Control and single-series prediction. A derivation of the mathematical equations of prediction had been accomplished in a limited sense some years before Wiener's work on cybernetics. In 1931 Wiener had collaborated with an Austrian-born U.S. mathematician, Eberhard Hopf, to solve what is now called the Wiener-Hopf integral equation, an equation that had been suggested in a study of the structure of stars but later recurred in many contexts, including electrical-communication theory, and was seen to involve an extrapolation of continuously distributed numerical values. During World War II, gun- and aircraft-control problems stimulated further research in extrapolation, and Wiener composed a purely mathematical treatise, *Extrapolation, Interpolation, and Smoothing of Stationary Time Series,* which was published in 1949. As early as 1939, a note on extrapolation by a Russian mathematician, A.N. Kolmogorov, had appeared in the French journal *Comptes Rendus.* Although the Wiener-Hopf work was concerned exclusively with astronomy and done without the guiding influence of computers, it was recognized in World War II that high-speed computations could involve input information from a moving object and, through prediction or extrapolation, provide output data to correct its path. This recognition was the seed of the concept of the guided missile and radar-controlled aircraft. Weather prediction was also possible, as was computerized research on brain waves whose traces on the electroencephalograph offered another physical realization of the time series that are predictable. The mathematics

that was necessary for a complete understanding of prediction included the concept of a stochastic process, as described in the article PROBABILITY THEORY.

The Wiener and Kolmogorov research on extrapolation of time series became known as single-series prediction and owed much to the studies (1938) of a Swedish mathematician named Herman Wold, whose work was predicated on the assumption that, if $X_1, X_2, X_3, \cdots$, are successive values of a series identified with discrete points in time $t=1$, $t=2$, $t=3, \cdots$, then the successive values are not entirely unrelated (for if they were, there would be no way for an algorithm or an automaton to generate information about later members of the sequence—that is, to predict). It was assumed, with anticipation that there is frequently such a thing in nature, that a transformation T relates members of the series by successively transforming an underlying space of points ω according to a rule. The rule states that the kth member of the time series is a function of an initial point ω that has migrated in the underlying space $X_k = X(T^k\omega)$. It was also assumed that, if sets of points $\{\omega\}$ constituted a region (of sufficient simplicity called "measurable") in space, then when the set was transformed under the influence of T its volume would not be changed. The last assumption had, in fact, been proved by a French mathematician, Joseph Liouville, a century earlier for a wide class of physical processes whose behaviour is correctly described by the so-called Hamiltonian equations. The clearly stated assumptions of Wiener and Kolmogorov, referred to as the stationarity of the time series, were supplemented with the idea (the linearity restriction) that a solution $S_k(\omega)$ for the predicted value of the series, displaced in time k steps into the future, should be restricted to a linear combination of present and past values of the series (see 3).

(3) $$S_k(\omega) = \sum_{n=0}^{\infty} X(T^{-n}\omega)\, P_n^{(k)},$$
with convergence defined in the L_2-metric.

(4)
An algorithm for computing the coefficients $P_n^{(k)}$ in the prediction $S_k(\omega)$ is the following:
From the auto-correlation (X_{-n}, X_0) of the time series compute $|\psi(\theta)|$:
$$\frac{1}{2\pi}\int_{-\pi}^{\pi} |\psi(\theta)|^2 e^{in\theta}\, d\theta = (X_{-n}, X_0).$$
From $|\psi(\theta)|$ compute $\psi(r, \theta)$:
$$\log \psi(r, \theta) = \frac{1}{2\pi}\left\{\sum_{n=1}^{\infty} r^n e^{in\theta}\int_{-\pi}^{\pi} \log |\psi(x)|^2 e^{-inx}\, dx + \int_{-\pi}^{\pi} \log |\psi(x)|\, dx\right\}.$$
From $\psi(r, \theta)$ compute (X, h_{-n}):
$$\psi(r, \theta) = \sum_{n=0}^{\infty} r^n e^{in\theta}(X, h_{-n}), \qquad 0 \leq r < 1.$$
From (X, h_{-n}) compute a_n:
$$(X, h)a_0 = 1$$
$$\sum_{n=0}^{m} (X, h_{n-m})a_n = 0; \qquad m > 0.$$
From a_n and (X, h_{-n}) compute $P_n^{(k)}$:
$$P_n^{(k)} = \sum_{m=0}^{n} a_{n-m}(X, h_{-m-k}), \qquad k > 0.$$

(5) $$\sigma_k^2 = \sum_{n=0}^{k-1} |(X, h_{-n})|^2$$

With the help of one other mathematical assumption, it was then possible to solve the single-series prediction problem by specifying an algorithm that would determine the coefficients in the linear combination for $S_k(\omega)$, in which k is a positive integer (see 4). It was possible also to solve for the error of prediction (see 5)—that is, a measure of the discrepancy between the value predicted and the true value of the series that would occur at time k in the future. This meant that for a variety of circumstances, such as the prediction of atmospheric pressure measured at one weather station, or the prediction of a single parameter in the position specification of a particle (such as a particle of smoke) moving according to the laws of diffusion, an automaton could be designed that could sense and predict the chance behaviour of a sufficiently simple component of its environment.

The assumptions of prediction theory

Multiple-prediction theory. Generalizations of the above limited accomplishments are tantalizing to mathematicians. If animals, and humans in particular, are viewed, even in part, as automata with varying degrees of accomplishment and success that depend on their abilities to cope with their environment, then human beings could be better understood and their potentialities could be further realized by exploring a generalized version of an automaton's ability to predict. Success in generalizations of this kind have already been achieved under the heading of what is called multiple-prediction theory. A reference to the problem of multiple prediction without a complete solution was made as early as 1941 by a Russian mathematician, V. Zasuhin. The first major step forward, after Zasuhin, was taken by Wiener in 1955 under the title "On the Factorization of Matrices." Many significant results soon followed.

If multiple-prediction theory is identified with part of automata theory (which is not always done), it is possible to consider the construction of a computing machine, or automaton, capable of sensing many interdependent elements of its environment at once and, from a long history of such data, of predicting a future that is a function of the same interdependent elements. It is recognized that multiple prediction is the most general approach to the study of the automaton and its environment in the sense that it is a formulation of prediction free of the linearity restriction earlier mentioned with reference to single series (see 3). To express a future point $S_k(\omega)$, for example, as a linear function of its present and past values as well as first derivatives, or rates of change, of its present and past values is to perform a double prediction or prediction based on the two time series $X_1, X_2, X_3, \cdots$; $X'_1, X'_2, X'_3, \cdots$, in which primes indicate derivatives with respect to time. Such double prediction is a first step toward nonlinear prediction.

Automata with unreliable components. In 1956 with the continuing development of faster and more complex computing machines, a realistic study of component misfiring in computers was made. Von Neumann recognized that there was a discrepancy between the theory of automata and the practice of building and operating computing machines because the theory did not take into account the realistic probability of component failure. The number of

Discrepancy between automata theory and practice

component parts of a modern all-purpose digital computer was in the mid-20th century already being counted in millions. If a component performing the logical disjunction (A or B) misfired, the total output of a complex operation could be incorrect. The basic problem was then one of probability: whether given a positive number δ and a logical operation to be performed, a corresponding automaton could be constructed from given organs to perform the desired operation and commit an error in the output with probability less than or equal to δ. Affirmative results have been obtained for this problem by mimicking the redundant structure of parallel channels of communication that is frequently found in nature—*i.e.,* rather than having a single line convey a pulse of information, a bundle of lines in parallel are interpreted as conveying a pulse if a sufficient number of members in the bundle do so. Neumann was able to show that with this redundancy technique (multiplexing) "the number of lines deviating from the correctly functioning majorities of their bundles" could with sufficiently high probability be kept below a critical level.

Automata with random elements. The term algorithm has been defined to mean a rule of calculation that guides an intelligent being or a logical mechanism to arrive at numerical or symbolic results. As discussed above under *Neural nets and automata,* a formalization of the intuitive idea of algorithm has led to what is now called an automaton. Thus, a feature of an automaton is the predictability, or the logical certainty, that the same output would be obtained for successive operations of an automaton that is provided with the same input data. If, as a substitute for the usual input data, random numbers (or results due to chance) are provided, the combination of input data and automaton is no longer completely predictable. It is notable, however, that unpredictable results that might be obtained with the use of uncertain input are not without their practical application. Such a method of combining the operation of a computer with the intentional injection of random data is called the "Monte-Carlo method" of calculation and in certain instances (such as in the numerical integration of functions in many dimensions) has been found to be more efficient in arriving at correct answers than the purely deterministic methods.

Quite apart from the questions of efficiency that might bear upon the addition of an element in a computing machine (automaton) that could produce numbers due to chance, the purely logical question has been asked: Is there anything that can be done by a machine with a random element that cannot be done by a deterministic machine? A number of questions of this type have been investigated, but the first clear enunciation and study of such a question was accomplished in 1956 by the U.S. engineer Claude E. Shannon and others. If the random element in the machine is to produce a sequence of digits 0 and 1 in a random order so that the probability is p for a digit 1 to occur, then (assuming that the number p is, itself, obtainable from a Turing machine as a computable number) the machine can do nothing new, so to speak, as compared to the unmodified Turing machine. This result is precisely expressed in the language of automata theory by saying that the sets enumerated by the automaton with random elements can be enumerated also by the unmodified automaton. The computability of p, however, is critical and is necessary for the result. It is also important to emphasize, in order to distinguish this result from what follows, that the computability of p is under discussion, not the computability of the sequence of random digits.

The computability condition for random elements

Computable probability spaces. Finally, it is to be observed that the concept of chance or random number, wherever it has occurred in the above discussion, submits to the interpretation of result of observation of an experiment or physical phenomenon. The chance ingredients in the weather data to which prediction theory applies could be due to molecular disturbances in the atmosphere that are of diverse and minute origin. The chance failure that might cause a component breakdown in a computing machine is due to the physical structure and environment of the defaulting part. The source of chance that could be used to augment the input of a computer for the purposes of the Monte-Carlo method of calculation may be chosen as the erratic emission of electrons from the cathode of an electronic tube and is frequently so chosen.

An entirely distinct question is involved in relating chance and computers. It would be important to know whether an automaton in the sense defined by Turing can generate random numbers. The question is tantamount to asking whether a Turing machine can logically describe the behaviour of those sources of chance that are found in nature and are the subject of the study of probability theory. Because there are many points of view—too many to consider here—more tightly phrased questions may serve as an introduction to the subject, and a few conclusions that can be brought as answers will be mentioned. At the outset, one limited question can be affirmatively answered: Can a computable sequence of numbers, $S = (a_1, a_2, a_3, \cdots)$, serve as the basic ingredient of a probability theory by providing all of the necessary points in a probability space? In this question the term computable sequence is defined to mean that the numbers a_k are real and there is a Turing machine that, for any pair of positive integers A, B, will print out in order the first A digits of all a_k, for k ranging from 1 to B, in a finite number of steps. It might appear that an affirmative answer to the above question is not striking if simple probability theory alone is considered—that is, a theory of events in which the number of possible outcomes is finite, as in the theory of dice, coins, roulette, and the like. On the other hand, it was shown in 1960 that, although a computable sequence can serve as a set of points in a simple probability space, the mathematical expectations of all random variables X defined on the space can be computed according to an explicit algorithm (see 6) that makes use of the sample values, $X(a_1)$, $X(a_2)$, $X(a_3)$, $\cdots$, which themselves are computable if X is computable. In this algorithm it is evident that the potential number of values to be calculated is infinite, though the number of possible outcomes (distinct values of X) might be finite.

Random numbers that a Turing machine can compute

In the language of the limited question considered, a listing of all sample values (random numbers) of an infinite sequence of statistically independent random variables can be printed out by a Turing machine, at least in the simple case, with strict adherence to the definition of all probabilistic terms as based on measure theory, the theory that generalizes the concept of length.

Extension of such constructions beyond the simple case has also been shown to be possible, provided the concept of a random variable can be extended to a class of functions that are more general than the measure-theoretic class. The most explicit formulation of a suitable generalization was given in 1966, and on the basis of this work it is possible to answer affirmatively a second question: For any sequence of probability distributions, is there a sequence of statistically independent random variables with these respective distributions, each of whose sample values can be computed on a Turing machine and whose mathematical expectations are also attainable by algorithm?

Such results would seem to affront the intuition that tends to divide phenomena into deterministic (or computable) and random (or uncomputable) parts. It is to be observed, however, that in probabilistic matters, passage to the limit and infinite collections are essential ingredients, and such entities are unfamiliar objects in the world in which intuitions are formed. (B.R.)

CLASSIFICATION OF AUTOMATA

All automata referred to from this point on may be understood to be essentially Turing machines classified in terms of the number, length, and movement of tapes and of the reading and writing operations used. The term discrete state automaton is sometimes used to emphasize the discrete nature of the internal states. The principal classes are transducers and acceptors. In automata theory, a transducer is an automaton with input and output; any Turing machine for computing a partial recursive function, as previously described, can stand as an example. An acceptor is an automaton without output that, in a special sense, recognizes or accepts words on the machine alphabet. The input of an acceptor is written on tape in

the usual way, but the tape is blank at the end of the computation, and acceptance of the input word is represented by a special state called a final state. Thus, a word x, or sequence of symbols from an alphabet denoted by the letter S, is said to be accepted by an acceptor A if A computes, beginning in an initial state q_0 with x on tape, and halts in a final state with tape being entirely blank. A subset designated U of the set of words S^* on an alphabet S is called an accepted set if there is an automaton A that accepts any word $x \in U$.

Acceptors. An elementary result of automata theory is that every recursively enumerable set, or range of a partial recursive function, is an accepted set. In general the acceptors are two-way unbounded tape automata.

