom able to tolerate more than a small part of that range.

Major divisions of the aquatic environment. The world ocean constitutes the largest ecological subdivision on Earth. Inland waters, which occupy far less area, are generally grouped into two categories on the basis of movement: standing water, or lentic environments; and flowing water, or lotic environments.

The marine division. The world ocean is enormously bigger than any lake, is much older, and has much greater local variation in surface illumination and temperature. Its biota is richer. Its chemical composition is relatively uniform, with about 3.5 percent minerals, mostly salts, and a smaller percentage of organic matter in solution. Unlike the separate lakes that constitute the rest of the standing water of the hydrosphere, the ocean may be thought of as a single system, with no part completely isolated from any other.

The inland divisions. Inland waters include the standing waters of puddles, ponds, and lakes; the critical element is size. Ponds and lakes present many of the same limiting factors and stratification. Smaller bodies of standing water, such as temporary ponds and puddles, are severely limited by drying out and thus maintain transient and quite variable communities.

In common usage many lakes are referred to as seas—*e.g.,* the Caspian Sea, the Dead Sea, and the Aral Sea. The important distinction between a lake and a true sea, such as the Baltic Sea or the North Sea, is that a sea is in open communication with the world ocean; however, a lake, if connected to an ocean at all, is connected through a river that flows in only one direction, from the lake to the ocean. The common criterion of saltiness, which separates most lakes so clearly from the ocean, is not universal. Some lakes are about 10 times as concentrated as open ocean water, and there are parts of the ocean, such as the upper Baltic, that would hardly be considered oceanic on the basis of salinity alone.

Distinction between a lake and a true sea

The other inland waters are the flowing waters, which include springs, brooks, creeks, streams, and rivers. Although springs present a wide spectrum of temperatures and chemical properties, they remain relatively stable—in some cases very stable—with time. The march of the seasons does not affect them to nearly the same extent that it does other ecosystems, so the observations on one aspect of their function may legitimately be compared with observations on other aspects taken at different times. Although the inorganic chemical composition of springs is diverse, springs share the feature of having a small part of their total content of nutrient salts combined into organic matter, either living or dead. During its long sojourn underground, springwater has lost by oxidation most of the dissolved and particulate organic matter it once contained but tends to be richer in available nutrients than most river water and therefore capable of supporting active plant growth as it issues forth into the sunlight. Rivers and streams are much more uniform in chemical composition than are springs, being integrations of the discharge of many individual springs and shallow seepage and surface runoff water. They are highly responsive to the vagaries of weather. From week to week, season to season, and year to year, the discharge and chemical composition of a river may show great variation. During a flood, when the water is laden with silt and spilling over the bank onto the floodplain, a river is a different ecological system than it is during the clear, quiet times of low discharge.

The ocean and its communities

THE OCEANIC ENVIRONMENT

The ocean is by far the largest of all aquatic ecosystems. Once the ocean basins seemed stable and permanent features of the Earth, but it is now known that they are continuously changing in size and configuration at rates that are almost directly observable. Seafloor spreading from the mid-oceanic ridges carries the entire mass of suboceanic sediments, together with everything living on them, on a giant "conveyor belt" that spreads out from the middle ridge, apparently to plunge into the relatively small and localized oceanic deeps.

There is good reason to believe that the ocean basins have been growing steadily since their beginning. The ecosystem consequences of the concept of young and dynamic ocean basins have not been fully examined, but it is likely that they will influence knowledge about the geochemistry of the oceans, and possibly the age, origin, and distribution of the ocean biota as well.

The water of the ocean circulates on a global scale with a pattern that is vital to the organisms (particularly the

Oceanic circulation

deep-sea organisms) dwelling in it. The circulation pattern of the ocean is determined both directly, by observation, and indirectly, by inference from the distribution of water density. The basic data have been obtained from oceanographic vessels and consist of vertical profiles of temperature and salinity, the two main variables influencing the density of seawater. The driving force of oceanic circulation appears to be a combination of wind stress on the water surface, so that the sea is carried along by the atmospheric circulation, and differential heating and evaporation of the surface water at different places in the ocean.

One of the most important features of the entire circulation, with biological consequences for the deep waters of the entire world, is the cooling of surface water in the Arctic North Atlantic to the temperature of maximum density. This water is fully charged with oxygen, then sinks to the ocean floor and spreads out to all the oceans of the world. As it moves south and away from the source area there is some mixing with warmer surface water, so that a perennial thermocline (a middle layer of water with a temperature gradient) is set up at a depth of many hundreds of metres. In the upper part of the mixed layer over this permanent thermocline in temperate climates, a seasonal thermocline develops, with a thin layer of light, warm, surface water riding over the much deeper layer of seasonally mixed water.

Much of the particulate organic matter carried down in the cold, descending water masses of the North Atlantic decomposes as the water sinks. In addition, there is a steady rain of dead organisms and feces from the overlying surface water in all parts of the ocean into the cold, slow-flowing, deep water of North Atlantic origin. The decomposition of organic matter consumes oxygen, but the rate of renewal of the deep water and its oxygen content are so great that the oxygen depletion of the deep water, though easily measurable, is not sufficient to prevent oxygen-requiring animals and bacteria from living in most of the deep sea. In only a few localities, such as the Black Sea, the Cariaco Basin, off Venezuela, and many fjords of heavily glaciated coastlines, as along Scandinavia and Alaska, is the renewal of water restricted enough to produce severe oxygen depletion comparable to that in the hypolimnion (stagnant water below the thermocline) or monimolimnion (water rich in dissolved salts, below the hypolimnion) of lakes.

As in lakes, plankton and detritus sink to the deep water, releasing the nutrient salts needed to sustain plant growth. When this nutrient-rich water wells up to the lighted surface, as it does in a ring around Antarctica, off the coast of West Africa, off California, off Chile, and in various other places, it supports rapid growth of planktonic algae, which, in turn, supports large populations of animals. Many on the major fisheries of the world, such as the Peruvian anchovy fishery, are sustained by the productivity of these localized areas of nutrient upwelling.

Mineralization

The mineralization of plankton and detritus in the sea is never complete. A residue of undecomposed organic matter remains in extremely dilute solution and extends to the greatest depths. Since living creatures are abundant only in the illuminated surface layer of water, the mass of dissolved organic material in the sea greatly exceeds the total mass of particulate matter of all kinds—from phytoplankton (*e.g.*, algae) to whales, both living and dead.

The upper atmosphere mixes with ocean surface water rapidly—in about 10 years—but exchange of gases at deep levels is much slower—on the order of 1,000 years. In other words, an average molecule of deep oceanic oxygen or carbon dioxide left the atmosphere about 1,000 years ago.

The ocean is the great sump, or drain, of the hydrosphere. Its chief contributors, the dissolved and suspended loads of rivers, are relatively easy to measure. Other gains and losses are less easily measured, but the ocean appears to have been in a chemical steady state before the advent of industrialized society. The main buffer in the system consists of reactions between seawater and solid compounds (silicates). This, for example, is the mechanism that buffers the ocean in the face of a continual input of acidic gases from volcanoes, although short-term and local buffering is dominated by reactions with carbonates and bicarbonates.

The ocean receives much of the total of human industrial, municipal, and agricultural wastes. Some persistent synthetic chemicals, such as the chlorinated hydrocarbon insecticide DDT, are carried to the sea, where they accumulate in the fatty tissues of organisms and become concentrated as they are transferred up the food chain. The lead content of surface seawater appears to be increasing rapidly. Oil spills and leaks from oil wells, which formerly had disastrous effects only locally, now appear to be polluting the surface water on a worldwide scale. The ecological effects of these chemical changes are cause for serious concern. If they are reinforced by further expansion of the present regrettable practice of using the deep sea as a dumping ground for noxious substances, such as radioactive wastes and nerve gases, it is possible that the deep parts of the entire ocean will be profoundly modified. Because of the slowness of the deep circulation, serious and irreversible harm to the ocean ecosystem could be inflicted before the effects became noticeable.

(D.A.L./Ed.)

CHARACTER OF OCEANIC COMMUNITIES

The fossil record shows that a rich and diverse marine fauna has persisted on Earth since the beginning of the Cambrian period (about 570 million years ago). The present oceanic fauna—clearly and smoothly traceable from that period—is incomparably richer than the fauna of any lake or river.

Habitat zonation

Life in the open sea occupies the vast extent of the sea bottom (benthic zone) and overlying water (pelagic zone). Assuming that 200 metres (660 feet) below the surface is the upper limit of the habitat of the deep-sea fauna, the surface of the deep-sea region lies under about 92 percent of the total surface of the sea, equivalent to about two-thirds of the total surface of the globe. This three-dimensional region of faint light or complete darkness, with its strange creatures, possesses monotonous uniformity and stands apart from other biological realms on Earth.

The lighted, shallow, populated pelagic zone extends upward and oceanward from the upper boundary of the continental slope. The dark, deep, sparsely populated pelagic zone extends outward and upward from the continental slope and the deep-sea floor and abyssal region. The corresponding zones of bottom-dwelling, or benthic, organisms are the archibenthic (800–1,100 metres, or about 2,600–3,600 feet) and abyssobenthic (below 1,100 metres) zones. The latter zone is sparsely populated and contains some of the most unusual animals known.

Organisms of upper layers of the open sea (Figure 17) are exposed to the full daylight spectrum. Relatively small numbers of organisms inhabit the offshore oceanic waters. The more conspicuous components of the surface population are the Portuguese man-of-war (*Physalia*), the purple sailor (*Velella*), the purple storm snail (*Janthina*), and a nudibranch mollusk, *Gaucus*.

The transient animal life of the surface layers includes many fishes. The relatively permanent surface fauna, apart from such large forms as cetaceans (whales), turtles, and sea snakes, are of two main types: animals adapted entirely to a surface existence partly in air and partly in water and animals that inhabit the immediately subsurface layers. The strictly surface forms usually have floats of various types; some are definite organs of buoyancy, while others are formed of bubbles or trapped air. The only known open-ocean insects are water striders (family Gerridae) that live on the surface film, buoyed by air trapped in the hairs on the body.

The subsurface layers of the lighted open sea contain many of the free-floating, or planktonic, forms, including many kinds of animal larvae. Apart from the blue coloration that is a most striking characteristic of plankton of the open ocean, there are few signs of adaptive characteristics special to this environment. The minute copepods of the family Pontellidae are capable of jumping out of the water to distances of about 15 centimetres (6 inches). The paper nautilus (*Argonauta*) is able to ride on the upper surface of the bells of certain jellyfish.

Seaweed buoyed by bladders is widespread in the oceans of the world and carries with it many associated animals that show adaptations of colour and form suitable to the habitat (interestingly, most are from near the shore, not oceanic).

Plankters such as diatoms and copepods migrate up and down in response to light. Illumination in the upper few metres is too bright for survival of most phytoplankton and zooplankton; hence, this vertical zone of distribution is sparsely populated. The zooplankton of the deeper but still lighted zone in which photosynthesis is active undergo diurnal migrations determined by food and light intensity. Vertical movements of plankton diatoms are related to variations in structure. Increase in spination (the distribution and arrangement of spines) increases the relative surface area and so retards sinking or flotation of the organism when its specific gravity differs from that of the water. Special types of plants adapted to a floating existence have evolved.

Diurnal migrations of zooplankton

In the open sea the chief grazers are the copepod crustaceans, semimicroscopic in size, that feed mainly on diatoms, dinoflagellates, and other microorganisms. Protozoans and the larval stages of larger invertebrates also graze upon the phytoplankton. Some fish, such as herring and menhaden, feed on phytoplankton but are mainly coastal forms.

Bathypelagic animals inhabit the deep, dark waters of the ocean above the bottom (Figure 17). The deep-sea plankton contains no algae except for a few so-called olive-green cells. At 50 metres (160 feet) or less, from 3,000 to 100,000 plankton forms occur per litre. The number of species in the plankton does not decline with depth as strikingly as its number of individuals. Unusual size characterizes some of the deep-sea plankton forms. Microscopic swimming forms such as crustaceans differ significantly from their relatives of shallow seas in usually being luminous and sometimes blind. Other forms have enlarged eyes and long appendages that assist in floating.

Life in dark open water

There is a great diversity of features and forms among the deep-sea fishes. Many of them are blind and small, from about 10 to 30 centimetres (4 to 12 inches) in length. One of the chief characteristics of this deep zone is food

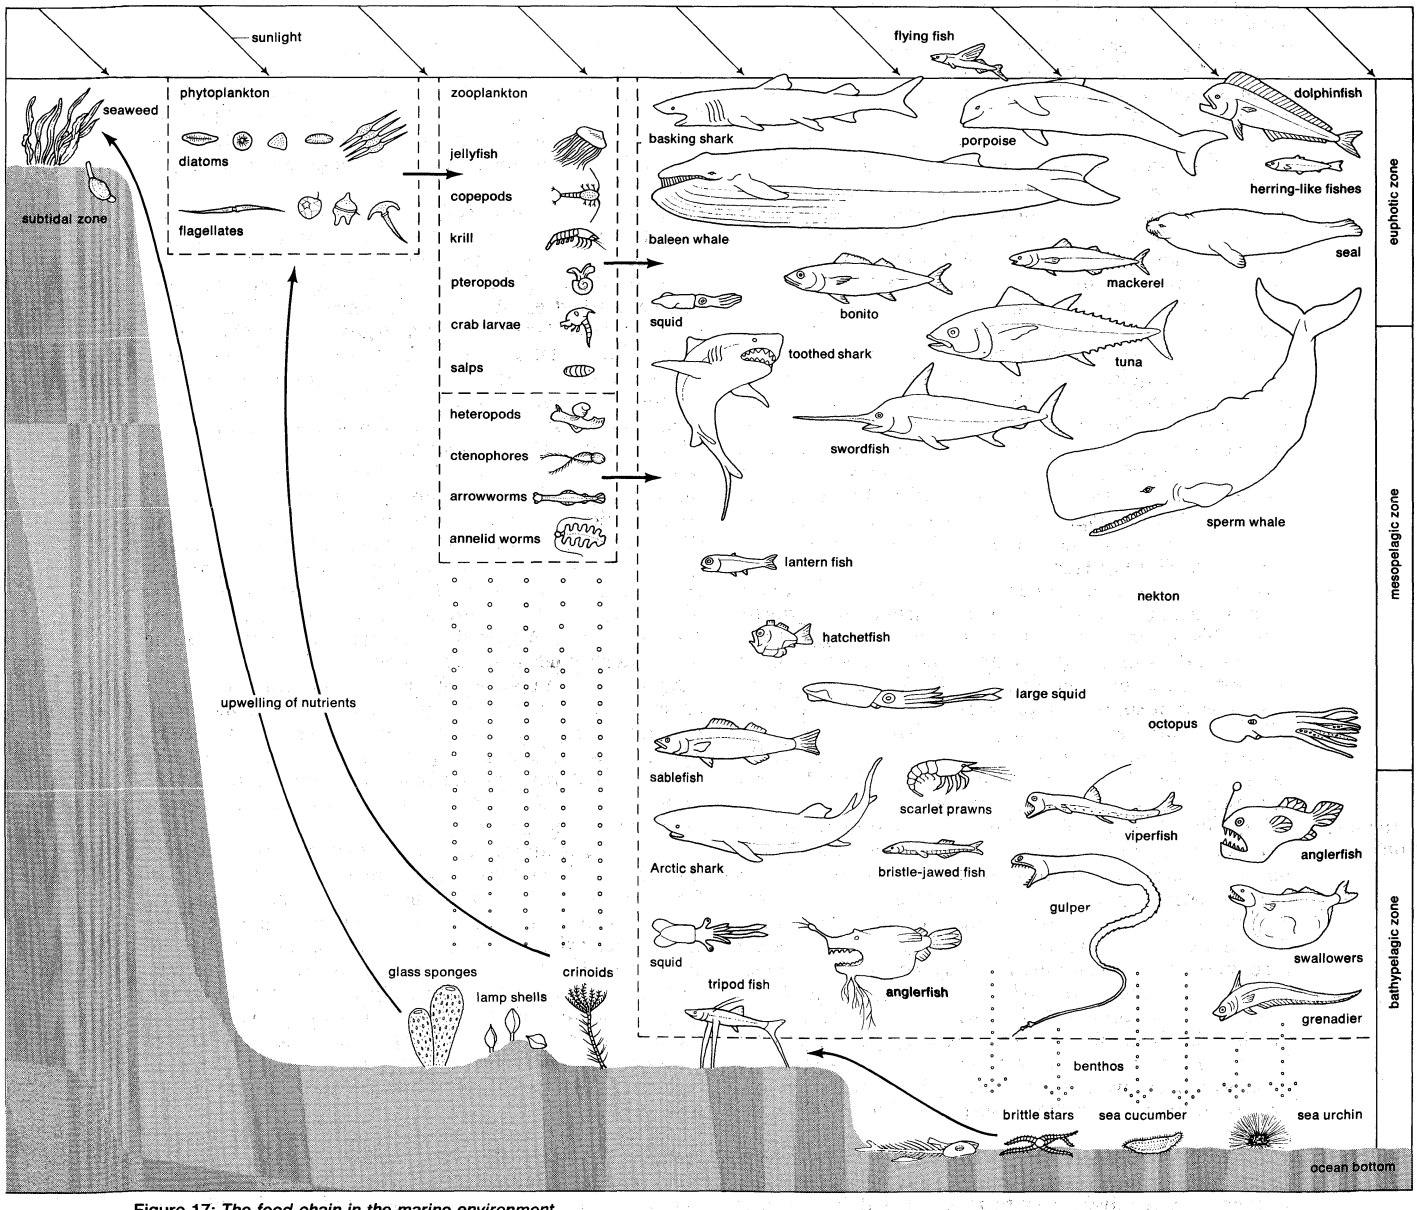

Figure 17: *The food chain in the marine environment.*
All life in the sea is dependent upon sunlight, which is directly converted into food by microscopic plantlike floating organisms (phytoplankton). Phytoplankton in turn is eaten by animal-like plankton (zooplankton). The plankton supports a succession of actively swimming predators (nekton). Organic debris rains down (dots) and provides food for animals at lower depths. Near-shore organisms are supported by land drainage. Coastal upwelling (upward arrows) provides the phytoplankton with nutrients released by decomposition of organic matter on the bottom. (Organisms not drawn to scale.)

scarcity. Another is the size and extension of locomotory appendages of crustaceans as well as fish. The scarcity of food near the sea bottom results in considerable modification of feeding structures: great teeth, enormous jaws, and uncannily extensible stomachs.

Organic material in various states of decomposition rains down from above and is consumed by mid-depth and abyssal detritus feeders. In fact, plant material as such probably never reaches the bottom but goes into solution to be reclaimed by bacteria and other consuming forms. The previously mentioned olive-green cells have maximum distribution below the euphotic zone and are believed to reclaim significant amounts of dissolved organic matter.

Deep-sea, or benthic, animal life shows special features. The abyssal region extends from 100 to 1,500 metres (about 330 to 4,920 feet) to the lowest depths. It is a zone of muddy bottom characterized by low temperatures (usually between 1° and 2.5° C, or 34° and 37° F) and by food scarcity. The population is sparse. Sessile animals (those that tend to remain in a given locale but that are not necessarily fixed) are characteristic and include sponges, stalked polyps, sea anemones, sea lilies, and rhizopod protozoans. Characteristic forms are the echinoderms, such as the sea urchins, some of which have abnormal body forms. There are giant isopods, 15 to 20 centimetres (6 to 8 inches) long, with large eyes. Some blind isopods have long legs and tactile feelers that enable them to move over the muddy ooze and feel for their prey. Deep-sea crabs often have long, slender extremities, sometimes armed with great spikes that keep them from sinking into the ooze.

ADAPTATIONS TO MARINE CONDITIONS

Structural adaptations. Structural adaptations pertain to the rigid conditions of existence at great depths. They relate to acquisition of food, absence of light, stillness of waters, low temperature, and great pressure. The uniformity of these factors is more marked in the deeps than elsewhere in the ocean. The enormous pressure experienced by deep-sea organisms is not countered by any special development. Because of the balancing of external and internal pressures, water pressure is apparently not felt. Pressure changes can be endured if they are gradual enough to permit adjustment. A swim bladder, the hydrostatic apparatus so widespread in surface-living fishes, enables them to float or, by varying the gas content, to rise or sink in the water. A number of deep-sea fishes possess swim bladders. At a depth of 1,000 metres (3,280 feet), with a pressure of 100 atmospheres, the gas content of the swim bladder is compressed to one-fifteenth of the volume it would have at a 10-metre (33-foot) depth.

Aids to buoyancy

The most widespread means of reducing specific gravity among pelagic forms is through the absorption of large amounts of water in, for example, connective tissue, thus producing transparent gellike tissue found in cnidarians (coelenterates), snails, annelid worms, and pelagic cephalopods. Certain decapods are so transparent because of such tissue that print may be read through their bodies. Plankton fishes and eel larvae are also watery and transparent.

More effective than the absorption of water is the storage of lighter materials, such as low-salinity water, fat, or even air. The fluid of vacuoles of radiolarians and certain ctenophores has a lower specific gravity than seawater. The accumulation of fat is widely distributed among pelagic animals, thus lowering the general specific gravity. It is present in protozoans, such as radiolarians that contain oil drops, in crustaceans such as cladocerans and copepods, in some mollusks, and in many fishes that store food in the form of fat in their livers and that have oil drops in their eggs.

The most effective buoyancy means is the inclusion of air or other gases in the body. Jellyfish have air sacs filled with gas from a gas-producing gland. Certain cephalopods, such as the nautilus, have a shell containing air in chambers. The air sacs of fishes have already been discussed.

The relative immobility of deep water favours special animal developments. Fragility of the skeleton and other structural elements of the body is an example. Occasional development of giant forms—sponges and coelenterates more than two metres high and sessile tunicates one metre high—are a product of perpetually still water. The deep-sea environment also produces the largest of the sea urchins, crabs, ostracods, isopods, and sea spiders. This unique environment also permits the degeneration of all supporting and strengthening elements of the body. Thus, the shells of unicellular radiolarians, skeletal spicules of sponges and echinoderms, shells of sea urchins, mussels, and snails, and bones of fish are often so thin and scarce that they could not provide support or protection in disturbed waters. Below 2,500 metres (8,200 feet), the water is so deficient in calcium that the element dissolves readily in it; hence, it is difficult for animals to build up and maintain calcareous supporting structures.

The common factor of all pelagic animals is their independence of the bottom. They have obvious means, already discussed, for maintaining themselves in open water without sinking. In addition, shelled pelagic protozoans have thinner shells than bottom species. The calcium carbonate content of the shells is higher and the size of the pores is larger in the pelagic forms, thus favouring suspension. The shells of pelagic crustaceans are less calcified than those of their benthic relatives; they also have a higher fat content. Pelagic snails have delicate shells or none at all. The pelagic bivalve mollusk *Planktomya* has uncalcified shells. The skeleton of many pelagic fishes is weak, little calcified, or significantly reduced. Reduction of weight in pelagic copepods is achieved by depositing their eggs singly instead of carrying the egg sacs with them.

Effects of light and oxygen content. Lack of light in oceanic depths has important implications for physiological vitamin balance. For example, vitamin D, needed for building bones of vertebrates, can form and function only in the presence of light. Perhaps the lack of this vitamin accounts for the slightness and delicacy of bones of deep-sea fishes and for the markedly distorted forms of many bottom-living fishes.

Lack of vitamin D

Pelagic forms of the deep usually have an adequate supply of oxygen. Because of the low temperatures, these animals have low oxygen requirements. But the benthic occupants of the deep-water sediments require adaptations to meet the problem of low oxygen content. Some bottom dwellers can survive for relatively long periods without oxygen in the liquid environment. Respiratory pigments may provide an oxygen reserve during short periods in oxygen-deficient depths. The shipworm (*Teredo*), which may be found at great depths, makes use of glycogen as an oxygen supply, the glycogen constituting half the dry weight of its tissues. The biology and physiology of inhabitants of such anaerobic sediments are specially adapted to their environment. Besides a biochemical adaptation through the breakdown of glycogen, some animals cease to move. Others have morphological features that enable them to supply aerated water to vital respiratory organs.

Bioluminescence, or the production of light by organisms, is especially characteristic of the deep-sea population. The bottom of the abyssal swarms with light producers, including coelenterates, echinoderms, and annelid worms. As many as 44 percent of the fishes of depths below 900 metres (3,000 feet) are light producers. The light organs of deep-sea fishes vary in size and form. Their source is functionally metamorphosed skin glands or trapped luminous bacteria. Bioluminescence serves to lure prey, to frighten enemies, to enable the sexes to find each other, and to enable species that move in schools to keep together.

Maximum diatom abundance in the open sea is at about 30 metres (100 feet). The daytime concentration of upper zooplankton is at about 125 metres (410 feet), the level varying with location and light intensity. Most of the zooplankton ascend to the surface at night. The echo phenomenon known as the scattering layer is caused by plankton or nekton or both throughout the oceans of the world at from about 400 to 800 metres (1,300 to 2,600 feet). Some of the animal components of this layer undergo diurnal migration of 400 metres or more.

The distribution of euphausid crustaceans has been explained in terms of temperature and salinity. In the Antarctic, there appears to be a regular cycle in which

the immatures and adults are carried into lower latitudes by shallow water movements, and the eggs are returned to high latitudes by deeper, southward-flowing water movements.

Associations. Mutualism, as discussed above in *The zone of life: an overview: Biotic interactions,* is illustrated by the widespread cleaning of fish surfaces of undesirable parasites by associated organisms in search of food. Many species of fish and shrimps, as well as other organisms, clean parasites from other animals. The host is relieved of irritation while the cleaning species gains food. An example is the Spanish hogfish (*Bodianus rufus*), which swims into the mouth of the barracuda (*Sphyraena*) and forages among its teeth for food.

Commensal advantages

The advantage derived by a commensal (species associated with the host) may be the provision of a resting place, shelter, or transport and often of food. Commensals in somewhat permanent contact with their hosts include many animals and plants that simply require physical support. Certain barnacles are found only on the backs of whales, where they benefit by being transported great distances. Pilot fish (*Naucrates ductor*) eat leftovers from sharks, which they follow at close range. Whiting (*Godus merlangus*) and man-of-war fish (*Nomeus gronovii*) shelter among the tentacles of jellyfish. Tiny gobies (suborder Gobioidei) hide under the gill covers of larger fish.

Fish serve as hosts to a large number of parasites, including protozoans and many kinds of worms. They are also plagued by fish lice or copepods. In many deep-sea angler fish, the male lives as a tiny permanent parasite upon the body of the female and obtains his entire nourishment from her blood supply. These species have solved the problem of finding mates in the inky blackness of the deep sea.

PRODUCTIVITY OF MARINE COMMUNITIES

The productivity of the oceans may be judged by the biological oxygen consumption of the water or by nutrient concentration, including soluble inorganic phosphates, nitrates, nitrites, ammonium salts, and silicates. These minerals are consumed in the upper lighted layers, the inorganic phosphorus and nitrogen are regenerated by bacterial decomposition or by dissolved organic debris, and silicates are reformed by the dissolution of planktonic tests. The return of nutrients to the upper photosynthetic layers is accomplished by upwelling and the action of currents.

There are vertical-distributional strata that may differ markedly in nutrient concentrations in any one ocean. Four layers are recognized: (1) the surface, well-mixed, euphotic layer of relatively low concentration that varies little with depth, (2) the layer in which the concentrations increase significantly with depth, (3) the layer of maximum concentration, which has a range of between about 500 and 1,600 metres (1,640 and 5,250 feet), and (4) the thick bottom layers of relatively uniform phosphate and nitrate concentrations and in which silicate content increases significantly with depth.

Differences in the nutrient concentrations of the oceans depend largely on the composition of the deep water masses at their origin and subsequent changes induced by circulation and biological processes. Meaningful comparisons of oceans are thus difficult to make. Available data for the Indian Ocean suggest annual biological oxygen-consumption levels of about 0.45 millilitre of oxygen per litre of seawater in the upper 400 metres (1,300 feet) in the Antarctic shelf area and corresponding levels in the equatorial region of about 1.5 millilitres per litre. The North Indian bottom water levels below 2,000 metres (6,600 feet) average about 0.04 millilitre per litre, and at depths between 600 and 1,200 metres (2,000 and 4,000 feet) biological oxygen consumption levels have been found to range from 1.5 to 2.0 millilitres per litre.

The standing crop, or abundance, of zooplankton in the Antarctic waters in summer has been found to be about 10 times greater than that in the tropical Atlantic waters. At low temperatures, a larger total number of organisms can be supported on the same amount of food; and, in colder waters, nutrients may be supplied more rapidly in relation to their use. In tropical waters with great upwelling of nutrients from the bottom layers, a large standing crop of plankton exists and can support a productive food chain.

Marine biomass

Probably the total marine biomass is far greater than the combined biomass of land and fresh water. Standing-crop data are commonly reported as milligrams of carbon (C) per cubic millimetre (or other unit of volume). The range is commonly 10 to 1,000 milligrams of carbon per cubic metre. Values are usually derived from measurement of phytoplankton pigments, especially chlorophyll *a*. Values for open-ocean areas may range around 5 to 150 milligrams of carbon per cubic metre.

The entire oceanic productivity falls in the range 1.6 to 15.5×10^{10} tons of carbon per year, compared with 1.9×10^{10} tons for the land. About 58×10^6 tons of fish and shellfish are produced annually by the oceans, an amount believed to represent only about 0.03 percent of the total amount of organic material estimated to be produced annually in the sea. Most of the fishery yield comes from waters over the continental shelves and within the 200-metre depth range where nutrient concentrations are high.

This productive area represents only about 3 percent of the total ocean surface. The deep, open-ocean areas are comparable to continental deserts. The reduction in biomass from shallow coastal waters to oceanic depths is about 10^6 for a benthos (organisms living on or near the bottom); and for the plankton it approaches 10^4. Undoubtedly, this low rate is associated with and indeed reflects the small amount of detritus and other food material reaching the bottom at great depths. The low temperatures of the ocean deeps reduces respiratory rates and growth rates. Maintenance demands in terms of food supply are correspondingly low. In summary, the pelagic and benthic zones of the deep open ocean are sparsely populated and the least productive of all oceanic areas.

Instances of productivity variations among the Atlantic, Pacific, Indian, and Arctic oceans are associated with latitudinal temperature differences and upwelling of deep water rich in nutrients. The maximum–minimum variations in standing crop of zooplankton during the year at a particular station in the open ocean may amount to a factor of two or three. With approach to continental regions, the productivity of the water is greater, and the seasonal variations in volume of dominant zooplankton forms is much greater, perhaps seven or eight times richer. Temperate areas of the Atlantic are much richer in macroplankton numbers than the sparsely populated waters of the Sargasso Sea, which are about four times less populated than continental-slope areas. The standing crop of zooplankton in cold northern waters is sometimes over eight times that of tropical waters, and there may be a possible tenfold to twentyfold increase in zooplankton from the winter minimum to the late summer maximum. (C.N./Ed.)

Inland waters and their communities

For purposes of convenience, ponds and lakes are described as lacustrine ecosystems and springs and rivers as riverine ecosystems.

LACUSTRINE ECOSYSTEMS

The lacustrine environment. Standing waters—ranging from days-old ponds to million-year-old lakes—despite differences in size and in age, share certain factors in common; these determine the kind of organisms that can live in such communities. Among the most important of these factors are light, temperature, and dissolved nutrients; wind waves are important in large lakes.

The influence of light. If a lake is turbid, photosynthesis is possible only in the uppermost lighted layers. In fact, when the sun is high in the sky, the illumination in the upper few centimetres of even a murky lake is likely to be too high, rather than too low, for optimum photosynthesis to occur. Deep in the lake, however, light is scarce. Attenuation of light is a logarithmic process; for example, if one-half of the incident sunlight reaches a depth of one metre (about three feet), only a quarter of it will reach two metres, an eighth of it three metres, and so on. Accordingly, the illumination and the amount of photo-

synthesis drop off extremely rapidly with increasing depth.

The food requirements of organisms, however, are nearly constant. Respiration of both plants and animals continues in the dark, so in the deeper levels of a lake respiration is likely to exceed photosynthesis. If the depth is great enough, plants will not be able to manufacture enough organic material to keep themselves alive, and the animals must depend upon food falling from the illuminated surface layers of the lake.

Lake stratification

It is convenient to think of a deep lake as divided into two layers (Figure 18), a food-generating, or trophogenic, zone, in which there is enough light for photosynthesis to exceed respiration over a 24-hour period, and a food-consuming, or tropholytic, zone, in which respiration exceeds photosynthesis. The boundary between trophogenic and tropholytic zones (the compensation level) commonly moves up and down with the seasons, particularly in polar lakes with their pronounced seasonal pulse of incident sunlight.

Temperature effects. Temperature is also important to life in lakes. It acts directly, of course; fluctuations in temperature are gradual and less extreme than they are in air. In the temperate zone during spring and summer and in the tropics during the dry season, solar heat is commonly delivered to the surface of a lake faster than the wind can stir it into the depths. Unless the lake is very shallow relative to its size, the warm surface water, being lighter, rides over the cool water beneath, and the lake is effectively divided into two compartments until either autumn or a rainy season cools the surface enough for complete mixing to occur.

The surface layer of a stratified lake is called the epilimnion and the deep layer the hypolimnion. The boundary zone between them, where temperature changes rapidly with depth, is usually known as the thermocline. Epilimnion and hypolimnion are not completely sealed off from each other. There is a continual rain of debris, largely corpses and feces, through the thermocline and some upward movement of gas bubbles, mostly methane produced by bacterial decomposition of organic sediment. Organisms with a broad enough range of temperature tolerance may move freely through the thermocline in either direction. In general, however, movement through the thermocline is slight.

The relative extent of the epilimnion and the trophogenic zone and of the hypolimnion and the tropholytic zone depends upon both the transparency of the water and the interplay of wind mixing and solar heating, but in general the epilimnion tends to be strongly trophogenic, the hypolimnion tropholytic. During stagnation, respiration by organisms in the deep water may use a large part of the hypolimnetic store of dissolved oxygen, so that only animals capable of respiring without oxygen can survive there. If the hypolimnetic volume is large or if it includes an appreciable part of the trophogenic zone, then an adequate supply of oxygen will be available throughout the period of stagnation, and the hypolimnion may provide a refuge for oxygen-demanding animals, such as lake trout or whitefish, which cannot tolerate summer surface temperatures (Figure 19).

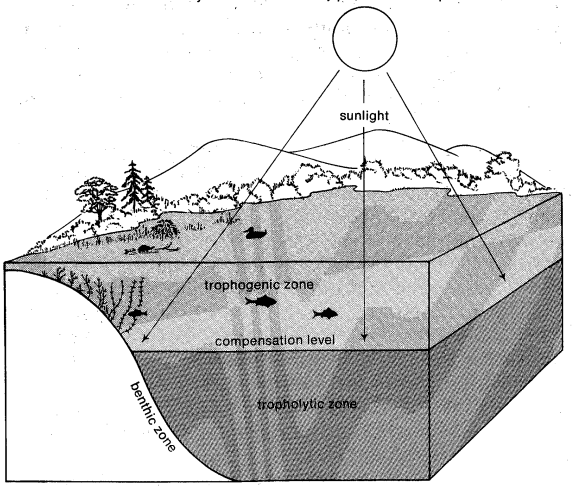

Figure 18: A lake in midsummer, showing zones of food production and consumption.

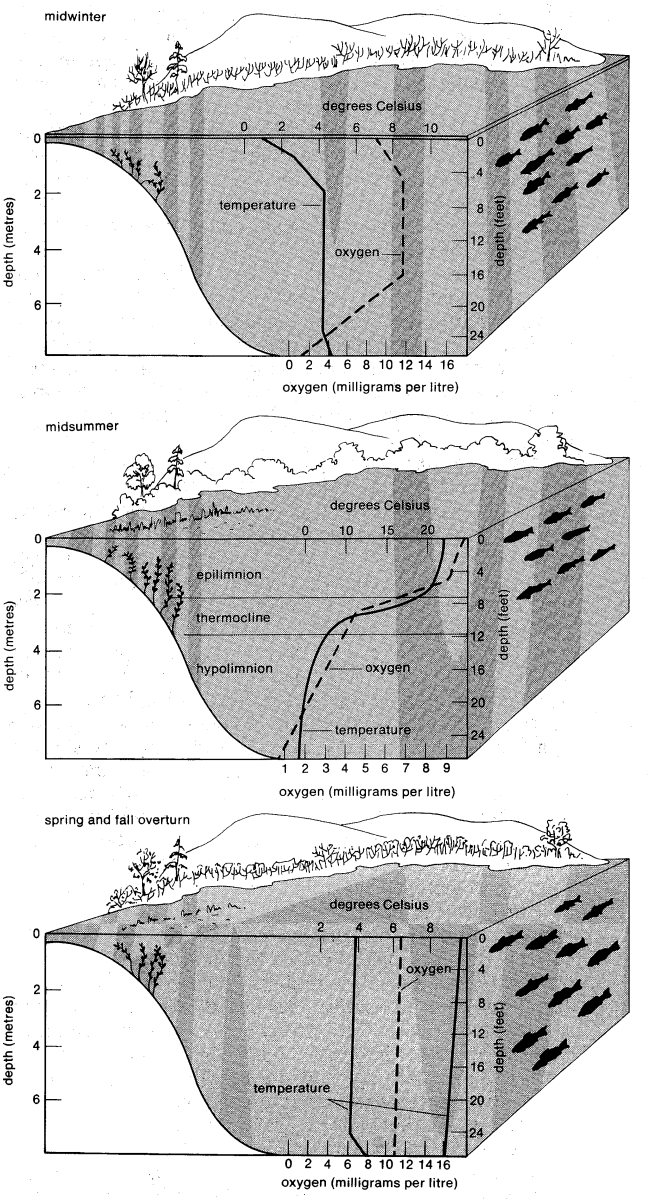

Figure 19: The influence of the seasons on lake stratification. The oxygen and temperature curves of the superimposed graphs are related to the depth of the water, as shown.

In most lakes temperature differences are the most important cause of stratification; of special interest, however, is the minority that are stratified because of chemical differences between deep and shallow water. In this condition, called meromixis, a pocket of dense water (the monimolimnion), rich in dissolved salts, lies under the fresher upper water of the lake.

Chemical stratification

The warmest lakes known are meromictic ones of such high transparency that an appreciable amount of solar heat penetrates to the monimolimnion, where it accumulates. The density changes in such chemically stratified lakes are much greater than those resulting from temperature changes in freshwaters and occasionally lead to the formation of a lake—such as Soap Lake, in Washington, U.S.—that in wintertime may have a surface layer of ice although its hypolimnion is almost hot enough to poach eggs.

Mineral factors. Life in calcium bicarbonate lake waters is determined less by changes in the major constituents—

calcium, magnesium, sodium, potassium, bicarbonate, sulfate, chloride, and silica—than by variations in biologically important substances that are commonly present in much smaller concentrations. The production of a lake commonly can be increased by adding phosphorus or compounds containing nitrogen; the addition of both increases production more than the addition of either alone. Changes in silica content have serious consequences for diatoms, algae with a siliceous cell wall; iron affects plant life directly and also chemically controls the availability of phosphorus.

In laboratory experiments it is possible to show that lake algae require numerous elements—nitrogen, phosphorus, sulfur, potassium, magnesium, silicon, sodium, calcium, iron, manganese, zinc, copper, boron, molybdenum, cobalt, and vanadium—and three vitamins. In most lakes, however, most of these materials are generally present in such adequate supply that it is usually difficult to demonstrate a deficiency.

Wind waves and seiche effects. Lunar tides are insignificant to life in lakes, being barely detectable on only a few of the world's largest lakes. Progressive wind waves, however, are a dominant influence on the plants and animals of the shore zone. In locales where the winds are strong and act over considerable surface area, waves more than 5 metres (about 16 feet) high can be produced—high enough to remove mud, clay, silt, and many organisms from beaches. Waves are probably the dominant influence on the distribution of shore plants and of the many smaller organisms of all sizes adapted to life among them.

The effect of an internal seiche

Less evident most of the time, though perhaps even more significant to life in many lakes, are standing waves called seiches, which are usually produced by the wind or by abrupt pressure disturbances. The initial disturbance tends to pile the water against one shore of the lake, leaving the opposite shore more exposed than normal. After the disturbance passes the lake, water rocks back and forth like soup in a bowl. Seiches only occasionally exceed one metre (three feet) in height. Biological significance is attached not so much to the surface seiche, however, as to the corresponding displacement of the thermocline, set up at the same time. Such an internal seiche is usually of greater amplitude than the surface seiche; in fact, all of the epilimnion may rock toward one shore, leaving hypolimnetic water exposed at the other. These large displacements of water are the main mechanism for generating turbulence in the hypolimnion of a stratified lake, and they play a vital role in the biological and chemical economy of such a lake.

Character of lacustrine communities. Suspended in the open water of a lake is a distinctive community of small—mostly microscopic—organisms, the plankton. Although many plankters can swim weakly, they do not use this ability to move from one part of the lake to another but only to maintain themselves at a desirable level in the water. They are thus at the mercy of the currents, and even turbulent eddies may overpower their slight capacity for directed movement; planktonic organisms were generally overlooked before the invention of fine silk nets and other devices that separated them from the water.

Sharing the open water with the plankton are the nekton; they are large, active swimmers able to move under their own power from one part of a lake to another. Fish, seals, turtles, hippopotamuses, and other large animals of lakes are all nektonic.

Often associated with the surface film of the lake is a well-developed community of plants and animals known collectively as the pleuston. Many of these organisms are small enough that the surface tension of the water supports them; microscopic members of the pleuston are sometimes distinguished as neuston.

More important in a quantitative sense is the benthos, the community of organisms inhabiting the lake bottom. If the water is shallow and transparent, the benthos may include an array of rooted vascular plants with microscopic algae living on them. Even deep or opaque lakes may have a dense population of benthic animals, sustained by organic matter descending from the trophogenic zone.

Lakes with waves adequate to maintain sand beaches are ringed with a psammon community, tiny organisms adapted to grow or move through the grains of sand. This community includes both plants and animals. Although sand grains reflect light in all directions and destroy visual images, a considerable amount of diffuse sunlight penetrates many centimetres into clean sand.

All the above-mentioned communities include microorganisms; some are only passive riders on the bodies of larger creatures. In addition, bacteria are found to depths of many metres in the mud under a lake—depths not considered part of the benthic habitat. Stratified lakes, especially meromictic ones, often have a layer of bacteria that live by reacting with sulfate compounds so as to form hydrogen sulfide at the interface between oxygenated and nonoxygenated (reduced) zones.

In the Arctic and in the temperate zone the abundance of plants of both major producing communities, the plankton and the shallow-water benthos, fluctuates with the seasons. This presents no problem as far as the higher plants ringing the shore are concerned: like the land vegetation, they sprout in the spring, grow more slowly during the summer, and die back in the fall in response to the same climatic controls that influence trees or grasses.

Plankton cycles

The fluctuation in abundance and activity of the planktonic algae, however, is more complex. A common pattern consists of two peaks of abundance and activity each year, one in the spring and one in the fall, with a period of relative quiescence during the summer. It appears that during the winter, when solar energy is scarce, photosynthesis is reduced, and many planktonic organisms die, releasing the nutrient salts of which they are composed. If the lake is covered with ice and snow, this process is so enhanced by the intensification of the darkness that oxygen may be sufficiently depleted to kill fish.