Step (vii): she is a pretty little girl, using rules: 12, 6, 8, 9, 11

Generative grammars

A useful classification of acceptors has been introduced in conjunction with a theory of generative grammars developed in the United States by a linguist, Noam Chomsky. A generative grammar is a system of analysis usually identified with linguistics. By its means a language can be viewed as a set of rules, finite in number, that can produce sentences. The use of a generative grammar, in the context of either linguistics or automata theory, is to generate and demarcate the totality of grammatical constructions of a language, natural or automata oriented. A simple grammar for a fragment of English, determined by 12 rules (see 7), can serve to introduce the main ideas.

In this simple grammar, each rule is of the form $g \rightarrow g'$ (read, "g' replaces g") and has the meaning that g' may be rewritten for g within strings of symbols. The symbol $\overline{S}$ that appears in the rules may be understood as standing for the grammatical category "sentence," $\overline{Pr}$ for "pronoun," $\overline{VP}$ for "verb phrase," $\overline{NP}$ for "noun phrase," and so forth. Symbols marked with a vinculum ($^-$) constitute the set V_N of nonterminal symbols. The English expressions "she," etc., occurring in the rules constitute the set V_T of terminal symbols. $\overline{S}$ is the initial symbol.

Beginning with $\overline{S}$, sentences of English may be derived by applications of the rules. The derivation begins with $\overline{S}$; the first rule allows $\overline{Pr}\ \overline{VP}$ to be rewritten for $\overline{S}$, yielding $\overline{Pr}\ \overline{VP}$; the fourth rule allows $\overline{V}\ \overline{NP}$ to be rewritten for $\overline{VP}$, yielding $\overline{Pr}\ \overline{V}\ \overline{NP}$; and so forth (see 8). A last step yields a terminal string or sentence; it consists solely of elements of the terminal vocabulary V_T. None of the rules apply to it; so no further steps are possible.

The set of sentences thus generated by a grammar is called a language. Aside from trivial examples, grammars generate denumerably infinite languages.

Recursively enumerable grammars and Turing acceptors. An elementary result of automata theory is that every recursively enumerable set, or range of a partial recursive function, is an accepted set. In general, the acceptors are two-way unbounded tape automata. On the other hand, a grammar consisting of rules $g \rightarrow g'$, in which g and g' are arbitrary words of $(V_T \cup V_N)^*$ is an unrestricted rewriting system and any recursively enumerable set of words—*i.e.*, language in the present sense—is generated by some such system. These very general grammars thus correspond to two-way acceptors, called Turing acceptors, that accept precisely the recursively enumerable sets.

Finite-state grammars and finite-state acceptors. Acceptors that move tape left only, reading symbol by symbol and erasing the while, are the simplest possible, the finite-state acceptors. These automata have exactly the same capability as McCulloch-Pitts automata and accept sets called regular sets. The corresponding grammars in the classification being discussed are the finite-state grammars. In these systems the rules $g \rightarrow g'$ are restricted so that g is a nonterminal v of V_N (as exemplified above) and g' is of the form us, $u \in V_N$ and $s \in V_T$. The languages generated by finite-state grammars, owing to this correspondence, are called regular languages.

Comparison with McCulloch-Pitts automata

Although these simple grammars and acceptors are of some interest in information theory and in neural network modelling, they are not descriptively adequate for English or for such standard computer languages as Algol because they are not able to account for phrase structure. In particular, finite-state grammars cannot generate self-embedded sentences such as "the man the dog bit ran away," nor can they produce sentences with several readings such as "she is a pretty little girl."

Context-free grammars and pushdown acceptors. Context-free, or phrase-structure, grammars, although apparently not affording completely adequate descriptions of vernacular languages, do have the desirable properties just noted. For this family, the rules $g \rightarrow g'$ contain single nonterminals on the left, as in the finite-state grammars, but allow g' to be any word of $(V_T \cup V_N)^*$. The example discussed above is a context-free grammar. These grammars can account for phrase structure and ambiguity (see 9).

Pushdown acceptors, which play a key role in computer-programming theory, are automata corresponding to context-free grammars. A pushdown acceptor is a finite-state acceptor equipped with an added two-way storage tape, the so-called pushdown store. At the beginning of operation this tape is blank. As the automaton computes, the store is used to analyze the syntactical structure of the sentence being read. The store moves left when printed, and only the last symbol printed may be read, then the next to the last, and so forth. The input is accepted if both the (one-way) input and storage tapes are blank when the automaton halts in a final state.

The representation of Turing machines in quadruple form may be replaced here by a somewhat clearer list of rules that simulate tape action in their application. Rules can be formulated for a pushdown acceptor P for a context-free language L of items xcx^{-1}, in which x is a word on an abstract alphabet $\{a, b\}$ and x^{-1} is x written in reverse. A first such rule can be formulated to mean that, if P is in state q_0 scanning a on input and any (defined) symbol on the pushdown store, it moves tape left, erases a from the input, prints a on the store, and goes into state q_1. A symbolic expression for the rule might be: $q_0a \rightarrow aq_1$. Another rule might be of the form: if P is in state q_1 scanning c on input and anything on store, it moves input left, erases c, and does nothing with respect to the store—briefly, $q_1c \rightarrow q_2$. Another requires that, if P is in q_2 scanning a on input and a on store, then it moves input left, erases a, moves store right, and erases a (see 10). An example is easily constructed to show that under certain rules a set, say, *abcba* is accepted (see 11). If q_0abcba indicates

(9)

At step (v) of the derivation in (8),
the 3rd rule of (7) could have been applied to (iv), yielding

(va) $\overline{\text{Pr}}\ \overline{\text{V}}\ \overline{\text{Art}}\ \overline{\text{Adv}}\ \overline{\text{Adj}}\ \overline{\text{N}}$.

Successive steps would again result in (vii), but now to be read with a different meaning than before because of an immediate constituent structure differing from (v). To emphasize this divergence the replacing word g' flanked by parentheses, (g'), may be inserted into a previously obtained word in a derivation. Thus at (ii),

(ii)′ $(\overline{\text{Pr}}\ \overline{\text{VP}})$

would be written; and at (iii),

(iii)′ $(\overline{\text{Pr}}(\overline{\text{V}}\ \overline{\text{NP}}))$.

Proceeding in this way, (v) and (va) would appear as

(v)′ $(\overline{\text{Pr}}\ (\overline{\text{V}}\ (\overline{\text{Art}}\ \overline{\text{Adj}}\ (\overline{\text{Adj}}\ \overline{\text{N}}))))$

and

(va)′ $(\overline{\text{Pr}}\ (\overline{\text{V}}\ (\overline{\text{Art}}\ (\overline{\text{Adv}}\ \overline{\text{Adj}})\ \overline{\text{N}})))$.

Sentences in which phrase structure is indicated by parentheses are *phrase markers*. Making the further substitutions (vi) and (vii) within (v)′ and (va)′ produces two phrase markers, which represent two readings of (vii).

(10)

1st rule: $q_0a \rightarrow aq_1$
2nd rule: $q_0b \rightarrow bq_1$
3rd rule: $q_1a \rightarrow aq_1$
4th rule: $q_1b \rightarrow bq_1$
5th rule: $q_1c \rightarrow q_2$
6th rule: $aq_2a \rightarrow q_2$
7th rule: $bq_2b \rightarrow q_2$

Accepted sets in specific calculations

the outset of a computation with P in the initial state q_0 scanning the first a in $abcba$ on input tape and blank on store tape, and if q_2 is a final state, then the computation is determined by the rules given above (see 10). At the end of the computation the automaton is in a final state q_2, both tapes are blank, and there is no rule with q_2 alone on the left; P halts and hence $abcba$ is accepted.

Reflection on the example and on others easily constructed shows that a pushdown acceptor is able, in effect, to parse sentences of context-free languages.

Context-sensitive grammars and linear-bounded acceptors. A fourth type of acceptor, which is mainly of mathematical rather than applied interest, is the two-way acceptor with bounded tape—*i.e.*, tape the length of which never exceeds a linear function of the input length. These are the linear-bounded acceptors. They correspond in the present classificatory scheme to context-sensitive grammars. Unlike the context-free grammars, these latter systems use rules $g \rightarrow g'$, in which the nonterminal symbol $v \in V_N$ in g may be rewritten only in a context xvy; thus $g \rightarrow g'$ is of the form $xvy \rightarrow xwy$, $x, y, w \in (V_T \cup V_N)^*$. An example of a context-sensitive language accepted by a linear-bounded automaton is the copy language xcx.

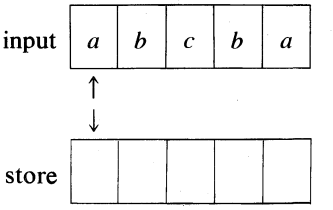
The family of recursively enumerable languages includes the context-sensitive languages, which in turn includes the context-free, which finally includes the regular, or finite-state, languages. No other hierarchy of corresponding acceptors has been intensively investigated.

Finite transducers. The most important transducers are the finite transducers, or sequential machines, which may be characterized as one-way Turing machines with output. They are the weakest with respect to computing power, while the universal machine (see above *The generalized automaton and Turing's machine*) is the most powerful. There are also transducers of intermediate power.

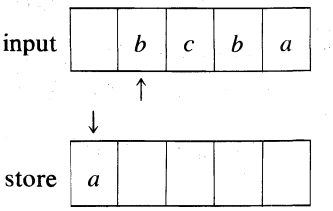
Algebraic definition. Because the tape is one-way with output, a finite transducer T may be regarded as a "black box" with input coming in from the right and output being emitted from the left. Hence, T may be taken to be a quintuple $\langle S, Q, O, M, N\rangle$, in which S, Q, and O are finite,

(11)

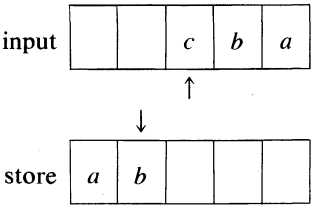
(i) q_0abcba initial tape
This represents the following situation



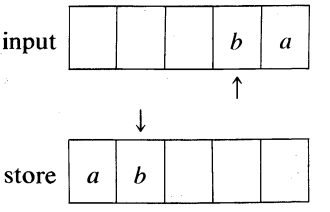
(ii) aq_1bcba by 1st rule (see 10)



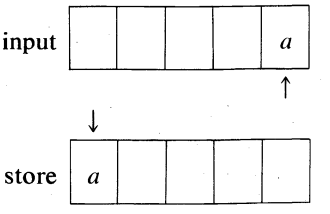
(iii) abq_1cba by 4th rule (see 10)



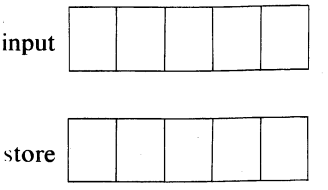
(iv) abq_2ba by 5th rule (see 10)



(v) aq_2a by 7th rule (see 10)



(vi) q_2 by 6th rule (see 10)



(12)

$M(q, \Lambda) = \Lambda$
$M(q, xs) = M(M(q, x), s)$
$N(q, \Lambda) = \Lambda$
$N(q, xs) = N(M(q, x), s)$,

in which the empty word $\Lambda \in S^*$, Λ is adjoined to 0, $x \in S^*$, and $q \in Q$.

(13) Let $\psi: Q_a \to Q_b$ be a map from the states of T_a into those of T_b. The map ψ is a homomorphism if furthermore,
$\psi M_a(q, s) = M_b(\psi(q), s)$
and
$N_a(q, s) = N_b(\psi(q), s)$ for all $s \in S$.

(14) $\phi_s(q) = q'$ if and only if
$M(q, s) = q' \qquad (q, q' \in Q \text{ of } T)$

(15) The *serial connection* of two transducers $T_a = \langle S, Q_a, O_a, M_a, N_a \rangle$ and $T_B = \langle O_a, Q_b, O_b, M_b, N_b \rangle$ is the transducer
$T = T_A \to T_B = \langle S, Q_a \times Q_b, O, M, N \rangle$.
$Q_a \times Q_b$ is the Cartesian product of states, and M, N are given by
$M(\langle q_a, q_b \rangle, s) = \langle M_a(q_a, s), M_b(q_b, N_a(q_a, s)) \rangle$
and
$N(\langle q_a, q_b \rangle, s) = N_b(q_b, N_a(q_a, s))$.

(16) The *parallel connection* of T_A and T_B is the system
$T = T_A \times T_B$
in which
$M(\langle q_a, q_b \rangle, s) = \langle M_a(q_a, s)\, M_b(q_b, s) \rangle$
and
$N(\langle q_a, q_b \rangle, s) = \langle N_a(q_a, s), N_b(q_b, s) \rangle$.

nonempty sets of inputs, states, and outputs, respectively, and M is a function on the product $Q \times S$ into Q and N is a function on the same domain into O. The values are written in the usual functional notation $M(q, s)$, and $N(q, s)$, $s \in S$ and $q \in Q$. M and N may be extended to the domain $Q \times S^*$ by four relations (see 12).

Equivalence and reduction. The most natural classification is by equivalence. If two machines (finite transducers) share the same inputs, then representative states from each are equivalent if every sequence x belonging to the set of words on the alphabet causes the same output from the two machines. Two finite transducers are equivalent if for any state of one there is an equivalent state of the other, and conversely. Homomorphisms between transducers can also be defined (see 13). If two automata are onto homomorphic they are equivalent, but not conversely. For automata that are in a certain sense minimal, however, the converse holds.

Homomorphisms between transducers

Each equivalence class of transducers contains a smallest or reduced transducer—that is, one having the property that equivalence between its states implies equality. There is an algorithm for finding the reduced transducer of a class, which proceeds in a natural way from equivalence classes or blocks of states of a given transducer, each such block being defined as a state of the reduced transducer. Reduced equivalent finite transducers are unique up to an isomorphism—that is to say, if two finite transducers are reduced and equivalent, they differ only in the notations for their alphabets.