In spring the ice melts and freely circulating water, rich in nutrients, is exposed to bright sunlight. The result, predictably, is a spurt of photosynthetic activity and an increase in plankton abundance. During summer, thermal stratification occurs and with it a gradual depletion of nutrients in surface layers.

With the autumn overturn, however, nutrient-rich water is once again exposed to surface light intensities, which, though lower than those of spring, are still sufficient to sustain a burst of plankton production. The fall "bloom" of plankton, however, is usually somewhat less intense than the spring one.

As might be expected, many variants of this basic pattern occur. In cool, deep Alpine lakes the summer drop in production may be slight; in very cold Alpine lakes or in Arctic ones, there is likely to be no drop at all but only one burst of production—starting much later in the spring, ending much sooner in the fall, and peaking in midsummer.

In addition to these regular and predictable fluctuations in total plankton production, there are changes in the plantlike plankton (phytoplankton), with first one species, then another, appearing in a fairly regular seasonal succession, repeated with minor variations from year to year. There is also a succession in the animal-like plankton (zooplankton), with some species remaining throughout the year but others appearing only during the winter or only during the summer.

These changes probably could be understood in terms of seasonally changing chemical and physical conditions, but the exact way in which the environment acts to control a single species throughout the year has not been worked out in a single lake as yet.

It seems likely that the appearance of blue-green algae in many lakes during midsummer, when dissolved nutrients are at their lowest ebb, has to do with their capacity to utilize atmospheric nitrogen, giving them an advantage over spring and fall species that must have their nitrogen presented to them in the form of nitrates or ammonia. It is also possible that biochemical factors may be important: perhaps the blue-greens require organic growth factors released by the dominant algae of spring.

Adaptations to the lacustrine environment. Compared with rivers and oceans, lakes are rather transitory features of the Earth. A lake is likely to fill in or be drained, to

evaporate or freeze solid, in a time that is short compared with the rate of evolution. Many ponds are seasonal, some desert lakes (playas) hold water for only a few weeks after each rain. Lake Eyre, in Australia, contains water so seldom that its flooding is usually recorded in the scientific literature.

Responses to the changes in lakes

Dormancy and emigration. Because of the ephemeral nature of lakes, many aquatic organisms have mechanisms of resting in a dormant state or for moving from one lake to another. Aquatic vascular plants are commonly provided with large, thick-coated seeds, with underground storage rhizomes (underground stems), or with overwintering buds that will keep the population alive while most of the active individuals succumb to drought or cold. Daphnia, the water flea, normally reproduces parthenogenetically (without the need of mating), but, when food gets scarce or the pond begins to dry up or some other unfavourable circumstances develop, males appear in the population and fertilize the females. The offspring of this sexual union develop inside a thick-walled resting egg, which is shed into the environment at molting, instead of being placed in the mother's brood pouch. The resting egg is capable of withstanding adverse conditions of cold or drought and does not hatch until favourable circumstances have returned. Similar resting eggs are produced by many other planktonic crustaceans and by bryozoans. In the fall, in temperate-zone lakes, large, globular, jelly-filled colonies of bryozoans are blackened by thousands of small, round resting eggs, each armed with a ring of anchorlike hooks that increase the egg's chances of being carried to a surface suitable for growth.

Many planktonic algae produce resistant spores capable of withstanding drought, and the larvae of bivalve mollusks are adapted to cling for dispersal to the gills of fish or to the feet of ducks. The short adult phase in the life of aquatic insects is also a device for moving from lake to lake. A large part of the lacustrine biota seems to consist of species well-adapted to fleeing to more favourable areas should the lake in which they live become unsuitable. This is true even of such large, self-sufficient animals as the hippopotamus and the crocodile.

Planktonic adaptations. Plankters must stay suspended in the light water to survive. If they sink into the tropholytic zone, they die, either by poisoning or by starvation. Many plankters have overcome this threat by moving enough to keep themselves suspended. A few have developed gas bubbles or oil droplets to aid buoyancy. Other plankters have adapted by becoming as small as possible; thus, they sink very slowly through the water, relying on normal turbulence to hinder sinking farther. If the growth of the population is greater than the slow loss to the depths, then the species can survive. This is probably the commonest way out of the dilemma and may explain why so many plankters are microscopic in size, especially in fresh water. In the sea, with its higher salinity, the sinking problem is less acute, and larger plankters are found.

Many of the planktonic organisms in lakes are surrounded either with a jelly coat or with long spines sticking out in all directions. Both are probably adaptations for increasing effective diameter without greatly increasing mass, thus reducing the sinking rate. Many diatoms are slightly asymmetrical—sigmoid or S-shaped, for example—a physical advantage that also reduces the rate of sinking.

Vertical migration and cyclic change of form

Many species of lake plankton show one or another of two bizarre phenomena that may adapt them to open-water existence, although just how is still obscure. The first phenomenon is daily vertical migration: the plankters move up and down in the water, often considerable distances, according to the daily cycle of solar illumination. The second phenomenon is cyclic change of form. This occurs in animals such as daphnia and in some plants, all of which reproduce asexually as they change in form from one generation to another. Some populations show only slight change during the course of each year; others go through such variation that the extremes in form would certainly be taken for different species if the intermediate types were not known. These form changes are induced largely by changes in temperature during development, although turbulence also plays a role. Of the many ideas that have been advanced for the adaptive value of the changes—that they are adjustments to the properties of warm water, that they keep the animals swimming in strata in which food is densest, that they are defense mechanisms against seasonal predators—none seems a convincing explanation for the general phenomenon.

Physiological adaptations. The ancestors of most animals that live in lakes were either terrestrial or marine. Adapted to a situation in which water was scarce, these ancestors had to be able to conserve water and to excrete extra salts and waste products with minimal water loss. The water in most lakes is much more dilute than is the body fluid of the animals; there is thus a strong tendency for the animals to gain water. This problem has been solved in two fundamentally different ways. One is typified by the freshwater mussels, which have an enormous area of mantle (an extension of the body wall) and gill exposed to the water; it might seem that they would take up water at a high rate. The mussel, however, has developed extremely dilute body fluid—thus minimizing the tendency for water to cross its membranes—and a kidney that, because it is able to excrete very dilute urine, can excrete the excess water that does happen to enter the body. The problem has been solved in a different way by most insects in fresh water, which have a hard outer skeleton (or exoskeleton), covering as much as possible of the body; because the exoskeleton does not allow water to pass through (*i.e.*, it is impermeable), water uptake is reduced and can be handled adequately by an excretory apparatus designed for terrestrial performance.

Not all lake dwellers face the problem of an excess of water. The problem of those who live in waters many times more concentrated than the sea is to conserve water and get rid of excess salts. Relatively little is known about the excretory mechanisms of animals in such environments, however.

Water and salt balance are more easily studied in large nektonic and benthic animals than in microscopic organisms, but the latter, with their relatively thin walls and enormous surface-to-volume ratio, are exposed to severe stresses. In the case of single-celled protozoans, the problem is met by a structure called a contractile vacuole, by which dilute fluids are excreted.

Oxygen sources

Lake animals such as mussels, which have a large permeable surface exposed to the environment, are able to obtain their oxygen by diffusion from the water. Many insects, however, exploit the natural advantages of air as their respiratory medium.

Lake plants are commonly well provided with hollow tissues in their stems, through which they are able to pump oxygen down to roots and tubers buried deeply in mud. Mosquito larvae of the genus *Mansonia* tap into this gas supply with their respiratory organs and so free themselves from the usual repeated journeys to the surface to replenish their air.

Species interactions. Probably because most lakes are young and transitory, they have few of the elaborate and subtle interactions between species that are so conspicuous a part of the marine or terrestrial scene. A few cases are reminiscent of sea corals and the algae that live in them (zooxanthellae). Freshwater sponges, for example, are green because of the algae within them when they grow in the light; the same sponges are white when they grow in darkness. Some salamander eggs are usually green as a result of algae growing in the jelly masses.

Among the fishes of the oldest lakes are some interesting cases of egg predation; in one, a species of cichlid fish feeds exclusively on the eggs of mouth-brooding cichlids of other species. The predatory cichlid mimics the prey cichlid closely in colour pattern and general appearance, persuading the mouth brooder to spit out its incubating eggs.

Parasitic relations between lake dwellers are elaborate, probably because the cycle has evolved in rivers and been secondarily extended to lakes. Many parasitic life cycles involve both lakes and terrestrial organisms; for example, the schistosomes, a group of blood flukes that are widely distributed in the lakes of the world, pass several larval stages in freshwater snails but spend their adult lives in

the bloodstream of a terrestrial vertebrate. In most of the temperate zone the vertebrate host is usually a duck. Occasionally, certain of the larvae may penetrate the skin of humans, where they die, producing an annoying but usually short-lived dermatitis called swimmer's itch. In Japan and much of the tropics, however, the larvae of several species complete their development in man and cause a serious human disease.

Biological productivity. Generally, the productivity of lakes is lowest in the Arctic, intermediate in the temperate zone, and highest in the tropics. The dark Arctic winter provides little solar energy for photosynthesis, and most of the springtime period of bright sunshine and long days occurs when the lakes are still covered by a thick layer of ice. In the tropics, on the other hand, where there is an adequate supply of solar energy all year and no ice cover to absorb it, high temperatures speed decomposition of plants and animals, so that nutrients of which they are composed are returned rapidly to the water and support new growth.

Correlations with latitude

A second important influence on the productivity of lakes is the nature of the underlying bedrock. Rocks that are readily soluble and rich in nutrient elements, such as calcium, potassium, silica, and phosphorus, provide for a high and sustained rate of photosynthesis. Lakes resting on insoluble rocks, even though located in the favourable light and temperature environment of the tropics, have a productivity so low as to be unmeasurable by standard methods. It is in tropical regions of internal drainage, with much volcanic ash in the rocks—such as the rift valleys of tropical East Africa—that the most productive lakes in the world are found.

Presumably, an estimate of the total amount of each nutrient in the water and organisms of a lake would show a clear relation with productivity, but such an estimate is difficult to make. Even for phosphorus, which can be detected easily by radioisotope-tracer methods, the estimate is too cumbersome to be used on a widespread comparative basis.

There is, on the other hand, a fairly strong correlation between the bicarbonate-carbonate content of lakes and their primary productivity. This is likely to be at least partly the result of a correlation between bicarbonates and the generally unknown and unmeasurable total supply of nutrient salts, but it also may mean that plants in most lakes are chronically short of a convenient carbon source for photosynthesis.

If a lake is deep and transparent, it can sustain a respectable productivity per unit surface area while at the same time exhibiting a low productivity per unit volume of water. In a shallow lake, on the other hand, all the primary production takes place in a short water column, so that its effects, such as the production of algal blooms, are much more pronounced. This concentration of such growth is beneficial to organisms higher up on the food chain, such as zooplankton and fish, because large volumes of water are not required to obtain food. This is probably one reason the shore zone of a lake normally supports much denser populations of fish than does the open water.

The depth of mixing is important to the phytoplankton in another way. If it is so great that the phytoplankters spend an appreciable part of their time in the tropholytic zone, they may use up a large part of the food they manufacture in their own respiration. This is probably why the dense perennial blooms of highly productive tropical lakes develop only in shallow lakes or in meromictic ones, in which mixing is shallow and contained largely in the zone of trophogenesis.

Lake food chains

In general, only about 10 percent of the energy passing through one level in any food chain is consumed by the next trophic level above, which places a severe limit on the possible length of lake food chains. Few, if any, consist of more than six links, and in small lakes they may be only three links long. A high-level predator can increase its population by shortening the food chain on which it is dependent, just as human populations can (and do) by shifting from a diet rich in meat to one that is largely cereal. The resulting increase of food from a short food chain, however, is obtained at a considerable increase in the energy used to gather the food. (D.A.L./Ed.)

RIVERINE ECOSYSTEMS

The riverine environment. By volume, the rivers of the world constitute a small fraction (1 percent) of the total amount of water in aquatic systems, but their high rate of flow gives them great ecological significance. As active agents of mechanical and chemical erosion, rivers exert a major control upon the terrestrial ecosystems of their watersheds, as well as any lakes or oceans into which they discharge.

There are significant differences among the rivers of the major continents regarding chemical composition, concentration, and rate of erosion. Australia is so dry and Antarctica so cold that they make little contribution to the global budget for river transport. The streams of Asia carry almost three times as much suspended material per unit area as do those of any other continent. The river waters of South America are the most dilute; those of Africa, being similar in composition, are about twice as concentrated. North America, Asia, and especially Europe differ from the two more southern continents in carrying a much larger quantity of calcium and bicarbonate. The low salt concentration of South American rivers is offset by their great discharge.

Rivers, particularly in arid lands, show great annual fluctuations in size and other properties. Variations of four times the normal discharge and six times the quantity of suspended particles are not unusual and are accompanied by changes in current velocity, concentration of dissolved substances, and shape of the channel. The formulation of the properties of a riverine ecosystem is accordingly more difficult than it is in lakes and the ocean, and, although considerable attention has been devoted to the biology of streams, the results have tended to be descriptive and individual, with little applicability to streams in general.

Zones of erosion and deposition

A distinction is often made between a zone of erosion and a zone of deposition in rivers, but it must be remarked that, whatever the size of the particle that is moved by a flood, it will be deposited when the flow is less. It is preferable to make the distinction between zones where the bottom has stones large enough for the biggest invertebrate animals to cling to and where the bottom is of sand or mud whose particles are so small that the larger invertebrates must burrow. If a river with a sandy or muddy bottom is shallow enough, rooted plants will grow in it. Between the two zones there will be an intermediate one where fine particles settle during low flow and are washed away by a flood, and the slope, or river bottom grade, may be such that this intermediate zone is longer than either of the other two. A river from source to mouth is a continuous whole, and attempts to divide it into zones must be arbitrary. Any classification system may prove useful for a particular purpose, without being a concept with fundamental significance for biologists.

Water emerging from deep underground layers is generally cold, often with but a small range of temperature change during the course of a year, but it may be warm if it drains shallow soil. The smaller the volume of water the warmer it will become in the sun and the more heat it will lose at night. Larger water volumes have less daily temperature fluctuation and they are never far from average air temperature. If there is not a big difference in altitude, headstreams may therefore reach a higher maximum temperature than the main river. This condition, of course, has importance regarding the type of life found in the various parts of a stream.

A torrential stream is nearly always well oxygenated. A slow river is often well oxygenated by day because of the activities of photosynthetic plants, but it may be depleted of oxygen by night, when only oxygen-consuming and decomposition processes are active. Turbidity, the muddiness and cloudy condition of the water, generally increases steadily from source to mouth. Accumulated organic matter washed from the land is believed to be the main base of the food chain in running water, and therefore in hilly or mountainous regions the amount of material entering the stream that may become a source of

food tends to increase as the area drained increases with distance from the source. The amount may decrease farther downstream where the carrying capacity of the river drops with reduced flow.

An old and well-known method of dividing rivers into zones is based on the presence of one of four fish species commonly found in western Europe: *Salmo* (trout), *Thymallus* (grayling), *Barbus* (barbel), and *Abramis* (bream). Each zone as defined by these fish coincides with a given slope, though for any zone the wider the stream the more gentle the slope. Even in western Europe there is a certain inconvenience in designating the zones by species of fish, for some, notably grayling, are not widespread. Elsewhere other species must be sought. Running water systems have also been classified into zones called the rhithron, which is roughly the stony upstream region, having well-oxygenated water and with temperature rising to no more than 20° C (68° F), and the potamon, which is the downstream portion, having a sandy or muddy bottom and temperature exceeding 20° C at the warmest time of year. Both rhithron and potamon are subdivided. Within any one subdivision, however, the composition of the living community may be changed by some factor unconnected with flow or temperature, and the terms therefore have no precise biological significance though they may be useful in a general sense.

Upstream and downstream zones

Character of riverine communities. *Organisms in streams.* The slower the streamflow, the more the composition of the living community resembles that of still water, and, therefore, any discussion of peculiar features of running-water organisms must centre largely round those that have colonized the swifter-flowing waters.

Stagnant waters fill and disappear but a watercourse must flow as long as there is precipitation to supply it. It is, therefore, not surprising to find in running water certain groups of organisms that have changed little during the millions of years in which others have evolved and adapted. Most stone flies (order Plecoptera) and many mayflies (Ephemeroptera) inhabit running water, and other primitive groups confined to it include the crustacean sea hare and the caseless free-ranging caddis fly larvae of the insect family Rhyacophilidae. Moreover there are few groups of freshwater organisms that are not represented in running water. The exceptions are extreme specialists such as the phyllopod crustaceans (fairy shrimps and related forms), which must swim to feed and have survived only in temporary water where they are free from the predation to which this mode of life exposes them.

Rapidly flowing water is well oxygenated, and a moving medium brings to its inhabitants a constant supply of oxygen and also salts, at the same time removing their waste products and carrying a constant supply of food. The disadvantage of life in a moving medium is that any accidental displacement must always be in one direction. Even the organisms that live in the substratum (various layers of the stream bottom) are occasionally subject to this hazard when exceptional flow causes the substratum to shift. A further problem is the accomplishment by organisms of colonization of a biotope (uniform habitat occupied by a uniform community of organisms) that may be very long and very narrow.

Hazards of the environment

Plant communities. Stones and rock are covered by algae, many of which are single cells, though some are filamentous and trail in the water in tresslike tufts. There are many species of these, and they are often scoured off their supports by sand and gravel when the rate of streamflow increases; there are marked changes in the communities with the seasons even when this does not happen. Algae tend to occur in irregular patterns varying considerably in species composition and abundance. It has not, therefore, so far proved possible to discern definite algae communities associated with given stream conditions, though it is known that temperature, light, substratum, and dissolved substances in the water are factors that influence the occurrence of certain species.

A stone or boulder that survives for a long time without being overturned, and that is not scoured by particles of sand and gravel, will become densely covered by mosses and liverworts.

Rooted plants grow thickly where substratum and water depth are suitable, but attempts to define communities comparable with those in still water have been unsuccessful. This is partly because of the instability of the flowing water system. Once established, a tuft of vegetation impedes flow and facilitates the deposition of silt, which may alter the substratum until it becomes favourable for some other species. Eventually the vegetation may present so much resistance to streamflow that the whole mass is washed away. Many species of plants in temperate latitudes die down in winter and no longer protect silt that settled round them in summer. Copious plant growth interferes with water flow to such an extent that it often becomes necessary to cut and remove it from some streams to prevent flooding.

Animal adaptations. *Life in the streambed.* There is a zonation of animals in the substratum, as may be seen in Figure 20. If bottom particles are not too fine, there is a rich and varied animal community down to 1 metre (3.3 feet) or more below the surface of the streambed. Certain crustaceans, mites, and nematodes are restricted to these deep habitats but also abundant may be tiny nymphs or larvae, the immature insects that, when they are larger, inhabit higher regions where the particles are coarser.

Stratification of life in the streambed

Nearer the surface, in sand and gravel, may be found various animals, notably segmented worms (of class Oligochaeta) and the larvae of certain families of flies (of the insect order Diptera) that, having come in from a similar habitat elsewhere, have been able to colonize running water with little change of form and habit. Nearer the surface still, but protected from the current by the large stones above, are many animals that show no structural adaptation to life in running water, though obviously without some modification of behaviour they would not survive. Most of the stone flies, various caddis fly larvae (order Trichoptera) that make cases, and amphipods (shrimplike crustaceans) such as *Gammarus* are examples that are likely to be familiar over most of the world. Some of the stone fly nymphs are long and thin and consequently are well designed to live among the spaces between small stones and pieces of gravel. There is no rigid line of distinction between the inhabitants of the three zones mentioned.

Life at the surface of the streambed. Finally come the animals that colonize the large stones forming the surface of the streambed. Many are structurally modified for swift-water environments. The freshwater limpets (family Ancylidae) have a simple conical shell that offers little resistance to the current and a foot that forms an efficient sucker. Larvae of the net-winged midges (family Blepharoceridae) have six suckers provided with muscles that can create a powerful suction. Another similar adaptation is seen in several families of beetles and reaches its highest development in the water pennies (family Psephenidae). The body is flat and wide, and the margin is pliable and beset with spines and hairs. It can be adjusted to fit the irregularities of the surface sufficiently to prevent any water flow underneath the larva, and the pressure on the rounded upper surface tends to press it against the substratum even though there are no suction-producing muscles. In certain mayflies, modification of the nymph's gills produces the same effect. Such nymphs are frequently confined to running water because they cannot use their gills to create a current if necessary. For example, the mayfly genus *Rithrogena,* which has modified gills, respires less rapidly as current speed falls, whereas related genera that can move their gills consume as much oxygen in still as in flowing water. They occur on stony lakeshores, and species of *Rithrogena* do not.

Nymphs of the mayfly family Ecdyonuridae (or Heptageniidae) have broad flat heads with thin margins, and upper leg segments are of a similar shape though less acute at the margins. The body and legs are pressed against the surface; retaining its hold by means of sharp claws, the nymph can scuttle across a flat hard surface with great nimbleness. In the Southern Hemisphere this adaptation is found in spinners (family Leptophlebiidae), which replace the Ecdyonuridae.

Larvae of the blackflies (family Simuliidae) may perhaps

Adaptation to the running-water environment

be said to be the most highly adapted of all running-water animals because they not only anchor themselves in swift currents but also make use of the flow to bring food. At the tip of the abdomen and on a proleg near the head are pads armed with concentric rows of hooks, of which the points can be directed outward by pressure of the body fluid and retracted by muscles. The larvae can produce threads of silk, and these they lay over the surface of a stone, often where the current is swift. At intervals, tangled masses of silk are laid down. The larva can move across its silken lattice with a looping action, taking hold with fore and aft pads of hooks alternately. Most of the time it trails in the water with the rear hooks embedded in one of the tangled blobs of silk. It extends a rakelike apparatus, and when this has strained a mass of fine particles from the water the appendage is retracted and the mass is eaten.

Three families of caddis flies utilize the current to bring food. None makes a case in the fashion of most caddis fly larvae but all spin nets. Members of two of these families feed on drifting organic matter, but the third is carnivorous and lives a life not unlike that of a spider on land. Members of this family occur in still water.

Adults of most beetles (order Coleoptera) and bugs (order Heteroptera) must come to the surface periodically to renew their store of air, a necessity that is plainly inconvenient in a medium flowing one way. It is not unexpected, therefore, that in swifter regions of rivers these two orders are represented mainly by families that have developed plastron respiration and can live permanently on the bottom (riffle beetles, family Elminthidae, and creeping water bugs, family Aphelochiridae).

Factors affecting communities in streams. Several factors influence the composition of the communities. It is impossible to separate the effects of streamflow and substratum. When current falls to a speed at which fine particles settle, the animals that inhabit the spaces between small stones and pieces of gravel are replaced by burrowing forms, of which the main groups are oligochaetes (worms), lamellibranchs (clams, mussels), and chironomid larvae (flies). Nymphs of the burrowing mayflies (family Ephemeridae) burrow in sand and mud, and some dragonfly nymphs have also taken to this way of life, particularly in Africa.

A varied animal community is found in vegetation, if this develops. Animals with adaptations for life on a hard flat surface, such as the mayflies of the family Ecdyonuridae or limpetlike mollusks, do not occur, but less specialized forms such as the shrimplike *Gammarus* may continue in great numbers. *Simulium* (gnats and blackflies) and *Baetis* (mayflies) are two genera that are also abundant in both stony and weedy zones, though the species are generally different in the two.

Within one zone, rate of flow is probably not of great importance for most species since they live among stones, avoiding places exposed to the full force of the current. It is important to the net-spinning caddis fly larvae, which must find a place where current speed lies within a narrow range. It has been shown experimentally that a change in the pattern of flow is quickly followed by a change in the distribution of their nets.

Relation between stone size and species colonization

Different kinds of rock break up into stones that differ in shape and size and texture, but whether this affects the communities that colonize them is not known. That the distribution of certain species that inhabit streambeds of fine particles is related to the size of the particles has been clearly established. In Europe the green drake mayfly (*Ephemera danica*) inhabits sand, and the common mayfly (*E. vulgata*) mud, and several similar examples have been described in North America. Stones that have been rounded by abrasion during transport by ice or water provide a difficult substratum colonized only by agile animals. Flat stones that move less easily harbour a more varied community, and it is richer still if, as generally happens, the stones become covered with moss.

Springs and the stretch immediately below them are often inhabited by species not found elsewhere, and some of these are confined there by their requirement of low temperature. One of the few species that has been thoroughly investigated, both in the field and in the laboratory, is the flatworm, *Crenobia* (*Planaria*) *alpina*. It is commonly

confined to water whose maximum temperature does not exceed 15° C (59° F), though it can tolerate 25° C (77° F), provided it is not exposed to it for too long. Reproduction generally takes place only in water colder than about 12° C (54° F). Other animal species are confined to cold water not by physiological limitations but by their inability to compete with a rival in warmer water. Britain for example lacks the amphipods *Gammarus fossarum* and *G. roeselii* and instead *G. pulex* ranges in British streams from source to mouth. In Europe *G. pulex* is confined to the middle reaches of flowing waters and is apparently kept out of the upper ones by *G. fossarum* and the lower ones by *G. roeselii*.

Animal populations tend to be densest in those places where the configuration of the bottom produces areas of still water with consequent settling of debris. In addition some of the most notable changes in the composition of the population can be related to food supply. Below lakes the water is rich in floating algae and tiny drifting animals as well as suspended organic matter, and here the numbers of net-spinning caddis flies and blackflies are much higher than elsewhere. They appear to exclude other species found under similar conditions of flow and substratum but without the augmented food supply. Slight enrichment by sewage leads to an increase in the number of flatworms and a decrease in the number of certain other species. It has been suggested but not proved that the flatworms eat them. In rivers enriched by the decomposition of sewage, great numbers of *Asellus* (a freshwater crustacean), leeches, mollusks, and alderflies (*Sialis*) are found. Below the zone of enrichment these animals become progressively scarcer and are replaced by the community associated with similar conditions of flow and substratum in unenriched water. Again the full interrelationships have not been worked out. Decomposition of sewage is accompanied by lowered oxygen concentration in the polluted waters, and the typical inhabitants of stony rivers require a high concentration. There is also evidence that they are adversely affected by the bacteria that coat the stones and indeed some of the animals themselves. In lakes the most plausible explanation at present is that predation by the species favoured by enrichment leads to the elimination of the species typical of areas where there is no enrichment, and it is reasonable to postulate that this factor operates in running water too.

Life cycles

Life cycles of running-water animals are unexpectedly diverse and offer a rich field for experimental investigation. Nearly all the observations have been made in temperate regions. A number of animals, notably the larger ones such as leeches, snails, bivalve mollusks, and crayfish, take more than a year to reach maturity. Many are univoltine; *i.e.*, they take one year to complete development. Some species in the genera *Baetis* (mayflies) and *Simulium* (blackflies) and in the caddis flies pass through two generations in a year. Quicker development is rare, *Gammarus pulex* being an outstanding example, completing its life cycle in less than two months.

Many of the univoltine species have a resting stage, which generally tides them over the warm period of the year. It is often the egg stage, sometimes the early nymphal stages, and sometimes, chiefly in caddis flies, the last larval molting stage. The common European spiny crawler mayfly (*Ephemerella ignita*), apparently spends some 10 months in the egg stage, at least in parts of its range; nymphs appear about midsummer, grow rapidly, and emerge in August or early September. In other species, the small minnow mayfly (*Baetis rhodani*) for example, some eggs remain unhatched for many months, whereas others hatch after a few weeks.

A net set so that water flows through it catches representatives of many of the species inhabiting the stream. Catches of most are much higher by night than by day and are often greatest just after dusk and sometimes again before dawn. This phenomenon, commonly referred to as drift, has been much studied and has provoked several controversies. The number of specimens drifting seems to bear some relation to the population in the stream and is at its highest during the period of most rapid growth. Therefore it probably represents to some extent a removal of surplus population. Drifting animals are likely to fall prey to fish, but there is evidence that those that escape this fate do not travel far before regaining the safety of the bottom. Some of the larger adult caddis flies have been observed flying upstream to lay their eggs, but there is evidence that other insects do not maintain the population in the upper reaches in this way. Many have been shown to move against the current during the aquatic stage of their life cycles, particularly when small, and it is likely that uniform colonization of all suitable stretches of a watercourse is maintained in this way.

Detritus, drifting organic matter originating from dead leaves and other vegetable fragments that are blown or washed into the water from the land, is the main primary source of food in rivers and streams. The limpets, the flat nymphs of the mayfly family Ecdyonuridae, and larvae of various caddis flies graze upon the algal felt that covers the upper surface of stones but probably subsist extensively on the detritus trapped in this. Detritus may also stick to the mucous trails left by flatworms or lodge in the irregularities of a rough surface. Little is known about the digestive powers of the various detritus feeders. That vegetable remains are not an easy source of food is indicated by the frequency with which they are passed twice through the same intestinal tract. It is likely that the actual source of food is the fungi and bacteria that are breaking down the vegetable tissue. The flatworms, the large stone flies, some of the caddis flies, and many fish are carnivores.

Detritus

Biological productivity. In a study of total production of flesh by trout (*Salmo*) per year in the Horokiwi Stream in New Zealand, there were about 50 grams per square metre (*i.e.*, 500 kilograms per hectare, which is approximately 450 pounds per acre). An important point that came out of this investigation was the large contribution to production made by young fish, whose size was very small but whose numbers were large. Fish are comparatively easy animals with which to work, mainly because of their large size and the fact that the eggs hatch within a short period. Moreover the young do not live in the substratum. The trout establishes territories whose sizes depend on the configuration of the bottom and not on food supply. Fish secure efficient exploitation of the resources of the environment by means of an indeterminate size at maturity. If food supply is poor, the fish remain small; if it is good, they grow much more rapidly; but sexual maturity is attained after a period that does not vary significantly with size, and the small fish reproduce just the same as normal adults. That calculations of production by populations of wild fish are of the right order can be confirmed by comparison with the extensive data obtained by commercial cultivators. Consequently there are reliable figures for the production by several species in the wild state.

Information about invertebrates is much less satisfactory. It was discovered how much the trout in the Horokiwi ate, and it turned out to be some 17 times greater than the number of invertebrates apparently available as food. This observation, known as Allen's paradox, has been confirmed also in other parts of the world. In other words, production is underestimated. It is possible that unaccounted-for populations among running-water animals are to be found well below the surface of the substratum, where it is known that tiny nymphs abound and where most sampling instruments do not penetrate. They may also be washed down from the smallest tributaries, which are too shallow or too swift for fish to enter. This explanation of Allen's paradox is speculation, but it is plausible. What can be stated with confidence is that, until an explanation has been provided and verified, calculations of production of invertebrates are premature.

Allen's paradox

Measurement of primary production by algae is difficult because any enclosing of them in containers, the technique that has been used extensively in lakes, alters the environment drastically by cutting off the current. Measurements of changes in the concentration of oxygen in a natural stream have been made, but the difficulty of ascertaining the amount of exchange between air and water has not been entirely overcome. Results suggest that primary production by algae is generally low. In contrast, that by rooted vegetation may be high. (T.T.M./Ed.)

Boundary ecosystems

Between the water and the land, and between one kind of water and another, a diversity of ecosystems exists. Small in extent, they differ from each other more, in some respects, than do standing and flowing waters; for convenience, they are here treated as a group.

BOUNDARY SYSTEMS BETWEEN WATERS

Estuaries. Boundary systems in which there is an appreciable current are most like oceans, lakes, and rivers. Estuaries, in which seawater is diluted by freshwater inflow, share many features with rivers and the ocean. An estuary has a net seaward flow equal to the discharge of its tributary rivers, but that flow is affected by the surge of tidal currents. It also has other distinctive features of circulation. As river water in an estuary reaches seawater, the river water, being lighter, rides on top and, having a considerable velocity, tends to drag the upper part of the seawater underlayer along with it. Under steady-state conditions, this salt water carried seaward by the fresh surface flow is continuously replaced by a landward flow of seawater at greater depths. Variations of this basic pattern are produced either by differences in size and shape of the estuary or by differences in the relative importance of river discharge and tidal mixing. The typical estuary may, however, be thought of as a two-way flow: the seaward-flowing water is lighter, at the surface, and of low salinity, and it courses along the right bank of the estuary (facing downstream) in the Northern Hemisphere and along the left bank in the Southern Hemisphere, because of the inertial effect of the Earth's rotation; the landward flow is heavy, deep, and saline and courses along the bank opposite from the seaward, surface flow.

Flow directions

A pollutant introduced into an estuary, therefore, is partitioned between the two flows and moves landward as well as seaward (see RIVERS: *Rivers as agents of landscape evolution: Estuaries*).

Lagoons. Coastal lagoons in arid regions have a current system that is opposite to that of estuaries. Seawater flows inward on the surface at the inlet to replace the water that is lost from the lagoon by evaporation, and dense water flows outward at depths and maintains the salt balance of the lagoon. In cases in which a lagoon is cut off from the sea, some parts of the lagoon may become two or three times saltier than the sea. The fauna is often that of brackish water—for example, nereides (polychaete worms), certain small clams, the barnacle *Balanus eburneus,* mullets, sand smelts, and cyprinodont fishes. Lagoons supplied with an inflow of fresh water that more than balances its loss due to evaporation may be much less salty than the sea and have a fauna with more fresh-water-tolerant, but related, species (see also OCEANS: *Features of the oceanic shoreline: Lagoons*).

BOUNDARY SYSTEMS BETWEEN WATER AND LAND

Shores. *The shoreline environment.* A great variety of plant and animal life is compressed into a narrow strip along the rim of the sea, stretching from the highest level wetted by waves at the highest tides down through low tide to a level where seaweeds cease to grow. This zone of coastal life can be as much as 100 metres (330 feet) in vertical extent but is usually much less. The upper limit of the zone depends on how high the waves can reach; cliffs exposed to frequent ocean storms may be wetted 30 metres (100 feet) or more above nominal high tide. The lower edge of coastal life may be the edge of the seaweed "forest" or the seaward slope of a coral reef, or it may merge imperceptibly with the benthic life of the seabed, as on many sand beaches. The lower limit of coastal life depends on extent of light penetration and varies from a few metres in muddy waters of temperate and Arctic regions to 100 metres in clear tropical seas.

A factor common to all coastal life is the continuous water movement: the daily or twice-daily rise and fall of the tide, the perpetual to-and-fro of alongshore currents, and the crash and wash of wind-formed waves. By these means the supply of oxygen and nutrients in the water is continuously renewed.

In most parts of the world, the tide is the most obvious environmental influence on the shore. The period of the tide and the extent of the rise vary significantly, and the part of the shore directly influenced—the intertidal zone—also varies greatly in extent and type.

Wave action along the shore also varies, but much more irregularly than the tide. Its influence is difficult to relate to the distribution of coastal life and almost impossible to separate completely from purely tidal factors.

It is obvious that physical forces mold coastal communities. Not so obvious, but just as certain, is that the organisms themselves affect the habitat. Gastropod mollusks such as winkles, limpets, and top shells (turban shells) contribute significantly to erosion of the rock while grazing on attached seaweeds. Erosion from such sources is uneven, resulting in the formation of pits and hollows that encourage other erosive forces. Along the open ocean coasts of Portugal, Spain, France, western Ireland, and the northwestern United States, sea urchins honeycomb the lower rocks. A group of bivalves found on most shores can tunnel into all but the hardest rock.

Organisms' effect on shore habitats

The animals living on sandy and muddy shores vary widely in response to the predominant size of particles making up the shore surface (*e.g.,* whether coarse sand, fine sand, silt, or mud). Many of the animals continually burrow in the deposit and turn it over much in the same way earthworms do on land. Where the deposit is sheltered from wave action, complex burrows and hollows may build up.

Many worms and some mollusks secrete tubes made of limestone or of sand grains cemented together. In some parts of the world, sizable aggregations of these tube-building creatures build up large reef structures near the low tide level of the shore. The greatest reef builders, of course, are the corals and other organisms associated with them in tropical seas.

The ecologist divides up the shore and shallow sea into a series of horizontal belts, or zones, according to the dominant plants or animals found in each (Figure 21). The widely used scheme of T.A. and Anne Stephenson recognizes three main zones and two fringing zones. The supralittoral zone, subject to salt air and some spray but not normally wetted by the highest tides, is inhabited by salt-tolerant lichens and maritime land plants, insects, and coastal birds. On sandy shores this is the seaward side of the dune formation, and in mangrove swamps the upper edge of the buttonwoods. On tropical shores there are animals of marine origin, including robber and ghost crabs. The supralittoral fringe extends from the highest level washed by the waves at high tide down to the upper limit of barnacles. The organisms in this fringing zone are wetted only by the higher tides each month and may thus remain dry for several days at a time. On a rocky shore the typical inhabitants are small winkles and the dark, encrusting marine lichens that form a black band on the

Habitat zonation

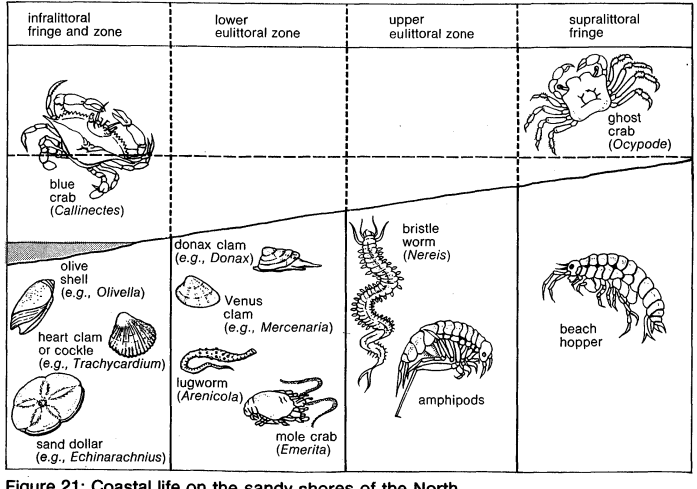

Figure 21: Coastal life on the sandy shores of the North American coast.

rocks (Figure 22). Some grapsid crabs and isopods may be found, though these all take refuge in crevices when disturbed. The red alga laver, or nori (*Porphyra*), and, in the North Atlantic region, two brown algae, *Pelvetia* and spiral wrack (*Fucus spiralis*), occur at the lower end of the zone. The eulittoral, or mid-littoral, zone can be divided into three subzones on most rocky shores. The uppermost part is usually dominated by barnacles (*Chthamalus, Balanus*) and by more of the winkles. In shelter, algae may take over from the barnacles—for example, in the North Atlantic and North Pacific, various species of brown seaweeds (fucoids) and the green alga *Enteromorpha.* The middle region of the eulittoral is often barnacle-dominated like the upper part, but limpets, mussels, and stalked barnacles (*Pollicipes*) may be present; in shelter from wave action, the barnacles tend to be overshadowed or replaced by algal growths. The lowest part of the eulittoral is the easiest to distinguish; it often lacks barnacles and may be dominated by a red algal turf or by an association of limpets and encrusting calcareous algae or by large brown seaweeds. Locally it may show reefs formed from the tubes of marine worms or mollusks or sheets of anemones. The

Infralittoral fringe

lowest part of the intertidal zone is called the infralittoral fringe and is often regarded as an upward extension of the infralittoral (sublittoral) zone. The fringe may be continuously submerged for days and is often characterized by growths of large brown seaweeds. Where the laminarian seaweeds are not present, the infralittoral fringe may take the form of a turf of small red seaweeds of many genera, without large limpets and with masses of encrusting calcareous algae, or in tropical regions it is part of the coral-reef formation. Other more local forms of the infralittoral fringe also can occur: groups of sea urchins, associations of anemones and starfish, and beds of marine grasses, which can mingle with the laminarian seaweeds present. In the Southern Hemisphere a fringe of sea squirts (class Ascidiacea) sometimes dominates this part of the shore.

Adapted from *Ecology and Field Biology* by Robert Leo Smith, illustrated by Ned Smith (Harper & Row, 1966)

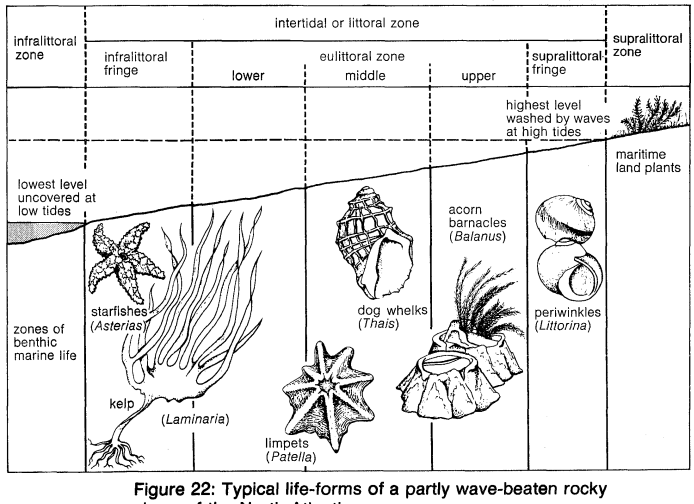

Figure 22: Typical life-forms of a partly wave-beaten rocky shore of the North Atlantic.

As already noted, the infralittoral or sublittoral zone itself is not unlike the infralittoral fringe, and many organisms are common to both. In temperate and cold climates it is preeminently the home of the large seaweeds (laminarians and giant kelps) that can reach up from as much as 30 metres depth to float part of their fronds at the surface. In warmer waters the corresponding algae are much smaller. As the influence of exposure to air and strong light decreases, the hardy forms typical of the intertidal zone become less abundant and their place is taken by more delicate forms; *e.g.,* smaller limpets, gastropod mollusks, sponges, long-spined sea urchins, starfish, and the finer red algae. In the tropics the infralittoral zone is often part of the coral reef formation.

Sand and mud shores

On sand and mud shores the same basic zones can be recognized, though the organisms are different from those described for rocky shores. The supralittoral fringe of a sandy shore is the semiarid region of loose sand near the high-water mark, with varying amounts of dried seaweed fragments and other detritus left by the tide; it is inhabited by sand hoppers, which live in burrows in the damp sand. The corresponding part of a mud shore may carry a typical salt marsh association (see below) or may be a shingle (pebbly) bank with sand hoppers among lines of rotting seaweed. The eulittoral of sand and mud shores is usually inhabited by several types of polychaete worm, the most typical being lugworms. Other worms, such as nereides and spionids, may be commonest near the upper edge, corresponding to the barnacle zone of rocky shores, while other nereides and *Nephtys* may predominate lower down. On wave-beaten shores, the worms are fewer but are accompanied by a large transient population comprising crustaceans, amphipods, isopods (which swim about in the sea at high tide), and the mole crab (*Emerita talpoida*). The fiddler crab (*Uca*) occurs widely on sand and mud shores. With increasing shelter from wave action, a beach becomes less sandy and more muddy and is inhabited by the smaller mollusks, which are common in the lower half of the eulittoral, and in full shelter the larger clams may be found. The infralittoral fringe of a sandy shore is usually inhabited by the same worms and mollusks found higher up, but in addition there are razor clams, cockles, heart urchins, and sand dollars. The infralittoral fringe is less marked than the rocky shores, and many of these organisms continue below the level of low tide. At locations where a few loose stones occur and where water movement is slight, brown seaweed occurs, while in muddy places the marine eelgrass (*Zostera*) forms dense beds.