Classification by semi-groups. A mathematically significant classification of transducers may be obtained in terms of the theory of semi-groups. In outline, if the transducer T is reduced, the functions φ_s given in terms of M, for fixed input, as maps from and to the space of states Q constitute a semi-group termed the semi-group of T (see 14). By a certain procedure these semi-groups and their associated transducers T may be decomposed into more elementary systems called serial-connected and parallel-connected transducers. In explanation, the next state (starting from state q_a, q_b in the serially connected machine $T_A \to T_B$ is the pair of states made up of the next state in T_A from q_a with input s and the next state in T_B from q_b with input N_a (q_a, s)—which latter is the output of T_a (see 15). Schematically, the connection may be depicted, indicating that in a serial connection the output of T_A is the input to T_B.

The parallel connection of two transducers is a system that may be rigorously defined (see 16) and that may be schematically depicted with input leading in parallel to both machines and output leading in parallel out of both machines. It has been shown that any finite transducer whatsoever can be decomposed into a system of series-parallel-connected automata, such that each element is either a two-state automaton or one whose semi-group is a simple group. This affords a classification of machines that depends ultimately on the determination of the simple groups of finite order.

Serial and parallel connections between transducers

An earlier decomposition scheme was based on a generalization of the concept of congruence relations over sets of states, but discussion of it is omitted here.

Post machines. Types of automata have been investigated that are structurally unlike Turing machines though the same in point of computational capability. The mathematician E.L. Post (U.S.) proposed in 1936 a kind of automaton (or algorithm) that is a finite sequence of pairs $\langle 1, a_1 \rangle, \langle 2, a_2 \rangle, \cdots, \langle m, a_m \rangle$, such that a_i is either an instruction to move an associated two-way tape one square right or left, an instruction to print a symbol, including a blank, from a finite alphabet, or an integer. A Post machine begins at 1 and at step n obeys the instruction a_n and then goes to step $n + 1$, unless a_n is an integer m, in which case it goes to step m if the square scanned at n is marked or to step $n + 1$ if that square is blank. Post machines are prototypes of the program schemes developed 10 years later by von Neumann and his associates. For any partial recursive function a Post machine can be found that is capable of computing it.

Generalizations to automata or information processors in which the restriction to finiteness on sets is dropped or in which additional information from arbitrary sets is available to a machine during computation continue to be considered in the literature. (R.J.Ne.)

BIBLIOGRAPHY. MARVIN L. MINSKY, *Computation: Finite and Infinite Machines* (1967); and R.J. NELSON, *Introduction to Automata* (1967), are the most comprehensive elementary introductions. MICHAEL A. ARBIB, *Theories of Abstract Automata* (1969), is an advanced introduction. MARTIN DAVIS, *Computability and Unsolvability* (1958); and HARTLEY ROGERS, JR., *Theory of Recursive Functions and Effective Computability* (1967), are concerned with the concepts of Turing computability and the theory of recursive functions. C.E. SHANNON and JOHN MCCARTHY (eds.), *Automata Studies* (1956), contains some of the original basic material concerning neural nets and automata with unreliable components or with random elements. BAYARD RANKIN (ed.), *Differential Space, Quantum Systems, and Prediction* (1966), discusses the automaton and its environment in the sense of prediction theory and gives reference to other literature in this area as well as the area of computable probability spaces. A good account of automata theory and its relations to switching theory is MICHAEL A. HARRISON, *Introduction to Switching Automata and Theory* (1965). The best introduction to machine decomposition theory is J. HARTMANIS and R.E. STEARNS, *Algebraic Structure Theory of Sequential Machines* (1966). NOAM CHOMSKY, "Formal Properties of Grammars," in R. DUNCAN LUCE, ROBERT R. BUSH, and EUGENE GALANTER (eds.), *Handbook of Mathematical Psychology*, vol. 2 (1963), is still the best survey of the field of automata and generative grammars. Articles presenting approaches to languages and automata from very general mathematical points of view are SEYMOUR GINSBURG and SHEILAH GREIBACH, "Abstract Families of Languages," *Mem. Am. Math. Soc.*, no. 87, pp. 1–32 (1969); and GENE F. ROSE, "Abstract Families of Processors," *J. Comput. & Syst. Sci.*, 4:193–204 (1970).

Automation

The term automation was coined around 1946 by the automobile industry to describe the increased use of automatic devices and controls in mechanized production lines. Today, it is widely used in a manufacturing context but is also applied outside of manufacturing in connection with a variety of systems in which there is a significant substitution of mechanical, electrical, or computerized action for human effort and intelligence. An operation is commonly described as automated if it is substantially more automatic than its predecessor.

In its most general usage, automation can be defined as a technology concerned with carrying out a process by means of programmed commands combined with the automatic feedback of data relating to the execution of those commands. The resulting system is capable of operating without human intervention. The development of this technology has become increasingly dependent on the use of computers and computer-related technologies. As a consequence, automated systems have become sophisticated and complex. Advanced systems of this sort now represent a level of capability and performance that surpass in many ways the abilities of humans to accomplish the same activities.

Automation technology has matured to a point where a number of other technologies have developed from it and have achieved a recognition and status of their own. Robotics is one such technology. It is a specialized branch of automation in which the automated machine possesses certain anthropomorphic, or humanlike, characteristics. The most typical humanlike characteristic of a modern industrial robot is its powered mechanical arm. The robot's arm can be programmed to do a sequence of motions to perform useful tasks, such as loading and unloading parts at a production machine or making a sequence of spot-welds on the body of an automobile. The robot will repeat the motion pattern until it is reprogrammed to perform some alternative task. As these examples of robot applications suggest, an industrial robot is typically used to replace a human worker in a factory operation.

This article covers the fundamentals of automation and robotics, including the basic components of an automated (or robotic) system, the technical and economic advantages and drawbacks of such systems, and their key applications. The article also reviews the historical development of automation and considers its impact on society. For related topics, see COMPUTERS and INFORMATION PROCESSING AND INFORMATION SYSTEMS.

This article is divided into the following sections:

THE DEVELOPMENT OF AUTOMATION

The technology of automation has evolved from mechanization, which had its beginnings in the Industrial Revolution. (The term mechanization is used to refer to the replacement of human [or animal] power with mechanical power of some form.) Mechanization, in turn, developed out of the human propensity to create tools and mechanical devices.

The first tools made of stone represented prehistoric man's attempts to direct his own physical strength under the control of human intelligence. Thousands of years were undoubtedly required for the development of simple mechanical devices and machines such as the wheel, the lever, and the pulley, by which the power of human muscle could be magnified. The next extension was the development of powered machines that did not require human strength to operate. Examples of these powered machines include waterwheels, windmills, and simple steam-driven devices. More than 2,000 years ago, the Chinese developed trip-hammers powered by flowing water and waterwheels. The early Greeks experimented with simple reaction motors powered by steam. Windmills, with mechanisms for automatically turning the sails, were developed during the Middle Ages in Europe and the Middle East. The steam engine represented a major step forward in the development of these powered machines and marked the beginning of the Industrial Revolution. Since the appearance of the Watt steam engine (developed in 1765 by the Scottish inventor James Watt), powered engines and machines have been devised that obtain their energy from steam, electricity, and chemical, mechanical, and nuclear sources.

Each new development in the history of powered machines has brought with it an increased requirement for control devices to harness the power of the machine. The earliest steam engines required a person to open and close the valves, first to admit steam into the piston chamber and then to exhaust it. Later, the development of a slide valve mechanism that was coupled to the piston shaft made it possible to accomplish these functions automatically. The only need of the human operator was then to regulate the amount of steam that controlled the engine's speed and power. Finally, the requirement for human attention in the operation of the steam engine was eliminated by James Watt's flyball governor introduced during the late 1780s. This device consisted of a weighted ball on a hinged arm, which was mechanically coupled to the output shaft of the engine. As the rotational speed of the shaft increased, centrifugal force caused the weighted ball to be moved outward. This motion controlled a valve that reduced the steam being fed to the engine, thus slowing the engine. The flyball governor remains an elegant early example of a negative feedback control system, in which the increasing output of the system is used to decrease (*i.e.*, add a negative value to) the activity of the system.

Need for control devices

Negative feedback is a widely applied means of automatic control used to achieve a constant operating level for a system. A common example of a modern negative feedback control system is the home thermostat. In this

device a rise in room temperature causes a bimetallic strip to flex, opening an electrical switch that turns off the furnace. As the room cools down, the bimetallic strip flexes in the opposite direction, closing the switch and turning on the furnace. The switch can be set to start up the furnace at a particular set point (*e.g.*, 70° F).

Another important development in the history of automation was the Jacquard loom, which demonstrated the concept of a programmable machine. This automatic loom, introduced by the French inventor Joseph-Marie Jacquard in 1805, was capable of producing complex patterns in textiles by controlling the motions of many shuttles of different coloured threads. The selection of the different patterns was determined by a program contained in steel cards in which holes were punched. These cards were the ancestors of the paper cards and tapes that control various modern automatic machines. The concept of machine programming was further developed later in the 19th century when Charles Babbage, an English mathematician, proposed a complex, mechanical device that could perform arithmetic operations, data processing, and limited decision making. Although Babbage was never able to complete his so-called Analytical Engine, it is generally considered the precursor of the modern programmable digital computer.

ıilding ocks auto- ation

The historical developments described above provided the four basic building blocks of automation: (1) a source of power to perform some action, (2) feedback controls, (3) machine programming, and (4) decision making. Over the years these fundamental elements have been refined and enhanced, so that modern automated systems can operate virtually without human intervention.

Some of the most significant refinements and enhancements of the four building blocks of automation have occurred during the 20th century and include developments in electronics leading to the electronic digital computer, improvements in program storage technology, development of new software used to write the programs, advances in sensor technology, and the derivation of a mathematical theory of control systems.

The development of the electronic digital computer (the ENIAC [Electronic Numerical Integrator and Calculator] in 1946 and UNIVAC I [Universal Automatic Computer] in 1951) has permitted the control function in automation to become much more sophisticated and the associated calculations to be executed much faster than previously possible. The trend in computer technology has led to machines that are markedly smaller and less expensive than their predecessors yet capable of operating at much greater speeds. This trend is represented today by the microprocessor (and corresponding microcomputer), miniature multicircuited devices capable of performing all of the logic and arithmetic functions of large digital computers.

npact ımputer ıd lated chnolo- es

Along with the advances in computer technology that have occurred since the mid-1940s, there have been parallel improvements in program storage technology for holding programming commands. Modern storage mediums include magnetic tapes and disks; magnetic bubble memories; optical data storage read by lasers; videodisks; and electron beam-addressable memory systems. In association with such developments in computer and storage technology, improvements have been made in the methods by which computers (and other programmable machines) are programmed.

Advances in sensor technology have provided a vast array of measuring devices that can be used as components in automatic feedback control systems. These devices include highly sensitive electromechanical probes, scanning laser beams, systems involving the use of electrical field techniques, and machine vision. Some devices and systems of this type require computer technology for their implementation. Machine vision, for example, requires the processing of enormous amounts of data, and this can only be accomplished by high-speed digital computers. This particular technology is proving to be a versatile sensory capability for accomplishing various sophisticated industrial tasks (*e.g.*, part identification and product inspection), as well as providing the basis for robot guidance systems.

Finally, there has evolved since World War II a highly advanced mathematical and logical theory of control systems. The theory includes traditional negative feedback control, optimal control, adaptive control, and artificial intelligence. Traditional feedback control theory makes use of linear ordinary differential equations to analyze problems such as that of Watt's flyball governor. This theory is basic in modern mechanical, electrical, and chemical engineering curricula. Both optimal control theory and adaptive control theory are concerned with the problem of defining an appropriate index of performance for the process of interest and then operating the process in such a manner as to optimize its performance. The difference between optimal and adaptive control is that the latter must be implemented under conditions of a continuously changing and unpredictable environment. Artificial intelligence is an advanced field of computer science in which the computer is programmed to exhibit characteristics that are commonly associated with human intelligence. These characteristics include the capacity for learning, understanding language, reasoning, solving problems, and rendering expert diagnoses of a condition or situation. Developments in artificial intelligence are expected to provide robots and other "intelligent" machines with the ability to communicate with humans and to accept very high-level instructions rather than the detailed step-by-step programming statements typically required by present-day programmable machines. In the future, a robot endowed with artificial intelligence may, for example, be capable of accepting and executing the terse command "Assemble radio." By contrast, existing industrial robots would have to be provided with a detailed set of instructions that would specify the locations of the radio components, the particular components to assemble first, and so forth.

Artificial intelligence and robotics

The various developments described here have made possible a wide range of automated systems both in industrial and nonindustrial applications. Examples of automated systems in industry are numerically controlled machine tools, industrial robots, automated guided-vehicle systems, and automated storage and retrieval systems. Automated systems commonly encountered in everyday life include programmable household appliances, microprocessor-controlled automobile engines, and automatic bank teller machines. (M.P.G./M.T.)

THE DEVELOPMENT OF ROBOTICS

The field of robotics has its roots in the development of automation technology. Numerical control (NC) and telecherics are two important areas of technology that constitute the foundations of robotics technology.

Importance of numerical control and telecherics

Numerical control is a method of controlling machine tool axes by means of numbers and other symbols that have been coded on a medium such as punched paper tape. It was developed during the late 1940s and early 1950s. The first NC machine tool was demonstrated in 1952 at the Massachusetts Institute of Technology, Cambridge. Subsequent research there led to the development of the APT (Automatically Programmed Tools) language for programming machine tools.

Telecherics is concerned with the use of remote manipulators controlled by humans. A remote manipulator is a mechanical arm and hand that translates the motions of a human being at one location into motions at a remote location. Such a device is sometimes called a teleoperator. Initial work on the design of teleoperators can be traced to the development of methods for handling radioactive materials in the early 1940s.