Character of shoreline communities. One of the most characteristic features of life on the rocky shore is the tenacity with which the organisms attach themselves. The large brown seaweeds have strong disk-shaped or root-like extensions of the thallus by which they hold fast to the rock. Many of the animals (*e.g.,* the barnacles and tube worms) are permanently cemented to rock. Other animals, such as the limpets, have a large muscular foot capable of strong temporary attachment to the rock surface. Some shore animals, such as small crabs, amphipods, and isopods, resist detachment by the waves by fitting themselves into crevices, using some of their legs as anchors. Small crustaceans and mollusks take refuge among the fronds of seaweeds. Perhaps the most highly adapted clinging organ is found in the sucker fish (family Catostomidae), which has pelvic fins modified as vacuum cups.

Attachment methods

Many inhabitants of severely wave-beaten rocky shores also show adaptations that reduce the effects of waves; *e.g.,* the depressed conic shape of limpets and barnacles, the short, relatively unbranched yet flexible and mucus-coated thallus of the seaweeds.

The animals of the shore are ultimately dependent on seaweed and larger plants for food, supplemented by plankton from the ocean and by organic debris from the land. The main herbivores of the shore—the limpets, winkles, and top shells—are all grazers. They feed on the mature, large algae directly or on the smaller recently settled plants and other simple algae that grow on rock surfaces. Pieces of seaweed that accumulate after a period of rough seas also are eaten by winkles and top shells, which can thus act as scavengers.

Most of the crustaceans of rocky shores feed on a wider variety of organisms and also are scavengers. The barnacles that sweep the water passing over them with a net formed from six of their appendages can eat anything from microscopic algae up to crustaceans a few millimetres long. Other crustaceans stir up and sort over the silt that often collects in crevices. Bivalve and vermetid mollusks, as well as some tube worms and sea squirts, feed on floating particles that they remove from the water by filtering.

The predators of rocky shores include dog whelks (*Thais*), phyllodocid worms, crabs, and shore fishes. Many of these predators, especially fishes and starfishes, lurk in pools and crevices or below low-tide mark and come up to feed only at high tide. In contrast, rodents and seabirds feed on mollusks and crustaceans when the tide is low. On sand and mud shores, large plants occur only at the upper and lower levels (*e.g.,* grasses at and above high tide, eelgrass at

low tide), but on very sheltered mud flats some green algae (*Enteromorpha, Chaetomorpha*) form mats on the surface in the eulittoral zone, while in salt marshes there may be clumps or beds of reedlike flowering plants. There may also be films of microscopic algae lying free on the surface or between the particles of the shore. These diatoms and flagellates can show daily and seasonal changes and may be numerous enough to give the surface a greenish or yellowish tinge.

Burrowers and tube formers

Larger animals of sandy and muddy shores include burrowers, which form galleries in the substrate, and tube dwellers, which live in tubes formed from secretions and sand grains or both stuck together. The burrows and tubes are only a few centimetres deep in the case of small amphipods and spionid worms, but half a metre or more with large worms and clams. Many of the animals feed by ingesting sand or mud and sorting out and digesting the organic fraction inside their gut. Some carry out more complex sorting operations to explore the surface of the ooze and suck in lighter particles. A large proportion of the mollusks of beaches are plankton feeders, who lie in the substrate with extensible siphons raised above the surface of the bottom. The sabellid worms found at low-tide levels feed in much the same way.

On the whole, predators are less common in sandy or muddy beaches or are less easy to recognize. There may be predatory gastropods and various small crabs, but much of the predation occurs at high tide, when crustaceans and fishes move in and attack exposed siphons and tentacles of partly buried plankton feeders. At low tide wading birds probe wet places with their beaks or puddle shallow pools with their feet to get at crustaceans and other small animals buried shallowly. Some animals of muddy shores are more or less sedentary (*e.g.*, tube-living worms such as the clymenids and sabellids), but others, like the small clams, are mobile and search for food. Generally, plankton feeders are evenly spread out, while deposit feeders aggregate where the organic content is highest or the particle size easiest to sort.

Productivity of shoreline communities. The large seaweeds are the most obvious primary producers of energy-containing matter. In the northern, cool temperate regions, the fresh weight of brown seaweeds such as knobbed wrack (*Ascophyllum*) can reach 32 kilograms per square metre of shore, and one kilometre of shoreline may hold up to 40 metric tons of one species of laminarian seaweed. The annual production of new organic matter from these plants averages about 10 to 20 metric tons per hectare per year. This production on rocky shores may be compared with production values of 20 to 30 metric tons per hectare per year from the best cultivated crops on land, and 30 to 75 metric tons per hectare per year from salt marshes and tropical swamps.

Primary and secondary producers

The algal symbionts in animal tissue are a special case. Primary production in coral may be as high as 30 to 40 metric tons per hectare per year, though the algal biomass may be no more than 700 grams dry weight per square metre. Of this, the larger proportion belongs to filamentous algae growing within the reef structure below the animal tissue, and not to the symbiotic algae. The total animal tissues in a coral reef may reach 200 g/m^2, and it appears that the primary production just about balances the needs of this animal tissue.

The phytoplankton in the sea is the least productive in terms of unit area and is generally found to be about one to five metric tons per hectare per year. The relatively greater production of coastal communities is a matter of greater actual utilization of energy in the shallow-water habitat and a better supply of nutrients circulated by vigorous water movements.

The production of animal organic matter, the so-called secondary production, is always less than the primary production on which it depends for its existence. On rocky shores the animal biomass may include 200 to 300 grams of dry organic matter per square metre of barnacles, 200 to 2,000 g/m^2 of mussels, but only 60 to 100 g/m^2 of littorinids. The barnacle zone of the eulittoral zone of a Pacific shore has been shown to contain 315 g/m^2 of algal tissue, 2.2 kg/m^2 of barnacles and other filter feeders, and 130 g/m^2 of limpets, winkles, top shells, and other herbivores. In limpet-dominated communities, there may be only from 20 to 50 g/m^2 of these herbivores, and since many of them live a long time and grow slowly, the annual production will be much less.

In sand and mud communities the biomass can be even smaller. For example, high values of the order of 20 to 80 g/m^2 of clams and 4 to 12 g/m^2 of lugworms (*Arenicola*) have been noted in favourable places, but average shores of muddy sand show a total biomass of only 1 to 15 g/m^2, of which the largest component are lugworms. There are as yet no estimates of production of animal matter in the entire community of a sand or mud shore, but in warm waters the small clams may grow fast enough to show an annual production of two to three times the biomass, which is, however, very small (0.2 g/m^2).

It seems that, of the high primary production of shore communities, only a small proportion, less than one-tenth, is turned into animal matter, even less if allowance is made for the contribution of organic matter from the land and the ocean. The shore is less efficient overall than the ocean in spite of having higher primary production, and much of the organic matter of the shore is lost to other communities—*e.g.*, to coastal plankton, to benthic life below the level at which seaweeds grow, and to land animals.

(A.J.So./Ed.)

Other boundary systems between water and land. Coral atolls and salt marshes are both systems in which a solid surface is bathed by a continuously renewed supply of water. In the case of the atoll, it is full-strength seawater, swept over the reef by the trade winds. In the case of the salt marsh, it is estuarine water flushed in and out by the tides.

The coral community is diverse, with many species of organisms. The salt marsh community, however, is simpler, with many individuals of a relatively small number of species. Both systems provide a surface to which producers can attach as they extract nutrient salts from the flow of water past them.

Groundwater is not without life. A sparse fauna lives in subterranean streams, feeding on the detritus washed down from the surface or carried into caves by other animals. Blanched and eyeless groundwater fishes and crustaceans are found chiefly in caves or where wells pierce the water-bearing layer in which they live.

Swamps, marshes, and bogs

In addition to salt marshes, with their abundant tidal flow, there are many kinds of wetlands that have so little flow that they are best considered as semiterrestrial analogues of standing waters. The principal distinction of importance is between swamps and marshes, on the one hand, which have access to mineral-rich groundwater; and bogs, on the other, which are insulated from groundwater by a thick layer of peat and receive most of their water and mineral salts through the atmosphere. The terminology of wetland types is confused by the use of many names, such as fen, mire, and carr, all of which, like swamp, marsh, and bog, are, by origin, simply local names meaning "wet land." For ecological purposes it seems sufficient to distinguish wetlands with trees as swamps; wetlands without them as marshes; and wetlands receiving their water and salts from rain as bogs.

Because of reactions between peat and bog water, the supply of dissolved salts is decreased below that in rain. As a result, the nutrients needed by plants for growth are in short supply, and many bog plants—such as sundews, pitcher plants, and bladderworts—have evolved the habit of trapping insects and other small animals to augment the meagre supply of mineral food in the water.

The great accumulation of acidic peat under a bog—often raised some metres above the level of the surrounding countryside—is an extreme case of one of the general puzzles of aquatic ecosystems: in few of them is all the organic matter produced in photosynthesis broken down completely after the death of organisms. A certain residue of organic matter remains and is preserved in a basin of sediment. Evidently, the sedimentary bacterial community is incapable of anything approaching complete decomposition of the organic matrix in which it lives. It is a curious fact that no microorganisms make use of this undecom-

posed residue—a fact to which human beings owe their supply of fossil fuels, such as coal, gas, and oil.

The best basis for comparison among ecosystems is probably photosynthesis by green plants. There are boundary systems without photosynthesizers—a cave stream, for example—but they have no primary production. The food that sustains them is imported from outside the system. They may have a productivity of blind crayfish, but their net production of organic material is negative.

Unfortunately, there is no generally applicable method for measuring primary productivity in all boundary systems. In places with a strong seasonal pulse of growth—as in a temperate cattail marsh—the maximal amount of plant material present after a growing season can be harvested in order to estimate net primary production, which is somewhat smaller than the gross rate because it takes no account of food consumed by the cattails (family Typhaceae) to maintain themselves over the season of growth or of cattail substance that may have been consumed by animals or bacteria during the same span of time. Other methods depend on measuring changes in the quantities of various substances, commonly oxygen or carbon dioxide, in the medium in which the plants are growing.

(D.A.L./Ed.)

TERRESTRIAL ECOSYSTEMS

A terrestrial ecosystem is a landscape that supports life; its components include earth materials at least as deep as roots extend, boundary layers of air, films of water, and interacting organisms. It is these components and the interactions and diverse relations among them that fulfill the concept of an ecological system.

Land as a medium for life. The complexes of terrestrial ecosystems in Table 9 indicate the wide range of temperatures and precipitation encountered in different communities throughout the world. If monthly or hourly extremes of these and other climatic variables are considered, as well as the conditions at different levels (microenvironments) above or below the ground, some idea may be gained of the constraints that land organisms had to overcome, during their evolution, after leaving the confines of water. Organisms that are available to colonize a given area and the local physical factors of soil, topography, and moisture availability limit what can arrive, survive, and thrive.

Pioneer organisms

Pioneer organisms may change a bare land surface, thus making it suitable for other species, which, in turn, further modify the local ecosystem and prepare the way for still later generations. Some combinations of species persist for hundreds or thousands of years if average rates of change of soil and other internal system conditions are slow enough. For intervals of more than a few thousand years, however, gradual shifts in the boundary conditions are imposed from larger systems (*e.g.*, climatic changes bringing on glaciers and major relocation of populations and life zones; gradual shifts and extinctions of species available over wide regions). Undisturbed natural systems adjust accordingly on a time scale that is long by comparison with the recovery times of communities resulting from perturbations of both human and natural impacts. Organisms along the evaporating fringes of the ice cap creeping into Antarctica's dry valleys may encounter water during only a few days in summer. Mountains—from Antarctica, along many Andean summits, around the Plateau of Tibet, and locally elsewhere—reach altitudes above which only wind-borne, wind-nourished life (with few or no vascular plants) persists. These and other extreme outposts of Earth's life were colonized from places where the obstacles to survival were not so severe.

The use of studies of successively smaller ecosystems and subsystems—not in isolation from one another but as nested in the progressively large systems—provides the breadth of data needed to comprehend fully the workings of the global ecosystem.

Smaller systems are dependent on larger ones in many ways. Like space vehicles or stations, some fascinating natural ecosystems depend on the importation of outside energy and some nutrients.

Fewer than 133 million square kilometres (51 million square miles) are accounted for by glacier-free land, compared with 362 million square kilometres (140 million square miles) by the oceans and adjacent waters. Small, but important, fractions of these areas lie in shifting boundary zones between land and water. Floodplain, swamp, and delta complexes include some of the world's most productive landscapes. Tides and currents, however, wash away some nutrients from these complexes—and from grassy salt marshes—fertilizing shallow marine waters and stimulating the aquatic food chain growth.

Even regions so dry that they have no exterior outlets of water to the sea gather saline waters in some rare storms or during moist years. Adjacent flatlands of sodium chloride and even sodium carbonate may be mostly barren but yet support salt-tolerant plants at certain times and places after water flows in from surrounding highlands.

As noted previously, such cases of shifting boundary conditions of land and water are of interest partly because special displays of clear-cut environmental control of life can be sorted out in the extremes. Similarly, bogs and mires receive widespread interest as wetlands dispersed widely, from the vast lowland Arctic tundras through boreal forest (taiga) belts to a few places farther south.

The ancestors of present land life evolved in fresh and salt waters with the appropriate membranes and metabolic processes for selecting the scarce elements and compounds that each cell requires for survival, possible genetic change (mutation), and further evolution.

Adaptation to land living

Limiting factors to living on land. Many adaptations were required before organisms could leave the seas and live on the land. Most green plants evolved from algae that had fluid sacs (vacuoles) inside cells which helped maintain water and chemical balances in the living cell substance. Vascular conducting systems help pipe water to all tissues. Impermeable outer coverings control outgoing water and incoming carbon dioxide through special openings called stomates, which are regulated by guard cells. Specialized adaptations have allowed desert succulents to take in carbon dioxide at night, when temperature and stress of moisture loss are low. Certain organisms have drought-resistant cytoplasm. Lichens, fungi that enclose algal cells in a biological partnership, survive far into the polar regions and into temperate and tropical deserts. The right species can photosynthesize for brief periods under favourable conditions of moisture or humidity, while resisting attrition of their accumulated assets of water and organic compounds during the long times of intervening aridity. In the dry as well as in fairly wet areas of tundra and taiga and especially in the rocky parts of mountain landscapes, other lichens and many mosses illustrate the patchwork patterns of colonization such as might have occurred as the continents first became populated by green plants. Microbes and animals were ready to follow, consuming dead or live organic matter, or both.

Major life forms and classes. *Growth habits and indicator organisms.* A classic ecological approach to interpreting environmental constraints on regional plant formations or local community and site types within regions is based on the kind of plant group, or life-form, that predominates (see Table 8). Anglo-American and Soviet forestry traditions have tended to emphasize the indicator value of such life-forms and, where possible, the genus and species of the main community or perhaps each of several layers (strata) approximating a class. The preliminary indications of community change are based on the prevailing heights of plants constituting the class and include the appearance of different species combinations in seedling or other young strata as compared with the vegetation that currently dominates.

In a complex ecosystem, however, the species of greatest abundance is frequently not such a sensitive indicator of habitat conditions as are others having lesser

Table 8: Life-Forms of Primary Producers

plant life-form group	height	Raunkaier categories*
Epiphytes (growing on plants of the following groups)		
Woody or evergreen perennials (bud-bearing shoots above ground)	buds more than 0.25 metre above ground	Phanerophytes
Trees (one to few stems; self-pruning)	taller than 30 metres	Megaphanerophytes
	10–30 metres	Mesophanerophytes
	less than 10 metres	Microphanerophytes
Shrubs (smaller woody plants, often with many stems and with shoot replacement)	taller than 0.5 metre	Microphanerophytes
	less than 0.5 metre	Nanophanerophytes
Subshrubs	less than 0.25 metre	Chamaephytes
Semishrubs	partly dying annually	Chamaephytes
Lichen–moss layer(s)	buds near ground surface	bryoid-chamaephyte
Perennial (or biennial) herbs		
Grasslike (including sedges, rushes, etc.)	buds near ground surface	Hemicryptophytes
Forbs (including non-grassy herbaceous plants)	buds below ground	Geophytes
Water plants	buds or bulbs below water	Hydrophytes
Marsh plants	buds or bulbs in wet ground	Hydrophytes
Annuals		
Summer, winter, and facultative perennial	"buds" in seed	Therophytes
Special forms†		

*A traditional standard terminology for life-forms as devised about 1900 by C. Raunkaier, a Danish botanist. †Including bamboos (woody grasses), tuft plants, climbers (lianas), succulents (stem and leafy).

Eurasian ecosystem classification

abundance but greater fidelity or differential occurrence. Several Eurasian schools of ecosystem classification and newer techniques of statistical analysis have introduced the relative importance of various combinations of factors distinguishing one ecosystem type from another.

Ecologically similar species within major genera are recognizable among distant areas—especially in the Northern Hemisphere. On the other hand, the physical constraints of water relations and energy balance have led to convergent evolution of similar life-forms from genetically distant stock. Notable examples among plants include the hard-leaved (sclerophyll), mostly evergreen scrub and woodland or forest in the winter-rain, summer-drought (Mediterranean-type) climates of Chile, Australia, and California, as well as southernmost Europe, northernmost and southwest (Cape) Africa, and areas of southwest Asia.

The evolution, successional change, and seasonal movements of animals are related directly to plants that provide them food and shelter. In the cold or dry regions noted earlier, herbivorous and especially predatory and scavenging animals may have to range widely to survive and reproduce. Warmer, humid regions include migrants as well, but they also allow many other organisms within almost any habitat.

Classification by habitat. The habitat—where an organism lives—is frequently used to categorize the living things in an ecosystem. The range of such categories within terrestrial ecosystems may be divided broadly into soil organisms, rooted plants, organisms attached to plants, and free-moving animals.

Soil organisms include a size range from microbiota (microorganisms and minute animals) through mesobiota (arthropods and smaller larvae) to macrobiota (roots of plants, larger invertebrates and burrowing vertebrates). Plants provide an aboveground layer consisting of prostrate herbaceous plants, shrubs, vines, and trees. The organisms that attach to such plants are called epiphytes; those that cling but can move are often called periphytes. The freely moving animals—both walking and flying—are referred to as permeants.

Classification by niche. Not only the habitats but the niches (operating roles of organisms throughout their life) are involved in a careful consideration of ecosystems and their evolving populations. Just as people "find their own niches" in a complex society and adapt, through learning, to their own special vocations, an indefinitely large number of species possibilities have been narrowed down during the course of evolution to those especially adapted to definite and perhaps discrete "vocations" in a natural ecosystem.

Considering first the environment as conditioning a local ecosystem through climate, the presence of other organisms, preexisting surface, surrounding relief, and related moisture factors, then within a specified local area, or volume, on the Earth's surface, the range of variables is seen to be much smaller than in the entire biosphere.

Measuring species' dimensions

If each available species in neighbouring ecosystems is allotted a dimension, for example, those that never become established in a local ecosystem in question measure zero. Whatever the measure used, pioneer species are those scoring high soon after a bare or disturbed area has opportunity for recovery but declining—usually to zero—as waves of replacement species arrive. Self-perpetuating (climax) species may have more dimensions than the pioneer species or those that typically rise and disappear in stages of succession.

All of the organisms with which a species coexists at one time or another (a kind of intersection set) constitute part of its niche. Microclimatic variables within the local habitat occupied by the species limit the range of favourable conditions. Soil conditions, microtopography, and moisture conditions, all of which change with the other variables, are additional ecosystem properties that influence most of its inhabitants directly or indirectly. Also upper and lower limits of physiological tolerance influence where and how long a species can persist—either locally, on the time scale of a species life cycle, or globally, on the time scale of evolution.

Not only mere survival but also the probable rates of intake of resources, of elimination, of growth and reproduction, and of death for each kind of organism are influenced by the other variables. An organism can fill any of three niches at any given time in its life: it can be a producer of goods, like green plants; a consumer of goods, like most animals; or a decomposer of goods, like many microorganisms. The entire complex constitutes a food web or network. Energy passes along this net as in a power grid and is dispersed as heat along the way (see above *The zone of life: an overview: Energy flow and material cycling*).

Major divisions of the land environment. *Polar regions and tundra.* The colder divisions of the land environment can be grouped broadly as tundra and polar barrens, which include cold "deserts" and spotty tundra (Table 9). Bogs and mires accumulate dead carbon wherever decomposition fails to match production over a long period. Altitudinal and local mixtures of tundra dwarf scrub and meadow extend to many boreal mountains (and also to Alpine temperate and tropical areas tabulated under grassland in Table 9). Subpolar areas also include cold maritime herb meadow and scrub, bogs with dwarf woods, and open-wooded or tall-shrub "tundra."

Boreal and temperate forest complexes. The boreal forest (taiga) is sometimes divided into northern (transitional to tundra), middle (open woodland to closed forest), and southern (denser forest) zones. Estimates of typical forest area (and total carbon in living organisms) are separated from figures for unwooded and sparsely wooded bogs on peaty soils. Although "boreal" is frequently used in the general sense to refer to anything northern, it is best distinguished from several other predominantly coniferous zones called semiboreal. These include the subalpine and montane zones of mountains, as in the North American Western Cordillera. A mixed-forest zone in eastern and western Eurasia has some broad-leaved species besides the usual poplar and birch that are common in the taiga and its grassland-fringe zone of western Siberia and south central Canada. Except in these and a few other areas in which aridity and local relief complicate the pattern, a broad climatic outline around most boreal and semiboreal ecosystems is bounded on the north by the farthest extent

Boundaries of boreal and semiboreal ecosystems

of the 10° C (50° F) July average temperature and on the south by areas with more than four months above this temperature.

Temperate areas include some predominantly coniferous forests—*e.g.*, from the central British Columbian interior to lower elevations around Alpine-subalpine-montane complexes farther inland in North America. Except in parts of a cool coastal belt and some other local rain forests, conifer growth is usually limited by droughts as well as by sporadic insect outbreaks. These repeated disturbances, plus sporadic lightning fires, have influenced the extent of most conifer stands. Giant evergreen forests locally attain much greater than average carbon mass. Evergreens of lesser stature, dwarfed in areas of salt-wind exposure, may line these and other vegetation belts in coastal strips too narrow to map on a global scale.

Temperate summer-green or cold-deciduous forests, in contrast to the drought-deciduous forests of tropical monsoon regions, prevailed originally in the now industrialized areas of the northeastern United States, mid-latitude Europe, central eastern Asia, and locally elsewhere. Conifers peculiar to special habitats, especially in mountains and sand plains, also may have been part of the original vegetation and certainly have been extended in plantings in much of the cool temperate zone. In North America, for example, below the latitudes or altitudes where spruce fir was common, pines were important pioneer species on burned-over forestland and abandoned clearings; eastern hemlock, which is more shade-tolerant, persists or even expands in areas protected from fire, especially in the Great Lakes and Appalachian regions.

Warm temperate zone

The warm temperate zone, as generally understood in English, is referred to as subtropical in Soviet atlases and literature (which provided many of the preliminary estimates in the tables included in this section). Broad-leaved forests are partly deciduous but increasingly evergreen near the southern coasts of the United States, Japan, and China. Only a few conifers are important.

Mostly evergreen broad-leaved forests prevailed in humid portions of the Southern Hemisphere areas: eucalyptus in Australia, false beeches (*Nothofagus*) in New Zealand and the southern Andes. Here oceanic climates moderate winter cold. Wet hard-leaved (sclerophyll) forest and temperate rain forest ecosystems are localized on favourable sites; dry sclerophyll communities of varied height and tree spacing are especially prominent in both temperate and subtropical parts of Australia. Monterey pine (*Pinus radiata*) outgrows other planted conifers and the several native evergreen genera.

Scrublands. Forest and woodland areas include also maquis and garigue scrub in the Mediterranean area, chaparral in California, and similar vegetation capable of maintaining its leaves through dry summers or wet winters or spring seasons. Such scrublands merge into steppes toward regions of decreasing precipitation.

Grasslands. As the cool temperate forests interfinger with grassland in the Soviet Union and the northern United States, so the warm temperate forest alternates with grassland on different substrates west of 95° W longitude in the south central United States. As in tropical savannas, burned fringes of all the foregoing forests included open woodlands and sparser groupings of trees. Semiarid grassland is here typical throughout, but gradations to cold Alpine vegetation and semidesert are also evident.

Tall grassland includes the belt of meadow steppe south of the Eurasian forest and the North American prairie. Short or mixed grassland prevails in the next drier belt. From Mongolia westward, barely interrupted by the mountain meadows and terraced conifer forests of the Altai and other mountains, the shortgrass steppes offered a corridor

Table 9: Approximate Zonal Distribution of Major Preagricultural Ecosystems

major bioclimatic zones, temperature, relief	moisture	ecosystem type	area* (000,000 sq km)
Polar to subpolar area			
Polar	arid to humid	tundra, barren	7.86
Polar to boreal	wet peat	open bog and mire	1.30
Boreal Alpine	mostly humid	"tundra" meadow	1.58
Subpolar	mostly humid	scrub, herb, bog-woods	2.80
Total			13.54
Boreal and semiboreal area			
Boreal	mostly humid	taiga	10.10
Semiboreal or montane	mostly humid	mostly coniferous	6.91

Total			14.37

*Areas regrouped after N.I. Bazilevich, L.E. Rodin, and Rozov.

for Asian horsemen to the Caucasus, the Crimea, and central Europe.

In the Southern Hemisphere occur the pampas of Uruguay and Argentina and the grassy parts of the South African veld, which share the scattered parklike tree growth of the subtropical savannas. With woodland or scrub mixed in, these latter are marked by seasonal moisture and fire.

Deserts and semidesert areas. Arid lands, climatically defined, include mixtures of grassy and open scrub or special life-forms. Cool semidesert steppes typically are marked in the north by silvery sagebrushes (*Artemisia*). Extremes of hot and cool temperatures, in addition to low moisture, further constrain plant growth in the warm semidesert. Saline deserts are interspersed among both of the above arid lands and even in some grasslands but occur in greatest extent in central Asia.

In Table 9, sandy landscapes, especially those with dunes, are probably estimated conservatively, but biomass is not great even in semiarid, grassy sand hills or in the saxaul (*Haloxylon*) sand woodlands actively cultivated in the Kara-Kum Desert. Almost 10 million square kilometres (4 million square miles), from semidesert savanna to absolute barren deserts of several kinds, are included as tropical desert.

Jungles and rain forests. When these and transitional semideciduous and semievergreen forest or woodland are taken into account, the area of completely evergreen tropical forest is more limited than many maps suggest. Substantial tropical or equatorial rain forests occupy only a fraction of this total area. Sites that are enriched by nutrients from upstream or upslope yield exceptionally high production, but only over still more limited areas, which have long been the first to attract shifting cultivation.

Other tropical-subtropical woodland complexes. Below the highest snowfields are equatorial mountains that include treeless zones with temperatures near freezing on most days of the year. These areas, with a peculiar combination of low and exceptionally tall cold-resistant herbs, are called paramo in Colombia and Ecuador. Far less localized are elfin woodlands and scrub vegetation, widespread near the summit of mountains in both the tropics and subtropics. Evergreen subtropical mountain forests are typical of monsoon regions that have drought-deciduous forests in the lowlands.

Development of savanna and scrub

Natural deterioration by leaching of nutrients and by clearing and erosion have already created much savanna and scrub in the coastal rain forest belt of eastern Brazil and in many areas of the Amazon basin. In West Africa, rain forest and moist evergreen forest appear to be more vulnerable to conversion to grassy savanna than are drier types of ecosystems because fire-resistant trees are not already present. Moist semideciduous forest, dry deciduous forest, and woodland are considered more likely for conversion to savanna woodlands through selection favouring resprouting of resistant trees already mixed in the vegetation or available for invasion from the vegetation of surrounding regions. Original savanna woodland maintains resistant trees but has opened up to allow more grass or scrub since burning has become an annual management tool—especially where fires are mostly started late in the dry season. (J.S.O./Ed.)

Polar barrens and tundra

The polar regions comprise the Arctic, in the north, and the Antarctic, in the south, and although these two are often confused they are indeed poles apart in their systems of animal and plant life, or biomes. The few similarities that exist result chiefly from the coldness, widespread aridity, and level of latitudes. (Because of the latitude, day and night practically divide the year: in both the Arctic and Antarctic the sun is continuously above the horizon in summer and below it in winter.) Even the criterion of coldness is useful mainly in contrast with more hospitable regions; although in the Arctic there is probably no lowland area that does not enjoy for at least one month in each year a mean temperature appreciably above the freezing point, in the Antarctic only the offshore islands and the coast of the Antarctic Peninsula are favoured with this warming.

Because the arbitrary latitudinal Arctic and Antarctic circles have no meaning as natural boundaries for plants and animals, biologists regard the polar regions in general as lying poleward of the limits of tree growth. One generally recognized natural boundary of the Antarctic is the Antarctic Convergence—a delimitation in the sea, where cold surface-water layers spreading northward from the Antarctic continent meet with and sink below warmer, mixed subantarctic waters. This boundary embraces to its south some of the subantarctic islands, such as Heard Island and South Georgia.

THE ENVIRONMENTAL SETTING

Fossil evidence indicates that in earlier geologic ages many parts of the Arctic and Antarctic had temperate or warmer climates favouring luxuriant tree growth. Over millions of years the change to relative barrenness has occurred probably both through variations in world climate (the ice caps are no more than 4.5 million years old) and through the drifting of landmasses poleward from lower latitudes. In any case the polar regions today—especially the Antarctic—are characterized by extremely harsh climates. Precipitation is generally so low—often only a few centimetres a year—in the highest latitudes that, coupled with the low temperatures and permanently frozen subsoil, there prevails a desertlike barrenness. Nevertheless, the availability of snow meltwater, often throughout the short growing season, and the long-lasting summer daylight favour some limited plant growth.

Desertlike barrenness

The Arctic. The highest latitudes in the north are occupied by the Arctic Ocean, the land farthest north being in Greenland and the Arctic Islands of Canada. To the south stretch islands or major landmasses, which in many sectors of the northern polar cap extend into the subarctic and then temperate zones, thus affording more or less continuous dispersal routes for plants and animals from the south. The Arctic Ocean is deep, but the surface is largely covered by floating ice. The land area is commonly rugged, with widespread mountain ranges and glaciers descending to the sea—especially in Greenland, occupied by the world's second largest ice cap (see ARCTIC, THE).

The Antarctic. The highest latitudes in the south are occupied by the continent of Antarctica, which is largely covered under the world's greatest ice cap. Only on projecting mountains (nunataks) and limited ice-free tracts near the shores can land plants grow. The continent is far more isolated than is any Arctic land, being fully 800 kilometres (500 miles) from the nearest continental landmass, though scattered and usually small subantarctic islands exist and probably act as "stepping stones" for some limited plant and animal dispersal. Nevertheless, for practical purposes the Antarctic is isolated by formidable sea barriers that have made it extremely difficult for colonization by plants and animals since the last glacial period (see ANTARCTICA).

THE BIOTIC COMPONENT

Arctic and Antarctic plants and animals are well adapted to their harsh and inhospitable environments. The form of adaptation is often similar in both polar regions, but few species are common to the two. While their terrestrial and freshwater ecosystems are widely different, the far more prolific marine ecosystems are comparable; indeed, in both the Arctic and the Antarctic, it is chiefly in the seas that life abounds.

Vegetation. Polar food cycles, from plant producers through various animal consumers, are relatively simple, with few organisms linked together. Unfavourable climatic and soil conditions combine to limit severely plant growth in the Antarctic. But in the Arctic, vegetation is often fairly luxuriant in the southern tundra ranges, and its component plants are diverse—as also are the dependent animal species. Of Arctic flowering plants and ferns, about 1,000 different species are known from regions north of the tree line. Some of these are confined to the Arctic, but the vast majority range far southward—especially on the mountain slopes above the tree line in temperate regions.

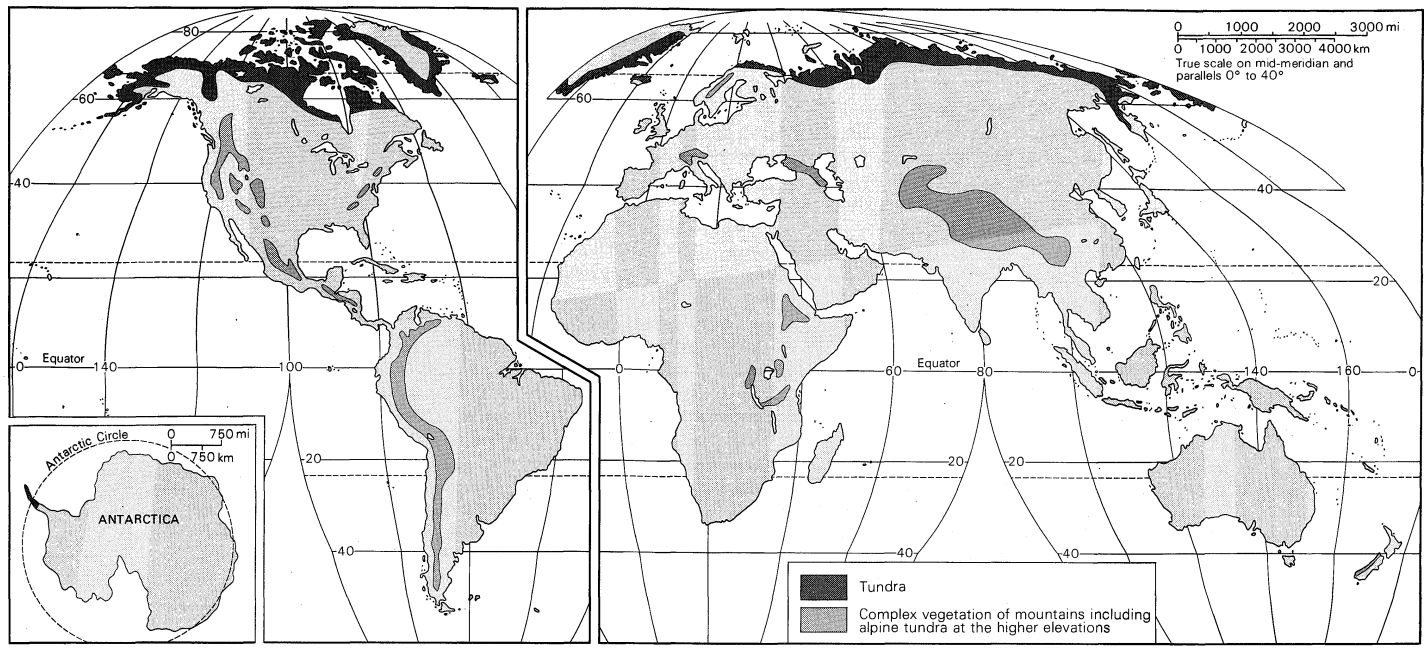

Figure 23: World distribution of tundra and mountain vegetation.
Adapted from *Biological Sciences Curriculum Study Green Version High School Biology*, 2nd ed.; Chicago: Rand McNally & Co., 1968

Such vegetation is known as Alpine tundra. Over much of the Arctic tundra and in many Alpine tundras the general appearance of the vegetation is that of a greenish brown, low grassland. While plants do not remain in flower for more than a few days or weeks, the blossoms are generally large in relation to plant size and are colourful, especially in Alpine habitats.

Coastal plain areas

Across the southerly Arctic tundra, with vast areas of low relief, boggy peat soils with an abundance of lakes and meandering rivers prevail. These coastal plain areas are dominated by sedges and cotton grass, and mosses including peat moss (*Sphagnum*) are common. On slightly elevated sites, often only 15 to 60 centimetres (6 to 24 inches) above the wet peaty soils, low willows, grasses, and rushes occur. Taller willows, grasses, and plants in the sunflower and legume families are common on the sands and gravels of riverbanks.

In marked contrast to the Arctic, the Antarctic proper possesses only three native flowering plants: two grasses of the hair grass genus (*Deschampsia*) and a relative of the pinks, *Colobanthus quitensis.* Although they are limited to favourable exposures in the peninsula sector, they also occur on the subantarctic islands and in southernmost South America. Apart from some algae and other relatively simple organisms, terrestrial life is restricted to the 4 percent of land area that is ice-free. There occur more than 70 species of mosses but relatively few liverworts. Lichens are the most successful and widespread group of plants in Antarctica because they have the ability to colonize bare rock surfaces and they have physiologically adapted to low temperatures and arid conditions; about 400 species have been recorded from the continent, although this number may be reduced by critical taxonomic study in the future. Lichens extend to slightly over 86° S and include *Verrucaria serpuloides,* the only known marine lichen, which passes its entire existence underwater. Of algae, there are approximately 360 nonmarine species that have been recorded from Antarctic ice, snow, soils, and temporary summer ponds. The snow algae, which give rise to reddish, yellow, or green patches of snow, are found only in the coastal areas where permanent snowfields undergo extensive annual thawing.

Fungi and bacteria

Compared with the Arctic, fungi and bacteria are few in the Antarctic. Bacteria that were isolated from lakes, and candida yeasts isolated from rock detritus and snow, proved remarkably well adapted to low temperatures. In the seas more than 200 species of algae have been recorded, the majority being diatoms; bottom-dwelling algae in shallow waters sometimes form extensive miniature "forests."

Animal life. Arctic animals tend to be far less numerous than plants, in both species and individuals. In North America the most notable among Arctic mammals on land are the Arctic hare, wolf, fox, collared lemming, polar bear (chiefly along coasts), short-tailed weasel, caribou, and musk-ox. Except for the musk-ox, these animals are all represented in Arctic Eurasia by the same or related species. All these mammals reach the far north, most of them practically to the northernmost limits of land, but some others, including the wolverine, shrews, ground squirrels, and some additional small rodents and weasels, range well into the Arctic without reaching so far north. This is also the case with the brown bear, red fox, and ermine.

Alpine tundras are similarly limited in the number of animal species and diversity. Accumulating evidence indicates that Alpine animal life in the Northern Hemisphere evolved in the central Asian highlands and spread to Europe via mountain systems and to North America via the Bering Strait.

Many animals found in Alpine tundras are not especially adapted for year-round Alpine life and undergo vertical migrations, descending into the less severe forest environments in winter and returning to the heights in summer. Such mammals include the mountain sheep, ibex, chamois, several wildcats, and many birds. Moun-

Leonard Lee Rue III

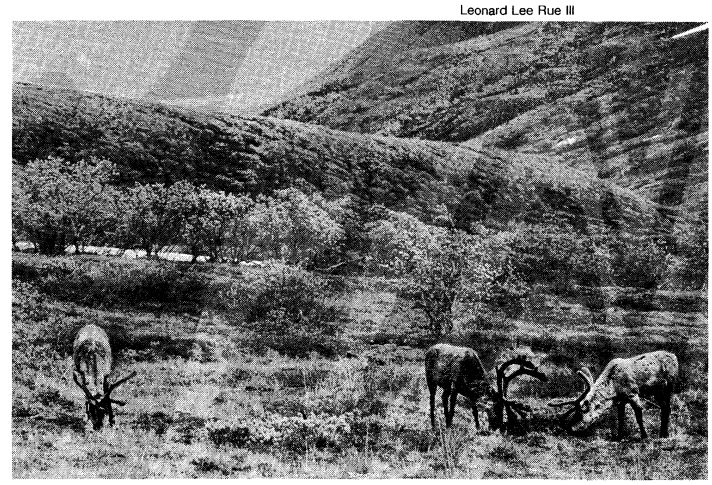

Figure 24: Caribou (*Rangifer*) feeding on mosses, lichens, and dwarf trees common to the tundra.

tain goats spend more time in winter at higher elevations than do ptarmigan.

In contrast with Arctic tundra mammals, some Alpine ones hibernate, such as marmots, ground squirrels, and zapodids. These animals consume large amounts of vegetation in summer and early fall before hibernation begins. Other small mammals, such as the pika and voles, cache hay in the fall for winter feeding, while rabbits and others forage as they can in winter. Foxes range over large areas of Alpine habitats in winter.

Many tundra animals sport white coats in winter, among them the foxes, wolves, and ptarmigan. This camouflage helps both predator and prey: predators can steal up without detection and prey can hide easily in the snow.

Arctic insects

Although the number of species of Arctic insects is small compared with that of temperate regions, those that are present are successful. Arctic insects resist freezing winter temperatures. In some species a high glycerol content acts as an "antifreeze" to lower the temperature at which freezing occurs. Many tundra insects and spiders are dark in colour, as a result of which they absorb more sunlight and maintain higher body temperatures. Some of the tundra species of blackflies and mosquitoes do not require a blood meal before depositing their eggs, in contrast to their temperate-region counterparts.

The Arctic seas are the habitat of various seals, whales, walrus, and narwhals, while belugas frequent narrow inlets and the mouths of rivers. (Humans in ever-increasing numbers threaten to change the fragile ecosystems of the Arctic as never before.)

Although a few marine birds range over the Arctic Ocean north of the northernmost coasts, most Arctic birds are limited to the vicinity of land and southward. Almost all of them migrate south to spend the winter, but Arctic ptarmigan (*Legopus*) regularly and snowy owls (*Nyetea scandiaca*) sometimes remain in the far north. On land, numerous ducks, geese, and waders, particularly, come to nest and pass the summer, as do some swans, while pipits and ravens are widespread, as are various falcons and other birds of prey. Often nesting in vast numbers collectively on birdcliffs or on the ground are various kinds of guillemots (murres) and terns, as well as puffins, little auks, and fulmars. Loons, or divers, call eerily from the numerous shallow lakes, and various kinds of gulls and skuas, or jaegers, screech from above. The Arctic, in fact, seems to abound in bird life in summer. At this time of year also the air inland (except in the far north) teems with insects, especially mosquitoes. Still farther south the insects probably contribute the greatest number of species to the total fauna; they diminish drastically in the far reaches of the north, except for the wingless springtails (order Collembola), which occur even on snow and ice.

Scarcity of animal life in the Antarctic

Like the land vegetation, the animal life of Antarctica is extremely poor. Truly terrestrial vertebrates are lacking, though various sea-feeding penguins and fulmars and other petrels come ashore to breed—as do also the great skua, Dominican gull, Antarctic tern, and Antarctic shag. There are four kinds of truly Antarctic seals—the Weddell seal (*Leptonychotes weddelli*), the leopard seal (*Hydrurga leptonyx*), the Ross seal (*Ommatophoca rossi*), and the crabeater seal (*Lobodon carcinophagus*), of which the last-named is the most abundant seal in the world, numbering an estimated five to eight million individuals. Several of the largest species of whale (order Cetacea) are still found in the open seas around Antarctica, though their populations have been drastically depleted by excessive hunting. By contrast the largest terrestrial animals of these rigorous regions are two species of small midges (family Chironomidae), one of which is winged and the other wingless; these, in addition to a limited array of mites, springtails, microscopic rotifers, tardigrades, protozoans, nematodes, and rare enchytraeid worms, constitute the native land fauna.

COMMUNITY STRUCTURE

Unlike the situation in most parts of the world, where plants form the main embellishment on land, the Arctic and, to a far greater extent, the Antarctic tend to have the framework of their terrestrial ecosystems dominated by the physical structures that locally make up the Earth's surface. In the Antarctic, nesting penguins, because of their accumulated mineral-rich guano (excrement), may create barrens on which no plant can grow. Thus on land it is chiefly in the low-Arctic and the subantarctic islands that plants really affect the landscape.

In the polar regions the struggle of the totality of organisms tends to be more with the exacting environments than with one another, though some competition for space and food does exist. This occurs among both animals and plants, but, in general, what one immediately sees of living materials in these regions consists almost entirely of plants, the greatest development of which is the Arctic tundra of low-growing species interspersed with lichen-covered rock fields and numberless ponds.

Besides marshy and other seaside vegetational types of limited extent, there may be extensive areas of sedges and cotton grasses and of true grasses, such as *Arctophila* and *Arctagrostis,* around lakes and ponds in the Arctic. Luxuriant "patchwork quilt" communities of mixed mosses and lichens are often found around and above bird-cliffs, nourished by guano. Where the snow drifts so deeply in winter that the growing season is drastically reduced by its late melting, zoned series of vegetation types develop. The seas abound in tiny free-drifting organisms, or plankton, of which the plant component, or phytoplankton, occur as deep as light penetration allows; these last support a wealth of crustacean and other zooplankton and, ultimately, fish and mammals (*e.g.,* seals and whales). Even floating ice bears a considerable population of diatoms on both its upper and lower surfaces, making the ice appear a dirty brown in summer.

Antarctic habitats

The Antarctic, by contrast, is impoverished. There is no true tundra on the continent, but only occasional thin tracts of sparse mossy vegetation and algal and lichen patches in especially favoured places. These tracts are found along coasts where the climate is mildest; they contribute to the peat formations on the west side of the Antarctic Peninsula. Other terrestrial habitats include rocky coastlines, the slopes of mountains projecting above the continental ice cap, glacial moraines, summer meltwater channels, and warmed areas around volcanically active fumaroles (holes emitting hot gases and vapour). There are also some lakes and numerous freshwater ponds and puddles. In all such areas on land and in fresh waters, however, the biomass is such that vegetation appears to be virtually lacking except in especially favoured areas that are merely tinted by it. By contrast, in shallow marine waters of the Antarctic the biomass of living matter may be considerable, being often greater than in the Arctic. This richness of sea life results in part from the upwelling of nutrient-rich waters in the Antarctic Ocean.

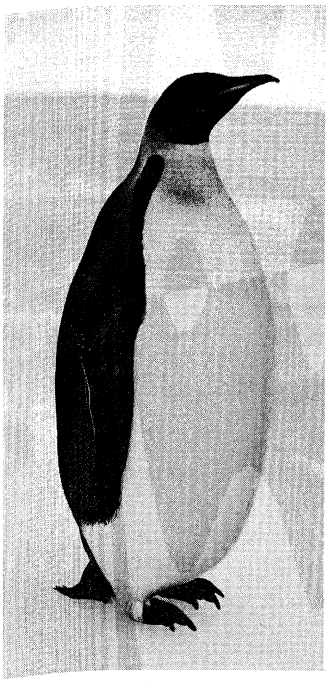
The subantarctic islands south of the Antarctic Convergence show polar affinities and are commonly included as part of the Antarctic in the broad sense, though on the islands of Kerguelen, Heard, and South Georgia, there occur coastal tussocky grasslands of meadow grass or fescue and inland fields of herbaceous plants, with mainly lichens and mosses on higher land. Especially notable is the Kerguelen cabbage (*Pringlea antiscorbutica*), the sole representative of its genus. Some ferns and a club moss occur in protected habitats. Animal life on these islands is more prolific than on the Antarctic continent; insects and birds are numerous.

BIOLOGICAL PRODUCTIVITY

In polar regions the greatest biological production occurs in marine waters rather than on land, with higher production occurring in the Antarctic than in the Arctic Ocean.

Production studies of Arctic tundra lakes indicate that there are many species of algae and even aquatic mosses living in the higher latitudes of the Arctic. These support a limited number of small crustaceans, worms, and insect larvae, which in turn support the Arctic char (*Salvelinus alpinus*), a fish related to salmon.

Plant production in the tundra appears to range from 3 to 10 grams of vegetable matter per square metre of area in willow–dryas barrens of the higher latitudes of the Arctic to values of 100 to 250 g/m^2 in lower-latitude



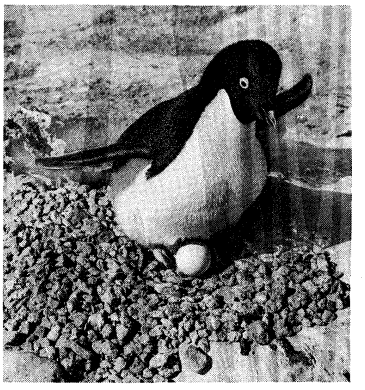


Figure 25: *Animal life in Antarctica.* (Top left) Emperor penguin (*Aptenodytes forsteri*), the only Antarctic bird that breeds in winter. (Top right) Adélie penguin (*Pygoscelis adeliae*) and (bottom) Weddell seal (*Leptonychotes weddelli*), two of the few types of animals native to Antarctica.

sedge-dominated wet sites. The widespread cotton-grass–dwarf-shrub heath communities produce about 50 to 75 g/m^2 in new shoots per year. Values for temperate region grasslands and forests are about four to six times as great as the maximum rates for the Arctic tundra.

The accumulating data for Alpine tundras show 50 to 100 g/m^2 in windswept habitats, 100 to 200 g/m^2 in meadows, and values of 250 to 300 g/m^2 in dwarf-shrub heath communities. These values are higher than those in the Arctic because the growing season is often longer by several weeks.

These data do not tell the entire story, for the amount of plant material (standing crop) is often 10 to 25 times greater below ground than above ground, which indicates that the soil environment may be more favourable for growth than is the air.

Herbivore consumption

In many tundras, the harvest by plant-eating animals amounts to no more than 0.1 to 2.0 percent of the live plants per year. This means that the great majority of the plants produced fall to decay and are decomposed by microorganisms.

With Alpine and Arctic vegetation so sparse, it is no accident that humans have harvested herbivorous animals, including caribou, reindeer, ducks, and geese, rather than harvesting native or cultivated plants as they do in other major vegetation complexes (forests, grasslands, and deserts). (N.Po./L.C.B./Ed.)

Boreal and temperate forests

Forests are complex ecosystems dominated by trees, which form a buffer for the Earth against the full impact of the sun, wind, and precipitation. Whatever the type of forest—whether evergreen or deciduous, boreal or temperate—the trees that constitute it provide special environments, which in turn affect the kinds of plants and animals that can live within the forest.

THE ENVIRONMENTAL SETTING

Climate. Forests may develop wherever there is an average temperature greater than 10° C (50° F) in the warmest months and an annual rainfall in excess of 200 millimetres (about 8 inches). Above these limits there exists an infinite variety of tree species grouped into a number of stable forest types that are determined by the particular conditions of the environment. Although boundaries between these types are difficult to determine precisely, the major forest communities can be linked to broad latitudinal zones (see Figure 26).

The forests of the high latitude subpolar regions constitute the taiga and are dominated by stands of such conifers as pines, spruces, and larches. Taiga forests are found only in the Northern Hemisphere, where winters are long, with six months of the year showing an average maximum temperature of less than 0° C (32° F), there is a growing season of one to three months, and precipitation varies between 250 millimetres (about 10 inches) and 500 millimetres (20 inches), evenly distributed throughout the year. Broad-leaved trees predominate in the middle latitudes, where there are six months with an average maximum temperature above 10° C (50° F), precipitation in excess of 400 millimetres (about 16 inches), and a growing season of between 100 and 200 days. Broad-leaved deciduous forests occupy the cooler regions and are dominated by associations of several species including oaks, beeches, birches, aspens, elms, and maples.

Mixed forests form a transition between the coniferous taiga and the deciduous broad-leaved forest. Farther south, as frost becomes infrequent, the composition again changes, and a temperate rain forest of evergreen broad-leaved species develops. In the Southern Hemisphere the forest type contains conifers similar to the true pines: Kauri pine, Chile pine, and white pine. The temperate rain forest, also known as temperate evergreen forest and laurel forest, has fewer tree species than other types of rain forests and is lower and less dense.

Determination of forest type

Precipitation and temperature play important roles in the determination of forest type. The combined effect controls the amount of soil water available for tree growth. Water is lost from the forest by evaporation from the tree crowns and by transpiration from the leaves, both processes in large measure controlled by air temperature.

The principal influence of sunlight is on the air temperature. At high latitudes the sun's rays strike the Earth at a larger angle and therefore give less heat than at low latitudes. Another influence of solar radiation is through the day length (photoperiodism), which varies according to the season and affects flowering, bud opening, and a range of other physiological activities.

Topography and soil. Topography is also an important influence on forest vegetation; an increase of 300 metres (984 feet) in altitude is equivalent to a movement of 480 kilometres (300 miles) closer to the pole at sea level, so that a broad correlation can be drawn between montane forests and those at higher latitudes. Exact duplication of forest type is not expected, however, since the montane environment differs in important respects from that at an equivalent lowland station; notably, it has a shorter day length, greater precipitation, and higher maximum temperatures. The altitude at which the lowland forest passes into an Alpine type depends chiefly on the length of the growing season and the frequency of frosts. The zonation of forest types with increasing altitude is seen in the subalpine forest formations of the middle latitudes and the montane forests of the tropics. In the middle latitudes the subalpine forest is dominated by the more tolerant conifers (pines and larches), with poorly formed deciduous broad-

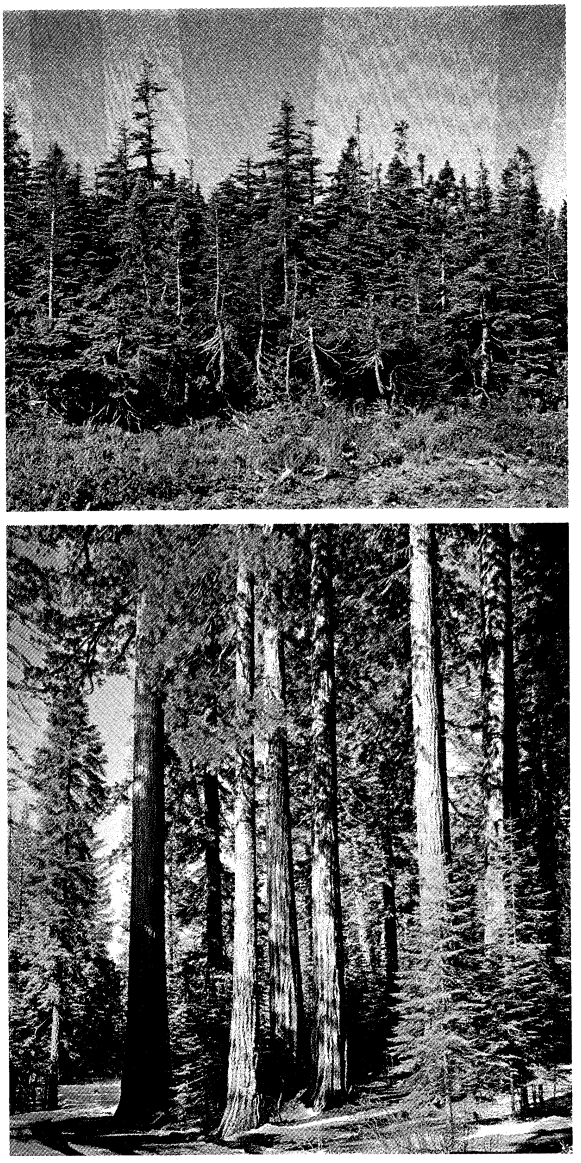

Figure 26: (Top) Northern coniferous forest in Nova Scotia, of red spruce (*Picea rubens*). (Bottom) Moist temperate coniferous forest in California, of redwood (*Sequoia sempervirens*).
(Top) Ken Brate—Photo Researchers, (bottom) A.C. Shelton—Publix

leaved species (beeches, birches, and willows) occupying the tree line, the upper limit.

Another important physical influence on forest type is the soil. The most important feature is soil depth, because this determines not only the capacity of the tree roots to reach for water and nutrients but also the stability of the trees. Forest soil shows considerable variability, but common features are depth, relative infertility, an undisturbed condition, a large quantity of woody perennial roots and characteristic plant and animal life. Quick-draining, highly stratified, sandy soils (podzols) are characteristic of the taiga. Brown forest soils, which are richer in nutrients, less porous, and less stratified than podzols, are characteristic of deciduous broad-leaved forests. Variation in soil type may be considerable even in small areas, *e.g.,* in regions subject to past glaciation; this variation is often reflected in species preference. In the mixed broad-leaved–conifer forests of the middle latitudes, conifers are usually found in poorer sandy soils of low alkalinity, whereas broad-leaved trees prefer richer clayey soils.

Wind and fire. Wind plays a primary role in the creation of the forest, by assisting in pollination and seed dispersal, but has only a secondary role in its maintenance. Air movement affects transpiration and may be a significant ecological factor in determining some forest types. Violent winds destroy forests by either uprooting or breaking stems; prevailing winds affect tree growth by producing eccentric stems and deformed crowns. Prominent among the physical destructive agents in the forest is fire, which usually results from human encroachment. Infrequent natural fires arising from lightning may be responsible for the development of stable fire forest types, such as Douglas fir (*Pseudotsuga menziesii*) stands in North America.

Prevailing winds

BIOLOGICAL FACTORS

Forests are distinguished from each other primarily by their composition. The number and variety of species present in the forest community depends on the age and density of the tree cover, the type of climate and soil, and the geologic history of the region. The richest forests in terms of total species composition are those having older and more open stands of trees, situated in favourable climates, and on fertile soils that have been relatively undisturbed in recent geologic time. Thus, within a given forest community there exists a complex interaction between the vegetation and the environment, which leads to the development of microenvironments with many physical properties.

Plant stratification and its influence on the forest environment. The forest community shows an extensive vertical stratification, from the tops of the tallest trees to the tips of the deepest roots. The effect on the stratification above ground is to moderate climatic extremes progressively downward from the treetops to the soil surface.

The pattern of vertical stratification varies with forest type. The conifer-dominated forest has the simplest structure: the tree layer is continuous up to 30 metres (100 feet) high, the shrub layer is absent or spotty, the field layer of herbaceous plants is best developed in more southerly forests, and the ground layer of liverworts, mosses, and lichens is almost uniform, particularly in the northerly forests. In the deciduous broad-leaved forests stratification becomes more complex. The continuous canopy of trees is between 10 and 30 metres (33 and 100 feet) tall but is subdivided into distinct upper and lower stories, in addition to the shrub field and ground layers.

Considerable lateral variability exists within each layer, or stratum, resulting from local differences in environmental conditions. Forests thus provide a great range of habitats for both other plants and animals. The most important physical factors influenced by forest structure are air temperature, precipitation, and soil characteristics; of secondary importance are sunlight and wind.

The forest environment exercises a moderating influence on air temperature, which is especially marked at the extremes of the temperature range. The forest is cooler in summer and warmer in winter, when compared with surrounding areas. The effect is most marked where seasonal temperature variation is greatest; *i.e.,* the farther removed from the equator, the greater the effect.

Vertical stratification and air temperature

The ameliorating effect of the forest on air temperature results from the vertical stratification of the forest vegetation and is less marked as the canopy cover decreases; thus, winter temperatures are little influenced in the leafless deciduous forest, although in the summer the same forest, in full leaf, shows not only differences in temperature compared with outside conditions but also a temperature gradient within the various strata of the forest. Daily fluctuations of temperature within the forest also depend on the nature of the vertical stratification. In the single-storied temperate conifer forest, temperatures are highest nearest the tree crowns. At night, heat is radiated from the crowns and the surrounding air is cooled, increases in density, and sinks to the ground. Subcanopy temperatures are therefore lower than canopy temperatures. During the day the temperature gradient is broadened; the crowns of the trees are warmed by the sun but at the same time shade the subcanopy region. As the canopy structure becomes more complex, more than one form of daily fluctuation in temperature can exist. Forest vegetation also has a marked effect on soil temperature. Forest soils are cooler in the day and warmer at night and show less seasonal fluctuation than similar soils outside the forest.

As precipitation falls on the forest, its movement is significantly influenced by the forest cover. The dense tree layer initially intercepts precipitations, some of which is immediately evaporated back to the atmosphere. Conifers tend to hold more water than broad-leaved trees (there is, of course, little or no interception from dormant leafless trees). Water penetrates to the soil from the canopy either through stem flow down the main trunks and thence into the soil along the root channels or by direct absorption in the litter of the forest floor. In either case the velocity of the fall is reduced and there is little soil compaction or surface runoff and consequently a reduced risk of soil erosion. Compared with stations outside the forest, the moisture content of forest soil, particularly at the surface, tends to be high. Water is lost through surface evaporation, which is low in the forest because of the ameliorating effect of the tree cover, and by transpiration, which is high and may be a limiting factor in tree growth. The water budget for the forest will vary significantly with type and situation, but the ability of the forest cover to reduce erosion and to even out the yearly fluctuations of stream flow are recognized advantages to water catchment areas. Although there is no evidence that forest conditions affect the amount of precipitation, the forest atmosphere is always more humid than surrounding areas.

Types of organic matter

The forest floor consists of a layer of organic matter overlying mineral soil. In the temperate regions two major types of organic matter predominate, the mull and the mor. The mull is associated with broad-leaved deciduous forests, especially those growing on relatively rich soils. It is less acid than the mor type, of a granular structure, and contains a considerable admixture of mineral soil. There is an indistinct boundary with the upper horizons, owing to the activity of earthworms moving freely between the decomposed layer of litter and the mineral soil. Mor humus, on the other hand, is strongly acidic and of a matted structure (attributed to the network of fine roots). There is a distinct boundary between mor humus and mineral soil, with little evidence of the activity of mixing agents. The earthworm population is smaller, although fungal activity may be greater, than in mull. Mor is characteristic of the northern coniferous zone and is especially evident under pines growing on mineral-poor soil, although some broad-leaved species, especially oaks (*Quercus*) and beeches (*Fagus*) produce a mor humus when growing on similar soils. The differences between mull and mor are generally attributed to differences in the chemical composition of the plant material from which they are derived and the nature of the mineral soil, rather than to the rate of decomposition. Occasionally in swampy conditions where acidic groundwater percolates laterally, and in conditions of heavy, regular rainfall, a thick peat, made up almost entirely of woody plant debris, may develop.

The forest structure produces less spectacular, though equally important changes in wind speed and solar radiation. Dense multistoried forests are most effective in reducing overall wind velocity in the subcanopy layers. The filtering of the tree strata also affects solar radiation. A conifer forest typically allows no more than 10 percent of visible light to reach the forest floor, and a deciduous forest about 5 percent when in leaf but between 50 and 90 percent when leafless. Forests in full canopy approach the maximum possible efficiency in their utilization of solar energy: 60–90 percent is absorbed, and the remainder is reradiated and used up by evaporation and transpiration. In qualitative terms the light values within the forest vary since the canopy vegetation absorbs more red than blue light. Blue light is, however, utilized at subcanopy and low-canopy levels and is said to reduce the tendency toward side branching, a possible explanation for the observation that understory trees are generally pyramidal but adopt a rounded crown when they achieve upper-story height. In their youth some trees, such as oak and pine (*Pinus*), require much sunlight, whereas others, spruce (*Picea*), firs (*Abies*), and beech, almost demand shade.

As indicated earlier, stratification within the forest supplies many habitats for both plants and animals and provides the opportunity for considerable interaction between organisms.

The role of decomposer organisms. The fungi of the litter and mineral soil layers play an important role in the chain of litter decomposition and the release of nutrients in the soil. Some species live in a mutually beneficial association (called mycorrhiza) with active tree roots, thus improving the efficiency of nutrient uptake by the trees. On the other hand, some species are parasitic and may cause devastation; *e.g.,* the chestnut blight, caused by the fungus *Endothia parasitica,* which has decimated the population of native chestnut (*Castanea dentata*) in North America, and the blister rust fungus, which is a serious pest of white pine (*Pinus strobus*). The fungus *Fomes annosus* attacks a number of conifer species; it is transmitted from tree to tree not only by spore infection via cut wood surfaces but also by root contact. Some higher plants are also parasitic; *e.g.,* the European mistletoe (*Viscum album*) and its North American counterpart cause stem and crown deformation. Among the animals, the insects are the most mobile in the forest. They are also the most numerous and the most highly adapted as to feeding habits. Insects are an important link in the food chain between vegetation and higher animals, particularly birds. Many tree species have flowers adapted to insect pollination; the range is wide from simple nectar-rich flowers to highly structured pollination mechanisms. Insects are often highly specialized in their feeding habitats; of 20 species known to occur on white pine, five are leaf feeders, three are bud feeders, three are twig borers, two are wood borers, and two are root borers. Species preference is also noticeable; of 43 species of British weevils whose larvae feed on Scotch pine, oaks, and birches, all except one attacks only one species of tree. Insect damage to forests reaches disaster proportions only when populations break through the natural control barriers; *e.g.,* the periodic defoliation of balsam fir (*Abies balsamea*) by the spruce budworm (*Choristoneura fumiferana*) is triggered by several summers of clear, dry weather, which favours a rapid increase in the insect population. Insects also are known carriers of the viral, bacterial, and fungal diseases of trees. As a proportion of the total insect population, however, the serious forest pests are small in number and localized in their influence.

Mycorrhiza

Forest animals and their adaptations. Larger forest animals are likewise especially adapted to their environment. Sharpness of sight and smell are apparently not as useful as a sense of hearing in the forest habitat, and most gregarious animals, including birds, are noisy in contrast to the animals of open country. The value of flying and running is also reduced, and true forest birds are poor flyers but good climbers. Movement on the ground is restricted, but deer and antelope, slender and lithe, can thread their way through the forest. Specialist adaptations include those that enable the animal to move through the dense canopy layers, sharp claws (as on woodpeckers, squirrels, martens), gripping feet or prehensile tails (as on porcupines, anteaters, marsupials), and parachute-like skin extensions (as on flying lizards and flying squirrels). Some animals, such as birds of prey, wolves, foxes, and stags, use the forest only for shelter. Although the forest is a sheltered and ameliorated environment, food is scarce and populations are relatively low.

Each forest type has its distinctive animal life. In the deciduous broad-leaved forests snails and slugs are more numerous than in the conifer forest, a reflection of the difference in the quality and quantity of the herb layer. In temperate zones forest birds distribute seeds and insects pollinate.

Animal damage rarely reaches catastrophic proportions in the forest, but local damage from grazing and browsing can result in bark stripping of young trees.

SEASONAL CHANGE

Forest rhythms

The forest community changes with the seasons. Superimposed on these changes are the daily rhythms of daylight and darkness; of these effects, the length of daylight, or photoperiod, is an important component of seasonal change, or aspection. The stimulus of these changes is environmental and as a consequence is most marked in regions where temperature, precipitation, and day length are seasonally variable. The responses of organisms to

periodic changes in the environment have evolved over a long period of time to parallel the external environmental conditions.

Aspection is also influenced by latitude, altitude, and rainfall distribution. At high latitudes the winters are prolonged, snow and frost occurring for as long as six to eight months continuously; the spring and autumn periods are short, and the growing season may be as short as three months. (Seasonal changes in the Southern Hemisphere are the reverse of those in the Northern Hemisphere.) Longer, cooler periods are associated with increasing altitude and are reflected in the forest composition. The seasonal changes in forest communities at high elevation are similar to those closely related communities at lower elevation but higher latitudes. Finally, aspection is affected by moisture availability; thus in Mediterranean climates, the resting period for many plants, presaged by leaf fall in deciduous species, results from a seasonal lack of moisture rather than from decreasing air temperature and decreasing day length.

In the middle latitudes of the temperate zone, characterized by the deciduous broad-leaved forest belt, six phases of the seasonal cycle are recognized. In this region aspection is most strongly evident, and the phases correlate climatic conditions with the outward appearance of the tree cover. In the early spring, or prevernal period, the hardy species and the lower-storied trees bud and bloom as air temperatures and day length increase. In the upper stories, bud break is delayed, but the sap rises from the roots to the crown. The late spring, or vernal period, sees soil temperatures rise with air temperatures and day length reach its maximum value. As the leaves expand, shoot growth accelerates; the transpiration rate becomes more rapid as the leaves mature and as moisture in the soil becomes more readily available. At this period the vegetation is most vulnerable to frost damage. The next two periods, estival (aestival) and serotinal periods, cover early summer and midsummer, when conditions for growth are optimal. Air and soil temperatures reach their maximum, the full-storied structure of the forest is operative, and the metabolic rate is at its highest. During this period, moisture availability becomes the critical, or limiting, factor to growth; high temperatures combined with extremely dry conditions may induce a lowering of the metabolism of the tree, characterized by premature aging of leaves and a slowing down of plant activity. The autumnal period is characterized by falling air temperatures, decreasing day length, and the advent of frosts. These changes induce a gradual reduction of metabolic activity and defoliation of deciduous vegetation. Finally, the winter, or hiemal period, is characterized by low daily maximum temperatures, heavy frosts, precipitation in the form of snow, and short day lengths. During this season the trees enter a dormant stage in which metabolic activity is diminished to the minimum level necessary for survival.

Hiemal period

Seasonal change is least marked in the higher latitudes of the temperate zone, characterized by the coniferous belt of forests. Here the species mixture is limited and simple in physiognomy, and although the conifers are evergreen, water loss through transpiration is considerably reduced as water becomes less available from the freezing soil. The evergreen habit does enable the maximum use to be made of the short growing season, and conifers are particularly well adapted to rigorous environments. The understory plants, mosses, ferns, lichens, and grasses, show no spectacular seasonal changes, and the trees themselves change little in appearance with the passage of the seasons, except for the deciduous species such as the larches (*Larix*). Even in the species-rich coniferous zones of western North America and in Asia, aspection is not well marked in the tree cover, although breaks in the canopy reveal herb and shrub layers that show the same periodic changes that are seen typically in the broad-leaved forest.

One common feature of the extratropical forest regions is the periodic activity of the tree growth. The growing tips (meristems) in the buds, which are responsible for height growth and crown development, are most active in the spring. The lateral, or cambial, meristem, which is responsible for increase in the diameter of the tree trunk, also is most active in the spring, slowing down in the autumn and ceasing activity in the winter. All temperate trees show an annual ring structure, roughly indicative of age, resulting from the episodic nature of this cambial activity.

COMMUNITY DEVELOPMENT

Forest communities represent the terminal aggregation of species in a series of associations that may have begun from primary succession—*i.e.*, colonization of bare mineral oil, exposed rock surfaces, volcanic ash, or sand dunes—or from secondary succession, in which the substrate had first been occupied by a community that, because of a catastrophic event (*e.g.*, wind devastation, fire, or human intervention), has since been destroyed. Although successional changes may vary considerably between these two major avenues of development, the time span in each case is long, and the biological interactions between the various plant and animal components are complex. Each recognizable stage in the development of a stable, or climax, community is known as a sere. Climax forest communities, because they usually represent the terminal point of seral development, are grouped together in more or less climatically controlled geographic groupings identified as forest biomes (see Figure 27).

Coniferous forests. *Taiga.* The circumpolar high-latitude forests of the Northern Hemisphere are dominated by pines, spruces, firs, and larches. The Eurasian and North American formations are similar in structure, and in both the species composition changes from east to west of the formation. Important eastern formations in Europe are the native stands of Siberian pine, Siberian fir, and Siberian and Dahurian larches; in North America, white spruce and balsam fir are the eastern dominants. In western Europe, Scotch pine and Norway spruce absolutely predominate; in western North America, lodgepole pine and Alpine fir are among the important species in the area.

Exploitation and recovery of the taiga

The taiga forests, especially in the almost pure stands, have been exploited on a large scale from the mid-19th century on. On cleared areas, on catastrophic burns, or whenever adequate precautions to ensure conifer regeneration are not taken, secondary succession begins. Dominated initially by herbaceous cover, the succession soon contains deciduous broad-leaved trees, especially birches (*Betula*) and aspens (*Populus*), prolific seed bearers, whose seeds are wind-dispersed and of a high germination capacity. Willows (*Salix*) and alders (*Alnus*) are also early arrivals in the hardwood stage of succession. Scotch pine (*Pinus sylvestris*) in Europe and jack pine (*P. banksiana*) in North America produce the advanced succession stage. Final reversion to the climax forest is achieved after a considerable time interval through the ability of the conifer species to regenerate and grow under the shade of the canopy. In addition, conifers tend to grow taller than the broad-leaved species when in direct competition and eventually shade them out. Broad-leaved species occur in the taiga in locally induced biotic climaxes and are common on the latitudinal and altitudinal margins of the biome.

Moist-temperate conifer forest. Forests of this distinctive type occur along the western seaboard of North America from Alaska to California and inland to the Rocky Mountains. Here conditions are humid and a high proportion of the precipitation occurs as mist. Species domination shifts from Sitka spruce (*Picea sitchensis*) in Alaska through the western red cedar (*Thuja plicata*)–western hemlock (*Tsuga heterophylla*) association in British Columbia to Douglas fir and finally the coast redwood (*Sequoia sempervirens*). Because of the high humidity a rich understory development, especially of mosses and other moisture-loving plants, is a feature of this forest formation. The trees are massive, and they constitute the richest commercial forest in the world. As in the taiga, secondary succession features the pioneer broad-leaved species, especially the alders and, in the south, maples (*Acer*). Where the humid conditions are maintained only under continuous conifer cover, oaks infiltrate late in the succession from the neighbouring transition to the Californian chaparral. Primary succession from the coast tends to be dominated by pioneer pine species, especially lodgepole pine (*Pinus contorta*), before the climax is rapidly formed.

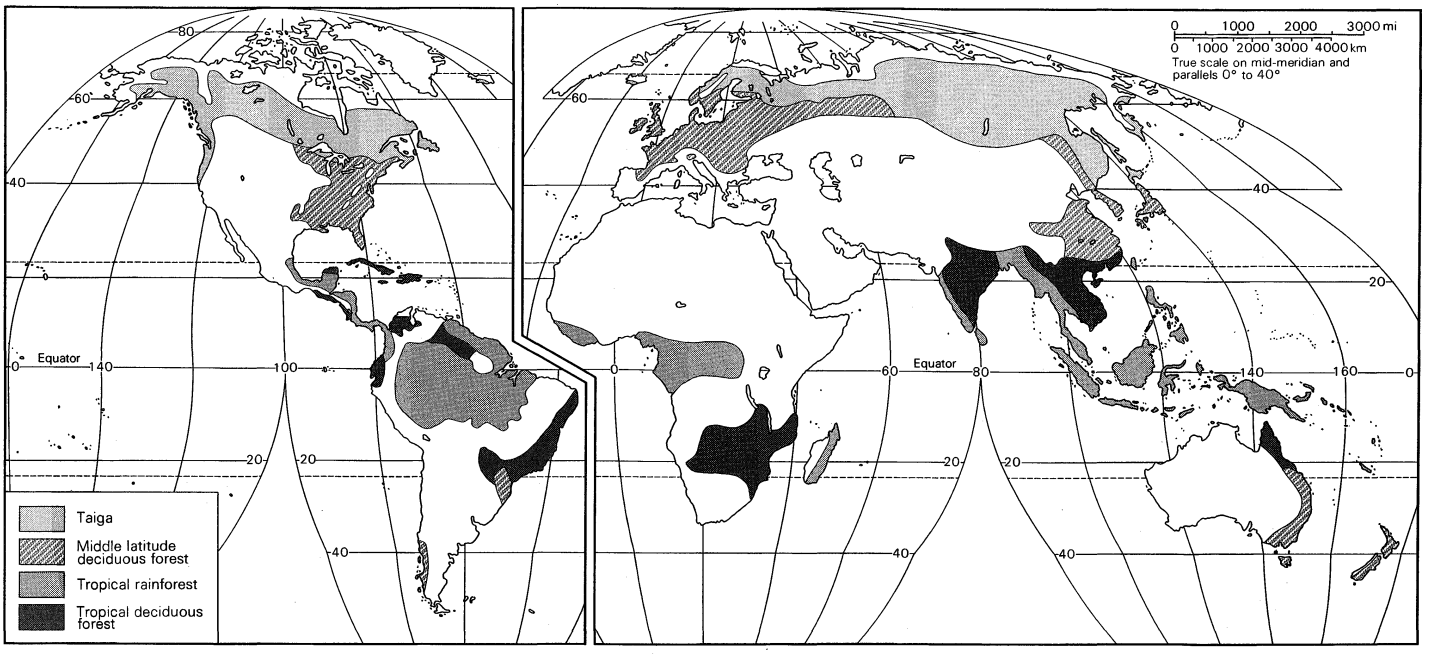

Figure 27: World distribution of major forest biomes.
Adapted from *Biological Sciences Curriculum Study Green Version High School Biology*, 2nd ed.; Chicago: Rand McNally & Co., 1968

Middle-latitude forests. *Deciduous broad-leaved forests.* This biome, which occurs in Europe and North America, is floristically the richest in the New World. Associations of beeches and maples occur in the north, maples and basswoods in the centre, oaks and hickories in the west and south, and oaks and chestnuts in the Appalachian Mountains. Native species of oaks, beeches, and birches form the associations in the northern European formation, limes, chestnuts, and elms appearing in the south. Community development in this region again arises from forest clearances; in North America, where population pressure is not so great as in Europe, abandoned agricultural land is a common starting point. The grassland community is first invaded by broad-leaved shrubby trees, and a mixed-species thicket stage develops. Later successional changes feature the invasion of jack pines for reasons analogous to those operating in the conifer biome. The richer soils and better growing conditions of the deciduous broad-leaved biome allow a more rapid growth of broad-leaved species, some of which are shade-tolerant. The pioneer pines soon become mixed with broad-leaved species, which in turn dominate the community as the climax forest develops. It is not uncommon for the succession to be deflected to a conifer climax by either regular burning or grazing. The pine barrens of southeastern North America, dominated by several pine species, are an example of such a climax.

Northern European forests

Evergreen broad-leaved forests. This formation occurs both north and south of the equator on the eastern seaboards of continental landmasses. The cooler temperate formation is found in the Southern Hemisphere; in New Zealand, southern so-called false beeches dominate. Although evergreen, the formation has much in common with the deciduous broad-leaved forest of the north. In the warm temperate forests of the Southern Hemisphere, the beeches are joined by the southern conifers: Kauri pine (*Agathis australis*) and yellowwood (*Podocarpus*) species in New Zealand, and *Araucaria* species in Chile. Particularly in the warmer regions secondary succession is complex and slow. Pure strands of southern beeches develop especially on the more exposed hillsides. The southern conifers are slow-growing and are susceptible to grazing damage; once removed they are unlikely to regain their place in the community. False beeches are very susceptible to grazing damage; recovery is difficult, and often the forest reverts to a thick grassy turf.

PRODUCTIVITY OF FOREST ECOSYSTEMS

Quantitative estimates for the productivity of forest communities are scarce and unreliable. Among the reasons for these conditions are the complexity of the forest community, the longevity of tree species, and the lack of historical records of routine weight data. Moreover, there are three levels of production that might be measured. Gross, or primary, productivity is the quantity of organic matter created by photosynthesis. From this value the energy used in respiration is subtracted to give the net production, which is measured as the dry matter, or dry weight of the total community. A third measure is the merchantable production, which is the dry weight of the usable tree stems only and is calculated by multiplying the stem volume by the basic density of the wood. Although volume figures are available for most of the species under regular forest management, this measure cannot be regarded as an estimate of total production; even for a single tree it represents less than 70 percent of the total dry weight, the unmerchantable stem (1–6 percent), stump (10–18 percent), green branches and foliage (10–20 percent) making up the remainder. For a complete evaluation of forest productivity, both the vegetation and the animal life need to be measured, a task that is overwhelming in magnitude. The difficulties of measuring even the dry weight of the total plant community present extreme sampling difficulties. Much of the data available are concerned with the plant biomass (net production), and often only for the tree component.

The three levels of production

Forests are the most efficient of all terrestrial communities in the production and storage of organic matter. A high proportion of the sunlight that falls on the forest is absorbed; the canopy provides a large area of chlorophyll-bearing tissue dispersed through a considerable volume of air for the absorption of carbon dioxide, and tree roots exploit a considerable volume of soil for water and nutrients. The three essential prerequisites for efficient photosynthesis are, therefore, effectively fulfilled, and as a consequence the forest system capitalizes on the production of organic matter. Additionally, the forest community operates efficiently through time, although forests of evergreen conifers are more efficient than deciduous broad-leaved forests in total as well as tree biomass production. Systematic studies of the changes in the rate of organic matter production through the life of the forest are lacking, but the data available from reforestation programs indicate that the tree component increases slowly as the canopy closes, maximizing at the point of greatest competition between trees, and thereafter falling as trees are removed or die. The contribution of the ground layer is most marked at the youngest and oldest ages of the crop—*i.e.*, when the canopy is open. Complementary data on

the dry weight of foliage confirms this pattern, and it is probable that the number of stems per unit area (stand density) is as important as geographic location for both the weight of foliage and the total biomass produced. Within a given geographic region there are considerable differences between tree species in their rate of organic matter accumulation. Various estimates of timber production indicate that conifer stands usually are more productive than deciduous tree stands. Despite the lack of comprehensive data, the biomass production from the forest community is impressive (Table 10). (G.K.E./Ed.)

Scrublands

Mediterranean vegetation

Scrublands are areas where low, evergreen, leathery-leaved, and often aromatic shrubs (or scrubs) dominate the vegetation. Mostly they are confined to a Mediterranean type of climate—hot, dry summers and cool, wet winters—and therefore are often called the Mediterranean vegetation. This type of climate is found most often near seacoasts, and it commonly occurs in a latitudinal zone between 30 and 40 degrees both north and south of the equator. Scrublands merge into monsoon forests and evergreen forests toward regions of wetter climate and into thorn-shrub vegetation and steppes toward regions of decreasing precipitation.

THE ENVIRONMENT AND BIOTA

During the dry summer months, the temperature differential between day and night in scrublands is much greater than during winter, and during the wet winter months the night temperatures are usually between 10° and 16° C (50° and 60° F), which is optimal for the growth of scrub vegetation. The night temperature is most important in the control of plant growth.

The high summer temperatures make the small amount of precipitation insufficient for growth of scrubland plants, and most of them become dormant. Scrub plants flower and produce fruit before the onset of the hot, dry summer, the scrublands bursting into colourful display during spring. In California, for example, sage, mountain lilac, tree poppy, and *Fremontia* bloom at this time. In Australia *Grevillea,* acacia bottlebrush, and *Dryandra* are the principal genera of spring flowering plants. In the Cape scrublands of South Africa various members of the protea family and heath colour the hillsides with spectacular displays of flowers. This same feature of the climate also conditions the dominance in the scrubland vegetation of winter annuals—*i.e.,* plants that complete their life cycle in a single growing season, in this case during the wet winter months. The summer drought makes it impossible for shallow-rooted herbs to survive, leaving most of the space between shrubs bare. Thus, at the beginning of the autumn rains, the seeds of annual plants are able to germinate on the bare ground.

The shrubs of the scrublands are adapted to growing in winters that combine low temperatures with adequate moisture. Typical desert plants that grow only at high temperatures, such as the creosote bush, or jarillo (*Larrea divaricata*), cannot live in the scrublands nor can shrubs native to areas with summer rains and winter drought (*e.g.,* in western Texas or the Transvaal).

The dry climate of the hot summer months predisposes scrublands to fires, and most of them can be described as being a fire-maintained vegetation. The shrubs are adapted to fires in being able to sprout from their root crown. Since most trees are unable to form new shoots from the base of their trunk, a scrubland vegetation is kept free from invading trees through frequent fires.

Many of the scrubland plants have seeds whose germination is stimulated by high temperature treatment. This is known, for example, for the chamiso (*Adenostoma fasciculatum*), whose seeds do not germinate until very old unless they are subjected to dry heat near 93° C (200° F) or else are treated by being placed near charcoal or by being leached for a long time in water.

Scrublands are not usually browsed by animals; although deer may live nearby, they normally do not eat the frequently aromatic or toxic shrubs. Another reason why the scrublands in general are not grazed or browsed by the larger mammals is their impassable, dense growth. Although not as forbidding as the thorn-shrub vegetation, scrublands are accessible to larger animals only with difficulty. In Australia, the wallabies (*Wallabia*) and even the so-called scrub wallabies (*Thylogale*) use the scrub vegetation only for resting during daytime, feeding in open grasslands during night. Scrublands also are impassable to the Australian flightless birds.

Scrubland animal life

While not inhabited by larger mammals, scrublands are frequented by small seed eaters. Typical of these seed eaters are small rodents, such as pocket mice (*Perognathus*) and kangaroo rats (*Dipodomys*), and quail. None of these animals is restricted to scrublands, however, and most prefer a more open vegetation.

Insects and insect-eating birds and reptiles are common in scrublands but not more so than in other types of vegetation. Because it is impossible to characterize scrublands by any typical animals, botanical criteria are relied upon exclusively.

SCRUBLAND DISTRIBUTION

The accompanying map (Figure 28) shows the distribution of the most important scrublands over the world. A description of each of them follows.

The Californian chaparral. The scrubland vegetation of the Californian chaparral occurs on the lower slopes (generally below 1,000 metres, or 3,280 feet) of the coastal and inland mountains of southwestern North America, wherever the yearly rainfall ranges from about 250 to 500 millimetres (10 to 20 inches) per year, with a pronounced dry summer. At higher altitudes with increasing precipitation, the vegetation gradually changes into fir and pine forests, and in the interior the scrubland flora is replaced by a steppe vegetation dominated by the sagebrush (*Artemisia tridentata*).

Along the coast and in the higher rainfall areas, the dominant shrubs of the chaparral are sages, mountain lilacs, rhuses, desert buckwheat, and the scrub oak. In

drier localities and on poorer soil, chamiso or ribbonwood becomes dominant. If left undisturbed, live oaks and big-cone spruce invade the chaparral on the better sites of north slopes, gradually transforming them into forests. Only in exceptional localities does the chaparral remain undisturbed; normally it burns over once every 10 to 40 years. After a fire the shrubs resprout from the root crown, and many germinate from seed, together with many herbaceous plants.

The Mediterranean maquis. Although human activities have removed much of the Mediterranean maquis, in Spain, southern France, Greece, Lebanon, coastal Israel, Tunisia, and Algeria a shrub vegetation still covers the lower slopes of the mountains bordering the Mediterranean Sea. This vegetation consists of many aromatic shrubs such as savory and other members of the mint family, rockrose, laurel, myrtle, and different brooms, with olives, carob, figs, and other semitrees transforming the scrublands into forests in the absence of human interference.

Where the soils are poorer and rockier, the maquis is more open, sometimes with shrub palms (*Chamaerops*), and is called garrigue in the French Mediterranean.

Many of the plants of these Mediterranean scrublands are well known, such as the laurel and the olive. The myrtle, and innumerable spices, such as rosemary, thyme, and marjoram, are also familiar members of this vegetation.

Boundaries of maquis

Northward, toward central Europe, summer rainfall increases, and a forest climate replaces the Mediterranean climate, whereas south and eastward the climate becomes drier and changes into a steppe and desert climate. This occurs along the Mediterranean shores in Libya and Egypt, where a semidesert vegetation replaces the maquis because of an absence of moisture.