Industrial robotics might be regarded as a combination of numerical control and telecherics. Numerical control provided the concept of a programmable industrial machine, while telecherics contributed the notion of a mechanical arm that could be utilized to perform useful work. The first industrial robot was installed in 1961 to unload parts from a die-casting operation. Its development was due largely to the efforts of two Americans—George C. Devol, an inventor, and Joseph F. Engelberger, a businessman. Devol originated the design for a programmable manipulator, the patent for which he titled "Programmed Article Transfer." The U.S. patent for the device was issued in

1961. Engelberger teamed with Devol to promote the use of robots in industry and, together, the two founded the first corporation in robotics, Unimation, Inc., Danbury, Conn.

PRINCIPLES AND THEORY OF AUTOMATION

As noted earlier, the four basic building blocks of an automated system are (1) a source of power to perform some action, (2) feedback controls, (3) machine programming, and (4) decision making. Any automated system must exhibit at least the first three of these elements. Modern automated systems often possess the fourth element as well.

Power source. An automated system is designed to accomplish some useful action, and that action invariably requires power. There are many sources of power available, but the most commonly used form of energy in present-day automated systems is electricity. Electrical energy is the most versatile because it can be generated readily from many sources (*e.g.,* fossil fuel, hydroelectric, solar, and nuclear) and to perform useful work can be converted readily into several types of power (*e.g.,* mechanical, hydraulic, and pneumatic). In addition, electrical energy can be stored in high-performance, long-lived batteries.

Types of actions performed by automated systems

The actions performed by automated systems are generally of two types: (1) processing, and (2) transfer and positioning. In the first case, energy is applied to accomplish some processing operation on some entity. The process may involve shaping metal, molding plastic, switching electrical signals in a communication system, or processing data in a computerized information system. All of these actions entail the use of energy to transform the entity (*e.g.,* metal, plastic, electrical signals, or data) from one state or condition into another more valuable state or condition. The second type of action performed by automated systems, transfer and positioning, is most readily conceptualized in automated manufacturing systems designed to perform work on a product. In such cases, the product must generally be moved (transferred) from one location to another during the series of processing steps. At each processing location, positioning of the product is often required. The transfer and positioning actions are called materials handling in automated production systems. In automated communications and information systems, the terms transfer and positioning refer to the movement of data (or electrical signals) among various processing units and the delivery of information to output terminals (printers, video display units, etc.) for interpretation and use by humans.

Feedback controls. Feedback controls are widely used in modern automated systems. A feedback control system consists of five basic components: (1) input, (2) process being controlled, (3) output, (4) sensing elements, and (5) controller and actuating devices. These five components are illustrated in the diagram of Figure 1. The term closed-loop feedback control is often used to describe this kind of system.

Basic components of a feedback control system

The input to the system is the reference value, or set point, for the system output. This represents the desired operating value of the output. With the previous example of the home heating system as an illustration, the input is the desired temperature setting for the room. The process being controlled is the furnace that provides heat to the room. In other feedback systems, the process might be a manufacturing operation, the rocket engines of the U.S. space shuttle orbiter, the automobile engine in a so-called cruise control system, or any of a variety of other operating mechanisms to which the action power is applied. The output is the variable of the process that is being measured and compared to the input. In the example, room temperature is the variable of interest.

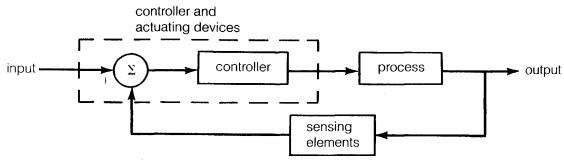

Figure 1: The five components of a feedback control system.

The sensing elements are the measuring devices used in the feedback loop to monitor the value of the output variable. In the home heating system example, a bimetallic strip in the thermostat performs the sensing function. The two different metals in the bimetallic strip possess different coefficients of thermal expansion; accordingly, the flex (deflection) of the strip is directly related to temperature. As such, the strip is capable of measuring temperature. Many different kinds of sensors are used in feedback control systems for automation.

The purpose of the controller and actuating devices in the feedback system is to compare the measured output value with the reference input value and to reduce the difference between them. In general, the controller and actuator of the system are the mechanisms by which changes in the process are accomplished to influence the output variable. These mechanisms are usually designed specifically for the system and consist of devices such as motors, valves, solenoid switches, piston cylinders, gears, power screws, pulley systems, chain drives, and other mechanical and electrical components. The switch connected to the bimetallic strip of the thermostat is the controller and actuating device for the home heating system. When the output (room temperature) is below the set point, the switch turns on the furnace. When the temperature reaches or slightly exceeds the set point, the furnace is turned off.

Machine programming. The programmed commands determine the actions that are to be accomplished automatically by the system. These commands specify what the automated system should do and how the various components of the system must function to accomplish the desired result. The content of the program varies considerably from one automated system to the next. In relatively simple systems, the program specifies a limited number of well-defined actions that are performed continuously and repeatedly in the proper sequence with no deviation from one cycle to the next. In more complex systems, the number of commands could be large and the level of detail in each command could be significantly greater. In relatively sophisticated systems, it is also possible to readily change the program to alter the sequence of actions to be performed by the system.

Programming commands are related to feedback control in an automated system in the sense that the program establishes the sequence of values for the inputs (set points) of the various feedback control loops that make up the system. A given programming command may specify the set point for the feedback loop, which in turn controls some action that the system is to accomplish. In effect, the purpose of the feedback loop is to verify that the programmed step has been carried out. In a robot controller, for example, the program might indicate that the arm is to move to a specified position. The feedback control system in this case would be used to verify that the move has been correctly made. The relationship of program control and feedback control in an automated system is illustrated in Figure 2.

Feedback loop

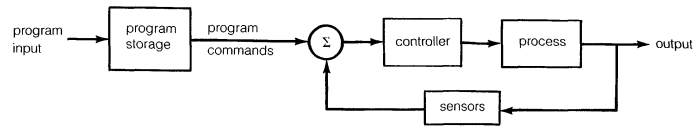

Figure 2: Relationship of program control and feedback control in an automated system.

Some of the programmed commands may be executed in an open-loop fashion—*i.e.,* without the need for a feedback loop to verify that the command has been properly carried out. For instance, a command to flip an electrical switch may not require feedback. An example of the need for feedback control in an automated system exists in a situation where there are variations in the raw materials being fed into a production process, and the system must take these variations into consideration by making adjustments in its controlled actions. Without feedback, the system would not be able to exercise a sufficient level of control over the quality of the process output.

The programmed commands may be contained on me-

chanical devices (*e.g.,* mechanical cams and linkages), punched paper tape, magnetic tape, magnetic disk, computer memory, or any of a variety of other mediums that have been developed over the years for particular applications. It is common today for automated equipment to use computer storage technology as the means for storing the programmed commands and converting them into controlled actions. One of the advantages of using computer storage technology is that that program can be easily changed or improved. Altering a program contained on a set of mechanical cams involves considerably more work.

Decision making. Most highly sophisticated automated systems are capable of making decisions during operation. The decision-making capacity is generally contained in the control program in the form of logical instructions that govern the operation of such a system under varying circumstances. Under one set of circumstances, the system responds one way; and under a different set of circumstances, it responds in another. There are several reasons for providing an automated system with decision-making capability. These reasons include (1) error detection and recovery, (2) safety protection, (3) interaction with humans, and (4) process optimization.

Error detection and recovery is concerned with decisions that must be made by the system in response to undesirable operating conditions. In the operation of any automated system, some form of corrective action must be taken to restore the system when malfunctions and errors occur during the normal cycle of operations. The typical response to a system malfunction has been to call for human assistance. There is a growing trend in automation and robotics to enable the system itself to sense these malfunctions and to correct them in some manner without human intervention. This sensing and correction (referred to as error detection and recovery) can be realized by programming a decision-making capability into the system.

ensing
nd
orrecting
alfunc-
ons
ithout
uman in-
ervention

Safety protection is a special case of error detection and recovery in which the malfunction involves a safety hazard. Decisions are required when the automated system detects, through its sensors, that there has developed a safety condition that is hazardous to either the equipment or humans in the vicinity of the equipment. The terms safety monitoring system and hazard monitoring system are typically used to refer to that portion of the automated system that includes the safety sensors and decision-making apparatus. The purpose of the safety monitoring system is to detect the hazardous condition and to take the most appropriate action to remove or reduce it. This may involve stopping the operation and alerting the maintenance personnel of the condition, or it may involve a more complex set of actions to eliminate the hazard.

Some automated systems are required to interact with humans in some way. An automatic bank teller machine, for example, must receive instructions from customers and make decisions according to these instructions. In some automated systems, a variety of different instructions from humans is possible, and the decision-making capability of the system must be sophisticated to deal with the array of possibilities.

rocess op-
mization

A fourth reason to endow an automated system with decision-making capacity is to optimize the process being controlled. This need for optimization occurs most commonly in production situations in which there is an economic performance criterion for the process and it is desirable to optimize this criterion. For example, minimizing cost is usually a key objective in manufacturing. An automated system would make use of optimal control or adaptive control principles in its program to receive appropriate sensor signals and other inputs and make decisions to drive the process toward the optimal state.

TECHNOLOGY OF ROBOTICS

The most widely accepted definition of an industrial robot is one developed by the Robotic Industries Association:

> An industrial robot is a reprogrammable, multifunctional manipulator designed to move materials, parts, tools, or specialized devices through variable programmed motions for the performance of a variety of tasks.

The technology of robotics is concerned with the design of the mechanical manipulator and the computer systems used to control it. The technology is also concerned with the industrial applications of robots. These will be dealt with below in the section *Manufacturing applications of automation and robotics.*

The mechanical manipulator of an industrial robot is made up of a sequence of link and joint combinations. The links are rigid members connecting the joints. The joints, also called axes, are the movable components of the robot that cause relative motion between adjacent links. Four principal types of mechanical joints are used to construct the manipulator—namely, a linear joint and three types of rotational joints. Figure 3 illustrates the four types. One way to define a robot is by the number of joints used in its construction. Typically three joints are used for a robot's arm and body and two or three joints for its wrist. This

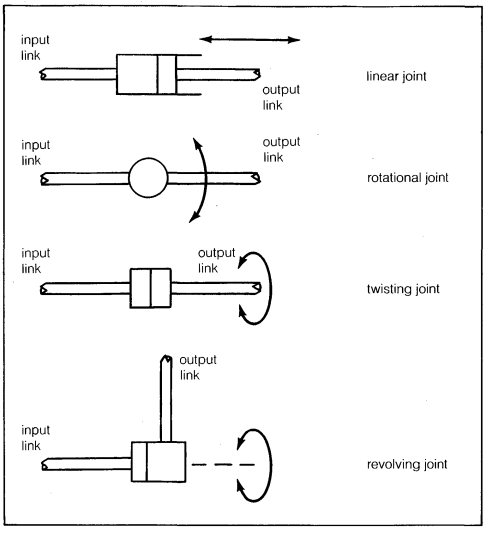

Figure 3: Four types of robot manipulator joints.

permits the robot to position and orient parts and tools in the work space. One possible configuration for a six-axis robot is pictured in Figure 4.

The computer system that controls the manipulator must be programmed to teach the robot the particular motion sequence and other actions it must perform to accomplish

By courtesy of Cincinnati Milacron, Inc.

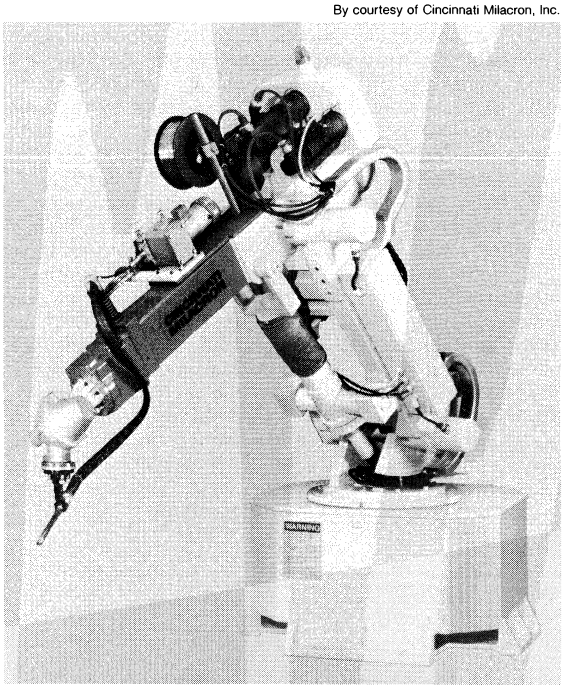

Figure 4: A six-axis, computer-controlled robot equipped for arc welding.

Programming industrial robots

its task. There are several ways that industrial robots are programmed. One method, called lead-through programming, requires that the manipulator be driven through the various motions needed to perform a given task and that those motions be recorded into the robot's computer memory. This can be done either by physically moving the manipulator through the motion sequence or by power driving the manipulator through the sequence using a control box called a teach pendant.

A second method of programming involves the use of a textual programming language very much like a computer programming language. However, in addition to many of the capabilities of a computer programming language (*i.e.,* data processing, communicating with other computer devices, and decision making), the robot language also includes statements specifically designed for robot control. The latter involves motion control and input/output commands. Motion control commands direct the robot to move its manipulator to some defined position in space. The statement "Move P1," for example, might be used to direct the robot to a point in space called P1. Input/output commands are employed to control the receipt of signals from sensors and other devices in the work cell, as well as to initiate control signals to other pieces of equipment in the cell. For instance, the statement "Signal 3, On" might be used to turn on a motor in the cell by means of output line number 3 in the robot's controller.