A vegetation similar to the Mediterranean scrublands extends from Turkey along the lower mountain ranges of Asia Minor. This is a reflection of the climate, with the rainfall decreasing eastward but increasing at higher altitudes. It is at the borders of the Mediterranean scrubland climate where the first successful attempts at agriculture occurred in Asia Minor, about 10,000 years ago.

With the unprecedented increase in population since Roman times, most of the original maquis vegetation has been transformed by humans into cultivated areas. River valleys are irrigated, and profitable crops now replace the maquis. On mountain slopes, olive orchards now grow in areas formerly occupied by a varied maquis vegetation.

The Australian scrublands. Australia has probably the most extensive and richest scrubland vegetation. In Western Australia rainfall ranges from about 250 millimetres (10 inches) in the interior to about 1,500 millimetres (60 inches) along the southwest coast. There are extensive eucalyptus forests in the high rainfall area, but in areas having between about 380 millimetres (15 inches) and about 1,000 millimetres (40 inches) of precipitation, varied scrub vegetation covers the land except near the roads, where extensive clearings have removed the shrubs. There are about 1,000 shrub species living in southwestern Australia, many of them with spiny branches and leaves and with brightly coloured flowers ranging from deep blue, lilac, yellow, and brown to red. Most of these shrubs belong to a few families, such as the pea family (especially the wattles [acacia]), the myrtle family, the protea family, and the rue family.

Eastward, past the desert of the Nullarbor Plain, another scrubland is found, commonly named mallee, where shrubby eucalyptus, wattles, *Banksia,* and other members of the protea family reign supreme in South Australia.

The Chilean scrublands. Also in the Southern Hemisphere are the scrublands of central Chile, where *Acacia cavenia,* groundsel bush, and tall cacti grow on the Pacific slopes of the Andes. Lower on the eastern slope of the Andes in Argentina grow desert shrubs, which are replaced farther eastward by chaco, a thorn-shrub vegetation that merges into *campos cerrados* (scattered trees in dense grasslands) in central Brazil and caatinga (stunted, sparse forests, leafless during the hot dry season) in eastern Brazil.

Caatinga

The Cape flora. The Cape flora is a restricted shrub vegetation in South Africa, consisting chiefly of heath and members of the protea family. This flora is remarkable in that it occupies an area of not more than 518 square kilometres (200 square miles), yet it is exceedingly rich in species, having more than are present on a several thousand times larger area of the central United States or of central Europe. It differs totally in its composition from the surrounding evergreen forest, karroo, veld, and desert vegetation, most of which occurs in a climate with winter drought and summer rains.

SCRUBLAND GROWTH AND DEVELOPMENT

Floristic comparisons between scrublands. All of the scrubland floras have developed locally and are not related to each other, except for a few genera they have in common. In the five main regions with scrubland vegetation, all major floral constituents are unique for each of them, yet there are certain plant genera or families that have representatives in more than one of the five areas. The scrublands of the Northern Hemisphere, for

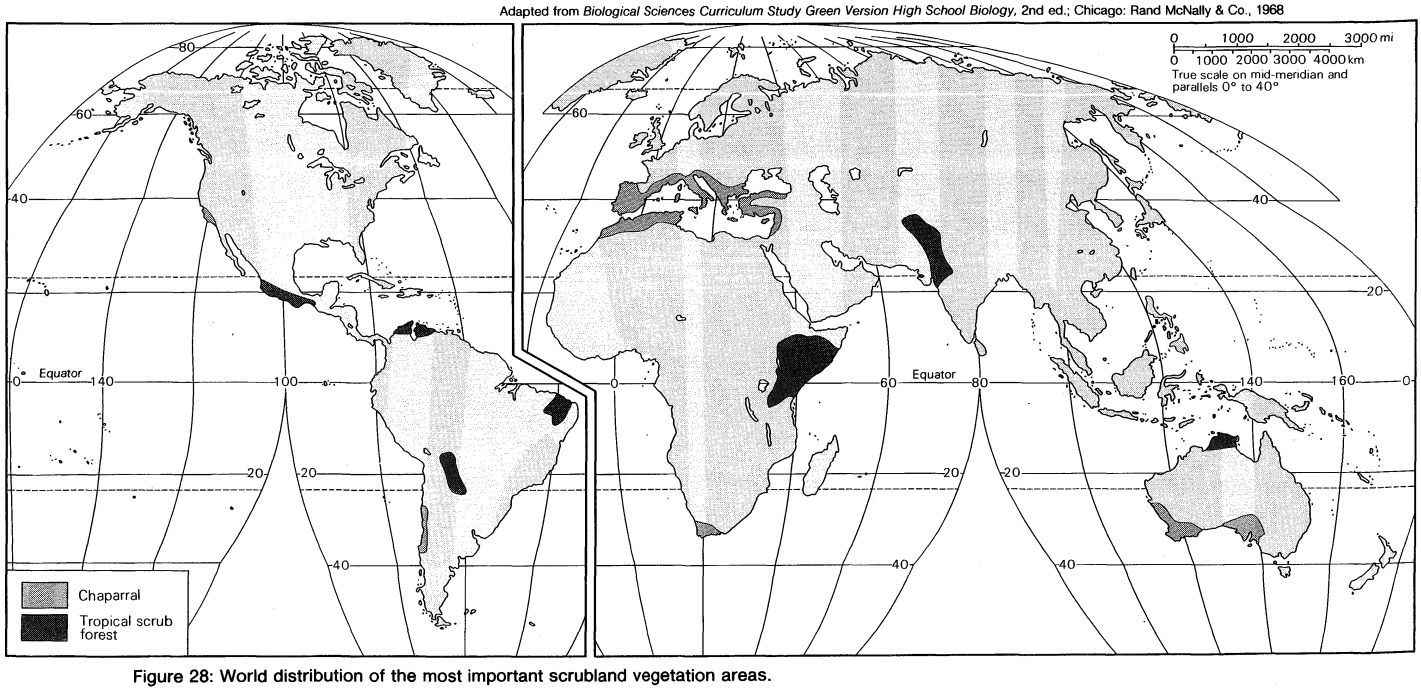

Figure 28: World distribution of the most important scrubland vegetation areas.

example, have a number of genera in common and so have those in the Southern Hemisphere. The scrublands on the same continental masses (Chile and California, Cape and Mediterranean) also have a number of related plant species. The Australian scrubland, however, has no relationship with either North American or European scrublands, nor has the South American scrubland any relationship with the European.

Seasonal aspects of scrublands. Scrublands in general do not change much in the course of a year. The shrubs are evergreen, and they change colour only slightly during the dry season, when the bright green foliage turns an olive green. After the first rains in late autumn, lush, new, green foliage appears and remains green into early summer.

The Mediterranean climate has mild winters, and most of the scrubland species are only mildly frost-resistant. In the chaparral, the laurel sumac (*Rhus laurina*) is probably the least frost-resistant, and after an exceptionally cold winter a number of shrubs of this species may be killed through freezing.

After an exceptional series of drought years, mortality among the less drought-resistant chaparral plants is greater than normal, and many sage shrubs die during such periods. The more resistant species, such as chamiso (*Adenostoma fasciculatum*) and desert buckwheat, survive even after drought periods. Thus these latter drought-resistant shrubs spread into the desert shrub vegetation. It is, therefore, not in the years with average winter temperature and average winter rainfall that selection in the chaparral occurs. It is in the exceptional years that the composition of the scrubland flora is determined.

Temperature and precipitation effects on scrubland composition

The most pronounced seasonal changes in the flora of scrublands are provided by annual plants. Their seeds germinate within a few days after the first extensive autumn or winter rain, and the plants continue to grow slowly during winter. In spring, flowers are produced in response to the lengthening of the days. Fruit is set and ripens before the long summer drought. Many of these annual plants occur both in the chaparral and in the desert. The major difference between these two habitats is the frequency of winters having rainfall sufficient for germination of the annual plants. Since annual plants require one inch of rainfall to germinate, they develop only when enough water has fallen to complete their life cycles.

Annuals occurring in both chaparral and desert are gold fields, which can produce spectacular displays in March and April, when large tracts of land become golden yellow with the flowers of this tiny composite, whispering bells, several poppy species, fiddle-necks, and different kinds of forget-me-nots.

In Western Australia the displays of annuals in the scrublands during September are just as spectacular, with the deep blue of *Leschenaultia* and *Dampiera* and the pinks of trigger plant (*Stylidium*) and sundew. Perennial herbs such as *Conostylis* and many orchids add to the flower displays in the underbrush. In the scrublands of the Mediterranean, mustards, legumes, and bulbous plants such as grape hyacinths lend special colour to the spring annual flora.

Evolution of scrublands. The scrublands vegetation provides many interesting evolutionary problems. In the southwestern United States, all scrub areas are relatively young in an evolutionary sense. Until 10,000 years ago the area now occupied by chaparral in southern California had a much denser forest vegetation in which sabretoothed tigers, giant sloths, and camellike animals lived. This oak woodland, which also occupied extensive areas in the Great Basin (now the semideserts of Nevada), gradually retreated against the onslaught of drought, which caused the disappearance of the great inland lakes—Bonneville and Lahontan—and which caused the extension of incipient deserts.

In the Mediterranean the climate probably was drier to start with and the vegetation did not change as rapidly as it did in the southwestern United States.

And in Australia the flora and fauna, like the continent itself, are very old. Consequently the mallee has not had invasions of exotic elements, and most of the shrubs growing in it have evolved in their present sites and long ago. They have evolved in directions different from other scrublands. The proportion of shrubs with spiny leaves, for example, is significant in Western Australia, as is the number of shrubs with spectacular flowers.

Occurrence of fires in scrublands. Scrublands form dense stands of vegetation that become tinder-dry toward the end of summers without precipitation and are particularly susceptible to fires. Not only the shrubs themselves but also the dry annuals and litter accumulation underneath provide plenty of fuel for extensive fires, which burn up into the forests bordering the scrublands at higher elevations. But they stop at the transition to the more arid regions where the vegetation becomes widely spaced. Not all scrublands are equally susceptible to fire. There are fewer and less extensive fires in the Mediterranean maquis than in the Californian chaparral or the Australian mallee.

All plants consist of combustible organic matter, but there are considerable differences in their flammability. There are two major factors that influence the ease with which a plant catches fire. One is obviously its water content, and thus water-filled cacti and succulents will not burn. The other is the quantity of aromatic flammable compounds contained in the plant and the ease with which they are released. The aromatic sage plants burn easily, whereas the Mediterranean rockrose (*Cistus*) is definitely fire-retardant.

Factors influencing plant flammability

A shrub fire is usually followed the next winter by destructive floods. For this reason attempts are made to reestablish as quickly as possible burned-over scrub vegetation. This is done by seeding a burned area with fast-growing annual plants. But since these plants—ryegrass and mustard—take some time before they produce a protective cover, and also because they need a good rain before they germinate, such seeding does not provide protection against the first rains after summer or autumn fire; moreover, a vegetation of annual plants needs to be renewed every year. The ideal solution, therefore, is to get as quickly as possible a renewal of the permanent perennial shrub vegetation. This is the natural sequence of events anyway. Whereas a climax forest vegetation usually does not directly regenerate itself and passes through one or several different successional stages before it becomes reestablished after destruction by humans or fire, chaparral regenerates easily. The old stumps of the burned shrubs often resprout and usually do so before the advent of the first rains. Secondly, the seeds of many chaparral plants are stimulated to germinate by the fire. Unfortunately, there usually are not enough seeds of chaparral plants present to get a good stand in the first year after the fire. Therefore a compromise is reached: as soon as possible after the fire, the slopes are seeded thinly with some annual plant that does not interfere with the reestablishment of the natural vegetation. The second year after the fire, the natural vegetation may have grown sufficiently to provide a fairly effective protection against erosion, which it does by shielding the soil against falling raindrops with foliage and litter. (F.W.We./Ed.)

Grasslands

Original extent of grassland

Evidence suggests that, before humans began the present rapid modification of environments by extensive agricultural and industrial operations, between 40 and 45 percent of the land surface of the Earth was occupied by grasslands, in which grasses and grasslike plants dominated in the absence of trees or with widely spaced trees. Although tracts of grasslands and savannas still survive in a modified state as rangelands for domesticated livestock and game animals, much has also been exposed to such intensive agriculture that the original plants and animals have been virtually eliminated.

THE ENVIRONMENTAL SETTING

Regions of natural grassland (Figure 29) occur where the environment is too arid for the development of closed forest but not so adverse as to prevent smaller, nonwoody but long-lived plants from forming a dense layer. Climate controls the biotic components of a region directly, through temperature and moisture extremes, as well as

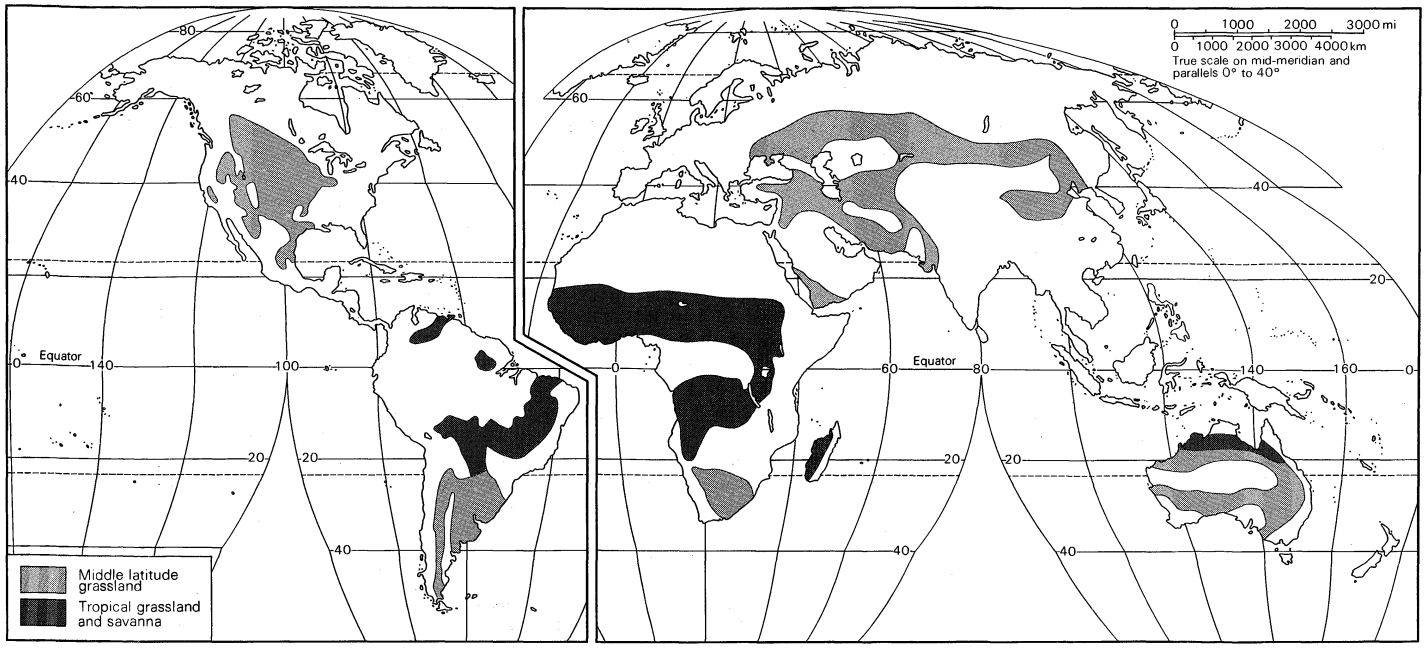

Figure 29: World distribution of grassland biomes.
Adapted from *Biological Sciences Curriculum Study Green Version High School Biology*, 2nd ed.; Chicago: Rand McNally & Co., 1968

indirectly, through its influence on soil development by such long-term physical and chemical processes as freezing and leaching. Within the grassland zone, however, local variations in topography and soils result in microclimatic conditions so different from the typical regional norms that nongrassland ecosystems dominated by plants and animals not characteristic of the remainder of the region may develop locally. In certain warm regions, for example, the woody habit is exhibited by many plant species even under arid conditions, so that specially adapted trees are scattered throughout the grassland to form a characteristic parklike vegetation type known as a savanna (see below).

Climate. The subhumid to semiarid climates of natural grassland areas are characterized by marked periodicity of precipitation, both from season to season within the year and between years. Consequently, annual drought periods of several weeks to several months are typical. The severity of drought increases with the distance from the forest margin. It is also accentuated by a cyclic climatic pattern that often results in several consecutive dry years. Droughts are particularly difficult for plants and animals in regions where the dry season is lengthy—as in the Mediterranean-type climate of some temperate grasslands and in most tropical and subtropical grasslands—or where a series of moister than average years is followed by several years of below-average moisture (see above *Scrublands*).

Annual precipitation in grasslands

Mean yearly precipitation in most temperate grasslands ranges from 250 to 750 millimetres (10 to 30 inches) and in tropical and subtropical grasslands from 600 to 1,500 millimetres (25 to 60 inches). Precipitation determines the nature and extent of natural grasslands through its effect on soil-moisture supply, since trees have difficulty competing with grasses in areas where upper soil layers are moist during part of the year but where deeper layers are continuously dry.

The adverse effect of drought on organisms is made more severe when accompanied by high temperatures. Increased duration and intensity of sunlight associated with decreasing cloudiness during periods of low rainfall tend to raise air and soil temperatures. In regions where the dry season is warm, the combined effects of drought and high temperatures make living conditions particularly adverse. Many organisms adapt to the hot, dry season in grasslands of tropical, subtropical, and Mediterranean climates and to the cold season (also a time of low precipitation) of many temperate regions by becoming dormant.

In the grasslands of tropics and subtropics, the length of the growing season is determined by the length of the rainy season, ranging from 120 to 190 days. In cold, temperate regions, however, temperature is a controlling factor. Growth begins in such regions when the mean daily temperatures reach 5° to 10° C (40° to 50° F). Although the frost-free season in cold, temperate grasslands may be as short as 100 continuous days, the vegetative season usually exceeds 165 days. Less temperature difference occurs among various grasslands during the growing season than during the dormant season. The temperatures during the warmest month in temperate grasslands are usually not lower than 15° to 20° C (60° to 70° F); in tropical and subtropical regions, the mean during the rainy season is commonly no more than 10° C (50° F) higher.

Grassland regions tend to have higher than average wind speeds, in part because of their low wind resistance.

Fire. Fire is an important feature of the grassland environment. Lightning-induced fires are common and, before their control by humans, periodically burned over extensive areas. The causes of fire are so closely related to the more or less arid nature of the grassland climate that it is not reasonable to separate fire from the more traditional climatic factors. Some geographers, however, have not been prepared to accept fires as a climatic factor and consequently have considered the natural vegetation to be that which would exist in the absence of fire. It seems more practical, in regions where aridity, continuity of combustible plant cover, and frequent thunderstorms lead to the frequent occurrence of natural fires, to consider the vegetation as it has been modified by fire to be the stable one. Fire maintains the boundaries of grasslands in climatic regions (usually the wetter portions of the grassland zone) capable of supporting forest growth. The effect of fire here, therefore, has been principally to prevent the extension of the forest into the grassland. The nature of the soil in such transition zones between grassland and forest is such, moreover, that the long-term existence of grassland is indicated.

In the temperate grasslands, a climate adverse to tree growth exists except near the forest edge, but, in the tropics and subtropics, trees and shrubs are often scattered throughout the grassland to form a savanna. The luxuriant growth of herbaceous (nonwoody) plants during the rainy season provides fuel, which, in the dry season, supports fires almost annually in many regions. Whether or not a forest would develop in the absence of fires in these tropical areas is speculative. It is most satisfactory to consider them as savannas in which the herbaceous layer predominates.

Fire's effects

Fire is more destructive to trees and shrubs than to grasses and other herbs, because the buds, from which new

growth will begin the next season, are located well up on the stems in a position vulnerable to fire. In herbaceous species, the growth zones are at or below the soil surface.

Topography. Many grassland regions are characterized by level to gently undulating topography. Often, however, the land surface is sufficiently irregular to provide variations in microclimate that result in a mosaic of vegetation types, as, for example, in the glacial moraines and loessial (loess is a soil material carried to its present location by winds) hills in parts of the Central Lowland and Great Plains of North America and in sandhills everywhere. Near the forest–grassland margin, grassland is favoured, even within the forest zone, on dry slopes that are subjected to greater radiation and wind than is level terrain. Conversely, patches of trees occur within the grassland zone on protected slopes.

Contrasts in vegetation on slopes with different characteristics are particularly noticeable in the higher latitudes, where the slopes facing the equator regularly receive more radiation than do poleward-facing ones. Various habitats also are found in sheltered basins and on exposed hilltops. Forest occurs within the grassland zone in protected basins, and patches of grassland occur within the forest zone on exposed hilltops.

Within the grassland zone, the herbaceous vegetation of depressions and poleward-facing slopes often consists of species that dominate on level ground in poleward areas. In the same regions, the species in exposed habitats are those that dominate communities that range toward the equator. Similarly, where grassland gives way to desert, desert species appear in exposed locations.

Soil. In regions where natural grasslands have developed, physical and biotic components have combined to produce soil different in its character from that of forest regions. In the temperate grassland, soil leaching (downward movement of water-soluble soil constituents) is restricted both by the scarcity of percolating water and by the low solubility of soil materials. The soil of natural grasslands, consequently, contains an abundance of organic matter at all depths, and chemical substances that are leached precipitate at the bottom of the soil profile (*i.e.,* the layering of soil as seen in a trench). Consequently, temperate grassland soils have the capacity to release nutrient elements to plants slowly and over a long period of time, thus permitting the production of annual crops, even after destruction of the natural plant cover. The abundance of organic matter (humus) in grassland soils is reflected in the colour of the upper part of the soil profile; in temperate grassland, the colour varies from black near the forest margin, where the organic content approaches 10 percent in some areas, to chestnut and to brown in areas where the organic content is below 3 percent.

Colour of grassland soils

In the tropical and subtropical grasslands, soil development is influenced by high temperatures and high precipitation in a process called laterization. By this process, soils become highly leached, and there is rapid decay of organic matter with low levels of humus accumulation. These soils are often reddish or yellowish in colour, reflecting the high content of iron left in the profile by the leaching of other minerals under conditions of high temperature. They are also much more subject to nutrient depletion under agricultural practice than are temperate grassland soils.

Differences in soil texture and soil structure throughout the grassland zones modify the vegetative cover because of influence on water regimes. Although sandy soils hold less moisture per unit volume, they permit more rapid percolation of surface moisture than do soils of finer texture, with a lower resultant loss by runoff and evaporation. Because of their greater moisture supply and the availability of moisture to greater depths, sands support stands of tall grasses or even trees in regions where grasses of smaller stature and less depth of rooting occur on soils of finer texture.

THE BIOTIC COMPONENT

Flora. The vegetation of natural grasslands is primarily composed of seed-bearing herbaceous plant species, which are classified, on the basis of gross morphology, into two groups: (1) grasses and grasslike plants (particularly sedges), which are collectively referred to as graminoids, and (2) nongrasslike herbs, mostly broad-leaved species, known as forbs. Woody components also occur, which, unlike the herbs, maintain perennial stems above the soil surface—*i.e.,* they live through several growing seasons. Frequently, there are dwarf shrubs that do not exceed the stature of the grasses; taller shrubs occur in some areas as isolated individuals or in patches. In some grassland areas, groves of trees are found in locally modified habitats such as along stream courses. Occasionally, colonies of non-seed-bearing plants, particularly lichens, club mosses, mosses, and algae, are found on the soil surface.

A considerable number of species constitute the vegetation of grasslands in areas of favourable moisture and temperature conditions, but the number decreases with increasing environmental adversity. In about 2.5 square kilometres (1 square mile) of rolling grassland in the black-soil region of eastern Nebraska, for example, more than 200 different prairie species are found; in a similar area of level brown soil 1,600 kilometres (1,000 miles) to the northwest in southern Saskatchewan, the flora of seedbearing plants is about 50 species.

The graminoids (grasses and grasslike plants) are well adapted to dominate in herbaceous communities, so that, although they typically make up less than 20 percent of the number of species present in grassland, they often furnish 90 percent or more of the plant biomass (dry weight) present. Similarly, though only a small percentage of the seed-bearing plant species belong to the grass family, their contribution to plant communities is great everywhere.

Success of grasses in occupying habitats

Grasses evolved from tropical woody ancestors, of which the bamboos are a present-day example. This origin is reflected in the relatively primitive nature of grasses composing the grasslands adjacent to forests in both tropical and temperate regions. Their adoption of the herbaceous habit, however, has permitted survival through such adversities as periodic burning and seasonal drought. Other adaptations that increase the chances of seed production in arid, windy, and cold environments include wind pollination, increased protection of flowers, and a reduced stature.

The graminoid life-form is particularly well adapted to dominate in competition with forbs. Success of grasses is associated with their ability to provide a dense plant cover in which seedlings of less aggressive species have difficulty becoming established. Graminoids are well adapted to exist in conditions of frequent fire and in areas of animal grazing by their manner of growth. New growth is from a zone of cell division located at the bases of leaves and stems rather than at the tips, as in forbs and woody plants. This permits continued growth when the upper ends of shoots or the leaves are cut, eaten, or burned. The growth zones in the stem also assist shoots that have been bent by trampling to regain a vertical position.

Grasses and the grasslands they dominate are sometimes classified as high, tall, mid, and short. High grasses, frequently reaching heights of 3 metres (10 feet) or more, are limited to tropical grasslands with high precipitation. Tall grasses are found in the most favoured parts of the temperate grasslands, moist habitats being particularly suited to them. Midgrasses, the flowering stems of which usually reach heights ranging from 30 to 90 centimetres (1 to 3 feet), dominate portions of the grassland closer to the woodlands of temperate regions. The short grasses, with leafy shoots often only 8 to 15 centimetres (3 to 6 inches) high, are dominant in the most arid grasslands. Between these extremes, the short and mixed grasses intermingle to form mixed-grass prairie, as in most of the Great Plains of North America.

The adaptation of each species of grass is also dependent on whether it is a turf former or a bunch grass. Turf-forming grasses spread by means of buds on lateral stems below the soil surface (rhizomes) or, much more rarely, above it (stolons). Bunchgrasses are able to spread horizontally only far enough to extend the size of the dense bunch, which eventually declines with age. Occasional development of seeds is necessary for the perpetuation of a bunchgrass cover but not of turf grasses. Bunchgrasses tend to dominate in arid habitats and turf formers in moist ones.

Grass species also differ physiologically in ways that adapt them to withstand adversity. Some species can continue growth during drought by extracting a greater amount of moisture from the soil. Others endure drought by achieving a dormant state before desiccation becomes excessive. Under extreme conditions, drought or overwinter, survival is achieved only by means of seeds, in which case the plants are known as annuals. Annuals are common in disturbed habitats in grassland, but they are more characteristic of the temporary herbaceous cover of deserts.

Root systems of grasses

The root systems of grasses are typically finely branched and rebranched to form a dense network extending through the soil. Depth of rooting of tall grasses and midgrasses is characteristically not greater than 183 centimetres (6 feet) and those of short grasses only 30 to 90 centimetres. These distances are also the maximum depths of moisture penetration in the soils of the habitats in which they dominate.

In some grasslands of both temperate and tropical regions, sedges (*Carex*) are associated with the grasses and have similar ecological relationships. The composites (*e.g.*, asters, sunflowers) commonly rank next to grasses and sedges in abundance. Under the favourable growing conditions near the forest boundary, forbs are abundant; the adverse conditions in the drier grassland regions, however, reduce their abundance relative to grasses in number of both species and individuals. Many forbs are adapted to arid conditions by rooting to depths much greater than the grasses, by surviving as dormant underground organs for periods as long as many years, and by storing water in their tissues. The root systems of some forbs are similar in structure to those of grasses, but a variety of other types exist, including taproots, bulbs, corms (rootlike or bulblike stem structures), and roots capable of forming shoot-producing buds. Species with the last type are particularly vigorous competitors with grasses and are especially abundant in the grasslands of the Soviet Union, where in some areas forbs are considered to dominate over grasses. Eurasian forbs with such root systems have become the most persistent introduced weeds of arable land in many parts of the world. Among them are perennial species of spurge, hoary cress, thistle, and morning glory.

The complexity of the vegetative cover of natural grassland is much greater than it appears to the casual observer. The many plants occupying grasslands may exhibit as much variety within a square metre as is present in about two hectares of forest.

The dominant and associated species are arranged horizontally into colonies and societies and vertically into layers, both above and below the ground. The number of layers discernible depends on the nature of the grassland. The uppermost one is composed of the tallest grasses and forbs. Some forbs have vegetative growth confined to lower layers but thrust their flowering parts, often on leafless stems, upward above the grass layer to ensure pollination and seed dispersal. Others grow vegetatively at a rate similar to that of the taller grasses and bear their flowers on leafy stems. A lower layer is made up of species of shorter stature, some of which are secondary species that grow early in the season, before the dominants cover them.

The lowest layer above the ground is the crust of lichens, mosses, club mosses, and algae that often occurs on the soil surface among the fallen stems and leaves (litter) of the upper layers. Various groups of plants tend to root to different depths, so that short grasses and small sedges form a shallow layer underground and taller grasses a deeper layer. The roots of some forb species often branch only below the deepest layer of grass roots; they sometimes penetrate to depths twice that of the dominants.

Seasonal aspects of grasslands

The appearance of temperate grasslands changes from season to season as a result of the successive flowering of different species. A few species thrust their flowering stems upward shortly after the disappearance of snow and before they are shaded by the spring growth of the cool-season grasses. These are followed by the spring flowers, which, in the temperate grasslands, are composed of many forbs including early legumes (members of the pea family). Early grasses and some sedges begin to flower near the end of this period. Most of the dominant grasses, of both warm and cool seasons, blossom during the summer, as do most of the legumes, all of which give a predominantly bluish and whitish tinge to the landscape at this time. The predominant colour of autumn flowers is yellow, and the floral display is made up principally of an abundance of composites. During these shifts in the seasons, the grasses also change in the early spring from the grayish colour of the preceding year's old growth through rich greens as the new leaves emerge to a straw-coloured hue of pale yellow in the late summer and early fall. Curing of shoots to a yellowish colour is characteristic of the more arid grasslands; those in more humid areas turn gray more rapidly. The growing season varies in character from year to year as differences in weather differentially stimulate or retard flowering of the various species. The grassland tends to be drab and relatively lifeless during the winter. The changes in the season have not been as well documented in the tropical grasslands, in which the main changes apparently take place with the shift of the season from dry to rainy, with the resultant prompt resumption of luxuriant green growth that ends only with the renewed onset of drought. Some tree and forb species in tropical savannas anticipate the change in the season by leafing out before the arrival of the rainy season.

Animal life. The natural animal populations in grasslands are much more diverse than is generally realized, as many surface species are small and inconspicuous, and many other species live underground for at least part of their lives. The best known are the large grazing mammals, or game animals. Other well-known groups in grasslands include grazing marsupials (pouched animals, such as the kangaroo), predators belonging to the cat and dog families, rodents of various sizes, birds, lizards and snakes, and the larger insects, particularly grasshoppers and locusts. A large proportion of surface species are either running or burrowing types. The characteristic aggregation into colonies or herds provides some measure of protection in the open type of habitat. Invertebrates of various kinds are abundant in the soil.

Vertebrates. The large grazing mammals, subject to the influence of humans, have been reduced in number, and some species survive only in protected areas. Their former ranges have become densely populated and are being grazed by cattle, sheep, horses, and goats. In some of the managed reserves in Africa, the natural and domesticated populations intermingle, but for the most part, the native grazing species are considered intruders, and their predators also are excluded by poisons, hunting, or fences.

Large animals of grasslands

The African grasslands were once abundantly supplied with a large number of species, of which perhaps the wildebeest, gazelles, and zebra were the most numerous over large areas. Other species included buffalo, giraffe, eland, antelope, hartebeest, hippopotamus, waterbuck, and impala. Some species, which are browsers as well as grazers, have had significant influence in restricting the growth of trees. These herbivores are accompanied by a variety of omnivores (animals, such as the warthog, *Phacochoerus aethiopicus,* that feed on both animal and vegetable substances) and carnivores (meat eaters), particularly the lion, leopard, hunting dog, and fox. The hyena (family Hyaenidae) is perhaps more truly a scavenger, but it also fills the role of predator while traveling in packs. The characteristic grazing species of the Asian grasslands include wild cattle, saiga antelope, wild horse, marmot, stag, and boar; predators are represented by the wolf and the fox. Wild horses and cattle, formerly abundant, have been exterminated by humans, and antelope and marmot have largely been forced out of the grassland region.

The number of species of large grazing mammals in the Western Hemisphere, while it was larger during the early geologic stages of development of grasslands, has been low in recent geologic time. In North America the principal species once were the bison and the pronghorn antelope. Their most important predators were the coyote and bobcat. In South America the large grazing mammals have been less influential; rather, the llama and its relatives and the ostrich, a native of Africa, are the most important. The isolated fauna of Australia includes several kangaroo species as the major large grazing animals, with the dingo as their prime predator.

In some grasslands the large grazing mammals are as important as climate and soil conditions in determining the nature of the vegetative community, since some plant species are more sensitive to grazing pressure than others.

Smaller herbivorous mammals, common in natural grasslands, include many species of rodents, such as mice, voles, shrews, ground squirrels, gophers, prairie dogs, hares, and rabbits. Some species have increased their populations in regions where humans have reduced the numbers of their predators, others, such as the prairie dog (*Cynomys*) in the Great Plains of North America, have suffered from a direct effort by humans to exterminate them. Rodents, now reported to be the most frequently found mammals in some grasslands, are credited with causing widespread range deterioration, because they modify the speciation of the plant cover and expose the soil surface to erosion.

Many birds, including herbivorous, carnivorous, and omnivorous species, inhabit grasslands. The herbivores are the least numerous in terms of different species, and the omnivores are most abundant. The passerines (perching birds) are particularly common and include larks, longspurs, meadowlarks, starlings, grouse, cranes, partridges, and doves. Hawks, owls, and eagles are important predators.

The amphibians and reptiles are important organisms in many grasslands. Lizards, toads, and box turtles are mainly functional as predators of insects; snakes are predators of rodents and some other small vertebrates. These organisms, probably the least conspicuous components of grasslands, are often, however, among the most abundant vertebrates.

Invertebrates. Great numbers of species of insects and other invertebrates inhabit grasslands, forming large populations of individuals. Most conspicuous are the grasshoppers (Orthoptera) and their relatives. The numbers of surface insects present in grasslands have been estimated to be as many as 1,000 per square metre (about 100 per square foot), and the number of species present in one type of grassland may exceed 200. Insect bulk, or biomass, has been reported to be greater in some areas than that of large grazing mammals. Next to the grasshoppers, the insects with the most pronounced effect on herbage are probably bugs, aphids, and leafhoppers. Ants and termites are found particularly in tropical and subtropical grasslands. The larvae of beetles (order Coleoptera) feed on roots of plants and on feces, especially those of large grazing animals. Larvae of flies (order Diptera) often affect seed production and are active in decomposing carrion. Larvae of moths and butterflies (order Lepidoptera) feed on the crowns of grasses; and thrips (order Thysanoptera) also affect seed production. The most abundant predatory invertebrates above the soil surface are spiders (class Arachnida).

Insect numbers and bulk

Small soil animals are important to the grassland ecosystem. Chief among them are roundworms, springtails, mites, and small segmented worms, as well as insects. Earthworms, although common in semipermanent and seeded grasslands, are rare in natural grassland conditions.

Microorganisms. Microflora (bacteria, actinomycetes, fungi, and algae) probably are found in greater numbers in grasslands than are microfauna (protozoans). The great majority of microorganisms present in the soil are apparently dormant or inactive at any one time, although the bacterial biomass to a depth of 15 centimetres (6 inches) in agricultural soil has been estimated to range from 330 to 720 kilograms per hectare. Grassland soils, because they have considerable root systems that provide habitats for markedly higher numbers of bacteria, thus contain an even greater bacterial biomass. Fungi, although present in appreciably lower numbers than bacteria, have much larger cell sizes and are estimated to possess a biomass twice that of the bacteria. Algae are commonly estimated to contribute less than 10 percent of the total microfloral biomass in mature soils.

COMMUNITY DEVELOPMENT

Stages. Grassland ecosystems have developed through an orderly series of changes in plant cover and soil, as one has affected the other through climatic influences. These progressive changes in plant cover are known as primary plant succession. As plant succession progresses toward a stabilized plant community, a soil gradually develops a profile that reflects the nature of the plants occupying it. The end of this process, a climax situation in which the organisms and soil are in equilibrium with the climate, is a stable system with many buffers to protect it from changes in climate and animal populations.

Primary succession of grasslands begins on bare, dry land surfaces or in water. In each situation, development is toward a more moderate water regime. This is accomplished in the dry habitat by the development of an insulating plant cover that protects the surface from the desiccating effects of the sun and wind and by the incorporation of organic matter into the soil, which increases its water-holding capacity. In wet habitats, the process involves gradual elevation of the substrate (bottom of the water body in question) by deposition of both organic and mineral particles.

The series of changes in plant cover resulting in grassland begins with a layer of crustose lichens, followed by foliose (leafy growth form) lichens. Eventually, annual herbs and a series of perennial species—first forbs and short-lived grasses, finally a stable community of long-lived grasses and forbs—becomes established.

Gradual succession of water bodies to grassland

The succession beginning in a body of water starts with submerged aquatic species and progresses through floating-leaf, reed-swamp, and sedge-meadow stages as the water level decreases. This moist habitat may survive for thousands of years and permit the development of various vegetative stages (even of shrubs and trees) before the depression containing the water gradually fills from the edges and the vegetation becomes dependent, for the first time, on climatic factors (chiefly precipitation) that permit the establishment of a climax grassland cover.

The uniformity of the climax vegetative cover depends on the degree of irregularity of the landscape, for the final stages of the dry-habitat succession will not be reached while exposed locations survive on sunny and windy slopes and on hilltops, and protected situations are preserved on sheltered slopes and in depressions. The regional characteristics of the vegetative cover, however, are expressed in topographic locations between these extremes. It is on this portion of the landscape, which in most grassland areas constitutes the major area, that the following brief survey of the grasslands of the Earth is based. While this survey considers the temperate regions separately from the tropical and subtropical grasslands, the distinction is arbitrary. Subtropical grasslands give way imperceptibly to temperate communities through the arid areas where contact usually takes place.

Temperate grasslands. The most extensive grassland areas of the temperate zone are the steppes of Eurasia, the prairies and plains of central and western North America, and the pampa and adjacent areas of Argentina. Less extensive areas are found in the velds of South Africa, in the mountain grasslands of South America, and in Australia and New Zealand.

North America. The North American grassland is composed of seven regional types. The largest, the mixed prairie, extending from southern Alberta and Saskatchewan southward to western Texas, lies between the 100th meridian (west longitude) and the foothills of the Rocky Mountains to the west. It is dominated in the north by bunch-forming spear grasses and turf-forming wheatgrasses, which are midgrasses that gradually give way to short grasses southward, particularly blue grama (*Bouteloua*) and buffalo grass (*Buchloë*). The next largest area of grassland east of the Rocky Mountains occurs in a higher precipitation belt extending from the mixed prairie to the eastern deciduous forest. Although it is now the "corn belt," this area was formerly dominated by spear grass and dropseed in the drier habitats and by bluestems in more favourable locations. Both types occur in areas east of the Rocky Mountains, where there is an early-summer peak in precipitation, followed by late-summer drought. West of the Rockies the most northerly grassland area occurs in eastern Washington and adjacent parts of Idaho and Oregon and in the valleys of British Columbia. The dominant grass species is a large, bunch-forming wheat-

grass. The upper slopes in the northern part of this region are occupied successively by remnants of mixed prairie to the east and then by fescue prairie. The latter also occurs as a belt around the mixed prairie's northern edge in the eastern foothills of the Rocky Mountains and in parklands of Canada's Prairie Provinces. Southward, in the Mediterranean climate of the valleys of California, the native, perennial grass cover has been replaced—through overgrazing—by annual weedy grasses, but spear grasses formerly dominated. The southwestern United States and north-central Mexico contain the most arid prairies, the desert plains grasslands, which surround the warm desert at elevations between 300 and 1,500 metres (1,000 and 5,000 feet). Short grama and wire grasses abound here in an environment similar to that of the dry subtropics. The region of Texas adjacent to the Gulf of Mexico also has subtropical vegetation characteristics.

South America. The best-known temperate grassland in South America is the pampa of east central Argentina, which occupies a region of level, black soil. The annual precipitation of 1,000 to 1,250 millimetres (40 to 50 inches) is the highest of the temperate grasslands, and frequent drought periods do not occur. Similar grassland extends on more rolling topography to the north through Uruguay into the semiarid campos region of southern Brazil and northwestward in Argentina. Westward, the pampa becomes drier and the soils gradually change to chestnut and brown and then to gray in colour near the Andes Mountains. In the driest areas, shrubs and small trees (mesquite, senna) form a dwarf savanna. Southward, the pampa gives way to the semiarid regions of Patagonia. Only part of these areas have grassland character. The extremely dry regions contain shrubby, cold desert vegetation. The pampa and the adjacent less humid grasslands have been exposed to grazing by domesticated livestock for about 400 years. Heavy grazing, particularly in the last century, has modified the vegetation to the extent that the identity of the natural dominant species is not known, although spear grasses are thought to have been included among them. The vegetation is now composed principally of introduced species. Cool mountain grasslands are extensive at various altitudes in the Andes, occurring at high elevations even in the tropics. These areas are dominated by species of spear grass, fescue, bluegrass, and reed grass.

The pampa

Eurasia. The body of natural grasslands in Eurasia lies within the Soviet Union, extending from north of the Black Sea in the southern Ukraine eastward through northern Kazakhstan and southern Siberia. These steppes are bordered on the north by forest steppe where the elements of the boreal forest intermingle with the grassland, as is the case in the similar climate at the northern edge of the Great Plains grassland of North America. Southward, the climate becomes warmer and drier, particularly in the Asian portion, and the soils gradually lighten in colour from black to dark brown, brown, and gray at the edge of the cold-shrub desert region. The most important dominants are species of spear grass, feather grass, and fescue. Here, the species of fescue that dominates over large areas is more drought-resistant than the dominant spear grasses and feather grasses, a situation the reverse of that in the northern American grasslands.

Africa and Australia. The South African veld, the tussock grasslands of New Zealand, and the grasslands of Australia are much less extensive. They are similar mainly in that oat grasses are dominants in each. In Australia, however, the oat grass-dominated grasslands are restricted to the southeast, with more extensive grasslands dominated by Mitchell grasses, which occur in arid situations blending into subtropics. Grassland of temperate character also occupies the highlands of East Africa.

Tropical and subtropical grasslands. Tropical and subtropical grasslands are located in central Africa and central South America.

Africa. In Africa, semidesert and desert grasslands occur in areas where the annual rainfall averages less than 500 millimetres (20 inches). Important species in such lands include spear grasses and wire grasses, and the woody element is limited to low, thorny shrubs.

South America. The most extensive tropical grassland area in South America is the Llanos of Venezuela, which lies between the Andes Mountains and the Orinoco River. This region is composed of a complex of plant communities including grassland and savanna, with high grasses dominating in some parts and tall grasses in others. Over large areas there are no trees, apparently because of waterlogging of soil. The best-known dominants in many of these areas are Para grass and guinea grass. The semiarid region of northeastern Brazil is similar to those on the equator side of the deserts in Africa, with wire grasses among the dominants and also with scattered shrubs.

The Llanos

Lands surrounding the Mediterranean Sea and those in Asia Minor and parts of southwestern Asia (Iran, Pakistan, Afghanistan, Tadzhikistan [in the Soviet Union], and India) have been exposed so long to the effects of human occupation that it is no longer possible to determine their original character. It is probable that many areas that are presently desertlike were previously grassland. Elsewhere, the change from grassland to desert because of human occupancy has been observed during the last century.

FUNCTIONING AND PRODUCTIVITY OF GRASSLAND ECOSYSTEMS

The organic component of a grassland ecosystem is a complex of producers, consumers, and decomposers that are highly organized into a food web. The system is driven by energy fixed from sunlight during the process of photosynthesis in the green tissues of plants (the producers). This energy is passed on in the form of organic matter—used as food—from one to the other of various groups of organisms, each of which liberates some of the energy in its own body functions. Finally, the photosynthetically produced organic matter is transformed back into mineral elements, which may again be used by plants in photosynthesis.

The biological productivity of such a system is expressed in terms of the rate of fixation of solar energy by the producers and is known as primary productivity. The rate at which the consumer biomass increases, by transformation of plant materials into animal tissue, is referred to as secondary productivity. Primary productivity for natural, temperate grasslands ranges mostly between 200 and 1,000 grams per square metre of dry matter per year; that in the most favourable tropical areas is much greater. Secondary productivity is considerably less than primary productivity in all regions. In the central Great Plains of North America, for example, yearling cattle consume only a portion of the vegetation present in their grazing area, and of this it is estimated that only 9 percent is used in meat production, 48 percent being lost as heat to the atmosphere and 43 percent to other food chains in the form of feces and urine.

Plant species in natural grasslands are sensitive to the removal of more than a moderate proportion of their shoots. Unconsumed shoots die and remain standing, in some communities for periods as long as two or three years, during which time they protect the soil against erosion and contribute toward increasing the rate of its water intake. In some grasslands, there is more of this "old growth" present than the current season's crop of green shoots. The old shoots gradually decay or fall to the ground to produce a litter layer. The depth of litter depends on amount of growth, amount of consumption, and rate of transformation (by microorganisms and soil animals) to soil humus.

Old growth

The plant biomass (including underground parts) of natural temperate grasslands is usually in the range of 1,000 to 3,000 grams per square metre of dry matter. As much as 85 percent of this biomass occurs underground. Dead material constitutes only a fraction of the aboveground parts (both standing and as litter) but up to 75 percent of the underground parts. About half of the energy fixed in a given year is deposited in underground tissues. The rate of decomposition of dead, unconsumed plant parts is such that, on the average, the amount of biomass present disappears in about two years above ground and about four years under ground. The amount of plant litter present usually reaches an equilibrium state (*i.e.*, the condition that exists when the rate of disappearance equals the rate

of new litter added), which varies from less than 100 grams per square metre in dry, temperate grasslands to about 1,000 grams per square metre in black-soil areas. Lower values than these prevail in areas where a higher than usual proportion of the shoots enter the consumer food web or where recurrent fires occur.

In grassland stands in the subhumid tropics and subtropics, biomass of herbage sometimes exceeds 5,000 grams per square metre; but the rate of decomposition of organic matter is high in such areas, leading to low quantities of litter and soil organic matter.

It has been estimated that about two-thirds of the energy of the grassland ecosystem is released through the activity of reducers and decomposer organisms that feed on detritus and animal wastes. This activity is almost all in the soil or in the litter at the soil surface. Only general conclusions can be given concerning the proportion of this activity caused by invertebrates and other decomposing reducers, since it has not yet been quantitatively evaluated. It is generally agreed, however, that the soil microflora (microscopic plants, including fungi and bacteria) is the single most important group of organisms affecting the turnover of energy. The biomass of soil microflora has been estimated to be 400 to 600 grams per square metre of soil surface on a dry-weight basis; however, probably less than 1 percent of this is active at any one time.

It is not yet possible to identify to what extent various groups of soil microflora contribute to the total of decomposer activity in any given system. The rate of decomposition in standing dead vegetation is usually slower, however, than in litter and in vegetation in contact with the ground. The bulk of the microbial decomposition does not occur until the litter has either made contact with the soil or has become densely compressed just above the soil surface. The smaller macrofauna (animals bigger than microbes), such as litter-feeding insects and worms, are active in bringing litter into more intimate contact with the soil.

UTILIZATION OF GRASSLANDS

Many early human civilizations developed in grassland regions, so humans should be familiar with the ecology of grasslands. Greater interest, however, has been shown in converting grasslands to the growth of annual crops than has been devoted to considering whether they would have been a more valuable resource in an untilled state.

Domesticated grazing animals

Domesticated grazing animals occupy the most important role in the human conversion of natural-grassland plant growth. While conservationists in the past may have seen the domesticated grazing animal as an intruder in natural grassland, this does not necessarily mean that the grassland environment deteriorates through the replacement of natural by introduced animals. The philosophy of range management that has developed in North America is based on the concept of obtaining the highest sustained level of animal production on natural grassland that is compatible with maintenance of the resource. Range ecologists have been much more conscious of the need to conserve land resources than have agriculturalists. In the management of arable lands, for example, the guiding principle has been almost exclusively determined by the need to produce the maximum harvestable yield, a practice hardly compatible with conservation. The advantage that ecologists see in the use of domesticated livestock in the rational management of rangelands is that the distribution and density of these animals is under their control to a far greater extent than would be possible with native animals. The domestication of the range is thus seen as a stabilizing situation.

The success achieved in increasing the harvestable yield of intensively managed arable land and improving semipermanent grasslands of woodland climate has led to the suggestion that the plant cover of nonarable grasslands should be changed as much as possible by the introduction of domesticated forage crops that have been selected and bred for high yield and for optimum response to fertilization and management. A high degree of environmental control is needed, however, to utilize the higher potential of these species, and the indication is that the native grass cover cannot be excelled by introduced species for range production on nonarable land.

Effects of herbicides and fertilizers

Attempts have been made to increase the productivity of natural grassland by the use of herbicides and fertilizers. Weed control of rangeland is economically practical only in cases where the weedy situation has been induced by mismanagement and when this situation is corrected. The effect of fertilizers is variable, yielding better returns where moisture conditions are most favourable. Some native species do not respond to increased levels of nutrient supply and may be replaced after fertilization by species that are more productive but dependent for survival on a continued supply of fertilizer nutrients.

After the initiation of tillage, highly fertile, temperate grasslands gradually (over a period of 50 to 100 years) attain a new level of equilibrium, which is associated with a lower content of soil organic matter. The full impact on organic-matter content will not occur until the original organic material is replaced by that formed from the annual agricultural plant cover. The concept that corrective measures can be taken by future human generations by addition of chemical fertilizer does not account for changes in soil structure that may be associated with declining organic content.

The maintenance of both arable and nonarable ecosystems in grassland zones is vital to the continued provision of food for the world. The temperate grassland zones include an important portion of the cropland of the Earth (for example, 90 percent of the grain for commerce originates here); the tropical and subtropical grasslands provide a possible means for expanding agriculture when technology is developed to manage these lands on a long-term basis. (R.T.C./Ed.)

Deserts

Deserts are arid areas of sparse to absent vegetation and low population density that constitute more than one-third of the Earth's land surface, if semiarid regions are included. Approximately 5 percent of the Earth's land area can be categorized as extremely arid; the regions involved are the central Sahara and the Namib Desert areas of Africa, the coastal areas of Ethiopia and Yemen (Ṣan'ā') near the southern end of the Red Sea, the Rub' al-Khali in Saudi Arabia, the Takla Makan Desert in central Asia, the Atacama Desert of Peru and Chile, and parts of the southwestern United States and northern Mexico. Although the desert environment exists on parts of each of the continents, the nature and diversity of deserts are not widely understood.

The fallacy of the popular view of deserts

The popular view of deserts as predominantly sandy areas that have existed in their present locations throughout geologic time is an unfortunate misconception. Sands, for example, may cover about 10 percent of the surface area in the Sahara and, where dunes or sand sheets occur, are certainly prominent features of the Namib, Arabian, and some other deserts. In general, however, desert sands must be regarded as a minor portion of the deserts as a whole and are essentially absent over vast reaches of arid terrain. And with regard to the permanence of deserts, it is fair to say that the land areas subjected to arid conditions have varied widely throughout Earth history. This is a consequence of both continental drift—the shifting about of landmasses on the Earth's surface, thus bringing different regions into conjunction with arid climatic zones—and climatic changes per se.

During the Quaternary period (the last 1.6 million years) some profound climatic changes of uncertain synchroneity with the ice ages affected some desert areas. Artifacts indicate that early humans hunted large mammals in areas that could not possibly sustain such life today; forests of oak and cedar grew in such highland areas as Tibesti, in the central Sahara; lakes and lake systems were at one time extensive in such regions as the Kalahari, the Iranian desert, and the western United States, where there is evidence of a former body of water 180–210 metres (600–700 feet) deep in Death Valley, for example. Indeed, relict surface features of many kinds, as well as some relict animals (specialized fishes and some crocodiles in oases), point toward the existence of former moist conditions in many of the world's desert areas in the relatively recent

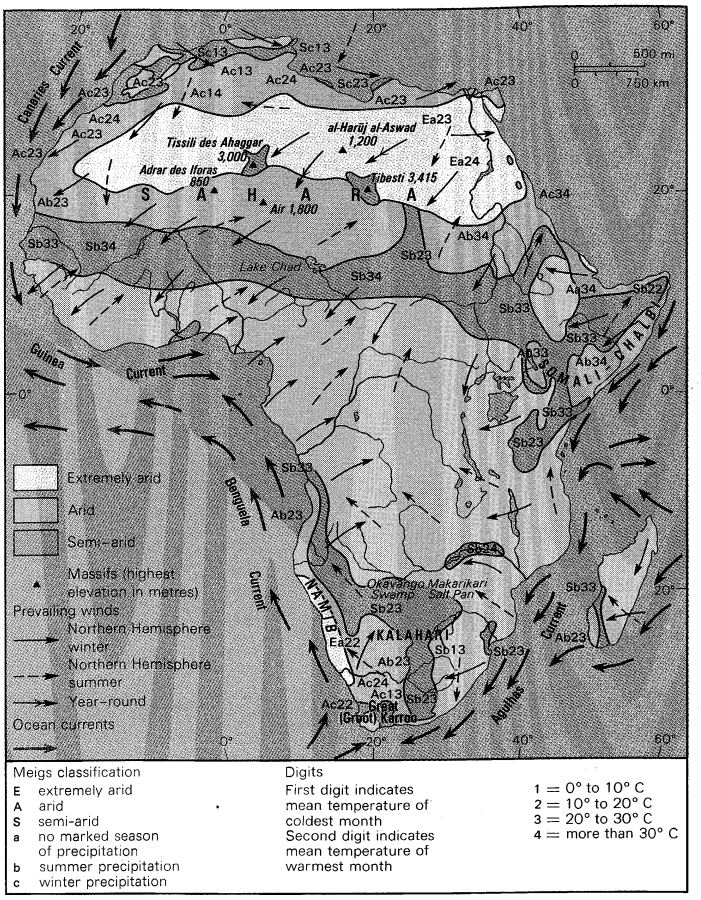

Figure 30: Deserts of Africa.

past. The same may be said of habitation in Roman times in North Africa. The theatre at Leptis Magna, near present-day al-Khums, Libya, for example, was designed to seat many thousands, but the site today is reminiscent of a ghost town.

ENVIRONMENTAL FACTORS

Topography. A considerable number of landforms occur in desert areas, and though some are considered characteristic of arid regions, nearly all have counterparts in the more humid environments. Mountain ranges and plateaus, volcanic peaks and isolated bedrock knobs, peripheral landforms that are alluvial fans if composed of sediment and pediments if consisting of a sloping rock surface, sand sheets and sand dunes, playas and other dry lakes, and desert plains and depressions—these are the principal elements of the desert landscape, which is often described as stark, harsh, and angular in profile. This is to some extent more closely related to the relative absence of vegetation and soil cover in arid regions than to some fundamental physiographic distinction that is climatically based (see further CONTINENTAL LANDFORMS).

Principal landforms

Aridity and its causes. The general cause of the arid zones of the Earth and, hence, of the present location of the world's deserts resides largely in the dynamics of the atmospheric circulation. In the simplest sense, the engine that drives the planetary atmosphere is incoming solar radiation combined with the effects of the Earth's rotation. Much more incident heat is received in the equatorial region than at the poles, and this tends to lead to a poleward transfer of heat and to a meridional atmospheric circulation pattern. The rotation of the Earth produces latitudinal wind zonation at the Earth's surface—*e.g.*, the trade winds, or easterly winds, in equatorial regions and the westerlies in middle latitudes. Although the physical causes of these two circulatory patterns are complex, the reason that they lead to the existence of arid zones is easily understood.

Trade winds and westerlies

Basically, air that is heated at the equator by incident solar radiation rises and cools; its moisture condenses and is released in the tropical zone; the air then subsides toward the Earth's surface near latitudes 30° N and 30° S, thus producing two great belts of subtropical high pressure. This descending air is also the source of the easterly trade winds that blow toward the equator. Some of the world's greatest deserts are located beneath or near these high-pressure belts—the hot, dry trade winds blow across the Sahara (Figure 30), the deserts of the Middle East and South Asia (Figure 31), and part of the North American Desert (Figure 32) in the Northern Hemisphere, and this effect of the general planetary circulation is also responsible for the occurrence of the Atacama-Peruvian desert of South America (Figure 33), the Namib Desert and the Kalahari in southern Africa, and the Australian desert (Figure 34) in the Southern Hemisphere. It should be noted, however, that where the trade winds blow onshore, as along the east coasts of Africa, South America, and Australia, the moisture they bear precludes the existence of deserts.

These generalizations concerning the locations of the world's deserts and wind systems are borne out by several of the maps shown in Figures 30 to 34. Aside from the disruption in continuity of the arid zone along the east coasts of the continents mentioned above, it also may be noted that several of the world's deserts can be characterized as high-latitude types—*i.e.*, they lie north or south of the principal arid belts. Included in this group is much of the North American Desert and the Patagonian Desert of Argentina. These arid areas result principally from physiographic causes: a rain-shadow effect is involved. The latter term is applied when warm, moisture-laden winds must cross a mountain system or similar topographic barrier. When this occurs, as on the west sides of the Andes and the Sierra Nevada, the air masses cool as they rise, and condensation and precipitation occur over the mountains proper. When the air descends on the leeward sides of such barriers, it is thus devoid of moisture and deserts result. The deserts of central Asia, principally the Takla Makan and Gobi, are also related to physiographic causes in the sense that their locations in the continental interior are remote from any sources of moisture. The distribution of land and sea can therefore be cited as a second general cause of aridity on the Earth's surface.

Principal hydrologic factors. The factors that govern the hydrology of arid regions are climatic, topographic, and geologic. Considering climatic factors first, precipitation and evaporation are perhaps most important because these two variables tend to control the water balance of an area. Precipitation is highly variable in arid areas, and as a general rule the variability is inversely related to the mean annual precipitation—*i.e.*, as annual precipitation decreases, the variability increases. This variability, in turn, is directly related to the nature of surface runoff in desert regions; it is spasmodic, and streamflow on a large scale will occur only after intense rainfall.

Variability of precipitation

Another moisture source in deserts is dew, which is worthy of mention because its contribution to the water input and, hence, to the general hydrology of an area has been overemphasized upon occasion. Dew can derive from the condensation of atmospheric water vapour or from water vapour that is emitted from moisture present in the soil. In the latter instance, there clearly can be no net water gain, so the dew derived from soil moisture can be disregarded. The maximum total dewfalls reported do not exceed 0.2 millimetre (0.008 inch) per day in any case, whereas total daily evaporation of about 5 to 6 millimetres is not uncommon. On these grounds it can be argued that the contribution of dew to the overall water balance in arid regions is of negligible import. Its greatest significance is (1) in west-coast deserts such as the Namib in Namibia, where the influx of humid air from adjacent oceans permits optimal dewfall that benefits vegetation and (2) as a necessary moisture source for the chemical weathering of rocks.

Evaporation in all desert regions is a factor of great significance. It is here designated a climatic factor, because it is related to incident solar radiation and air temperature and to atmospheric humidity. The total annual evaporation

Evaporation in desert regions

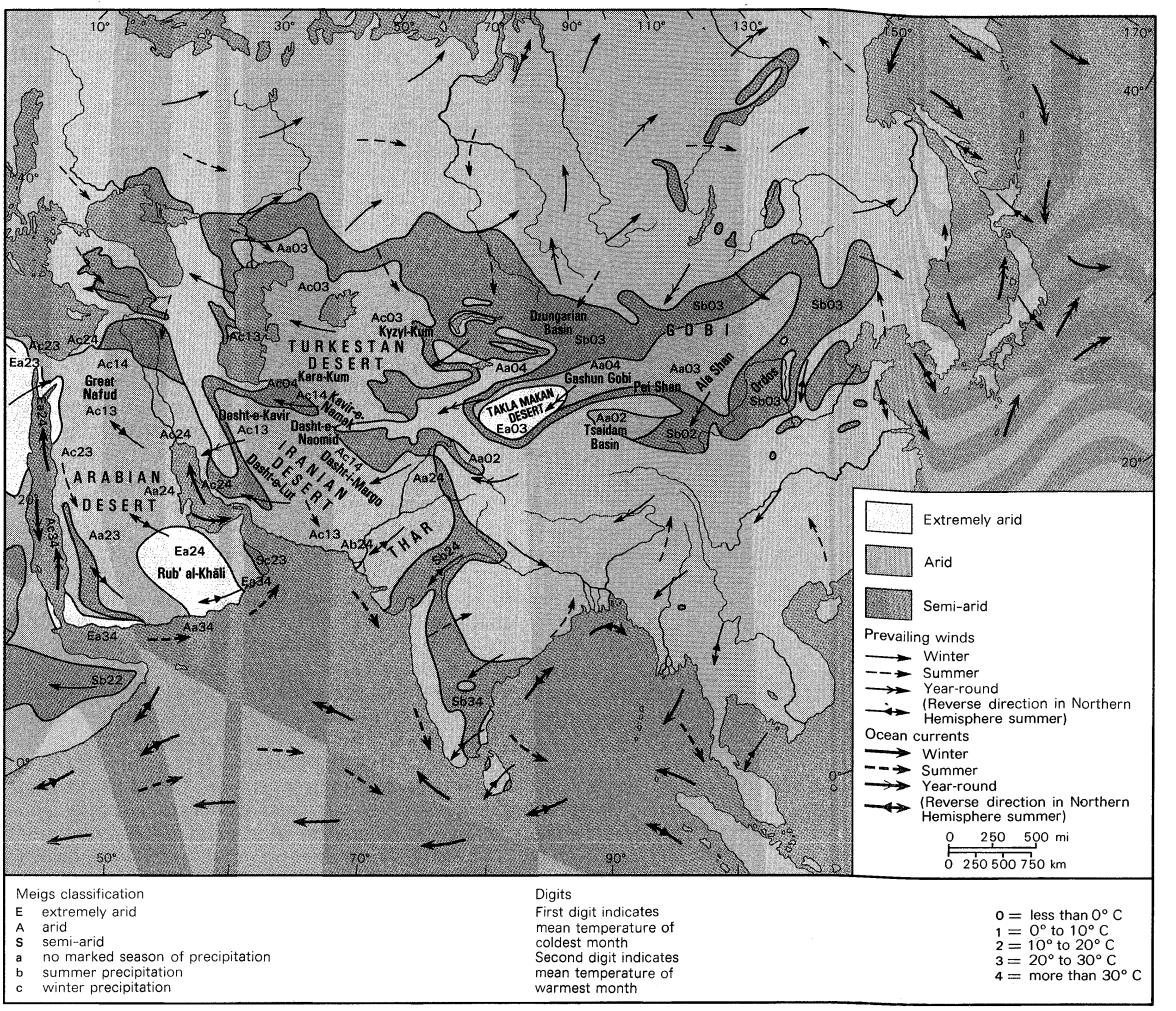

Figure 31: Deserts of Asia.

Adapted from UNESCO, Reviews of Research on Arid Zone Hydrology, "World Distribution of Arid and Semi-arid Homoclimates" (1953)

everywhere exceeds total precipitation significantly, and, indeed, this relationship can be considered one of the climatic hallmarks of the arid regions. Wherever evaporation exceeds precipitation, the presence of free-standing natural water bodies such as lakes is generally precluded, unless some permanent source of water is involved. The Nile, for example, can cross the eastern part of the Sahara despite high evaporation rates (approximately 3,000 millimetres [120 inches] per year at ʿAṭbarah, The Sudan) because its source is in the equatorial highlands and because groundwater contributes to its flow over part of its course. This is flowing water, however; an equal volume of standing water whose only input was derived from precipitation would eventually dry up.

Evaporation is greater over water surfaces than over bare soil surfaces, but it occurs over the latter as well and has much to do with depleting soil moisture and inhibiting plant growth. The occurrence of hot dry winds will tend to increase evaporation rates, and for these and other reasons—including difficulty of accurate measurement—existing evaporation data are in some instances debatable.

With regard to topographic and geologic factors that influence desert hydrology, these can best be considered together. Topography may on occasion promote increased aridity by the rain-shadow effect previously mentioned, but it also may promote rainfall where highlands occur within arid regions. The Tibesti massif (Figure 30), within the central Sahara, for example, attains a maximum elevation of 3,415 metres (11,204 feet); this is sufficient to render it a semiarid "island" in an extremely arid area by reason of the increase of precipitation with increasing elevation.

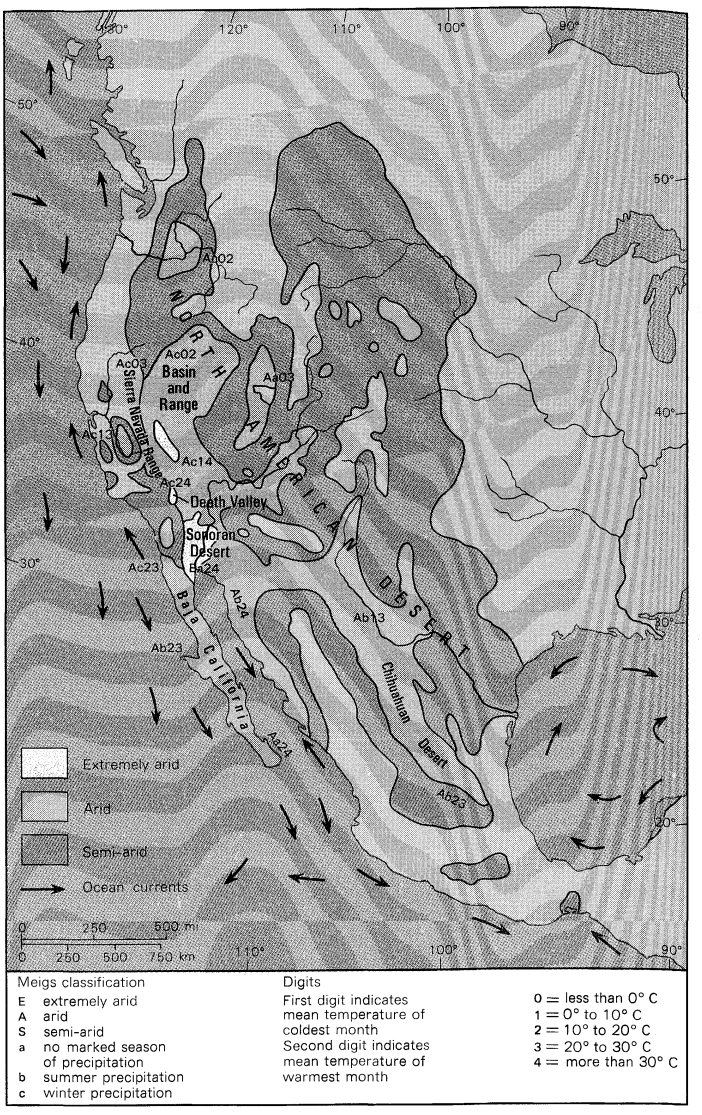
Geologic factors such as rock type and structure, the character of the soil, and the porosity and permeability of surface materials in general also can affect the hydrology in two ways. If water will readily seep to the subsurface because of the presence of rock fissures and fractures or of highly permeable materials, then the runoff from a given amount of precipitation will be less than normal because of water losses. On the other hand, this same set of conditions may promote recharge (the addition of water) of the groundwater reservoir in the area. Where geologic factors inhibit the downward percolation of water, runoff following a storm may be enhanced, but, ultimately, greater evaporation may result.

Geologic factors

Surface water. Although hydraulic and hydrologic principles are unvarying in all environments, some substantial differences exist between the characteristics of streamflow in arid regions and in more humid areas. The drainage networks that exist in the latter, for example, generally reflect the nature of runoff conditions today, whereas in desert areas there are many drainage systems that reflect establishment during Pleistocene time (1,600,000 to 10,000 years ago), when moister conditions prevailed and streamflow was more abundant.

Streamflow in humid and semihumid areas has been studied in detail, and it has been established that the channels of all rivers are in adjustment to a number of hydraulic parameters—*i.e.*, the width, depth, and velocity of flow and the sediment discharge are related to the bank-full water discharge, and this water discharge governs the nature of the channel. The frequency of occurrence of the bank-full discharge is generally about once every 1.5 to 2.5 years, and overbank floods of great magnitude tend to occur every 50 to 100 years. Rivers in these regions exhibit far more days of low flow than of high flow per

Streamflow in humid areas



Meigs classification		Digits	
E	extremely arid	First digit indicates mean temperature of coldest month	0 = less than 0° C 1 = 0° to 10° C 2 = 10° to 20° C 3 = 20° to 30° C 4 = more than 30° C
A	arid

year; they usually transport the bulk of their suspended sediment load during high-flow stages, but the many low flows during a year serve to transport much of the total load (the suspended load, dissolved load, and bed load). Finally, flow is perennial, with rivers linking up to ultimately reach the sea.

In desert areas, streamflow is extremely sporadic. An effective precipitation sufficient to overcome both evaporation and seepage losses into the channel bed and the surrounding dry terrain of the drainage basin involved is required for streamflow to occur. This usually involves a storm yielding relatively intense precipitation (*e.g.*, 36 millimetres [1.4 inches] of rain were recorded in 40 minutes during a storm at Tamanrasset, Alg., in the central Sahara). Low flows tend to be few by reason of the seepage and evaporation losses, and, when flow does occur in arid areas, it will likely be of high stage, violent, and highly charged with sediment that is derived from the abundance of loose sand and gravel that blankets most areas. Discharge of any magnitude, however, and particularly bankfull discharge, may have a frequency of occurrence that is as small as once in 100 or more years, and the recurrence interval of major overbank floods may be measured in thousands of years in extremely arid areas. Streamflow is thus characterized as ephemeral rather than perennial, and because drainage generally fails to reach the sea, save for rivers of the first rank such as the Nile or those with relatively short distances to traverse such as the Kuiseb in the Namib Desert, it is termed interior drainage (Figure 35).

Where surface flows are ponded or terminate in low depressions, marshy areas or lakes may result. If there is sufficient precipitation over the site of termination or if there is sustenance by groundwater flow, then a relatively freshwater lake may result. Most desert lakes are without outlet, however, and thus become highly saline, because each increment of inflow transports additional salts in solution and the constant evaporation of water from the lake causes salt concentrations. Salinity values as high as 200 to 300 parts per thousand are not uncommon.

Subsurface water. Subsurface water is present in each of the desert areas, but lack of exploratory drilling precludes definitive statements on the total amount of water involved in most instances. Groundwater is easily the principal water resource of the arid regions. Water seeps into the ground and flows downward under the influence of gravity—always assuming, of course, that the materials through which it migrates possess the requisite porosity and permeability. Some of this water migration occurs in the deserts proper; surface water losses caused by downward percolation into the sands and gravels of stream beds have been previously mentioned. Indeed, there is always some close relation between groundwater and surface water wherever stream channels occur, but much of the groundwater also is related to the vast areas over which rain may fall and ultimately reach the saturated zone in the subsurface.

Soil moisture

In the near-surface zone, the water present, principally derived from rainfall, is termed soil moisture. Some of the moisture is lost because capillary action brings it back to the surface, where it may form dew and is in general subject to evaporation. There is a second zone extending to perhaps 100 metres (330 feet) beneath the zone of soil moisture in many areas. This is a relatively dry zone, but it may contain lenses of water-bearing sediments surrounded by more impermeable beds or layers. Such groundwater is termed perched in reference to its mode of occurrence. Beneath this zone the groundwater proper occurs; the surface of this saturated zone is called the water table.

In many instances the general subsurface structure, or configuration of strata, in desert areas is that of a basin. When the principal water-bearing strata, or aquifers, are upturned and are exposed at the surface in regions of high rainfall, much of the water input to the groundwater system will be so derived—rather than from seepage due to rainfall over the entire basin region. In the Great Artesian Basin, in Australia, for example, the total area is about 1,760,000 square kilometres (680,000 square miles), but the principal water intake is on the eastern edge of the basin, over an area of about 100,000 square kilometres (38,610 square miles), in which precipitation is 625 millimetres (25 inches) per year. The water flows downward through upturned sandstone aquifers and thence into the centre of the basin, which attains depths of as much as 2,100 metres (6,900 feet). This circumstance of distant intake for groundwater, wherever it occurs, is responsible for the age of the water that has been determined in North America, in the Libyan Desert of the eastern Sahara, and elsewhere. All absolute age measurements on groundwaters in desert areas indicate a range in age of between 20,000 and 35,000 years. This means that waters tapped by wells in Egypt, Libya, and adjacent regions of the Sahara entered the groundwater system from Pleistocene rainfall in highland areas to the south. The groundwater is often called fossil water for this reason.

Age of groundwaters

If the principal water intake is at the upturned edge of a basin structure and if the water-bearing strata crop out at the surface (or occur near the ground surface) farther out in the basin, then there will be a pressure difference caused by the difference in elevation of the water within the aquifer. When this condition exists, the flow of water is termed artesian, and artesian water is the source for most springs, oases, and near-surface water wells in desert regions. The other principal mode of occurrence of these lifesaving caravan stops is also related to groundwater flow. Instead of artesian conditions, the termination of a subsurface aquifer within permeable sediments or the existence of fractures that penetrate the aquifer may be responsible. (L.K.L./Ed.)

Climatic patterns and the biota. Biological activity is inevitably limited when water is scarce or lacking. Above all, it is the green plant that is so limited. Few plants can continue photosynthesis for long in the absence of water; and in the absence of plant growth other living forms have no opportunity to develop. Animals and microorganisms can exist only if energy sources from green plants are available. They are further limited, though, in the absence of water, for most animals and all microorganisms can be active only while moisture is adequate.

In the cold deserts in the interior of continental masses, drought is severe for at least a part of the year, and the daily and annual range of temperature may be great. Moreover, low winter temperatures have a more severe impact on the biota than they might in a region with greater precipitation, because the protection by snow cover is less.

In the tropical deserts cold is no problem, but the clear skies result in a high radiation load on organisms and in high daytime temperatures, often with large fluctuations from night to day. These factors, too, create more intense stresses on organisms than occur in most environments.

Other effects on the biota of the desert environment arise from the abrasive effects of windblown sand and from the high surface salinity in areas where temporary waters accumulate and evaporate or where evaporation leads to upward movement of salts through the soil profile.

Limited leaching and the small accumulation of organic matter in deserts result in desert soils remaining much closer to the types found in pioneer habitats than do soils in more moist environments. Desert soils seem particularly subject to the formation of impervious surface layers—either by physical processes or through the surface development of algae and lichens—so that the effective drought is accentuated by excessive runoff.

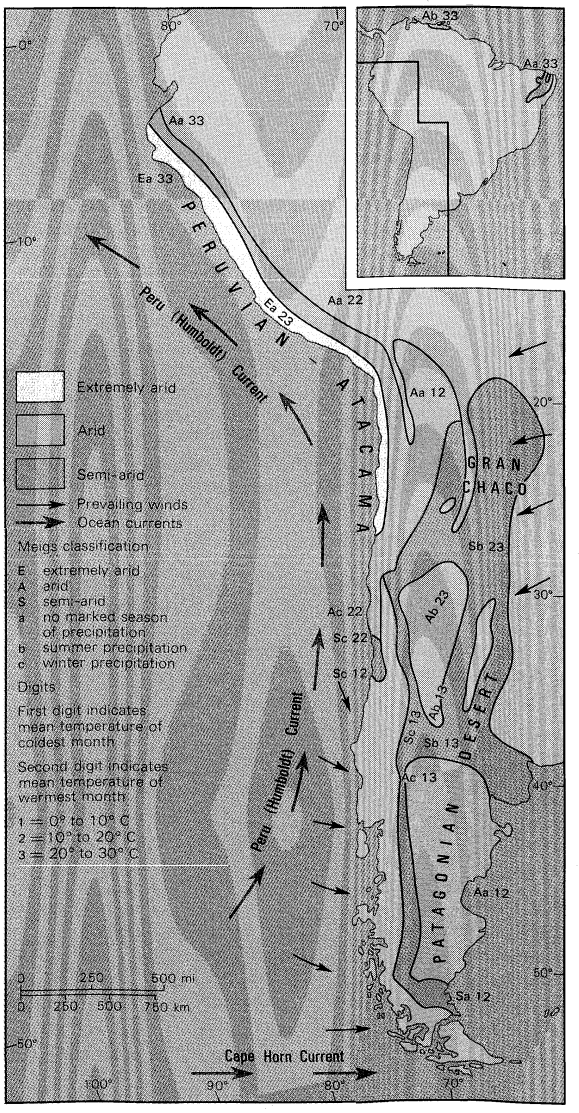

Figure 33: Deserts of South America.

The pioneering conditions that organisms encounter in the desert are permanent, unlike those of other bare and inhospitable habitats, such as coastal sand dunes, rocks, and denuded areas left by human activity. In these climatically more favoured situations, the pioneering organisms initiate changes in the parent soil material that render it more hospitable to newcomers; and a succession of different living communities, each more complex than the last, can take place, leading to a climax community. In the deserts, harsh conditions are not ameliorated by biological activity, and the pioneers themselves constitute the climax community.

Pioneering organisms form the climax community

There are limited desert areas—notably along the coast of South America but also in Baja California, Mauritania, and Namibia—where the extremely low rainfall is supplemented by dew and the aridity is ameliorated by frequent mist and cloud. The relatively low evaporation rates make conditions in such areas much more moist than a simple examination of their precipitation records would suggest.

Spatial dispersion of biota. All of the organisms in a desert do not live under the same environmental conditions. Although the variety of habitats is less than in many wetter environments, it is still great enough to provide effective living conditions for a wide diversity of organisms. Moreover, many organisms show structural and behavioral responses to the environment that tend to neutralize at least some of its extreme features.

It is well known, for instance, that perennial plants in the desert tend to be widely spaced. But, although there are large unoccupied areas between the aerial parts of the plants, excavation may reveal that the root systems are in contact and they exploit the soil so effectively that establishment of new individuals becomes difficult. When rain penetrates the soil, it is rapidly absorbed by the continuous net of roots, and little penetrates to the subsoil. If situations differing in rainfall but otherwise similar are compared, it is found that the plants are more widely spaced as the rainfall decreases. This implies that the amount of plant material remains roughly proportional to the rainfall and that the individual plant is receiving about the same amount of rainfall, thanks to its inhibitory effects on the establishment of competitors.

Perennial-plant spacing

A similar response leads to the establishment of denser vegetation around the watercourses, even when they run infrequently, for there the longer periods of availability of subsoil water permit more plants to have similar productivity without more water per individual.

Different plant species in the desert under the same climatic conditions may differ markedly in their local environment, thanks to differences in soil conditions and topography. Even in the tropics there may be a marked difference in growth conditions between the steeper slopes that face north and those that face south. Desert soils, though with little organic matter and less well-developed profiles than are usual in more humid conditions, differ sufficiently in their mechanical and chemical properties from place to place to support different types of vegetation. And, where stones and boulders are scattered over the soil surface, the microclimates they generate—and the local increase in rainfall penetrating the soil around their edges—permit even some moisture-loving plants such as mosses to develop. Oases similarly are places where a locally dense vegetation corresponds with a locally available water supply.

For animals, the variety of habitats is still greater, for they are generated by the vegetation itself, and since animals are not rooted and dependent on light as green plants are—facts that oblige plants to be more or less exposed to the prevailing atmospheric conditions, however harsh they may be—animals are free to move to more comfortable locations if they desire, even underground. Each species of plant modifies the conditions for the animals around it and may generate living conditions that permit particular animal species to exist, whether providing food,

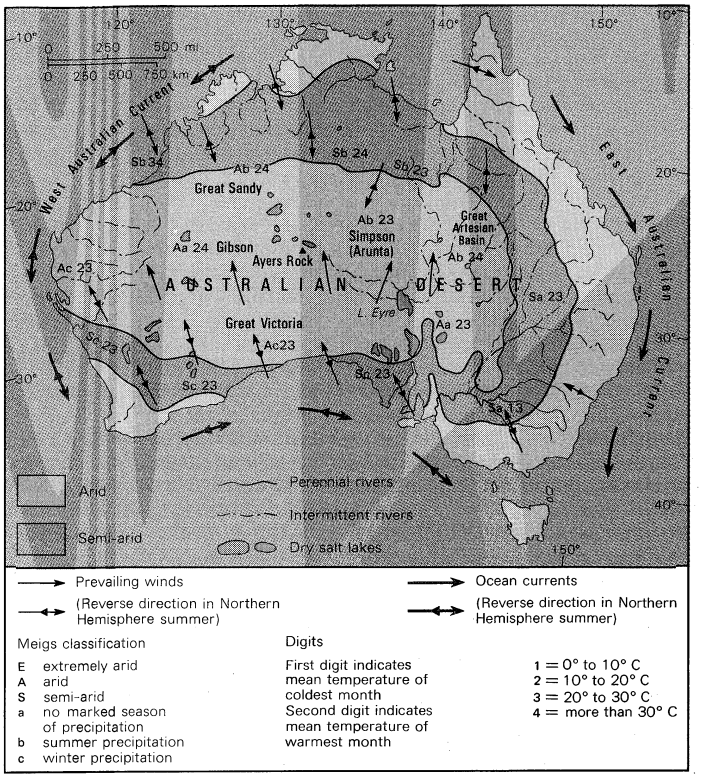

Figure 34: Deserts of Australia.

shelter (shade or protection from predators), or layers of litter in which they can live. Movement between different habitats further varies the living range of animals, as when bats (order Chiroptera) roost in caves during the day and emerge in the evening to feed or when the subterranean larvae of darkling beetles (family Tenebrionidae), feeding on living and dead roots, emerge as adults into the harsh world of the desert soil surfaces to begin their reproductive activities.

Movement between habitats

Like plants, some animals may show a wider dispersion in deserts than elsewhere, thus giving each individual a broader area of ground as "its own." Kangaroo rats (*Dipodomys*), for instance, are reported to manifest more aggressive behaviour in the deserts than in other habitats, resulting in larger and more effectively defended territories for each individual animal.

TYPES OF DESERT ECOSYSTEMS

Cold deserts. These occur mainly in the interior of Asia and in the intermountain zone of North America. Winter temperatures are well below freezing, and the ground may be snow-covered for considerable periods. Summer temperatures are moderately high (up to 40° C [104° F]), though the temperature extremes of regions farther south near the tropics are avoided since the sun is not so high in the sky. Precipitation often is between 200 and 300 millimetres (8 and 12 inches), and a good part of it commonly falls as snow.

The dominant vegetation is of shrubs, with a discontinuous canopy, but not as widely spaced as in the drier deserts nearer the equator. In the spring, as the snow melts, there is a flush of growth, and many short-lived annual plants occupy the soil surface. Among the shrubs, sagebrushes are prominent, as are a number of species of the goosefoot family (Chenopodiaceae), particularly in lower-lying areas, where there is some accumulation of salt.

Shrub deserts and thorn scrub. These ecosystem types occupy a large part of the area of the tropical deserts. The peripheral zone of the Sahara (the Sahel) is dominated by the acacias, many of them thorny. The Mojave and Chihuahuan deserts in North America are dominated by a range of shrubs, of which the creosote bush is probably the commonest. The same is true in similar deserts of South America. Much of the Australian dry country is dominated by many sparse, small acacia trees, while other acacias, *Eremophila,* sennas, and members of the goosefoot family form a denser understory. In other peripheral parts of the Australian arid zone, the low-growing mallees (eucalyptus) take the place of the treelike acacias.

Under the shrubs there is often a partial ground cover of tufted perennial grasses, while the interspaces are filled with short-lived, small flowering plants following rain.

Larger plant-eating animals are not uncommon in this type of country, entering from the surrounding areas of somewhat higher rainfall and more grass during periods when forage is more abundant and retreating when times are harder. Some, such as the desert white-tailed deer (*Odocoileus virginianus*) and collared peccary (*Dicotyles tajacu*) in America and the kangaroo (family Macropodidae) in Australia, make their permanent home in such conditions.

The deserts of cactus and cactuslike plants

Stem-succulent deserts. These striking formations are of limited extent and consist of only the Sonoran Desert (Gran Desierto) of Arizona and northwestern Mexico, the area between Peru and Argentina, and the Namib Desert in Namibia. The special appearance of stem-succulent deserts rests on the geographic availability of certain plant groups absent from many of the deserts—the cactus family (Cactaceae) of the Americas and the arborescent members of the spurge family (Euphorbiaceae) mainly found in Africa. These plants have adopted a special growth habit that provides one alternative solution to the problem of survival in drought. Elsewhere, their role is taken over by shrubs.

Herbaceous deserts. There are desert areas where shrubs or stem succulents are few or absent and where the bulk of vegetative matter is in the form of perennial herbs. These are nonwoody plants whose tops die back each year but whose roots survive to produce new tops year after year. The Nullarbor Plain in southern Australia is of this type; the soil is thin over a continuous limestone substrate, permitting water to penetrate freely, and these harsh conditions are doubtless responsible for the lack of shrubs. Even the perennial species of the goosefoot family form only a sparse ground cover. In southern Africa, there are areas where the dominant vegetation is formed of low-growing succulents.

Salt deserts. Within the deserts, there are many areas where the soil contains a high concentration of salts; most commonly sodium chloride is predominant, but in some places sulfates or carbonates may be more important, and other substances may also, in part, take the place of sodium. These areas are usually in basins of internal drainage, and they may surround highly saline lakes, such as the Dead Sea in Jordan and Israel and the Great Salt Lake in the western United States, or large salt pans flooded only after exceptional rains, such as Lake Eyre in South Australia. Few organisms can grow in a concentrated salt solution, and in consequence the area of a salt pan has a simple community and may appear bare. As

L.K. Lustig—EB Inc

the salinity decreases, either around margins of such an area or through seasons of high rainfall, a limited range of higher plants can establish themselves—mainly shrubs or subshrubs of the goosefoot family. It is noteworthy that these are closely related to—sometimes, indeed, the same as—the species found in the coastal salt marshes. There, too, a high and variable salinity prevails, and near the spring high-tide mark, in some seasons, high salinity and low moisture content persist for a week or more. In the salt deserts, on the other hand, these conditions may persist for months. Whereas in salt marshes the increase in soil level with buildup of organic matter may eventually take the area above tide level, so that leaching can take place and succession proceed, the vegetation in salt deserts is a soil-dependent climax and will not develop further.