Robots of the future are likely to receive instructions (programming commands) by voice input/output. They would therefore have to have artificial intelligence, which would make possible the proper interpretation and execution of the commands. The commands would be expressed in a very high-level language. Unlike today's programming languages in which detailed instructions must be provided in precise syntax, those of the future would be less demanding in terms of format, and the commands would be more task-oriented. That is to say, the programmer would give a command such as "Assemble radio," and the robot would need to develop its own step-by-step procedure for doing the task. The robot would have to possess a high level of intelligence for it to be programmed in this manner. Robots of the future also will necessarily make greater use of sensors for determining positions of objects in the work cell, for safety monitoring, and for error detection and recovery. Machine vision is expected to be an important sensor technology for coming generations of robots.

MANUFACTURING APPLICATIONS OF AUTOMATION AND ROBOTICS

One of the most important application areas for automation technology is manufacturing. To many people, automation means manufacturing automation. Three different types of automation in production can be distinguished: (1) fixed automation, (2) programmable automation, and (3) flexible automation.

Fixed automation

The term fixed automation refers to an automated production facility in which the sequence of processing operations is fixed by the equipment configuration. This is sometimes called "hard automation." The programmed commands are, in effect, contained in the machines in the form of cams, gears, wiring, and other hardware that is not easily changed over from one type of product to another. This form of automation is characterized by high initial investment and high production rates. It is therefore suitable for products that are made in large volumes. Examples of fixed automation include machining transfer lines found in the automotive industry, automatic assembly machines, and certain chemical processes.

Programmable automation

Programmable automation is a form of automation used in the production of batches (or quantities) of products. The products are made in batches ranging from several dozen to several thousand units at a time. For each different batch of product, the production equipment must be reprogrammed and converted to accommodate the new product configuration. This reprogramming and changeover (called the setup in many industries) take time to accomplish, and there is thus a nonproductive period followed by a production run for each new batch. Production rates in programmable automation are generally lower than in fixed automation because the equipment is designed to facilitate product changeover rather than for product specialization. A numerical control machine tool is a good example of programmable automation. The program is coded on punched paper tape for each different product style, and the machine tool actions are controlled by the punched tape. Industrial robots are another example of programmable automation.

Flexible automation

Flexible automation is an extension of programmable automation. The difficulty with programmable automation is the time required to reprogram and change over the production equipment for each new batch of product. This process takes time, and time is expensive. In flexible automation, the variety of products is sufficiently limited that the changeover of the physical setup of the equipment can be done quickly and automatically. The reprogramming of the equipment in flexible automation is done off-line (*i.e.,* the programming can be accomplished without using the production equipment itself). Accordingly, there is no need to group identical products into batches; instead, a mixture of different products can be produced one right after the other. Flexible automation is a relatively new concept in automation. Consequently, there are not many examples of this form of automation compared to the other two types. The economics of flexible automation, however, are advantageous enough that it is expected to become an important method of production in future automated factories.

Applications of automation can be found in nearly all types of production. Many of the important examples are reviewed here.

Machining. The shaping of metal by means of cutting tools was one of the first manufacturing processes to be mechanized and then automated. There are three examples of automation in the machining process that relate to the previous descriptions of the three types of production automation.

Transfer line

The first of these is the transfer line, which is used for machining metal parts in large volumes at high production rates. This is an example of fixed automation, because transfer lines are typically set up for long production runs, perhaps for making millions of parts and running for several years between changeovers. A transfer line is divided into a series of workstations, with each station designed to perform some specific machining operation on a part. The workstations are connected by a parts handling system that moves the parts from one operation to the next. The raw work part enters at one end of the transfer line, proceeds through each workstation, and emerges at the other end as a completed part. In the normal operation of the line, there is a work part being processed at each station, so that many parts are processed simultaneously and a finished part is produced with each cycle of the line. The origins of present-day transfer lines date back to the 1940s and earlier.

Numerical control

The second example of automation in machining is numerical control. The first NC machine tool was invented during the early 1950s. Numerical control is a form of programmable automation in which the machine is controlled by means of numbers (and other symbols) that have been coded on punched paper tape or some alternative storage medium. The program represents the set of machining instructions for a particular part; it is therefore called the NC part program. The coded numbers in the program (specifying x-y-z coordinates in a Cartesian axis system) indicate to the machine tool the various positions of the cutting tool relative to the work part. By means of a sequencing of these positions in the program, the machine tool is directed to accomplish the machining of the part. A position feedback control system is used in most machines to determine that the coded instructions have been correctly performed. Since the early 1980s, a microcomputer has typically been used as the controller in an NC machine tool, and the program is actuated from computer memory rather than from punched paper tape. Initial entry of the program into the computer memory is still accomplished by means of punched tape in many cases. This form of numerical control is called computer numerical control (CNC). Another variation in the imple-

mentation of numerical control involves the capability of sending the part program over telecommunications lines from a central computer to individual machine tools in a factory, thereby eliminating the use of punched tape altogether. This form of numerical control is known as direct numerical control (DNC).

The third example of automation in machining is the flexible manufacturing system (FMS). The FMS is a form of flexible automation in which several machine tools are linked together by a materials handling system, and all aspects of the system are controlled by a central computer. The materials handling system is capable of delivering parts to any machine in the FMS. Each machine is controlled by CNC, and a central computer sends programs to each controller according to a preplanned schedule. The FMS represents a high level of technological sophistication and a highly integrated form of production automation.

Chemical processing. Some of the most highly automated production facilities are found in the chemical-processing industries. These industries include petroleum refining, food processing, and other operations in which the products are processed in gas, liquid, or powdered form. Such forms facilitate the movement of products through the various steps in the production process. In addition, these products are usually made in large quantities. Because of the ease of handling the products and the large volumes involved, a high level of automation has been accomplished in these industries.

The typical modern process plant is computer-controlled. In one advanced petrochemical system that produces more than 20 different products, the facility is divided into three areas each with several chemical-processing units. Each of the three areas has its own process-control computer to perform scanning, control, and alarm functions. The three computers are connected to a central computer in a hierarchical configuration as illustrated in Figure 5. The central computer calculates how to obtain maximum yield from each process and generates management reports on process performance.

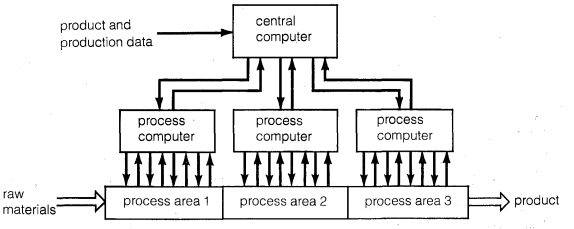

Figure 5: Hierarchical configuration typical of computer process control in a modern plant.

Each process computer monitors up to 2,000 process parameters, such as temperature, pressure, flow rate, liquid levels, chemical concentrations, and other variables required to control the process. These measurements are taken on a sampling basis; the time between samples varies between 2 and 120 seconds, depending on the relative need for the data. Each computer controls approximately 400 feedback control loops. Under normal operation, the control computers maintain operation of the process at or near optimum performance levels. If process parameters exceed the specified normal or safe ranges, the control computer actuates a signal light and alarm horn and prints a message for the technician indicating the nature of the problem.

The central computer receives data from the process computers and performs calculations to optimize the performance of each chemical-processing unit. The results of these calculations are then passed to the individual process computers in the form of commands to change the set points for the various control loops.

ıtegration f data ·om ıultiple ɔntrol ɔops

Substantial economic advantages are obtained from this type of computer control in the process industries. The computer hierarchy is capable of integrating all of the data from the many individual control loops far better than humans can, thus permitting a higher level of performance. Advanced control algorithms can be applied by the computer for optimal process control. In addition, much more quickly than humans, the computer is capable of sensing process conditions that indicate unsafe or abnormal operation. All of these improvements increase productivity, efficiency, and safety during process operation.

Basic metals industries. Like the chemical-processing industries, the basic metals industries (aluminum, iron and steel, etc.) have adopted automation for many of their processes. Similar to the chemical industries, the metals industries deal in large volumes of products, and so there is a substantial economic incentive to invest in automation. Metals, however, are typically produced in batches rather than continuously, and handling metals in bulk form is generally more difficult than handling chemicals that flow. Consequently, automation in the basic metals industries has not achieved as high a level as that in the chemical-processing industries.

One example of process automation in the metals industry is the rolling of hot metal ingots into their final shapes (*e.g.,* coils and strips). This was first done in the steel industry; similar processing is also accomplished in aluminum and other metals. In a modern steel plant, hot-rolling is accomplished with the aid of computer control. The rolling process involves the forming of a large, hot metal billet by passing it through a rolling mill consisting of one or more sets of large cylindrical rolls that squeeze the metal and reduce its cross section. In most cases, several passes are required to gradually reduce the ingot to the desired shape. Sensors and automatic instruments measure the dimensions and temperature of the ingot after each pass through the rolls, and the control computer calculates and regulates the roll settings for the next pass.

Control programs have been developed to schedule the sequence and rate at which the hot metal ingots are fed through the rolling mills. In a large plant several different orders for rolled products with different specifications may be in process at any given time. The production control task of scheduling and keeping track of the different customer orders in the mill requires rapid massive data gathering and analysis. In the most modern plants this production control task has been effectively integrated with the computer control of the rolling mill operations to achieve a highly automated production system.

Assembly. Assembly operations have traditionally been performed manually, either at single assembly workstations or on assembly lines with multiple workstations. Because of the high labour content and the high cost of manual labour, greater attention has been given in recent years to the use of automation and robotics for assembly work.

For high production work, automated assembly machines have been developed that operate in a manner similar to machining transfer lines. Instead of performing machining operations at the workstations, assembly operations are performed. A typical assembly machine consists of several stations, each equipped with a supply of components and a mechanism for delivering the components into position for assembly. A workhead at each station performs the actual adding and fastening of a component. Typical workheads include automatic screwdrivers, staking or riveting machines, welding heads, and other joining devices. A new component is added to the partially completed product at each workstation, thus building up the product gradually as it proceeds through the line. Assembly machines of this general type are considered to be examples of fixed automation because they are usually configured for a particular product that is made in large quantities.

Typical assembly machine

Since the late 1970s, there has been a growing effort to use robots in assembly operations. Because robots are programmable, the objective in using them for assembly work is to produce parts in medium quantities and to produce a mixture of different models on the same production line. An important research and development project in this general area was the Adaptable Programmable Assembly System (APAS) Project, conducted from 1980 to 1983 in the United States by the Westinghouse Electric Corporation under sponsorship of the National Science Foundation. The assembly of small electric motors was selected as the basis for the APAS development study. The assembly system for the project consisted of six workstations, four

of which used robots to perform the assembly operations. A conveyor system was utilized to move partially assembled motors between the stations. Control of the system was accomplished by means of a master supervisory computer, which communicated with local control computers at each workstation. The master computer scheduled and coordinated production and informed the local workstation computers of the tasks that had to be performed.

One of the significant lessons learned from the APAS Project was the importance of designing products for ease of automated assembly. The assembly methods that are satisfactory for humans are not necessarily the most suitable methods for automated workheads. For example, using a screw and nut as a fastening method is suitable for manual assembly but not for automated assembly. Designing the components to be added from the same direction through the use of snap fits and other one-step fastening procedures are much more easily accomplished by automated and robotic assembly methods.

Electronics manufacturing. A basic feature of the electronics industry is the need to achieve a high level of coordination in the design, fabrication, and testing of a product. A good example of the need for coordination is in large-scale integration (LSI) and very large-scale integration (VLSI), both of which involve the fabrication of electrical and electronic circuits on small semiconductor chips. LSI and VLSI products are extremely miniaturized and very complex. Computers must be used to perform much of the design analysis and synthesis and then to transfer the design specifications directly to the equipment that produces the chips. Also, electronic components such as LSI and VLSI chips are often produced in relatively low yields, meaning that the proportion of good units to total units made is significantly less than 100 percent. To separate the good units from those that are defective, testing of each unit must be done as part of the production sequence. This need for integration has motivated the introduction of automation into the electronics industry.

Design analysis and synthesis by means of computers

Two examples of automation in electronics manufacturing are part insertion machines and wire wrap machines. Part insertion machines are used to position electronic components (LSI chip modules and other devices) relative to a printed circuit board. It is basically an x = y positioning table that moves the printed circuit board relative to the part insertion head, which places the individual components into position on the board. Wire wrap machines are used to make wired connections between terminals on the back of an electrical panel automatically. The wiring head is positioned at the desired terminal pin, after which it wraps the wire around the pin, leads the unconnected end of the wire through a prescribed path to the second terminal pin, and cuts and wraps the wire around the second pin. An electrical test is then made to ensure that the proper terminals have been connected. Faulty connections are identified on a computer-generated report.

Part insertion and wire wrap machines both are production machines that utilize numerical control principles in which programmed commands are communicated to the machine from the design data base for the product. In the part insertion machine, the positioning of the table and the determination of the component to be inserted are contained in the numerical control program. In the wire wrap machine, such a program defines the connections that are to be made. Both the part insertion machine and the wire wrap machine are examples of programmable automation because they can be reprogrammed to accommodate different product configurations.

Application of numerical control principles

New inspection and testing equipment is being designed to perform a variety of checks automatically on electronic parts and products. Machine-vision systems are being developed to check the circuits and other quality features of microelectronic chips. These vision systems scan the chips to detect any irregularities from a given standard. Other automated test equipment is designed to perform electrical testing of the circuits more accurately than humans and in a fraction of the time that humans would require to make the tests.

Computer-aided design/computer-aided manufacturing (CAD/CAM). Since about 1970, there has been a growing trend in manufacturing firms toward the use of computers to perform many of the functions related to design and production. This trend is popularly known as CAD/CAM. The technology of CAD/CAM is based largely on the capability of a computer system to process, store, and display large amounts of data representing part and product specifications. For mechanical products, the data represent graphic models of the components; for electrical products, they represent circuit information; and so forth. CAD/CAM technology has been applied in many industries, including those involved in machined components, electronics products, and equipment design and fabrication for chemical processing. It reflects not only the automation of the manufacturing operations but the automation of elements in the entire design-and-manufacturing procedure as well.

Computer-aided design entails the use of computer systems to assist in the creation, modification, analysis, and optimization of a design. The designer, working with the CAD system rather than with the traditional drafting board, creates the lines and surfaces that form the designed object (product, part, structure, etc.) and stores this model in the computer data base. By invoking the appropriate CAD software, the designer can perform various analyses on the object, such as stress-strain analysis and heat-transfer calculations. By making adjustments in the design on the basis of these analyses, he develops the final design of the object. Once the design procedure has been completed, the computer-aided design system can be used to prepare the detailed drawings required to make the object.

Computer-aided manufacturing is defined as the use of computer systems to assist in the planning, control, and management of production operations. This can be accomplished by either a direct or an indirect connection between the computer system and the production operations. In the case of the direct connection, the computer is used to monitor or control the process in the factory. Computer process monitoring involves the use of the computer system to observe the manufacturing process, collect data on process performance, and report the performance to plant management. In this way, the plant can be operated more efficiently. Computer process control involves the use of the computer system to execute control actions to operate the plant automatically without significant human intervention. In most cases, process control includes observing the process (*i.e.*, taking feedback measurements) as part of the control function. Several applications of computer process control have been described above, as, for example, in the discussions of the chemical-processing and basic metals industries.

The indirect connections between the computer system and the process are those applications in which the computer is used to support the production operations without actually monitoring or controlling the operations. These applications typically involve planning and management functions that can be performed by the computer (or by humans working with the computer) more efficiently than by humans alone. Examples of these functions include planning of the step-by-step processes for the product, part programming in numerical control, and scheduling the production operations in the factory.

Robots in manufacturing. Today, robotics technology is limited almost exclusively to industrial applications, usually as direct contributors to the production operation. Industrial robot applications can be divided into three categories: (1) material transfer and machine loading/unloading, (2) processing operations, and (3) assembly and inspection.

Material transfer consists of applications in which robots are used to move materials or work parts from one location to another. Many of these tasks are relatively simple, requiring robots to pick parts from one conveyor and place them on another conveyor. Other transfer operations are more complex materials handling tasks, such as placing parts onto pallets in an arrangement that the robot must calculate. In machine-loading and machine-unloading operations, a robot tends a production machine in place of a human worker. Depending on the production operation, the robot either loads parts into the machine or unloads

Material transfer and machine loading/unloading operations

them from it. To perform the task, the robot has to be equipped with a special hand, called a gripper, to grasp a part. In most cases, the gripper must be designed for the particular geometrical shape of the part. An example of a robot load/unload application is an automated machining cell, in which the robot works with a numerically controlled machine tool. The robot loads raw work parts into the machine tool and unloads finished parts from it, and the machine performs the production operation under automatic cycle.

Robot processing operations

By contrast, processing operations require the robot to manipulate some tool to perform a process on the work part. Examples of these applications include spot welding, continuous arc welding, and spray painting. As of the mid-1980s, spot welding of automobile bodies was the most common application of industrial robots in the United States. In this operation, a robot is used to position a spot-welding apparatus against automobile panels and frames to complete the assembly of the basic car body. Arc welding is a continuous process in which the robot must move the welding rod along the seam to be welded. Spray painting involves the manipulation of a spray-painting gun over the surface of the object to be painted. Other processing operations that utilize robots include grinding, polishing, and routing processes in which a rotating spindle serves as the robot's tool.

Assembly and inspection applications

Robot assembly applications were discussed above with particular attention to APAS. The use of robots in assembly operations is expected to increase because of the high cost of manual labour in this area. Inspection is another area of factory operations in which the use of robots is growing. In a typical inspection application, the robot positions a sensor with respect to the work part and determines whether the part is consistent with the quality specifications.

In nearly all of these applications, the robot performs a repetitive operation as a substitute for human labour. Another characteristic of industrial robot applications is that the tasks are hazardous or unpleasant for human workers, as in the case of spray painting, spot welding, arc welding, and certain machine-loading/unloading tasks. Other situations where robots prove attractive as alternatives to humans are those in which the work part or tool is heavy and awkward to handle and in which robots can be used on two or three shifts. (M.P.G.)

NONMANUFACTURING APPLICATIONS OF AUTOMATION

In addition to the manufacturing applications of automation technology, there have been significant achievements in such areas as communications, transportation, the military, and the service industries. Some of the more significant are described in this section.

Telephone switching

Communications. One of the earliest practical applications of automation was in telephone switching. The first switching machines, invented near the end of the 19th century, were simple mechanical switches that were remotely controlled by the user pushing buttons or turning a dial on the telephone. The next generation of automatic switching equipment consisted of electromechanical control systems that were developed for public use around the 1920s and 1930s. They were made up of electromechanical relays and switches that performed functions such as monitoring thousands of telephone lines, determining which were demanding service, providing the dial tone, remembering the digits of each telephone number as it was being dialed, setting up the required connections, sending electrical signals to ring the receiver's unit, monitoring the call during its progress, and disconnecting the telephone when the call was completed. These systems also were used to time and bill toll calls and to transmit billing information and other data relative to the business operations of the telephone company. The introduction of these electromechanical systems into the nation's telephone system required many years to complete, but they gradually assumed nearly all of the functions of the human telephone operator.

Modern electronic telephone switching machines are based on highly sophisticated digital computers that perform all of the functions of their electromechanical predecessors with much greater speed, reliability, functionality, and economy. In addition to the functions mentioned above, the newest electronic systems automatically transfer calls to alternate numbers, call the user back when a busy line becomes free, and perform other customer services in response to dialed codes. These systems also perform function tests on their own operations, diagnose problems when they arise, and print out detailed instructions for maintenance personnel.

Other applications of automation in communications systems include local area networks, communications satellites, and automated mail-sorting machines. A local area network (LAN) operates like an automated telephone company within a single building or group of buildings. Such networks are generally capable of carrying not only voice messages but also large quantities of digital data between terminals in the system. Communications satellites have become essential for relaying telephone or video signals across great distances. These satellite communications would not be possible without the automated guidance systems that place and maintain the satellites in a predetermined orbit around the Earth. Finally, automatic mail-sorting machines are being used or installed in post offices throughout the United States to read ZIP codes on envelopes and sort mail according to destination.

Transportation. Automation has been applied in various ways in the transportation industries. Major applications include airline reservation systems, automatic pilots in aircraft and locomotives, and automated transit systems.

Airlines utilize automated reservation systems to continuously monitor the status of flights. With these systems, ticket agents at widely separated locations can obtain information about the availability of seats on any flight in a matter of seconds. The reservation systems compare requests for space with the status of each flight, grant space when available, and automatically update the reservation status files. With contemporary systems passengers can secure their seat assignments well in advance of flight time.

Automatic pilots

Nearly all commercial aircraft used by the airlines are equipped with instrument systems called automatic pilots. Under normal flying conditions, these systems can guide an airplane over a predetermined route by detecting changes in the aircraft's orientation and heading from gyroscopes and similar instruments and by providing appropriate control signals to the craft's steering mechanism. Automatic navigation systems and instrument landing systems operate by using radio signals from ground beacons that provide the aircraft with course directions for guidance. When an airplane is within the traffic pattern for ground control, its human pilot normally assumes control.

The BART system

The Bay Area Rapid Transit (BART) system in the San Francisco–Oakland area of California represents an ambitious undertaking in automated rail transportation. It has been a model for rapid transit railways in Washington, D.C., Atlanta, Ga., and various other U.S. cities. The BART system consists of more than 75 miles (120 kilometres) of track, with about 100 trains operating at peak hours between roughly 30 stations. The trains sometimes attain speeds of 80 miles (128 kilometres) per hour with intervals between trains as short as 90 seconds. Each train carries one operator whose role is that of an observer and communicator capable of overriding the automatic system in case of an emergency. The automatic system protects the trains by assuring a safe distance between them and by controlling their speed. Another function of the system is to control train routings and make adjustments in the operation of each train to keep the entire system operating on schedule.

As a BART train enters the station, it automatically transmits its identification and destination, which are flashed on a display board for passengers. Such information is also transmitted to the control centres, from which signals are automatically returned to the train to regulate its time in the station and its running time to the next station. At the beginning of the day an ideal schedule is determined. As the day progresses the performance of each train is compared with the schedule, and adjustments are made to each train's performance as required. If an unexpected situation such as a train breakdown arises, the system can automatically adjust itself to minimize the effect. The

entire system is controlled by two identical computers so that if one malfunctions the other assumes control. In the event of a complete failure of the computer control system, the aboard train operators resort to manual control.

Military applications. The possibility of using robotics and other advanced automation technologies in military operations has much appeal. As yet, few actual applications have been developed. Many of the routine and sometimes dangerous tasks conducted during land and naval operations and the logistical support of these operations, however, could be performed by sophisticated robots of the future. Some examples include driving trucks in a convoy following a lead vehicle operated by a human, refueling tanks and other vehicles on the battlefield, loading artillery, and working in the engine room on board ship. The possibility of sending soldier robots on a suicide mission deep inside enemy territory is surely a prospect that would interest any military strategist.

Service industries. Automation of the service industries encompasses an assortment of applications as diverse as the services themselves. The services include health care, banking and other financial services, government, and retail trade.

In health care the use of computer systems is increasing dramatically and is helping to improve services and relieve the burden on medical staffs. In hospitals computer terminals on each nursing care floor are used to record data on patient status, medications administered, and other relevant information. Besides providing an official record of the nursing care given to individual patients, the computer system facilitates the nurse's task of updating reports at the time of shift changes. Moreover, the system is connected to the hospital's business office so that proper charges can be made to each patient's account for services rendered and medicines provided.

Banks and other financial institutions have embraced automation in their operations because of the large volume of documents and data that have to be processed in their daily business. The sorting of checks and verification of account balances have been computerized by virtually all banks and savings and loans. An increasing number of institutions have gone a step further by establishing systems of electronic banking, including the use of the automatic teller machine (ATM). Located in shopping centres, business buildings, and other convenient places, ATM's permit customers to carry out basic transactions without the assistance of bank personnel.

Electronic banking

Credit card transactions also have become highly automated. Many restaurants and retailers employ systems that automatically check the validity of a credit card and the credit standing of the cardholder as the latter waits for the transaction to be finalized. It is anticipated that future credit card transactions may involve an immediate transfer of funds from the cardholder's account into the merchant's account via high-speed communications lines linking computerized point-of-sale terminals and banks.

Increased reliance on computers and computerized data bases have highly automated the operations of government services. The Internal Revenue Service (IRS) of the U.S. government must review and approve the tax returns of millions of taxpayers each year. The detailed checking of returns—a process known as auditing—is a task that has traditionally been done on a sampled basis by large staffs of professional auditors. In 1985 the IRS began using a computerized system to automate the auditing procedure for the 1984 returns. This system is programmed to perform complex tax calculations on each return being audited. As tax laws change, it can be reprogrammed so as to audit new returns in accordance with the revisions. The IRS expects that the computer-automated auditing system will substantially increase the work capacity of its auditing department without a corresponding increase in manpower.

The retail trade has seen a number of changes in its operations as a result of automation. Selling merchandise has typically been a labour intensive activity, in which salesclerks need to assist customers with their selections and then finalize transactions at the cash register. Each transaction depletes the inventory of the store, and so the item purchased must be identified for reorder. Computer-automated systems have been installed in most large department stores and supermarkets to speed up sales transactions and to provide efficient inventory control. Such a system features a laser light pen or similar sensing device designed to read an identification symbol consisting of a series of bars printed on or affixed to each product. By scanning the symbol with the optical reading unit at the register or checkout counter, the salesclerk quickly identifies the item being sold, records its price into the total of the sale, and enters the transaction into the inventory files of the store. The store's central computer automatically updates these records, subtracting the item sold from the total number of items of the same kind and brand still in stock.

Automated checkout and inventory control

Consumer products. A wide variety of consumer products have been automated to enhance performance and user convenience. Microwave ovens, washing machines, dryers, compact disc players, videocassette recorders, and a number of other modern home appliances are equipped with a microprocessor that serves as the computer controller for the machine. By simply pressing a series of buttons in proper sequence, the user can program the operation of the appliance. Many videocassette recorders, for instance, can be programmed to automatically tape several television programs transmitted on different channels at different times during the course of a week or longer.

The automobile is another example of a highly automated consumer product. Most recent model cars come equipped with several microprocessors that regulate the operation of the engine (fuel-air ratio and other functions) and of the clock, radio, and automatic speed control (popularly known as cruise control). Special options on some models include the capability to monitor sensors in the car to alert the driver to specific problems (*e.g.,* low fuel, door ajar, and engine temperature) and the ability to compute such information as average gasoline mileage and driving range on remaining fuel supply. One automotive manufacturer has pioneered the use of an electronic voice system, in which the car communicates problems to the driver by means of simple verbal messages delivered through its radio speakers. (M.P.G./M.T.)

AUTOMATION AND SOCIETY

Over the years, the social merits of automation have been argued by labour leaders, government officials, business executives, and college professors. No doubt the biggest controversy has focused on the employment issue: What is the effect of automation on employment? There are other important aspects of the automation issue as well, including its effect on productivity, economic competition, education, and quality of life. These social issues will be explored here.

Impact on the individual. Nearly all industrial installations of automation, robotics in particular, involve a replacement of human labour by an automated system. Therefore, one of the direct effects of automation in factory operations is the dislocation of human labour from the workplace. The long-term effects of automation on employment and unemployment rates are debatable. Most studies in this area have been controversial and inconclusive. Workers have indeed been lost by automation, but population increases and consumer demand for the products of automation have compensated for these losses. Labour unions have argued, and many companies have adopted the policy, that workers who are displaced by automation should be retrained for other positions, perhaps increasing their skill levels in the process. This argument succeeds so long as the company and the economy in general are growing at a fast enough rate to create new jobs as the jobs replaced by automation are lost.