Vegetation on dunes and along ephemeral streams

Sand dunes. Where sand dunes occur in deserts, their consolidation or stabilization by vegetation is much more difficult than along seacoasts. In both situations consolidation depends on plant species with wide-spreading root or rhizome (underground rootlike stems) systems. At the coast, this normally permits invasion and establishment of other species, and thus begins a succession. In the desert, the pioneers are the climax, and the barely consolidated dunes are likely to become mobile again if any disturbance breaks the fragile cover and permits wind blowouts. The free drainage of the sands implies that moisture conditions, as well as substrate mobility, are particularly harmful to plant life; and sand dunes in an arid landscape are likely to be among the most persistently bare areas on the Earth's surface.

Wadis and watercourses. Along the ephemeral wadis and watercourses of the desert, the occasional violence of the waters discourages perennial plants; but along the sides, where flow is less frequent and less violent, a special vegetation of deep-rooted moisture-requiring shrubs and trees develops. These benefit not only from water that actually flows down the channel but also from its much deeper penetration into the soil—often quite permeable in these situations—and consequent longer availability. Some of these plants, called phreatophytes, may be able to tap water many metres below the surface and thus survive a drought during which most of the vegetation around dies. A special population of birds and other animals is associated with the vegetation around the watercourses.

Aquatic ecosystems in the deserts. A torrent that flows for two or three days and is then dry clearly does not permit the development of an aquatic ecosystem. But some waters in the deserts are longer-lived, and they have their own special biota. Even in the temporary watercourses, there may be pools that remain filled for weeks, and in these an ecosystem with algae, insect larvae, and amphibians will develop. The same applies to the temporary lakes known as playa lakes lying in hollows and filled for a month or so following rain. If these temporary lakes are saline, the ecosystem may be much simpler, for the salt concentration may considerably exceed that of seawater and the species that can endure it are few.

Virtually the only permanent waters of low salinity originating in the deserts are springs, renewed by flow from underground. These may develop complete ecosystems of similar structure to aqueous systems elsewhere, though generally simpler—due, doubtless, to isolation. These include rooted aquatic and riparian higher plants, algae, crustaceans, insects, amphibians, and fish.

THE DESERT BIOTA AND THEIR ADAPTATIONS

Protists. Soil microorganisms occur in desert soils in about the same degree of diversity as in other soils and can survive frequent desiccation and remoistening. In some deserts, there is a noteworthy development on the soil surface of blue-green algae, which are thought to be active in nitrogen fixation (converting atmospheric nitrogen to forms that plants can utilize) and may also modify the infiltration properties of the soil.

Algae, fungi, lichens, and mosses

Plants. A great deal has been written of desert plants and their adaptations to the rigours of desert life. Apart from the blue-green algae mentioned above, other algae are practically confined to the limited water areas of the desert. Parasitic fungi are as abundant as in other environments, though mainly confined to the higher groups not requiring free water for swimming reproductive cells. Saprophytic fungi (*i.e.*, fungi obtaining food from dead organic matter) are not abundant, the limited organic matter in and on the soil providing little in the way of nourishment, and active growth being possible only during the short periods when the soil is moist.

*Six-year record. †Fifty-four year record.

Lichens are numerous and often prominent—particularly the crustose types. They often form an almost continuous covering to the soil surface and are then able to take advantage of any wetting of the soil for short-lived periods of photosynthesis.

Mosses and liverworts are few and are often confined to special habitats more moist than the deserts as a whole. Ferns are not infrequently found in rock crevices and similar habitats. Club mosses also occur, some showing the remarkable adaptation of being able to dry out and withstand desiccation and lack of active growth in the form of a ball, which may be blown about freely.

Some gymnosperms (nonflowering seed plants) are noteworthy inhabitants of the deserts. Conifers and cycads are few in desert areas, but several ephedras are important desert shrubs—a role to which their near leaflessness suits them; on the other hand, the remarkable Tumboa (*Welwitschia*), with its large, split leaves, is also a desert plant, confined to the Namib in Namibia.

Among the angiosperms (flowering seed plants), there are some families that are especially characteristic of the deserts. The goosefoot family is such a characteristic inhabitant of salt deserts (and other saline habitats) throughout the world. Some members of the caltrop family (Zygophyllaceae) are also normally desert plants. In the Americas, species of the cactus family are characteristic of the deserts, and the small candlewood family (Fouquieriaceae) are found there only. Another group playing an important part in many of the world's deserts, though not confined to them, is the family Mimosaceae, and particularly the genus *Acacia*. Species of this genus characterize the peripheral zones of the Sahara, are dominant in many parts of the Australian desert, and are far from negligible in the American and Asian deserts.

Plants in the deserts have to surmount a difficulty that the photosynthetic mode of nutrition imposes on them. In order to produce food by means of photosynthesis, carbon dioxide from the atmosphere must be taken into the plant. This unavoidably leads to the loss of water from the plant at the same time, since the same small openings in the plant surface (called stomates) serve for both purposes. Various solutions to this problem are to be seen in desert plants.

One way to avoid the adverse effects of limited water availability is to live through dry periods in a completely inactive form—as a seed. This is the solution to the problem adopted by the ephemerals, or short-lived annual plants. These plants shorten the duration of their life cycle so that seed germination follows promptly after an adequate storm and seed formation is already in progress by the time soil moisture is reduced to the wilting point. This means, of course, that the total period of photosynthesis is limited to a few weeks every year—perhaps in some years to none at all. Nevertheless, this group of plants is a successful element in desert vegetation, as is evident in the flowery display often seen over the desert floor a month or so after rain.

Annuals' solution to limited water

Another solution, rather similar, is for the plant to restrict itself during the dry season to inactive tissues that have limited gas exchange and to form tissues capable of free gaseous diffusion only during periods when soil moisture is available. This mode of growth is called the deciduous habit, and it is expressed by plants everywhere that drop their leaves during winter or, in the case of deserts, during dry periods. A good many species of desert plants have short-lived leaves and are bare for much of the year. The spectacular ocotillo (*Fouquieria splendens*) of the Sonoran Desert of southwestern North America is one example.

Another solution is to separate temporally (*i.e.*, in time) the gaseous-diffusion process from that of energy utilization. Normally, the photosynthetic surfaces must be open to carbon dioxide diffusion during daylight periods, in order that radiant energy may be converted to chemical energy in the photosynthetic process, and this incurs the penalty of water-vapour loss at a time when the diffusion gradient for it is particularly high because of high daytime temperatures and dry air and that for carbon dioxide is no more favourable than at any other time. If carbon dioxide can be taken up at night instead, the concomitant loss of water can be much reduced. Many desert plants have this ability, carbon dioxide being stored in the form of carboxylic acids at night, which are converted to carbohydrates when radiant energy becomes available in the day. The stomates in these plants open by night to allow entry of carbon dioxide into the intercellular spaces and close by day to restrict loss of water vapour while photosynthetic reduction of the "stored" carbon dioxide proceeds. This so-called crassulacean metabolism is not confined to the stonecrop family (Crassulaceae) but is found in a good many other plants of the deserts.

Another mechanism, like the deciduous habit, restricts gas exchange when drought conditions prevail not by loss of leaves (a wasteful process) but by direct restriction of gaseous diffusion. The stomates, through which most gas exchange occurs, can generally open or close according to prevailing environmental conditions; adaptations may increase their responsiveness to water stress and at the same time reduce the amount of gaseous diffusion in other ways. The means used include increased thickness of the cuticle (outer layer of stem and leaves), development of wax layers, rolling of leaves in drought, and so forth—a series of adaptations often described under the heads of xeromorphy or xerophily.

Another mechanism, often combined with restriction of gaseous diffusion by stomates during periods of drought and with crassulacean metabolism, is water storage in succulent tissues. This has developed in rather few taxonomic groups—the families of carpetweed (Aizoaceae), stonecrop, cactus, some milkweeds (Asclepiadaceae—especially the subfamily Stapeliae), some goosefoots, some lilies (family Liliaceae), the arborescent spurges, and a few others.

In some cases, plants can grow in deserts without suffering water shortage through having an extremely deep root system penetrating to subsoil water. A high ratio of root to shoot tissue is indeed a common feature of desert plants, whether the root system is deep or spreads widely.

A hazard of the deserts, when water loss from aerial parts is restricted, is the high temperature in these organs that may result from intense sunlight when cooling by evaporation is limited. Resistance to high tissue temperatures may be part of the adaptational equipment of these plants.

Adaptations of plants to high temperatures

Temperatures on the soil surface in deserts may be very high (70° C, or 158° F), and plants growing there must be prepared to endure them. Lichens and blue-green algae, which compose the bulk of the soil-surface flora, are usually dry at times when the soil-surface temperature is highest, in which state they are highly resistant to extreme heat. Perennial plants usually provide shade to the soil immediately around their bases, so that high temperatures are eliminated there. For small annuals, on the other hand, high soil temperatures around their stem bases when soil moisture has been depleted may cause some death of tissues and accelerate flower and seed maturation.

Another factor to which adaptation is required in some desert situations is the high salinity of the soil solution. Usually plants growing in such situations have difficulty taking water into their roots from such solutions. Many plants have adapted to these conditions with a highly concentrated sap, enabling the root to take up water even from saline solutions.

Invertebrate animals. Many groups of invertebrates require a marine environment and are consequently absent from the deserts; other groups occur in desert waters but not on land. The flatworms (phylum Platyhelminthes) occur as parasites inside the bodies of animals, as elsewhere. The various groups of nematodes (phylum Aschelminthes)—animal parasites, plant parasites, and those living free in the soil—are found in the deserts as in other habitats, though activity in the soil is restricted by their need for free water. The segmented worms (phylum Annelida) are represented by a few earthworms, occurring only in favoured situations. There are a fair number of snails (class Gastropoda) found in deserts, some species of which are remarkably resistant to arid conditions.

It is, however, of the insects and spiders and their relatives (phylum Arthropoda) that one thinks when desert invertebrates are mentioned. The crustaceans of that phylum are represented by the brine shrimps that live in

concentrated salt solutions and by the terrestrial isopods (wood lice, or sow bugs) that occur fairly widely. Myriapods are reasonably numerous in the desert, both the vegetarian millipedes and the carnivorous centipedes. All the groups of arachnids (spiders, scorpions, etc.) except the primitive marine horseshoe crab (*Limulus*) occur in the deserts, and some are more at home than in many other environments. Scorpions are numerous, as are ground-dwelling spiders (web-building spiders are not particularly common), and there are plenty of mites, including those inhabiting the soil.

Insects are abundant, though forms with aquatic larvae such as the dragonflies (order Odonata) and mayflies (order Ephemeroptera) are found only around the waters; termites, beetles, butterflies, moths, flies, ants, bees, and wasps are all universally present in deserts, as are the grasshoppers and true bugs.

Adaptations to desert conditions by insects and their relatives

For many insects and arachnids, the problems of life in the deserts are easier than for most vertebrates. Like many desert plants, they have a waterproof cuticle, or skin, to retain water; and the frequently short life cycle, often combined with metamorphosis (changes during the life cycle from egg to larva, etc.), enables vulnerable stages to be timed for the less adverse seasons. By persisting through unfavourable periods in an inactive stage (egg or pupa), the animal can avoid many of the difficulties of desert life, much as does the ephemeral plant that persists as a seed or the deciduous plant when reduced to inactive woody tissue during dry periods. Another means of avoiding environmental difficulties is to burrow beneath the soil. Many arthropods burrow for at least a part of their life cycle; and there is an abundant fauna that spends its whole life beneath the soil. This is true of nematodes and the few desert earthworms, of course, as well as large numbers of mites and almost all the springtails (order Collembola). These soil arthropods form part of a trophic cycle (food chain) within the soil mass, in which material originally derived from plant roots is eaten by herbivores and they, in turn, by several carnivore levels. This material eventually returns to detritus, or the decaying organic state, to be acted upon by microorganisms, which are again taken into the animal sequence.

Some of the subterranean arthropods are larval stages of adults that spend their life on the soil surface. There are important groups, however, whose adult life is divided between the upper and lower worlds. The most important are the ants (order Hymenoptera) and the termites (order Isoptera). Not all ants have subterranean nests, but, in deserts, by far the majority do so; and all termites avoid the light, building covered runways when they come above ground or developing channels through woody stems. Thus the ants, and even more the termites, avoid the risk of exposing the more vulnerable immature forms to the high radiation, temperature, and evaporation rate of the open desert; and they limit the time of exposure of the more resistant adults to what is required for food gathering (in the case of ants) and defense.

Vertebrate animals. The desert waters, when permanent and not too saline, contain fish, and in some cases the species are endemic (peculiar to the locality), because of the isolation of some of these ecosystems. They are generally closely related to species in nearby nondesert areas. Little is known of their special adaptations, though they must often tolerate a higher and more variable salinity than do their relatives elsewhere.

Frogs and toads are far from uncommon in the deserts, despite their need of an aqueous environment for reproduction. Consequently, desert amphibians need to be opportunistic, responding quickly to rain that leaves standing water and then passing through the stages of egg laying and larval life before this water dries up. The selection pressure for rapid larval development must be intense, for those larvae still dependent on gill breathing when the pools dry will die. The adults, with a moist and unprotected skin, are also vulnerable to high evaporation rate and spend most of the time between rains inactive in a protected spot, often burrowing deep into the soil.

Reptiles are perhaps the most characteristic group of the desert animals. Lizards and snakes are numerous, tortoises occur, and crocodiles are common in some tropical desert waters. The majority of the lizards are insectivorous, though some are herbivores. The snakes mostly feed on other vertebrates, chiefly small mammals and birds' eggs and nestlings. Some of them have refuges in holes in the soil—perhaps more from predators than from the climate. But the majority spend most of their life exposed to high temperatures and evaporation on the surface of the soil. Their scaly skin is indeed resistant to water loss, but the radiation load they suffer is often considerable. They have no means of temperature regulation except seeking shade, and their tissues must be resistant to temperatures well above the normal limits for warm-blooded animals. Though some show bright warning coloration, many are camouflaged in the colours of the soil surfaces on which they live.

Desert birds

Birds are as numerous in deserts as food availability permits but often spend only part of their lives in this environment. Apart from seasonal migration, they may move between roosting or nesting sites and feeding areas. The lack of trees or tall shrubs to provide nesting positions excludes many species (apart from foraging excursions), and many desert birds nest on the ground. The eggs are in some cases covered with mounds of vegetable material, which give partial protection and provide a more uniform temperature for incubation. Running birds are numerous in the deserts and include some of the largest—the ostrich (*Struthio camelus*) in Namibia (and previously in North Africa and the eastern Mediterranean countries); and the emu (*Dromaius*) in Australia, both of which are herbivores. Some birds are present that are prominent predators and carrion eaters, such as the roadrunner (*Geococcyx*) and magpie (family Corvidae) of the North American deserts. Raptors (hawks, eagles, etc.) are important and have in the deserts excellent visibility for attacking prey from the air. They may nest in rocky parts of the deserts themselves, but their range of movement is such that they can often operate from areas in adjacent but different vegetation.

Some bird species show notable adaptation to the desert environment in their reproductive habits. Gambel quail (*Lophortyx gambelii*), for instance, do not reproduce in years with below-normal rainfall, when food for the young would be scanty; ducks (family Anatidae) in central Australia have lost the annual reproductive rhythm and will breed at any time when rain falls.

There are many mammals in the deserts, though the modifications required in behaviour or physiology (or in both of these) are considerably greater than for the reptiles. This is largely because they are warm-blooded and because they excrete urea rather than uric acid, which imposes extra demands on body water.

Most mammalian orders, other than those that are purely aquatic, are found in the deserts. Primates (apes, monkeys, etc.), mainly tree dwellers, are naturally not prominent, although several species of baboon are found in the African and Arabian deserts. Edentates (anteaters) and insectivores are few, but bats are often numerous, roosting in the caves and rock crevices that are commonly found in desert regions. The rodents (rats, mice, etc.) and lagomorphs (rabbits, hares, etc.) form the largest group of desert-inhabiting mammals. Some of them are remarkably successful there—the European rabbit, for instance, introduced in the 19th century. The native rodents of the deserts often show marked physiological adaptation to the desert, water requirements being reduced to a minimum. Some, in fact, can subsist on the metabolic water produced by respiration of their foodstuffs. Many desert mammals avoid high radiation loads and decrease their water losses by spending the midday hours in the shade of bushes and feeding in the early morning, late evening, or at night. Many seek the shelter of burrows in the earth, with their much more moist and consistent conditions, at least during the daytime hours, and their life above ground may be limited to nocturnal foraging.

Herbivorous mammals

Herbivores in the desert can benefit from the ability to move rapidly, from one feeding place to another or between feeding and drinking places, so it is not surprising that a fair number of ungulates (hoofed animals) make the desert their home. Many are nomadic and range over large

areas, thus being able to benefit from vegetation growth following local storms, without the risk of starvation imposed by eating out the forage within a limited territory. There are numerous antelopes, goats, and sheep in the deserts of all continents but Australia. Some of the wild asses are at home in the deserts of western Asia and North Africa, and escaped domestic equines (burros in North America, brumbies in Australia) have taken successfully to the deserts and desert margins. Outstandingly successful among ungulates in the deserts, however, are the camels (*Camelus*), whose adaptation to life there is well known. Their broad feet suit them to movement over sandy areas (though such areas are extensive only in limited parts of the desert regions); they have large reserves of fat, to enable them to live through long periods of scanty forage; and they can live for many days without drinking, making up their water deficit by enormous drafts when opportunity presents itself.

Among the carnivores, lions inhabit the desert margins of Africa and Asia, and some smaller cats also hunt in the deserts, in both the Old World and the New. Several of the hyenas are desert animals, and some of the dogs are also prominent desert carnivores, notably the coyote (*Canis latrans*) and kit fox (*Vulpes macrotis*) in North America and the dingo (*Canis dingo*) in Australia.

The marsupials (pouched animals) include a number of species well adapted to life in the Australian desert—many of the kangaroos and wallabies and a variety of smaller herbivorous and omnivorous species.

Man. A wide variety of human races have adapted successfully to life in the deserts. Caucasoid peoples inhabit the deserts of North Africa and western Asia, and the Australian Aborigines, thought to be more closely related to them than to other major racial groups, live in the deserts of Australia. Negroid peoples live on the southern margins of the North African desert and in Namibia. Mongoloid peoples occupy the central Asian deserts and those of North and South America.

Human uses of deserts

As would be expected in an animal of such behavioral diversity as man, his adaptations have been behavioral and cultural rather than physiological. Irrigation civilizations have been developed in many arid regions of the world—in fact, the Nile valley and the valley of the Tigris and Euphrates, which were two of the cradles of civilization, run through deserts. Where irrigation was not possible, low vegetative productivity imposed a nomadic culture on desert-dwelling societies.

Apart from nomadism and irrigation works, man's behavioral adaptations include his use of thick-walled dwellings with few windows; water storage in deep, covered cisterns; clothing, often white, protecting against the sun; and domestication of desert animals, notably the camel.

PRODUCTIVITY OF DESERT ECOSYSTEMS

The natural productivity of the deserts is low compared with that of most other ecosystems. The dependence of all plants on water and of other organisms on plants means that the arid conditions limit productivity where radiation, temperature, and other growth factors would otherwise permit the highest levels of productivity on the Earth. The proportion of solar energy incorporated in organic matter, rarely exceeding 2 percent in natural communities, is in the deserts a small fraction of 1 percent. The bulk, or biomass, of vegetation in the Syrian Desert has been reported as ranging from 470 to 4,800 kilograms per hectare (kg/h), and in the cold deserts of central Asia from 55 to 7,000 kg/h.

In cold deserts in North America dominated by sagebrush, figures between 1,000 and 3,000 kg/h of dry matter per year have been recorded, as compared with 50,000 to 100,000 kg/h for mountain forests in the same latitude. For the Sonoran Desert a figure of 1,400 kg/h per year has been quoted.

While the standing plant biomass may be well over 1,000 kg/h, the animal biomass is far less. Figures on which to base even a rough estimate are scanty, but 100 kg/h would probably be exceptionally high, and 10 kg/h the more usual order of magnitude.

The deserts have been used by food-gathering human societies for many millennia. Provided the population is sparse and nomadic, a reasonably reliable living may be wrung even from these unpromising habitats. Good examples are the Australian Aborigines, who made use of a wide range of fruits and roots and insects, reptiles, and mammals. Other peoples use the deserts by grazing on them flocks of domesticated livestock and constantly moving the flocks to fresh pastures as the limited growth is grazed off. (D.W.G./Ed.)

Jungles and rain forests

In modern usage the term jungle has come to mean tropical forest and connotes luxuriant, tangled, impenetrable vegetation in a hot, steamy environment, teeming with wildlife. The rain forest exhibits many forms but seldom approaches its popular image; in fact, it is darkly shaded, with little ground cover, and is fairly easy to travel in. Where light can penetrate to the ground, however, as along tracks and riverbanks, a dense and tangled mass of vegetation appears, and because most people see the forest from a track or from a boat it is easy to believe in the impenetrable jungle. Tangled and dense bush often invades as a secondary growth after a rain forest has been cleared, and the word jungle is sometimes used in a more technical sense for such regrowth.

Characteristic amount of rainfall

Rain forests, as the name suggests, occur in regions of high rainfall, commonly over 1,800 millimetres (70 inches) per year. It is overall wetness that forests require, however, and no single figure really expresses the most desirable conditions. This is because the effectiveness of precipitation depends on losses from runoff and evapotranspiration (the amount of water that is lost by direct evaporation and by transpiration through plants) that in turn depends on topography, soil, and temperature. Rain forests, therefore, span a wide range of environments, with widely varying geology, water regime, soils, landscapes, and potential use.

Commonly, most rain forest areas are places of relatively low human-population density. The rapid clearing of rain forests in the late 20th century for commercial uses, however, promised an increase in human habitation as well as far-reaching negative consequences from the unchecked destruction of these ecosystems, which contain the vast majority of the world's species and account for a significant portion of oxygen production in the biosphere.

THE ENVIRONMENTAL SETTING

Varieties and characteristics of rain forests. Some authorities divide the tropical rain forest into "equatorial" and "tropical" or "tropical" and "subtropical" forest, the former in each case being the more permanently wet. Here, "equatorial" and "subtropical" are used for these divisions, and "tropical" is a general term for both. The term selva is synonymous with tropical rain forest. The world distribution of jungles and rain forests is shown in Figure 27.

Equatorial rain forests. Equatorial rain forests grow in areas of little varying climate with rain throughout the year, no frost, high average temperatures, and no marked seasonal variations, though occasional dry periods of a month or two can occur. Average daily temperatures in equatorial rain forest regions usually range between a daytime maximum of about 30° C (86° F) and a nighttime minimum of about 20° C (68° F), with a monthly and yearly average of about 27° C (81° F). Wide variations from these temperatures are exceptional, and the average annual range is usually only one or two degrees. The average daily range, normally between five and eight degrees, is greater than the annual range, so it may truly be said that night is the winter of the tropics. Any seasons that can be recognized are dependent on variations in the amount of rainfall rather than in the amount of temperature.

Rainfall in equatorial forests

Annual rainfall generally amounts to between 1,500 and 3,500 millimetres (60 and 140 inches), generally well distributed throughout the year (see Figure 36). There may be a drier period, and some places have two periods of maximum rainfall that roughly coincide with the two periods of vertical noonday sun. Some equatorial rain originates from thermal convection, but most comes from organized,

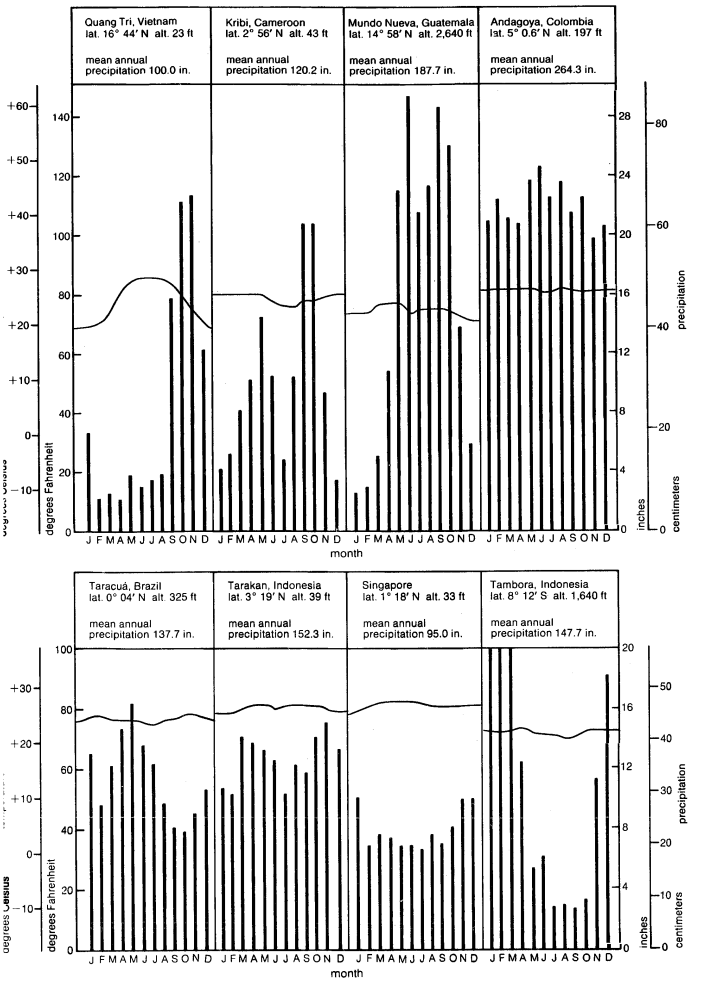

Figure 36: Representative temperatures (lines) and rainfall regimes (bars) in tropical areas.

migrating atmospheric disturbances. Relative humidity in an equatorial rain forest is high at all times.

There is a large water surplus and thus a large runoff; soils are permanently moist, leaching is intense, and erosion is potentially severe. Chemical reactions affecting soil and vegetation take place rapidly because of the high temperatures and abundant rainfall. Plant growth is continuous, though individual species have their own seasons of leaf shedding. The light intensity on the forest floor is usually less than 1 percent of that just above the forest canopy. The ground is littered with fallen leaves and wood, and low-growing plants are few except for tree seedlings.

Main areas of equatorial forest

The main areas of equatorial forest are the Amazon lowlands, the Congo lowlands (together with a coastal zone extending from Nigeria to Guinea), parts of Indonesia (especially Sumatra), and several Pacific islands.

Rain forest can sometimes extend into areas where rainfall appears to be inadequate if it is augmented by groundwater—forests often extend along valleys surrounded by other vegetation types—or if generally high humidity effectively reduces water losses, as in parts of southern Nigeria.

Equatorial forest grades into subtropical rain forest on windward coasts, into monsoon forests in parts of Southeast Asia and Australia, and into montane forest with increasing altitude.

Subtropical rain forests. Subtropical rain forest is located on the windward coasts, roughly from 10° N and 10° S to the tropics, but occasionally it extends farther. It differs from the equatorial rain forest by having a season of reduced rainfall or even drought, although the wet season is dominant. With distance from the equator, there is greater variation in length of day and greater seasonal variation in temperature; as a result, this type of rain forest is slightly more open and lower and has a smaller number of species and fewer lianas.

Such forest is found in Central America and in the Caribbean—especially on the windward side of islands; in the Western Ghāts of India and coastal areas of Myanmar (Burma), where there is a short dry season; and in Vietnam, the Philippines, parts of the Brazilian coast, and Madagascar. In the Everglades of Florida there are small patches of such jungle, known as hammocks, which contain mahogany, strangler fig, and epiphytes (air plants).

Monsoon forests. Monsoon forest, also known as tropical deciduous forest, occurs in regions with a large total rainfall but a marked dry season. Monsoon climates are characterized by seasonal pressure and wind reversal resulting in heavy rainfall during the high-sun period of onshore winds and little or no rain during the low-sun period of offshore winds. Average temperatures are high, often over 25° C (77° F), but the annual range is greater than in areas of equatorial rain forest. This forest is lower than equatorial forest, trees have more spreading branches, and there is more light penetration. Because of the dry season, a high proportion of the trees are deciduous, and there is a general period of leaf shedding. Teak is a common species, lianas and epiphytes are locally abundant, and thickets of bamboo are common. Undergrowth is likely to be denser in monsoon forest than in equatorial rain forest because of the greater openness and light penetration, and there is more "jungle" formed after clearing than in tropical rain forest.

This sort of forest is found in monsoon Asia, Myanmar (behind the coastal tropical forest already mentioned), Thailand, Kampuchea (Cambodia), Indonesia (especially Java and Celebes), northeastern Australia, and in parts of West Africa and South America bordering the tropical rain forest.

Mangrove forests. Mangrove forest grows along many tropical coasts, especially on low-lying muddy shores. Trees are commonly between 2 and 10 metres (7 and 33 feet) high, but some reach 30 metres (100 feet). The tangle of stilt roots, air roots, and general debris unites to trap mud and thus build up the land along a low coast. Mangrove can tolerate a wide range of salinity and often lines tropical estuaries and deltas, sometimes extending for tens of kilometres inland. Several species may grow in belts parallel to the coast. Mangrove wood is used for fuel in some areas.

Land development

Montane forests. Montane forest occurs in the high altitude regions within or bordering the tropical rain forest and includes the Ruwenzori Range of central Africa, the New Guinea highlands, the Amhara Plateau of Ethiopia, and the Gotel Mountains of Cameroon. With its lower temperatures, this forest has many affinities with the temperate rain forest (see above); but, although altitude brings lower average temperatures, other features, such as length

Eric Lindgren—Ardea Photographics

Figure 37: Tropical rain forest in New Guinea, showing the discontinuous character of the upper tree stratum.

of day, cloudiness, and seasonal variation, are unlike those of the temperate regions, and the two forest types are therefore dissimilar. Tropical forest gives way to submontane forest at an average altitude of 1,000 metres (3,280 feet) and to true montane forest, or "mossy forest," at about 1,500 metres (4,900 feet).

Rock type and landscape. Rain forest is found on many rock types and in a wide range of topographic situations, but a few major varieties of landscape may be distinguished.

High plateau and gentle uplands are found in large areas of Africa and in the highlands of the Guianas, Brazil, and other parts of South America. Broad, shallow valleys are separated by broad, gently convex or flat interstream areas, on which erosion is slight. Weathering to a depth of 100 metres (330 feet) is common, and detailed investigations usually show that the lower limit of weathering is irregular with respect to depth; rapid lateral changes in the depth of weathering occur. Occasional hills of fresh rock rise abruptly from a surrounding plain, to a height of tens or hundreds of metres. Such hills are called inselbergs, and some authorities regard them as typical of the humid tropical environment.

Inselbergs

Where erosion has followed widespread laterite formation (see below *Weathering and soils: Lateritic soils*), flattop hills capped by lateritic ironstone are common. Lateritic ironstone requires seasonal drying out for its formation, however, and so is more frequent in savanna regions and around the edges of the tropical forest than in the pure forest.

A completely different kind of landscape is present in some rain forest of highland areas and even in areas of low hills, where V-shaped valleys with sharply angular interstream areas produce a landscape consisting entirely of slopes that are often steep and straight. This landscape is dominant in the New Guinea highlands, in the island arcs and mountain belts of Indonesia and Central America, and around the edges of high plateaus. Similar topography may also be found in mountainous areas of temperate forest, as in New Zealand.

Volcanoes in various stages of dissection by erosion are found in several parts of the humid tropics, including Central America and Indonesia. These often produce fertile soils. Limestone areas in tropical forest often give rise to a distinctive kind of landscape with "haystack hills," which rise abruptly from the surrounding plains. Broad alluvial plains, such as the lowlands of the Amazon, the Congo, and the Fly in New Guinea, make up large areas of rain forest. There is much variation in alluvial landforms, and these lowlands are by no means uniform with regard to sediments, landforms, or soils.

From A.N. Strahler, *Introduction to Physical Geography* (1965); John Wiley & Sons, Inc.

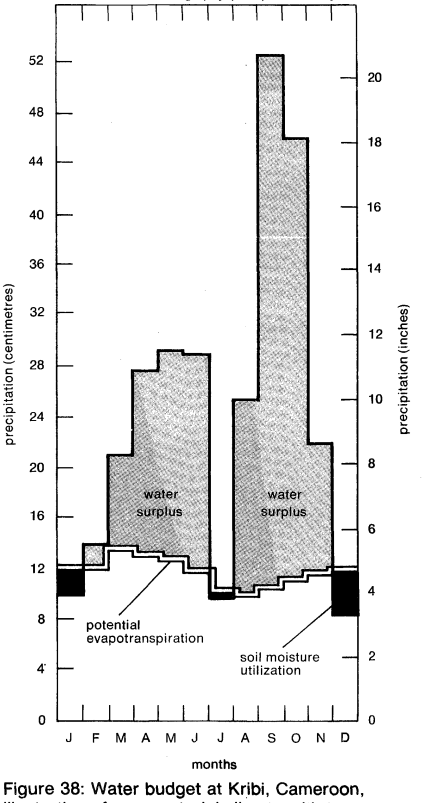

Figure 38: Water budget at Kribi, Cameroon, illustrative of an equatorial climate with two rainfall maxima.

Precipitation, evapotranspiration, and runoff. In rain forest areas there is an excess of precipitation over evapotranspiration for most, if not all, of the year (Figure 38). Only a small proportion of the raindrops fall directly to the ground except at canopy openings. Most are intercepted by the leaves in the canopy and either re-form as waterdrops that fall from the drip tips of the leaves or trickle down the tree trunks. Tropical forest trees generally have broad leaves with drip tips to help shed the water, but, even so, the rain forests probably intercept more rain than any other cover. Estimates of precipitation reaching the ground under various types of cover are: dense forest, 70–80 percent; dense, high grass, 80 percent; cereals and other crops, 80–85 percent; and bare soil, 100 percent.

These data are based on an assumed average of 4 millimetres held (intercepted) per shower. This means that rains of less than 4 millimetres (0.2 inch) do not contribute much to the supply of soil moisture or runoff. The amount retained depends on the total rainfall per day; with heavier showers a greater proportion gets through.

The approximate quantity of rainfall retained by vegetation in a typical site in Indonesia was estimated to be:

Average rainfall	2,400 millimetres (95 inches)
Number of rainy days	160
Rainfall per rainy day	15 millimetres (0.6 inch)
Retained by vegetation (160 × 4)	640 millimetres (25 inches)
Amount reaching soil	1,760 millimetres (69 inches)

Similar results were obtained in Brazil, where it was estimated that about two-thirds of the total rainfall reaches the ground, one-third as raindrops and waterdrops and one-third by streaming down tree trunks.

Evaporation rates can be determined, but results are difficult to correlate with evaporation from a ground surface. Available data indicate an annual evaporation of 542 millimetres (21 inches) at Jakarta, Indon.; 1,139 millimetres (45 inches) at Surabaya, Indon.; 2,300 millimetres (91 inches) from a pond in Madras, India; and 1,930 millimetres (76 inches) from a reservoir in Bombay.

Evaporation from soil is hard to determine, but, in Indonesia where temperature is fairly uniform throughout the year, it was found empirically that evaporation (in millimetres for periods of a month) could be expressed by the formula $E = 60 + 0.125P$, in which E is evaporation and P is precipitation. This means that with less rainfall there will be less evaporation, and with no rain at all there will still be 60 millimetres (2 inches) of evaporation per month.

Extent of transpiration

Transpiration usually accounts for a major share of the water lost by an area, and different species of plants transpire differently under similar conditions. Some types of vegetation, including many trees, may utilize moisture equivalent to nearly all of the rain falling even during the wettest months, whereas grasses or mixed forest may transpire only a fraction of the available moisture. This may account for a rise in the water table after land clearance. The average annual transpiration of plants in Java (in millimetres) has been estimated to be:

Mature forest (trees 740) (undergrowth 130)	870 (34 inches)
Bamboo forest	1,500 (60 inches)
Jungle below 1,000 metres	1,200 (45 inches)
Jungle at 1,000 metres	1,200–500 (45–20 inches)
Jungle at 2,500 metres	600–500 (25–20 inches)

The annual evapotranspiration in the forest zone of the Congo basin is estimated to be 1,650 ± 100 millimetres (65 ± 4 inches).

Forest soils tend to be permanently moist and spongy, but their structure allows a great deal of infiltration. Nevertheless, tropical storms are usually of such great intensity that runoff is common during rains, especially on steeper slopes. There are significant differences between the hydrologic regimes in areas of different topography, especially between the plateau landscapes and the ridge and valley landscapes.

Sediment transport by streams

In ridge and valley areas large runoff produces high rates of erosion, and rivers carry a large sediment load. In flatter areas, minor streams are frequently blocked by fallen trees and associated plant growth to form swamps and lakes. This reduces the ability of the streams to transport debris and leads to sedimentation in temporary pools. Major streams, however, are open and often fast-flowing, their sediment load depending on their catchments (drainage areas).

In the Amazon basin there are "black water" streams, that is, streams draining swamp-forest peats that carry black, acid water that is stained with organic matter but has little sediment. This black water contrasts markedly with the muddy water of other streams and has the incidental advantage to explorers of being free from insects. In New Guinea the Fly River has a comparatively small sediment load, although it is nevertheless murky and opaque; however, its tributary, the Strickland, coming from a more mountainous interior, carries much greater quantities of sediment in its turbulent waters. The difference in the two streams is sufficient to give rise to different alluvial landforms and different vegetation patterns along the respective rivers.

Flooding is important in lowland rain forest. It is often of considerable range, such as the 8-metre (26-foot) variation of the Fly River, which is a great obstacle to development or permanent settlement of such areas. Such floods cover the ground and trees over many square miles. Over-bank floods spread out over the land, depositing new sediments, building levees, and adding new layers of silt to the soils of the lowland forest.

Change occurs in the water table after forest clearance. In Nigeria a rise of 60 metres (about 200 feet) has been noted in 50 years. Larger streams continued to flow in the dry season longer than they formerly did, new springs appeared, and one valley was drowned by a new lake.

Climatic changes also alter hydrologic regimes, but not always in easily predictable ways. In main valleys the reduction in flow due to greater desiccation might be more than offset by increased flow from runoff and from accentuation of groundwater ridges.

Weathering and soils. *Tropical weathering.* In hot, wet areas, chemical weathering is most intense, and, in the intertropical zone, weathering of rock produces clay-rich weathering mantles up to 100 metres (328 feet) deep or even more. The distinction between soil and weathering mantle is hard to draw.

The weathered rock that is still in place retains features of the unweathered hard rock and is separated from an overlying loose mantle of more or less transported material by stone lines of varied composition and controversial origin. All of the rain forests have abundant rainfall, so on well-drained sites there is a washing out, or leaching, of dissolved chemicals. In all of the rain forests, bases such as calcium and magnesium tend to be leached out, but in the tropics there is also removal of silica, which leads to the formation of different soils under tropical and temperate rain forest.

On well-drained sites in the tropics the leaching of bases and silica leads to an accumulation of aluminum and iron oxides and hydroxides and the formation of the clay mineral kaolinite, which is relatively poor in silica (see further MINERALS AND ROCKS: *The major rock-forming minerals: Clay minerals*). Many upland soils in the tropics consist of little more than kaolinite and iron hydroxides, which give the soil a red or yellow colour. There are two main divisions among the tropical red soils: tropical red loams and lateritic soils.

Tropical red loams

Tropical red loams (known also by other names, such as krasnozem and tropical red earth) are deep, friable, and easily tilled soils. They are porous and freely drained at all depths, and there is little change in colour or texture of the soil material in the vertical soil profile. Clay is common, but it is so combined with the iron oxides that it behaves more like a loam and retains a porous, freely drained structure even when wet. It does not break into larger clumps, such as commonly happens in clay-rich soils of temperate regions. Soil profiles of this kind are not affected by water tables within the soil profile. In the tropical rain forest these soils are much more common than the lateritic soils.

Lateritic soils. In contrast to the uniformity of the tropical red-earth profiles, lateritic soils have profiles with well-marked horizons (layers). The uppermost horizon is variable but is commonly a red loam, lighter in texture than the underlying horizons and sometimes containing ironstone gravel. Beneath this is a layer rich in iron. So long as it is kept moist under a forest cover this material will remain soft, but if it is dried out it will irreversibly harden and may even be used for brickmaking. It was to such material that the term laterite was first applied, but the word has been used loosely since then. There was in the 1970s a tendency among soil scientists to return to this early usage, and the whole sequence of associated horizons may be referred to as a laterite, or lateritic, profile. In some profiles the laterite horizon is hard, even within the intact soil profile. Beneath this layer there may be a mottled zone and beneath that a bleached-white, kaolin-rich zone, known as the pallid zone. These zones may be many metres thick.

The formation and potential hardening of the iron-rich zone of lateritic soils are their most distinctive and important features. Hardening can come about in several ways: forest clearing by humans, drying out of the soil due to climatic change, and drying of the soil due to valley downcutting and drainage change.

The iron-enriched layer occurs closer to the ground surface with increasing distance from the equator, and north of 14° N only fossil crusts are found. In Côte d'Ivoire, for instance, there is a latitudinal sequence: in the south, under rain forest that receives more than 1.5 metres (5 feet) of rain annually, are soils that do not form crusts so long as the forest cover is intact; whereas to the north, under subtropical forest that receives less than 1.5 metres of rainfall, the soils are less deep, and ironstone crusts exist on dry sites.

With increasing distance from the equator and longer dry seasons, less silica is removed, and the soils of the humid tropics give way to the ferruginous (iron-rich) soils of the savanna areas. In extremely wet and hot areas, on the other hand, even more silica is leached away, leading to the formation of aluminum-rich bauxite rather than laterite. In the humid tropics the influence of parent rock is less than in temperate areas, and lateritic soils can form on practically any parent rock.

Nevertheless, there is considerable variation. In South America, for example, dark lateritic soils occur in humid areas or on rocks that are rich in calcium and magnesium; red lateritic soils occur on acid rocks (rich in soda and potash); and brown lateritic soils occur on volcanic ash or basalt. Volcanic soils are generally more fertile than others, and in regions of active volcanoes, such as parts of Indonesia, occasional eruptions produce layers of ash that act like a rich topsoil in restoring fertility. Terra rossa soils (clay-rich, red, granular soils) are common on limestone, including that of coral islands, which often have rain forest cover.

Volcanic soils

On base-poor rocks, such as sandstones, podzols (leached soils with distinct sandy topsoils) may form. Tropical podzols are widespread in the catchment areas of the Negro River in the Amazon basin and in Guyana, Malaya, Borneo, and Thailand. These podzols are not under normal forest but instead are under "heath forest," the padang of Southeast Asia.

On tropical mountains there is a general tendency for tropical red loam or lateritic soils to be produced on lower slopes and podzols to be formed higher up, but there

are many complications due to parent material, erosion, aspect, drainage, and other factors.