Of particular concern for many labour specialists is the impact of industrial robots on the work force, since robot installations involve a direct substitution of machines for humans at a ratio of from two to three humans per robot. During the first half of the 1980s, however, the effect of robotics on labour was relatively minor in the United States at least, because the number of robots in the nation's factories was small compared to the number of human

workers. By the end of 1984, only about 10,000 robots had been installed, while the total work force stood at more than 100,000,000 persons, approximately 19,000,000 of whom worked in factories. This would indicate that the impact of robots on unemployment has been relatively modest to date.

Automation affects not only the number of workers in factories but also the type of work that is done. An automated factory is oriented toward the use of computer systems and sophisticated programmable machines rather than manual labour. Greater emphasis is placed on knowledge-based work and technical skill than on physical work. The types of jobs that must be done in modern factories include more machine maintenance, improved scheduling and process optimization, systems analysis, and computer programming and operation. Thus workers in automated facilities must be technologically proficient to perform such jobs. Professional and semiprofessional positions, as well as traditional labour jobs, are affected by this shift in emphasis toward factory automation.

Impact on society. Besides affecting the individual worker, automation has an impact on society in general. Productivity is a fundamental social and economic issue that is influenced by automation. The productivity of a process is traditionally defined as the ratio of output units to the units of labour input. A properly justified automation installation will provide an increase in productivity due to increases in production rate and reductions in labour content. Over the years productivity gains have led to reduced prices for products and increased prosperity for society.

ncreased
roduc-
ivity

A number of issues related to education and training have been raised by the increased use of automation, robotics, computer systems, and related technologies. As automation has increased, there has developed a shortage of technically trained personnel to implement these technologies competently. This shortage has had a direct influence on the rate at which automated systems can be introduced. The shortage of skilled staffing in automation technologies increases the need for vocational and technical training to develop the required work force skills. Unfortunately the educational system is also in need of technically qualified instructors to teach these subjects. The laboratory equipment available in schools, moreover, all too often does not represent the state-of-the-art technology typically used in industry.

Advantages and disadvantages of automation. The advantages commonly attributed to automation include increased production rates, more efficient use of materials, better product quality, improved safety, shorter workweeks for labour, and reduction of factory lead times.

Automated machines are usually designed to operate at higher production rates than humans are capable of achieving. This increased productivity has been one of the biggest reasons for justifying the adoption of automated systems. Notwithstanding the claims of high quality from good workmanship by humans, automated systems are generally capable of carrying out the manufacturing processs with less variability than humans, thus yielding greater control and consistency of product quality. In addition, the increased process control makes possible more efficient use of materials, resulting in less waste.

Automated manufacturing systems often remove workers from the workplace, thus safeguarding them against hazards in the work environment. In the United States, the Occupational Safety and Health Act of 1970 (OSHA) was enacted with the objective of making work safer and protecting the physical well-being of the worker on a national scale. OSHA has had the effect of promoting the use of automation and robotics in the factory.

lenefits for
he factory
/orker

Another of the benefits of automation noted above is the reduction in the number of hours worked on average per week by factory workers. Around the turn of the century, the average workweek was about 70 hours. This has gradually been reduced, so that today the standard workweek in the United States is about 40 hours. Mechanization and automation have played a significant role in this reduction. Finally, the time required to process a typical job through the factory is generally reduced with automation. Referred to as the manufacturing lead time, this is the amount of time between the beginning of a project or process and the appearance of its results.

Among the major disadvantages associated with automation is worker dislocation. This problem was touched upon earlier. Whatever the ultimate social benefits that might result from retraining displaced workers for other (perhaps more skilled) jobs, in almost all cases the worker whose job is taken over by a machine suffers considerable personal stress. In addition to displacement from work, the worker may be displaced geographically. To find other work, an individual may have to relocate, which is itself another source of emotional stress.

Another significant disadvantage associated with automation is high capital expenditure. Automated systems can cost millions of dollars to design, fabricate, and put into operation. Still other problems characteristic of automated equipment include a higher level of maintenance than is required by manually operated hardware and an inherent lack of flexibility in terms of the variety of products that can be produced.

Also, automation is not without its potential dangers. As often suggested in works of science fiction, the technology associated with automation might ultimately subjugate rather than serve humankind. There is a possibility that workers will become slaves to automated machines, that the privacy of humans will be invaded by vast computer data banks, that human error in the management of technology will somehow endanger the health of civilization, and that society will become completely dependent on automation for its economic well-being.

These dangers notwithstanding, there are substantial opportunities that may arise from the wise and effective use of automation technology. There is an opportunity to relieve humans from boring, repetitive, hazardous, and unpleasant labour in all forms. Then, too, there is an opportunity for future automation technologies to provide a growing social and economic environment in which humans can enjoy a higher standard of living and a better way of life.

Bach

Although he was admired by his contemporaries primarily as an outstanding harpsichordist, organist, and expert on organ building, Johann Sebastian Bach is now generally regarded as one of the greatest composers of all time and is celebrated as the creator of the *Brandenburg Concertos, The Well-Tempered Clavier,* the *Mass in B Minor,* and numerous other masterpieces of church and instrumental music. Appearing at a propitious moment in the history of music, Bach was able to survey and bring together the principal styles, forms, and national traditions that had developed during preceding generations and, by virtue of his synthesis, enrich them all.

Bach, lithograph by Rudolf Hoffmann.

He was a member of a remarkable family of musicians who were proud of their achievements, and about 1735 he drafted a genealogy, *Ursprung der musicalisch-Bachischen Familie* ("Origin of the Musical Bach Family"), in which he traced his ancestry back to his great-great-grandfather Veit Bach, a Lutheran baker (or miller), who was driven from Hungary to Wechmar in Thuringia, a historic region of Germany, by religious persecution late in the 16th century and died in 1619. There were Bachs in the area before that, and it may be that, when Veit moved to Wechmar, he was returning to his birthplace. He used to take his cittern to the mill and play it while grinding was going on. Johann Sebastian remarked, "A pretty noise they must have made together! However, he learnt to keep time, and this apparently was the beginning of music in our family."

Until the birth of Johann Sebastian, his was the least distinguished branch of the family; its members had been competent practical musicians, but not composers, such as Johann Christoph and Johann Ludwig. In later days the most important musicians in the family were Johann Sebastian's sons, Wilhelm Friedemann, Carl Philipp Emanuel, and Johann Christian (the "English Bach").

LIFE

Early years. J.S. Bach was born at Eisenach, Thuringia (now in East Germany), on March 21, 1685, the youngest child of Johann Ambrosius Bach and Elisabeth Lämmerhirt. Ambrosius was a string player, employed by the town council and the ducal court of Eisenach. Johann Sebastian started school in 1692 or 1693 and did well in spite of frequent absences. Of his musical education at this time, nothing definite is known; but he may have picked up the rudiments of string playing from his father, and no doubt he attended the Georgenkirche, where Johann Christoph Bach was organist until 1703.

First keyboard lessons

By 1695 both his parents were dead, and he was looked after by his eldest brother, also named Johann Christoph (1671–1721), organist at Ohrdruf. This Christoph had been a pupil of the influential keyboard composer Johann Pachelbel, and he apparently gave Johann Sebastian his first formal keyboard lessons. The young Bach again did well at school, until in 1700 his voice secured him a place in a select choir of poor boys at the school at the Michaelskirche, Lüneburg (now in West Germany).

His voice must have broken soon after this, but he remained at Lüneburg for a time, making himself generally useful. No doubt he studied in the school library, which had a large and up-to-date collection of church music; he probably heard Georg Böhm, organist of the Johanneskirche; and he visited Hamburg to hear the renowned organist and composer Johann Adam Reinken at the Katharinenkirche, contriving also to hear the French orchestra maintained by the Duke of Celle.

He seems to have returned to Thuringia in the late summer of 1702. By this time he was already a reasonably proficient organist. His experience at Lüneburg, if not at Ohrdruf, had turned him away from the secular string-playing tradition of his immediate ancestors; thenceforth, he was, chiefly, though not exclusively, a composer and performer of keyboard and sacred music. The next few months are wrapped in mystery, but, by March 4, 1703, he was a member of the orchestra employed by Johann Ernst, Herzog (Duke) von Weimar (brother of Wilhelm Ernst, whose service Bach entered in 1708). This post was a mere stopgap; he probably already had his eye on the organ then being built at the Neukirche in Arnstadt; for, when it was finished, he helped to test it, and in August 1703 he was appointed organist—all this at the age of 18. Arnstadt documents imply that he had been court organist at Weimar; this is incredible, though it is likely enough that he had occasionally played there.

The Arnstadt period. At Arnstadt, on the northern edge of the Thuringian forest, where he remained until 1707, Bach devoted himself to keyboard music, the organ in particular. While at Lüneburg, he had apparently had no opportunity of becoming directly acquainted with the spectacular, flamboyant playing and compositions of Dietrich Buxtehude, the most significant exponent of the north German school of organ music. In October 1705 he repaired this gap in his knowledge by obtaining a month's leave and walking to Lübeck (more than 200 miles [300 kilometres]). His visit must have been profitable, for he did not return until about the middle of January 1706. In February his employers complained about his absence and about other things as well: he had harmonized the hymn tunes so freely that the congregation could not sing to his accompaniment, and, above all, he had produced no cantatas. Perhaps the real reasons for his neglect were that he was temporarily obsessed with the organ and was on bad terms with the local singers and instrumentalists, who were not under his control and did not come up to his standards. In the summer of 1705 he had made some offensive remark about a bassoon player, which led to an unseemly scuffle in the street. His replies to these complaints were neither satisfactory nor even accommodating; and the fact that he was not dismissed out of hand suggests that his employers were as well aware of his exceptional ability as he was himself and were reluctant to lose him.

Acquaintance with Buxtehude's music

During these early years Bach inherited the musical culture of the Thuringian area, a thorough familiarity with the traditional forms and hymns (chorales) of the orthodox Lutheran service, and, in keyboard music, perhaps (through his brother, Johann Christoph) a bias toward the formalistic styles of the south. But he also learned eagerly from the northern rhapsodists, Buxtehude above all. By 1708 he had probably learned all that his German pre-

decessors could teach him and arrived at a first synthesis of northern and southern German styles. He had also studied, on his own and during his presumed excursions to Celle, some French organ and instrumental music.

Among the few works that can be ascribed to these early years with anything more than a show of plausibility are the *Capriccio sopra la lontananza del suo fratello dilettissimo* (*Capriccio on the Departure of His Most Beloved Brother,* 1704, BWV 992); the chorale prelude on *Wie schön leuchtet* (*How Brightly Shines, c.* 1705, BWV 739); the fragmentary early version of the organ *Prelude and Fugue in G Minor* (before 1707, BWV 535a). (The "BWV" numbers provided are the standard catalog numbers of Bach's works as established in the *Bach-Werke-Verzeichnis,* prepared by the German musicologist Wolfgang Schmieder.)

The Mühlhausen period. In June 1707 Bach obtained a post at the Blasiuskirche in Mühlhausen in Thuringia. He moved there soon after and married his cousin Maria Barbara Bach at Dornheim on October 17. At Mühlhausen things seem, for a time, to have gone more smoothly. He produced several church cantatas at this time; all of these works are cast in a conservative mold, based on biblical and chorale texts and displaying no influence of the "modern" Italian operatic forms that were to appear in Bach's later cantatas. The famous organ *Toccata and Fugue in D Minor* (BWV 565), written in the rhapsodic northern style, and the *Prelude and Fugue in D Major* (BWV 532) may also have been composed during the Mühlhausen period, as well as the organ *Passacaglia in C Minor* (BWV 582), an early example of Bach's instinct for large-scale organization. Cantata No. 71, *Gott ist mein König* (*God is My King*), of February 4, 1708, was printed at the expense of the city council and was the first of Bach's compositions to be published. While at Mühlhausen, Bach copied music to enlarge the choir library, tried to encourage music in the surrounding villages, and was in sufficient favour to be able to interest his employers in a scheme for rebuilding the organ (February 1708). His real reason for resigning on June 25, 1708, is not known. He himself said that his plans for a "well-regulated [concerted] church music" had been hindered by conditions in Mühlhausen and that his salary was inadequate. It is generally supposed that he had become involved in a theological controversy between his own pastor Frohne and Archdeacon Eilmar of the Marienkirche. Certainly, he was friendly with Eilmar, who provided him with librettos and became godfather to Bach's first child; and it is likely enough that he was not in sympathy with Frohne, who, as a Pietist, would have frowned on elaborate church music. It is just as possible, however, that it was the dismal state of musical life in Mühlhausen that prompted Bach to seek employment elsewhere. At all events, his resignation was accepted, and shortly afterward he moved to Weimar, some miles west of Jena on the Ilm River. He continued, nevertheless, to be on good terms with Mühlhausen personalities, for he supervised the rebuilding of the organ, is supposed to have inaugurated it on October 31, 1709, and composed a cantata for February 4, 1709, which was printed but has disappeared.

Cantatas of the Mühlhausen period

The Weimar period. Bach was, from the outset, court organist at Weimar and a member of the orchestra. Encouraged by Wilhelm Ernst, he concentrated on the organ during the first few years of his tenure. From Weimar, Bach occasionally visited Weissenfels; in February 1713 he took part in a court celebration there that included a performance of his first secular cantata, *Was mir behagt,* or the *Hunt Cantata* (BWV 208).

Late in 1713 Bach had the opportunity of succeeding Friedrich Wilhelm Zachow at the Liebfrauenkirche, Halle; but the Herzog raised his salary, and he stayed on at Weimar. On March 2, 1714, he became concertmaster, with the duty of composing a cantata every month. He became friendly with a relative, Johann Gottfried Walther, a music lexicographer and composer who was organist of the town church, and, like Walther, Bach took part in the musical activities at the Gelbes Schloss (Yellow Castle), then occupied by Herzog Wilhelm's two nephews, Ernst August and Johann Ernst, both of whom he taught. The latter was a talented composer who wrote concertos in the Italian manner, some of which Bach arranged for keyboard instruments; the boy died in 1715, in his 19th year.