Thus far, discussion has centred on the soils of leached sites, the well-drained areas on higher ground. A well-marked division is found in many tropical areas, however, with red, leached soils on the uplands and black clays, gray soils, and fresh alluvium in the lowlands. Furthermore, swamp forest with acid soil consisting largely of peat is found in Java, Sumatra, Borneo, Celebes, Malaya, and Guyana, although it is apparently absent in Africa. This peat occurs in large areas, is often more than 6 metres (20 feet) thick, and is composed almost entirely of the remains of trees and other woody plants of the swamp forest.

The common idea that all of the tropical soils are laterites is a gross oversimplification, and detailed investigations in New Guinea and elsewhere reveal many soil types.

Despite the luxuriant plant growth, tropical forest soils are not particularly fertile. Under intense weathering, leaf litter quickly decomposes and thus provides the nutrients essential for the trees, which absorb some of the released ions before they are leached from the soil profile. Most plant nutrients are thus recycled by the trees, and there is little reserve of nutrients in the soil. The humus layer is normally only a few centimetres thick, and decomposition of vegetation is rapid.

Removal of tropical rain forest to allow cropping swiftly eliminates leaf litter, and the water-retaining, spongy soil structure is destroyed. The mineral cycle is broken and the soil productivity declines; laterite dries out because of increased evaporation and so accelerates the development of undesirable physical features. Clearing of lateritic soils also accelerates erosion of the meagre upper horizon, exposing the ironstone layer and facilitating its hardening. Ironstone crusts have been known to form in as little as 30 years in West Africa from such causes.

Cleared forest is therefore of use for only a short time before it is exhausted, so indigenous inhabitants of tropical forest practice shifting cultivation. If only small patches of forest are cleared, regeneration is possible, but on any large scale the changes of soil become progressively worse and irreversible, and the forest gives way to other vegetation types. In some areas there is tangled secondary regrowth, or jungle, while in others, especially in areas of climatic stress, savanna expands at the expense of forest; in New Guinea, for example, large areas of kunai grass (*Imperata*) appear to be of anthropogenic origin, replacing original forest. (C.D.O./Ed.)

Cleared-forest succession

BIOTIC FACTORS

The tropical rain forest is the most complex ecosystem on Earth, and its plant and animal life is richer and more diverse than that of any other type of forest. A two-hectare (five-acre) sample often has more than 100 different species of trees 30 centimetres (12 inches) or more in diameter (in the Malay Peninsula more than 200 species have been recorded), compared with about 25 tree species in the richest temperate broad-leaved forests (North America). Similar data for animals are difficult to obtain, but comparisons have been made of the number of bird species: more than 600 in a 780-kilometre-square area of rain forest in Panama, as against about 100 in a similar area of temperate forest of the eastern United States. The number of bird species, however, is small compared with the number of insects.

Climate and the biota. One obvious reason for the enormous variety of plant and animal life in the rain forest is the climate, which is hot and moist throughout the year. The soil never dries out, and the humidity of the air is always high. This constantly warm and moist environment allows plants and animals to grow and reproduce all year long, though they may not in fact do so. In the rain forest the struggle for survival is, thus, less against a hostile physical environment, as in climates with a cold winter or summer drought, than against the competition of other organisms. This has led, among both plants and animals, to the evolution of many species filling many different niches, or ecological roles, some of which are highly specialized.

Another and less obvious reason for the great diversity of species in the rain forest is probably its age. In the tropics the climate has changed little since the Cretaceous period, and therefore evolution has proceeded uninterrupted for some 66 million years.

Forest structure and microclimates. The trees and other plants that grow together in a primary, or undisturbed, tropical rain forest may seem a chaotic mass of vegetation, but the forest, in fact, has an irregular pattern of structure not easily discernible at ground level. Tree crowns are arranged in several stories, or strata (Figure 39), called A, B, C, D, and E from above downward. These layers are generally poorly defined, so that only an arbitrary boundary can be drawn between one stratum and the next. Most of the trees in the lower strata are immature individuals of species that may later reach a higher stratum. The A stratum, of trees 30 to 50 metres (100 to 165 feet) high, is never continuous; their crowns rarely touch and may be widely separated. For this reason, the roof of the forest, as seen from the air, has an uneven surface, the crowns of the largest trees standing out like gigantic, dark green cauliflowers (Figure 37). The B-stratum trees, whose crowns are smaller and more closely spaced, likewise do not generally form a continuous layer. The trees of the A and B strata are often called the emergents; together they form the forest canopy.

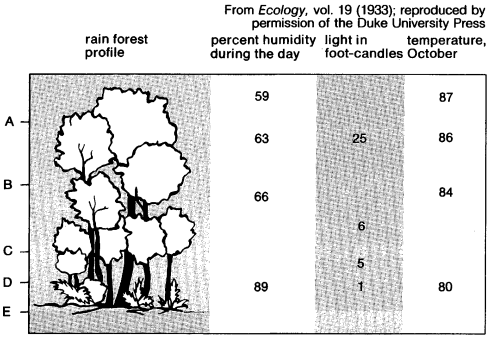

Figure 39: Stratification of a tropical rain forest (see text).

The C and D strata constitute the densest layers of the forest, where little space is unoccupied by trunks, branches, twigs, or foliage. In contrast, the lowest, or E, stratum is often thinly stocked, and much of the ground surface itself is bare except for a thin covering of dead leaves and litter. Contrary to popular belief, the undergrowth of the rain forest is seldom impenetrable: it is usually possible to walk about and to see another person from at least a distance of 50 metres. Only where sunlight reaches the ground in sufficient intensity, in clearings and on the edges of roads and rivers, does the undergrowth become the dense jungle commonly described. Similarly, the undergrowth of young secondary forests, which spring up in clearings left by timber operations or by agriculture, is much denser and more tangled than that of undisturbed primary forest.

The scant undergrowth of jungle

The leaves and branches act as a filter to light and heat radiation and as a barrier to air movements, resulting in wide differences in temperature and humidity of the air in the lower stories, compared with the relatively open canopy. In the undergrowth there is little air movement, and, apart from occasional flecks of sunlight, most of the light has passed through or been reflected from leaf surfaces. Within the forest, conditions are different from those in a clearing or in the open, and there is a range of "local climates" (microclimates).

At midday in sunny weather the temperature in the A and B strata might be 32° C (90° F), while in the undergrowth it could be 26° C (79° F). During cloudy or rainy weather the difference would be smaller, but the upper strata are always warmer than the undergrowth during the day. At night the position is reversed, and, especially on clear nights, the air around the treetops is cooler than that near the ground. Although at night the air in all strata is nearly saturated with moisture, during the day there are considerable differences in humidity between the upper strata, where relative humidity often falls to 60 percent in the afternoon of a sunny day, and the undergrowth,

where the humidity rarely drops below 80 to 90 percent. The undergrowth of the tropical rain forest is in fact one of the most constant biological environments on Earth, and it is not surprising that, as in caves, another unusually constant environment, some strange forms of animal life are found—some of which, such as the ricinuleids (class Arachnida) and the wormlike walking worm (*Peripatus*), can be regarded as "living fossils."

Character of rain forest communities. The rain forests of tropical America, Africa, and Southeast Asia to Oceania (northern Australia and the western Pacific islands) are similar in many features, but each has a distinctive plant and animal life, with almost no species common to all three and not many common to any two of the tropical land sectors. Whole groups of organisms are confined to a single sector. For example, the dipterocarps (family Dipterocarpaceae), are the most important family of trees in Indo-Malayan rain forests but are absent in the Americas and in Africa are represented by only a few small trees of the savannas. The pineapple family (Bromeliaceae), so common as air plants (epiphytes) in the American tropics, have only one species in the Old World tropics. Much the same is true of the animals: tropical America alone has monkeys with prehensile tails, sloths, toucans, and leaf-cutting ants, but it has no apes, hornbills, or large mammals, such as elephants and rhinoceroses, all of which are confined to tropical Africa and Asia. Often a group in one sector replaces one of another; thus, the flower-visiting sunbirds (family Nectariniidae) of the Old World occupy a niche similar to that of the hummingbirds (family Trochilidae) of tropical America.

Plants. The tropical rain forest is overwhelmingly dominated by trees and woody-stemmed vines (lianas). Woody plants are the chief producers of the food on which all the animals depend and of the shelter in which they live. Most of the nonwoody plants are epiphytes living on the trunks and branches of the trees, but a few, including grasses, grow on the ground.

Rain forest trees

Rain forest trees range from giants 60 metres (almost 200 feet) high down to treelets of not more than 1 metre (just over 3 feet). The great majority belong to the large group of flowering plants known as dicotyledons, but palms and other monocotyledons occur in the lower stories and in open areas. Conifers are found only in certain parts of the rain forests of Borneo, New Guinea, and neighbouring areas. Although belonging to a large number of different families, rain forest trees are remarkably uniform in appearance, the majority having thick, leathery leaves, like those of temperate laurels in size and shape. Most are evergreen, but some are deciduous, remaining leafless for a few days or weeks. Because the behaviour of the different plants is not closely synchronized, the forest as a whole always appears in full leaf. The young leaves of the trees are often bright red and hang limply, as if wilted.

Flangelike buttresses, extending up the trunk for 3 to 4 metres (10 to 13 feet) and outward for about the same distance, are characteristic of many of the larger trees, and stiltlike aerial roots are not uncommon among the smaller trees. Root systems in general are shallow—even those of the largest trees seldom penetrate deeper than a metre—and most of the fine nutritive roots are concentrated in the humus-rich layer within a few centimetres of the soil surface.

Large, brilliantly coloured flowers are not common in the rain forest; those of many trees are inconspicuous and white or greenish. The production of flowers on the main trunk, rather than on the twigs or branches, is characteristic of many small- to medium-sized trees; this feature may be related to pollination by bats or other animals that cannot easily reach flowers hidden within a mass of twigs and leaves.

Lianas are plentiful, especially where clearings are formed by the death of old trees. These woody vines reach the tops of all but the tallest trees, linking them together and competing with them for space and light. In the eastern tropics, climbing palms (rattans) are common and grow to a length of 100 metres (328 feet) or more. Strangling plants, which include many figs (*Ficus*) and, in the American tropics, species of autograph trees (*Clusia*), also compete with the trees. These plants start life as epiphytes on tree branches to which their seeds are carried by birds; later they send aerial roots to the ground and enclose the host trunk in a network of stout, woody roots that may kill it, leaving the strangler as an independent tree.

Epiphytes are commonest on branches 30 metres (about 100 feet) or more above ground in positions fully exposed to the sun. Common rain forest epiphytes include orchids, bromeliads, and specialized ferns as well as lichens, mosses, and liverworts that grow on the surface of leaves in the humid, shaded undergrowth. Most epiphytes do not harm the host tree but simply depend on it for physical support. They obtain mineral nutrients from rainwater and from the organic debris that collects among their roots, often brought there by ants. Many epiphytes have special adaptations, such as bracket- or pitcher-shaped leaves that collect water and humus. The most remarkable of such adaptations are the "tanks" of bromeliads, formed by closely overlapping leaf bases. These may hold several litres, or quarts, of water and provide a home for many kinds of aquatic organisms, including mosquito and other insect larvae, tadpoles, and even crabs.

Many rain forest plants are not green and so cannot make their own food; they live either on decaying matter as saprophytes or on other living plants as parasites. Although most of these nongreen plants are fungi, a few are specialized flowering plants. One of the most spectacular of all rain forest plants is the Malaysian monster flower (*Rafflesia*), which is a parasite of certain woody vines; its flowers may be a metre (more than three feet) in diameter.

Animals. The variety of animals even in a small area of tropical rain forest is so vast that a large proportion of species of all of the groups, except the vertebrates, are still unnamed and unclassified, a formidable obstacle to research in rain forest ecology. All groups of vertebrates except fishes are represented and almost all groups of terrestrial invertebrates. Even groups that are normally aquatic, such as flatworms (planarians) and polychaete worms, are able to live in the continually moist undergrowth of the rain forest. Land leeches (class Hirudinea) that attach themselves to passing animals (including man) are one of the most troublesome pests of the rain forests of the Philippines and other parts of the eastern tropics.

Wide representation of animal groups

Rain forest mammals range from such large creatures as the elephant (of Africa and Asia) and forest rhinoceros (of Malaysia) down to tiny mice and shrews. In tropical America the range of size is less, because there are no mammals larger than jaguars and tapirs. A tendency to gigantism is shown among rain forest invertebrates, which include the giant snail of Africa, "bird-eating" spiders, and the goliath beetle. The splendid *Ornithoptera* butterflies of Malaysian forests, the blue morpho butterflies of tropical American forests, and the huge Atlas moth of Asian forests are among the largest Lepidoptera.

Although the animals of the tropical rain forest are abundant and many striking and colourful in appearance, often few can be seen except for some butterflies and bees, an occasional hummingbird, ground squirrel, or armadillo, and the omnipresent ants. One reason for this is that a large proportion of the animals, including most of the birds, live in the trees and rarely come down to ground level. Others are extremely well camouflaged—*e.g.*, the leaf butterflies, which are virtually invisible when they rest on dead leaves; green tree snakes, which hide among the foliage; and the numerous shy, brownish birds and mammals, which are well concealed until they move.

Another reason for the apparent scarcity of animal life is that many of the rain forest animals are nocturnal, including such mammals as lemurs and tarsiers, such birds as nightjars and owls, most toads and frogs, and most moths, as well as a host of other insects of many different families. All of these animals become active only after dark, when the temperature is lower and the dangers from water loss and predators less than in the day. Many nocturnal animals are highly adapted to their way of life; the large saucer eyes of tarsiers, bush babies, and owls and the luminous organs of fireflies are a few examples of the ways in which nocturnal animals are adapted to their way of life.

Often more evident than the animals themselves are their habitations. Birds' nests are seldom easy to find, but the beautifully constructed nests of wasps, bees, ants, and termites are everywhere to be seen. Termites, which are among the most abundant of all of the forms of life in the rain forest, play a vital part in removing deadwood and plant debris. During the day they remain within their nests (termitaria) and in covered passages of cemented wood and soil particles. Termitaria are found both on trees and rising from the ground as fantastic, spired or conical structures sometimes a metre or more in height. Both types of nests often have highly developed rain-shedding devices: in the tree nests, chevronlike arrangements of ridges direct the water away, and in some freestanding termitaria superposed "hats," somewhat like the roof of an African grass hut, drain water away.

Animal stratification

The animals of the tropical rain forest, like the plants, are stratified, but, because of the difficulty of exploring the forest above ground level, zoologists usually divide the forest merely into canopy and undergrowth, or into top, middle, and lower layers, rather than into the five strata mentioned earlier.

In the canopy not only is there more open space but, because of the higher light intensity and greater photosynthetic activity of the foliage, more young leaves, fruits, and flowers are available as food. In the undergrowth there is less variety of plant food, though leaves and wood that continually fall from above provide a plentiful source of food for some animals and plants.

For the larger animals the canopy provides opportunities for flying, gliding, and leaping, as well as for climbing and running along branches; both sight and hearing are important senses in seeking food and escaping predators. The life of an undergrowth animal is different. Running, fluttering, hopping, and climbing are the chief modes of locomotion, and, because the animals tend to be camouflaged, communication between them is more by sound than by sight. Many undergrowth birds—for example, the bellbirds, which include the cotingas, honeyeaters, and some of the thickheads and shrikes—have dull, concealing colours but surprisingly loud, clear calls.

The American naturalist William Beebe was one of the first to study the stratification of animals in a tropical forest. In Guyana he recognized five height "zones," each mainly inhabited by different mammals and birds. More recent studies in Malaya, where the forest animals are similarly stratified, have shown that the animals of each level tend to differ in both their mode of locomotion and their feeding habits. For example, the mammals living on the ground include large species, such as the elephant and rhinoceros, with no climbing ability, and smaller species that climb only to a limited extent. This group includes herbivores, which browse on leaves and eat fallen fruits (elephant, deer), mixed feeders (sun bear), and carnivores (tiger, leopard). The inhabitants of the middle levels and canopy have little contact with the ground; they climb, leap, or swing from branch to branch (gibbons, monkeys) or glide for long distances (flying squirrels, flying lemur). Mostly they are fruit and insect eaters, though some are carnivorous (clouded leopard, marten). The birds of different strata show similar differences in their movements and feeding habits.

The animals of the rain forest show many striking structural adaptations to their mode of life, those of the treetops, in particular, having evolved special characteristics not found in those living nearer the ground—*e.g.*, the winglike skin flaps of the flying squirrels and lemurs, the prehensile tails of the New World monkeys, the peculiar limbs of sloths (which allow them to hang from branches upside down), the stiff tails of woodpeckers (used as an aid to climbing), and the beaks of parrots (well adapted to cracking nuts and to assist in climbing).

Adaptations to the requirements of climbing in different strata are particularly well shown among rain forest primates. The only forest primates that live mainly on the ground are the chimpanzees and gorillas of Africa; they have limbs adapted to walking and climbing but not to venturing high in the trees. The tarsiers, galagos, and lemurs, found mostly in the small trees of the B and C strata, have short legs and arms; they climb well, run, and make short jumps. The primates of the treetops include the orangutan and the athletic gibbons of Malaysia and monkeys of many kinds. The orangutan and the gibbons have long arms with which they swing from branch to branch, while the monkeys are better adapted to running along branches and leaping from tree to tree. In feeding habits the different groups of primates are also well adapted to the strata in which they mainly live.

Specialized tree-bound animals

Among the animals that rarely come down to earth are certain frogs and toads, which must obtain water for their tadpole stage. Some lay their eggs in water held in holes in trees or by epiphytic bromeliads; in others the tadpole stage is abbreviated, and the developing eggs are carried attached to a moist membrane on the mother's back. One Central American species lays its eggs in packets fixed to branches of trees overhanging streams, so that the tadpoles fall into the water when they hatch.

Rot holes and bromeliad "tanks" also provide treetop habitats for mosquitoes and other insects with aquatic larvae. Mosquitoes that breed in the treetops are of much practical importance because some are carriers of malaria, yellow fever, and other diseases of humans and animals. Malaria-carrying anopheles mosquitoes breeding in forested regions of tropical America sometimes come down to ground level and become a source of infection for people living in the area. Similarly, aëdes mosquitoes, which carry yellow fever, normally bite monkeys living in the treetops in the forests of Africa and the Amazon, but when trees are felled these mosquitoes may bite lumbermen and initiate epidemics among susceptible human populations.

There are many rain forest inhabitants normally found below the soil surface to a depth of a metre or more (three or four feet). This underground community includes burrowing vertebrates, such as armadillos, which also spend much time above ground, and others, such as caecilians (wormlike amphibians), worm snakes, and many more, which are wholly subterranean. Much more important than these, however, is the host of small soil invertebrates (worms, mites, insects, etc.) that, together with fungi and microorganisms, play a large part in decomposing dead vegetation and freeing the elements contained therein for recirculation in the forest ecosystem.

The year-round warm and moist conditions in the rain forest are of great significance for animals as well as for plants. In general, rain forest animals are unrestricted in their activities by seasonal changes of climate. The environment demands no prolonged rest periods—neither hibernation nor estivation—and resting stages of insects are either absent or short, with little relation to the time of year.

An important aspect of the environment for animals is that food is always available. Foods such as leaves, flowers, and fruit may vary in abundance but are never unobtainable as in a temperate-zone winter. Many forest birds depend exclusively on fruits, and bats as well as hummingbirds and sunbirds have evolved flower-visiting habits.

Some animals actually reproduce at all times of year. Some African forest birds, such as fruit pigeons (family Treroninae) and flycatchers (families Muscicapidae and Tyrannidae), breed at all of the seasons, and some tropical butterflies, such as the swallowtails (*Papilio*), have a succession of broods throughout the year rather than the one or two as in temperate Europe and America. Although breeding is always possible, the majority of animals have fairly definite breeding periods; these periods, however, are not synchronized for different species, so there is no time at which some birds, mammals, and insects are not reproducing. The breeding season of many rain forest birds and mammals seems to be related to variations in abundance of their chief foods.

Reproduction tends to take place more frequently or over a larger part of the year than in temperate animals, and there is a tendency for fewer young to be born in each brood. This is especially true of tropical birds, which lay fewer eggs at a time than do temperate birds.

Relationships between organisms. The large and diverse populations of organisms in a tropical rain forest interact

Complex association forming a stable ecosystem

with each other and with their environment to form an extremely complex but stable ecosystem. As in any other natural community, the basic relationships between the constituent organisms are the food and energy links. Radiation from the Sun provides energy for the photosynthesis of trees and other chlorophyll-containing plants. These are eaten by herbivorous animals, the most important of which in the rain forest are probably the insects. These primary consumers are the food of secondary consumers, such as insectivorous birds, which are in turn eaten by others, so that there are food chains with up to four or five "links" (trophic levels). The food chains end with such predators as jaguars, eagles, and owls, all of which are relatively scarce and, because of their size and large food requirements, unselective in their diet. Most rain forest plants and animals have parasites, which may in turn be attacked by parasites (hyperparasites), establishing another kind of food chain.

An important difference between a tropical forest and other ecosystems is that the food chains (or food webs, because they are interconnected) are so many and so complex. A further characteristic of the rain forest is that within the main ecosystem with its food webs, there are small subsidiary systems, which are partially isolated. One subsidiary system is that of the bromeliad tanks in tropical American rain forests. In these the chief sources of food are plant debris falling into the tanks or brought there by ants and production of food by populations of certain green algae. The consumers are worms, insect larvae, tadpoles, etc., some of which remain in the tanks, whereas others, such as frogs and mosquitoes, leave them when mature to find food elsewhere in the forest.

Another subsystem consists of the large number of organisms dependent in one way or another on ants. Many kinds of insects live in ants' nests in various relationships with their hosts, the nature of which is often not clear. Some large predators, such as anteaters, feed largely on ants and termites, while antbirds (family Formicariidae; a characteristic group of thrushes and other species) follow the migratory army ants (*Eciton*) of tropical America and the similar driver ants (subfamily Dorylinae) of Africa as they advance through the forest, eating not the ants themselves but the insects and small vertebrates disturbed by them.

There are also many kinds of ant–plant relationships, the most remarkable perhaps being that between green plants and the tropical American leaf-cutting ants (*Atta*). These ants bite out small semicircular pieces from leaves and carry them in procession into the recesses of their moundlike nests. Special fungi, which grow on the leaf bits, produce knoblike outgrowths on which the ants feed.

Another kind of ant–plant relationship found in all of the tropical rain forests is that between certain types of ants and certain species of plants in which they nest, known as myrmecophytes ("ant plants").

Stratification of pollinators and seed dispersers

Among rain forest trees, in contrast to temperate trees, pollination by wind is uncommon, and insects, birds, or bats are generally the pollinators. Specialized coadaptations between flower and pollinator have often evolved, the most extraordinary being perhaps the fantastically elaborate pollination mechanisms in some tropical orchids. Several unusual features common among rain forest trees, such as flowers borne on the main trunk or hanging from the branches on long cordlike stalks, seem to be adaptations to bird or bat pollination.

Animals of many kinds play a part in dispersing the seeds of many rain forest trees and vines, though some, especially species colonizing gaps and clearings, have windborne fruits. Trees of the A and B strata often have heavy fruits that crash through the foliage beneath and are subsequently distributed by rodents and other small animals. Other trees have edible nuts or berries, which are dispersed by parrots, monkeys, and other treetop inhabitants.

Many forest plants have evolved protective features that make them distasteful or toxic. Members of the pea family, to which many rain forest trees and vines belong, often have bitter seeds avoided by insect larvae. Similarly, the leaves of the madder family (Rubiaceae), the largest family of tropical plants, often contain poisonous or bitter compounds; it can hardly be a coincidence that few caterpillars are known to feed on them.

BIOLOGICAL PRODUCTIVITY

The luxuriance of the tropical rain forest and the speed with which clearings are invaded by secondary growth suggest that the rates of photosynthesis, growth, and other physiological processes in tropical plants must be high compared with those in temperate climates. To test such impressions, estimates of biomass (total quantity of organic material per unit of land area) and of the amount of new material added yearly (biological productivity) are required.

A few estimates for some primary rain forests indicate that from 300 to 400 metric tons of plant material occupy a hectare, which is greater than the biomass of most temperate forests but less than that of the redwood forests of California. It is probable that the biomass of the forests of the Malay Peninsula, however, reaches as much as 500 metric tons per hectare.

In every case, more than 80 percent of the rain forest biomass consists of woody stems and branches, leaves forming only a small proportion of the total. The organic material that is available as food for herbivorous insects and other leaf feeders is thus a small fraction of the total amount present. If the biomass can be regarded as the forest's capital, then the annual increment of organic material is its income, and this latter depends on several factors, of which the most important is the amount of available energy. More solar radiation falls on the tropical zone than on any other part of the Earth. In the humid tropics the radiation actually reaching the Earth's surface is about double the amount received at 60° N, the latitude of Leningrad, and the northern tip of Newfoundland. It might, therefore, be expected that the tropical rain forest would produce more organic matter per unit of land surface than any other kind of vegetation, but this does not in fact seem to be the case.

Surprisingly low organic productivity

A reliable estimate of organic production in the tropical rain forest of Côte d'Ivoire (West Africa) gave the figure of nine metric tons per hectare per year, not much higher than the productivity of a beech wood in Denmark. For several reasons this forest was perhaps untypical, but estimates for other tropical areas do not suggest much higher figures.

If it is indeed true that tropical forests are not much more productive than those in temperate climates, the explanation may lie mainly in the high respiration rates of tropical plants. The total amount of organic material produced by a tropical tree in a year may be prodigious (about two or three times that produced by a temperate tree), but much of it is unavailable for plant growth because it is lost in respiration, the process by which oxygen is taken in and carbon dioxide given out, with release of heat and chemical energy. It seems that, generally, tropical plants lose through respiration a larger proportion of the carbohydrate material they build up during the day than do temperate plants.

The tall trees of the forest, whose crowns are more or less fully exposed to the sun, photosynthesize more actively than those in the shaded undergrowth. In Kampuchea (Cambodia) the A stratum contributes more than half the productivity of the forest, though its foliage forms only about a fifth of the total leaf area.

The rate of growth in girth and height, like the productivity, of primary rain forest trees does not seem to be unusually high. The evidence suggests that primary rain forest trees do not, in general, grow as rapidly as the fastest-growing temperate trees, such as poplars, eucalyptus, and some pines. Very high growth rates, however, are found in trees of young secondary rain forests, such as the trumpet tree (*Cecropia*) of tropical America and the African parasol tree (*Musanga cecropioides*). The latter can reach a height of more than 20 metres (65 feet) in 20 years. Such trees do not, in fact, grow as fast as such temperate plants as the sunflower under comparable conditions. Temperate plants, however, grow fast only during a short summer season, whereas the growth rates of trees such as the parasol tree are maintained through the year.

At tropical temperatures, decomposition is normally much faster than under temperate conditions. As a result, plant and animal remains do not accumulate as litter or as humus incorporated in the soil. Studies in the Thailand rain forest showed that more than 80 percent of the carbon present is in the form of living wood and leaves and less than 20 percent as dead material on and in the soil. By contrast, in a northern coniferous forest more than half the carbon may be present as organic matter in the soil or as litter on its surface.

Elements released from the dead organic material by decomposition are almost immediately reabsorbed by tree roots, often with help from fungi living in close association with them. The small amounts of nutrients washed down into the soil by the rain or carried away by streams are replaced by additional nutrients set free by the weathering of soil minerals. There is thus an almost closed cycle of mineral nutrients, and a rain forest soil is able to support a luxuriant vegetation and abundant animal life in a permanent equilibrium with its environment. Because the loss of nutrients is so small, the concentration of mineral elements in the water of rivers, such as the Amazon, that drain large rain forest areas is scarcely higher than in rainwater.

Effect of forest clearing

In the undisturbed rain forest the greater part of the mineral resources is locked up in the biomass itself, but there is a drastic change if the forest is felled. When clearings are made by the slash-and-burn system—the commonest method of growing food crops in rain forest areas—good harvests are seldom obtained after the first year. When the vegetation is burned, the minerals contained in it are suddenly released in soluble form, and a large proportion is washed away in surface erosion or carried down into the soil and drained away later to the rivers. The conversion of vast tracts to pastureland results, in addition to the destruction of species, in the rapid depletion of nutrients and an inferior utilization of solar energy. (P.W.R./Ed.)

Other tropical-subtropical woodland complexes

At the edge of forests are transitional woodland formations called forest ecotones. Two types are briefly described below. In tropical latitudes the savanna and thorn forest ecotones are intermediate formations between the rain forest and semiarid desert.

SAVANNAS

Savannas lie between the tropical rain forest and semidesert vegetation in a broad latitudinal zone between 5° and 20° N and S of the equator (Figure 29). The dominant vegetation is an open parklike tree cover over dense, tufted and often tall grass. The climate is tropical and semihumid, with summer rain and a long dry season. Precipitation varies between 600 millimetres (about 23 inches) and 1,500 millimetres (about 60 inches); at the lower range of rainfall the savanna passes into thorn scrub, whereas at the upper limit the savanna grades into semievergreen or mixed deciduous forest. The savanna occurs extensively in Africa, both north and south of the equator, covering most of the East African highlands. In South America the savannas of Venezuela and Brazil are separated by the Amazon forests. In Australia savannas are found between the forests of the wet coastal regions and the deserts of the interior. These "savanna woodlands" of tropical Australia include many areas in which the tree cover consists mostly of eucalyptus. In all localities the savanna offers a unique environment for large animals, many of which, such as the zebras and giraffes of Africa, are particularly adapted to the open woodland and some, like the carnivores, to sparse woodland conditions. The environment is especially prone to fire, and it is probable that large areas of savanna are stabilized by fire. Annual burning is a common practice in Africa, and the savanna vegetation is subject to severe selection; only species resistant to periodic fires can maintain themselves. If burning is abandoned, increase in woody plant development takes place.

Savanna trees

The dominant tree species of the savanna are typically deciduous, shedding their leaves during the dry season; they have a gnarled, Y-shaped form, branching a few feet above the ground and spreading out to an umbrella-shaped crown. In Africa, outside the influence of the savanna-closed forest margins, the miombo (*Brachystegia-Isoberlinia*) woodland grades into an acacia formation as drought conditions increase. This formation includes also elephant grass mixed with other tussock grasses of the genera *Imperata, Andropogan,* and *Hyparrhenia.* At their most luxuriant they are often more than 3.6 metres (12 feet) tall at the end of the growing season; their stature diminishes as conditions become drier, until, under the acacias at the border of the semiarid desert and thorn forest, they give way to triple-awned grasses.

THORN FORESTS

The thorn forest is stabilized by the climate over most of its area, although occasionally it is maintained by grazing or burning. It is found on the equatorial margins of subtropical and tropical semideserts, where rainfall in a two-to four-month summer season rarely exceeds 700 millimetres (about 27 inches). The forest resembles the savanna woodland, but it is somewhat shorter in stature; the ground layer is confined to sparse arid-adapted grasses but is richer than its savanna neighbour in understory woody species.

The vegetation of thorn forests is markedly adapted to dry conditions, the trees being deciduous or, if evergreen, with leaves protected against drying; the branches often bear thorns as protection against grazing animals. Cacti and other spiny succulents appear in the ground layers and understory. The common dominant trees are native acacias, which appear in the South American, African, and Australasian formations, in the last case displacing the eucalyptus of the savanna. In the Asian formation khair (*Acacia catechu*) is associated with teak (*Tectona hamiltoniana*), a deciduous nonthorny species. Like the tree species of the savanna, the thorn forest dominants are deep-rooted, competing most successfully on soils where water penetrates deeply and quickly. (G.K.E./Ed.)

BIBLIOGRAPHY

General works: EUGENE P. ODUM, *Fundamentals of Ecology,* 3rd ed. (1971), is a comprehensive college textbook and reference, designed also for the citizen, educator, and political leader. *Scientific American,* vol. 223, no. 3 (1970), is an entire issue devoted to the ecology of the biosphere, with excellent general articles. W.C. ALLEE *et al., Principles of Animal Ecology* (1949), is a classic reference work that is valuable for most topics. N.M. JESSOP, *Biosphere: A Study of Life* (1970), includes discussion of energy flow and material cycling. Three works that emphasize the ecosystem approach to ecology are EUGENE P. ODUM, *Ecology* (1963); EDWARD J. KORMONDY, *Concepts of Ecology,* 3rd ed. (1984); and ROBERT H. WHITTAKER, *Communities and Ecosystems,* 2nd ed. (1975). HOWARD T. ODUM, *Environment, Power, and Society* (1971), is a semipopular introduction to systems ecology, with emphasis on technological, political, and economic solutions to environmental problems. JOHN WIENS (ed.), *Ecosystem Structure and Function* (1972), contains the proceedings of the 31st Biology Colloquium, in which five authors deal with ecosystem concepts. ALDO LEOPOLD, *A Sand County Almanac, and Sketches Here and There* (1949, reissued 1987), is an environmental classic, with near-poetic essays on "The Land Ethic," "Wilderness," and "Conservation Esthetic," all imbued with ideas about the place of humans in ecosystems. EDWARD J. KORMONDY and J. FRANK MCCORMICK (eds.), *Handbook of Contemporary Developments in World Ecology* (1981), provides good summaries of developments in countries in five continents. (D.M.G./E.P.O./Ed.)

Distribution of organisms: Local distribution is considered in detail in H.G. ANDREWARTHA and L.C. BIRCH, *The Distribution and Abundance of Animals* (1954, reissued 1970); and VERA COPNER WYNNE-EDWARDS, *Animal Dispersion in Relation to Social Behaviour* (1962, reissued 1972). Large-scale distribution is dealt with in LÉON CROIZAT, *Panbiogeography,* 2 vol. in 3 (1958); PIERRE DANSEREAU, *Biogeography: An Ecological Perspective* (1957); PHILIP J. DARLINGTON, JR., *Zoogeography: The Geographical Distribution of Animals* (1957, reprinted 1982); L.F. DE BEAUFORT, *Zoogeography of the Land and Inland Waters* (1951); DAVID J. DE LAUBENFELS, *A Geography of Plants and Animals* (1970); M.J. DUNBAR (ed.), *Marine Distributions* (1963); SVEN EKMAN, *Zoogeography of the Sea* (1953, reissued 1967; originally published in German, 1935); PETER A. FURLEY, *Geography of the Biosphere: An Introduction to the Nature, Distribution, and Evolution of the World's Life Zones* (1983); WILMA B. GEORGE, *Animal Geography* (1962); RONALD GOOD,

The Geography of the Flowering Plants, 4th ed. (1974); ROBERT H. MACARTHUR, *Geographical Ecology: Patterns in the Distribution of Species* (1972, reprinted 1984); and NICHOLAS POLUNIN, *Introduction to Plant Geography and Some Related Sciences* (1960). The factors behind dispersal are examined in SHERWIN CARLQUIST, *Island Life: A Natural History of the Islands of the World* (1965); CHARLES S. ELTON, *The Ecology of Invasions by Animals and Plants* (1958, reissued 1977); CARL H. LINDROTH, *The Faunal Connections Between Europe and North America* (1957); ROBERT H. MACARTHUR and EDWARD O. WILSON, *The Theory of Island Biogeography* (1967); MIKLOS D.F. UDVARDY, *Dynamic Zoogeography: With Special Reference to Land Animals* (1969); and L. VAN DER PIJL, *Principles of Dispersal in Higher Plants,* 3rd rev. and expanded ed. (1982).

(P.R.G./Ed.)

Biotic interactions: PAUL BUCHNER, *Endosymbiosis of Animals with Plant Microorganisms,* rev. ed. (1965; originally published in German, 1953), provides a detailed, authoritative treatment of symbiosis between insects and microorganisms. THOMAS C. CHENG, *Symbiosis: Organisms Living Together* (1970), a semipopular book, encompasses types and origins of symbiotic associations, including human parasites and their life cycles. PAUL DEBACH (ed.), *Biological Control of Insect Pests and Weeds* (1964, reissued 1973), is a technical treatise, with detailed accounts of the biotic interactions on which biological control is based. PAUL L. ERRINGTON, *Of Predation and Life* (1967); and S. MARK HENRY, *Symbiosis,* 2 vol. (1966–67), survey the symbiotic associations of microorganisms, plants, marine organisms, invertebrates, birds, ruminants, and other organisms. See also L. MARGULIS, "Symbiosis and Evolution," *Scientific American,* 225:48–57 (1971). (P.S.M./Ed.)

Biological populations: MAURICE E. SOLOMON, *Population Dynamics,* 2nd ed. (1976), is a short introduction to the principles of density-dependent regulation, primarily in insects. G.F. GAUSE (GAUZE), *The Struggle for Existence* (1934, reprinted 1971), is a classic discussion of the first laboratory experiments with protozoa in the study of predator–prey interactions and competitive exclusion. DAVID LACK, *Population Studies of Birds* (1966), summarizes and relates many studies by a number of authors. T.T. MACAN, *Freshwater Ecology,* 2nd ed. (1974), discusses species behaviour and interrelationships. R.M.F.S. SADLEIR, *The Ecology of Reproduction in Wild and Domestic Mammals* (1969), includes information on litter size and age of breeding. T.R.E. SOUTHWOOD (ed.), *Insect Abundance* (1968), includes a study of the winter moth. ADAM WATSON (ed.), *Animal Populations in Relation to Their Food Resources* (1970), collects reviews of the influence of food on numbers in many types of animals. (D.L.L./Ed.)

Biological communities: JARED DIAMOND and TED J. CASE, *Community Ecology* (1986), provides a good introduction. J. BRAUN-BLANQUET, *Plant Sociology: The Study of Plant Communities* (1932, reissued 1987; originally published in German, 1928), is the standard European textbook on plant communities. S.R. EYRE, *Vegetation and Soils: A World Picture,* 2nd ed. (1968, reissued 1977), offers a concise treatment of world vegetation. S. CHARLES KENDEIGH, *Animal Ecology* (1961), discusses animal communities, niches, and biomes. A.W.F. SCHIMPER, *Plant-Geography upon a Physiological Basis* (1903, reprinted 1964; originally published in German, 1898), is one of the classic treatises on plant communities of the world. ROBERT H. WHITTAKER, *Classification of Natural Communities* (1962, reprinted 1977), *Ordination of Plant Communities,* 2nd ed. (1982), and *Classification of Plant Communities,* 2nd ed. (1982), review theories and approaches to classifying communities.

(R.H.W./Ed.)

Aquatic ecosystems: Introductions to various aspects of oceanic ecosystems include WILLIAM J. CROMIE, *The Living World of the Sea* (1968), a popular book on marine subjects of wide general interest; KLAUS GÜNTHER and KURT DECKERT, *Creatures of the Deep Sea* (1956; originally published in German, 1950), a classic work on deepwater animals; GEORGE E. MACGINITIE and NETTIE MACGINITIE, *Natural History of Marine Animals,* 2nd ed. (1968), an excellent, generalized treatment of the ecology of widely representative marine animals, with emphasis on those from the Pacific coast of North America; ROBERT C. MILLER, *The Sea,* 2nd ed. (1975), a fascinating book on marine life, habitats, and phenomena; HILARY B. MOORE, *Marine Ecology* (1958), an authoritative book on marine ecology, suitable for use as a college text; and J.A. COLIN NICOL, *The Biology of Marine Animals,* 2nd ed. (1967), a scholarly, exhaustive treatment of physiological topics and mechanisms pertaining to marine organisms.

Analyses of ecosystems in lakes and rivers can be found in DAVID G. FREY (ed.), *Limnology in North America* (1963), a geographically organized account of the lakes—and, to some extent, of the rivers, springs, estuaries, and wetlands—of North America, with a useful annotated bibliography; G. EVELYN HUTCHINSON, *A Treatise on Limnology,* 3 vol. (1957–75), an encyclopaedic work on lakes, probably the most comprehensive ever attempted for any type of aquatic ecosystem; H.B.N. HYNES, *The Ecology of Running Waters* (1970), a comprehensive book on the biology of rivers; GEORGE K. REID and RICHARD D. WOOD, *Ecology of Inland Waters and Estuaries,* 2nd ed. (1976), a unique attempt to cover the ecology of lakes, rivers, and estuaries in relatively simple fashion; BRIAN MOSS, *Ecology of Fresh Waters,* 2nd ed. (1988); and FRANZ RUTTNER, *Fundamentals of Limnology,* 3rd ed. (1963, reprinted 1974; originally published in German, 1962), a short introduction to lakes, with emphasis on their biology.

Studies of special ecosystems include JAMES GREEN, *The Biology of Estuarine Animals* (1968), which contains information about estuarine animals and how they fit into the ecosystem; JOHN TEAL and MILDRED TEAL, *Life and Death of the Salt Marsh* (1969), a lyrical but authoritative account for nonspecialists of the salt marsh ecosystem; N.A. HOLME and A.D. MCINTYRE (eds.), *Methods for the Study of Marine Benthos,* 2nd ed. (1984), a biological handbook with a section on coastal life and on primary production of coastal communities; J.R. LEWIS, *The Ecology of Rocky Shores* (1964, reissued 1976), a detailed, well-illustrated treatment of zonation on rocky shores in the British Isles; and T.A. STEPHENSON and ANNE STEPHENSON, *Life Between Tidemarks on Rocky Shores* (1972), a summary of the Stephensons' investigations of seashore life and zonation in both hemispheres, together with a review of other investigations in places not visited by the Stephensons.

(C.N./D.A.L./A.J.So./Ed.)

Terrestrial ecosystems: Information on terrestrial ecosystems can be found in the voluminous literature on biology and the Earth sciences.

Methods and results of research are provided in the series *Ecological Studies,* the first volumes of which are DAVID E. REICHLE (ed.), *Analysis of Temperate Forest Ecosystems* (1970); and H. ELLENBERG (ed.), *Integrated Experimental Ecology* (1971). Forest ecosystems are emphasized in the two volumes cited above and in V. SUKACHEV and N. DYLIS, *Fundamentals of Forest Biogeocoenology* (1968; originally published in Russian, 1964). Other major ecosystem types are treated in the following works: M.J. DUNBAR, *Ecological Development in Polar Regions: A Study in Evolution* (1968), on the adaptations of polar organisms, especially marine, to low temperatures and on the evolution of polar ecosystems; NICHOLAS POLUNIN, *Botany of the Canadian Eastern Arctic,* part 3, *Vegetation and Ecology* (1948); *Circumpolar Arctic Flora* (1959); HEINRICH WALTER, *Vegetation of the Earth and Ecological System of the Geobiosphere,* 3rd rev. and enlarged ed. (1985); originally published in German, 5th rev. ed., 1982), on the regional distribution of vegetation types over the world; J.W. BEWS, *The World's Grasses: Their Differentiation, Distribution, Economics, and Ecology* (1929), a comprehensive review of the nature of grasses and grasslands of Africa and their relation to those of other parts of the Earth; G.W. BROWN, JR. (ed.), *Desert Biology,* 2 vol. (1968–74), a symposium volume in which numerous specialists discuss their own fields of desert biology in varying depth, with attention concentrated on the deserts of North America; J.L. CLOUDSLEY-THOMPSON and M.J. CHADWICK, *Life in Deserts* (1964), a general account intended for use in colleges; and PAUL W. RICHARDS, *The Life of the Jungle* (1970), a lavishly illustrated popular account of rain forest ecology, and *The Tropical Rain Forest: An Ecological Study* (1952, reissued 1979), a standard work on the tropical rain forest.