Unfortunately, Bach's development cannot be traced in detail during the vital years 1708–14, when his style underwent a profound change. There are too few datable works. From the series of cantatas written in 1714–16, however, it is obvious that he had been decisively influenced by the new styles and forms of the contemporary Italian opera and by the innovations of such Italian concerto composers as Antonio Vivaldi. The results of this encounter can be seen in such cantatas as numbers 182, 199, and 61 in 1714; 31 and 161 in 1715; and 70 and 147 in 1716. His favourite forms appropriated from the Italians were those based on refrain (ritornello) or da capo schemes in which wholesale repetition—literal or with modifications—of entire sections of a piece permitted him to create coherent musical forms with much larger dimensions than had hitherto been possible. These newly acquired techniques henceforth governed a host of Bach's arias and concerto movements, as well as many of his larger fugues (especially the mature ones for organ) and profoundly affected his treatment of chorales.

Italian influence on Bach

Among other works almost certainly composed at Weimar are most of the *Orgelbüchlein* (*Little Organ Book*); all but the last of the so-called 18 "Great" chorale preludes; the earliest organ trios; and most of the organ preludes and fugues. The "Great" *Prelude and Fugue in G Major* for organ (BWV 541) was finally revised about 1715, and the *Toccata and Fugue in F Major* (BWV 540) may have been played at Weissenfels.

On December 1, 1716, Johann Samuel Drese, musical director at Weimar, died. He was then succeeded by his son, who was rather a nonentity. Bach presumably resented being thus passed over; and in due course he accepted an appointment as musical director to Prince Leopold of Köthen, which was confirmed in August 1717. Herzog Wilhelm, however, refused to accept his resignation—partly, perhaps, because of Bach's friendship with the Herzog's nephews, with whom the Herzog was on the worst of terms. About September a contest between Bach and the famous French organist Louis Marchand was arranged at Dresden. The exact circumstances are not known; but Marchand avoided the contest by leaving Dresden a few hours before it should have taken place. By implication, Bach won. Perhaps this emboldened him to renew his request for permission to leave Weimar; at all events he did so but in such terms that the Herzog imprisoned him for a month (November 6–December 2). A few days after his release, Bach moved to Köthen (in modern East Germany), some 30 miles (50 kilometres) north of Halle.

The Köthen period. There, as musical director, he was concerned chiefly with chamber and orchestral music. Even though some of the works may have been composed earlier and revised later, it was at Köthen that the sonatas for violin and clavier, viola da gamba and clavier, and the works for unaccompanied violin and cello were put into something like their present form. The *Brandenburg Concertos* were finished by March 24, 1721; in the sixth concerto—so it has been suggested—Bach bore in mind the technical limitations of the Prince, who played the gamba. Bach played the viola by choice; he liked to be "in the middle of the harmony." He also wrote a few cantatas for the Prince's birthday and other such occasions; most of these seem to have survived only in later versions, adapted to more generally useful words. And he found time to compile pedagogical keyboard works: the *Clavierbüchlein* for W.F. Bach (begun January 22, 1720); some of the *French Suites;* the *Inventions* (1720); and the first book (1722) of *Das Wohltemperierte Klavier* (*The Well-Tempered Clavier,* eventually consisting of two books, each of 24 preludes and fugues in all keys and known as the Forty-eight). This remarkable collection systematically explores both the potentials of a newly established tuning procedure—which, for the first time in the history of keyboard music, made all the keys equally usable—and the possibilities for musical organization afforded by the system of "functional tonality," a kind of musical syntax consolidated in the music of the Italian concerto composers of the preceding generation and a system that

Influence of *The Well-Tempered Clavier* on keyboard music

was to prevail for the next 200 years. At the same time *The Well-Tempered Clavier* is a compendium of the most popular forms and styles of the era: dance types, arias, motets, concertos, etc., presented within the unified aspect of a single compositional technique: the rigorously logical and venerable fugue.

Maria Barbara Bach died unexpectedly and was buried on July 7, 1720. About November, Bach visited Hamburg; his wife's death may have unsettled him and led him to inquire after a vacant post at the Jacobikirche. Nothing came of this, but he played at the Katharinen-kirche in the presence of Reinken. After hearing Bach improvise variations on a chorale tune, the old man said, "I thought this art was dead; but I see it still lives in you."

On December 3, 1721, Bach married Anna Magdalena Wilcken, daughter of a trumpeter at Weissenfels. Apart from his first wife's death, these first four years at Köthen were probably the happiest of Bach's life. He was on the best terms with the Prince, who was genuinely musical; and in 1730 Bach said that he had expected to end his days there. But the Prince married on December 11, 1721, and conditions deteriorated. The Princess—described by Bach as "an *amusa*" (that is to say, opposed to the muses)—required so much of her husband's attention that Bach began to feel neglected. He also had to think of the education of his elder sons, born in 1710 and 1714, and he probably began to think of moving to Leipzig as soon as the cantorate fell vacant with the death of Johann Kuhnau on June 5, 1722. Bach applied in December, but the post—already turned down by Bach's friend, Georg Philipp Telemann—was offered to another prominent composer of the day, Christoph Graupner, the musical director at Darmstadt. As the latter was not sure that he would be able to accept, Bach gave a trial performance (Cantata No. 22, *Jesu nahm zu sich die Zwölfe* [*Jesus called unto Him the Twelve*]) on February 7, 1723; and, when Graupner withdrew (April 9), Bach was so deeply committed to Leipzig that, although the Princess had died on April 4, he applied for permission to leave Köthen. This he obtained on April 13, and on May 13 he was sworn in at Leipzig.

He was appointed honorary musical director to Köthen, and both he and Anna were employed there from time to time until the Prince died, on November 19, 1728.

Years at Leipzig. As Director of Church Music for the city of Leipzig, Bach had to supply performers for four churches. At the Peterskirche the choir merely led the hymns. At the Neukirche, Nikolaikirche, and Thomaskirche, part singing was required; but Bach himself conducted, and his own church music was performed, only at the last two. His first official performance was on May 30, 1723, the first Sunday after Trinity Sunday, with Cantata No. 75, *Die Elenden sollen essen.* New works produced during this year include many cantatas and the *Magnificat* in its first version. The first half of 1724 saw the production of the *St. John Passion,* which was subsequently revised. The total number of cantatas produced during this ecclesiastical year was about 62, of which about 39 were new works.

Production of the *St. John Passion*

On June 11, 1724, the first Sunday after Trinity, Bach began a fresh annual cycle of cantatas, and within the year he wrote 52 of the so-called chorale cantatas, formerly supposed to have been composed over the nine-year period 1735–44. The Sanctus of the *Mass in B Minor* was produced at Christmas.

During his first two or three years at Leipzig, Bach had produced a large number of new cantatas, sometimes, as recent research has revealed, at the rate of one a week. This phenomenal pace raises the question of Bach's approach to composition. Bach and his contemporaries, subject to the hectic pace of production, had to invent or discover their ideas quickly and could not rely on the unpredictable arrival of "inspiration." Nor did the musical conventions and techniques or the generally rationalistic outlook of the time necessitate this reliance, as long as the composer was willing to accept them. The Baroque composer who submitted to the regimen inevitably had to be a traditionalist who willingly embraced the conventions.

Symbolism. A repertory of melody types existed, for example, that was generated by an explicit "doctrine of figures" that created musical equivalents for the figures of speech in the art of rhetoric. Closely related to these "figures" are such examples of pictorial symbolism in which the composer writes, say, a rising scale to match words that speak of rising from the dead or a descending chromatic scale (depicting a howl of pain) to sorrowful words. Pictorial symbolism of this kind occurs only in connection with words—in vocal music and in chorale preludes, where the words of the chorale are in the listener's mind. There is no point in looking for resurrection motifs in *The Well-Tempered Clavier.* Pictorialism, even when not codified into a doctrine, seems to be a fundamental musical instinct and essentially an expressive device. It can, however, become more abstract, as in the case of number symbolism, a phenomenon observed too often in the works of Bach to be dismissed out of hand. Number symbolism is sometimes pictorial; in the *St. Matthew Passion* it is reasonable that the question "Lord, is it I?" should be asked 11 times, once by each of the faithful disciples. But the deliberate search for such symbolism in Bach's music can be taken too far. Almost any number may be called "symbolic" (3, 6, 7, 10, 11, 12, 14, and 41 are only a few examples); any multiple of such a number is itself symbolic; and the number of sharps in a key signature, notes in a melody, measures in a piece, and so on may all be considered significant. As a result, it is easy to find symbolic numbers anywhere, but ridiculous to suppose that such discoveries invariably have a meaning.

Use of pictorial symbolism

Besides the melody types, the Baroque composer also had at his disposal similar stereotypes regarding the further elaboration of these themes into complete compositions, so that the arias and choruses of a cantata almost seem to have been spun out "automatically." One is reminded of Bach's delightfully innocent remark "I have had to work hard; anyone who works just as hard will get just as far," with its implication that everything in the "craft" of music is teachable and learnable. The fact that no other composer of the period, with the arguable exception of Handel, even remotely approached Bach's achievement indicates clearly enough that the application of the "mechanical" procedures was not literally "automatic" but was controlled throughout by something else—artistic discrimination, or taste. "Taste," a most respected attribute in the culture of the 18th century, is an utterly individual compound of raw talent, imagination, psychological disposition, judgment, skill, and experience. It is unteachable and unlearnable.

As a result of his intense activity in cantata production during his first three years in Leipzig, Bach had created a supply of church music to meet his future needs for the regular Sunday and feast-day services. After 1726, therefore, he turned his attention to other projects. He did, however, produce the *St. Matthew Passion* in 1729, a work that inaugurated a renewed interest in the mid-1730s for vocal works on a larger scale than the cantata: the now-lost *St. Mark Passion* (1731), the *Christmas Oratorio,* BWV 248 (1734), and the *Ascension Oratorio* (Cantata No. 11, *Lobet Gott in seinen Reichen;* 1735).

St. Matthew Passion* and *Christmas Oratorio

Nonmusical duties. In addition to his responsibilities as director of church music, Bach also had various nonmusical duties in his capacity as the cantor of the school at the Thomaskirche. Since he resented these latter obligations, Bach frequently absented himself without leave, playing or examining organs, taking his son Friedemann to hear the "pretty tunes," as he called them, at the Dresden opera and fulfilling the duties of the honorary court posts that he contrived to hold all his life. To some extent, no doubt, he accepted engagements because he needed money; he complained in 1730 that his income was less than he had been led to expect (he remarked that there were not enough funerals); but, obviously, his routine work must have suffered. Friction between Bach and his employers thus developed almost at once. On the one hand, Bach's initial understanding of the fees and prerogatives accruing to his position—particularly regarding his responsibility for musical activities in the University of Leipzig's Paulinerkirche—differed from that of the town council and the university organist, Johann Gottlieb Görner. On the other

hand, Bach remained, in the eyes of his employers, their third (and unenthusiastic) choice for the post, behind Telemann and Graupner. Furthermore, the authorities insisted on admitting unmusical boys to the school, thus making it difficult for Bach to keep his churches supplied with competent singers; they also refused to spend enough money to keep a decent orchestra together. The resulting ill feeling had become serious by 1730. It was temporarily dispelled by the tact of the new rector, Johann Matthias Gesner, who admired Bach and had known him at Weimar; but Gesner stayed only until 1734 and was succeeded by Johann August Ernesti, a young man with up-to-date ideas on education, one of which was that music was not one of the humanities but a time-wasting sideline. Trouble flared up again in July 1736; it then took the form of a dispute over Bach's right to appoint prefects and became a public scandal. Fortunately for Bach, he became court composer to the Elector of Saxony in November 1736. As such, after some delay, he was able to induce his friends at court to hold an official inquiry, and his dispute with Ernesti was settled in 1738. The exact terms of the settlement are not known; but, thereafter, Bach did as he liked.

Instrumental works. In 1726, after he had completed the bulk of his cantata production, Bach began to publish the clavier *Partitas* singly, with a collected edition in 1731, perhaps with the intention of attracting recognition beyond Leipzig and thus securing a more amenable appointment elsewhere. The second part of the *Clavierübung,* containing the *Concerto in the Italian Style* and the *French Overture* (*Partita*) *in B Minor* appeared in 1735. The third part, consisting of the *Organ Mass* with the *Prelude and Fugue* ["St. Anne"] *in E Flat Major* (BWV 552), appeared in 1739. From *c.* 1729 to 1736 Bach was honorary musical director to Weissenfels; and, from 1729 to 1737 and again from 1739 for a year or two, he directed the Leipzig Collegium Musicum. For these concerts he adapted some of his earlier concertos as harpsichord concertos, thus becoming one of the first composers in history—if not the very first—of concertos for keyboard instrument and orchestra, just as he was one of the first to use the harpsichordist's right hand as a true melodic part in chamber music. These are just two of several respects in which the basically conservative and traditional Bach, as is becoming increasingly recognized, was a significant innovator as well.

nnova-ions as a :eyboard :omposer

About 1733 Bach began to produce cantatas in honour of the Elector of Saxony and his family, evidently with a view to the court appointment he secured in 1736; many of these secular movements were adapted to sacred words and re-used in the *Christmas Oratorio.* The Kyrie and Gloria of the *Mass in B Minor,* written in 1733, were also dedicated to the Elector, but the rest of the *Mass* was not put together until Bach's last years. On his visits to Dresden, Bach had won the regard of Graf Hermann Karl von Keyserlingk, the Russian envoy, who commissioned the so-called *Goldberg Variations;* these were published as part four of the *Clavierübung* about 1742, and Book Two of the "Forty-eight" seems to have been compiled about the same time. In addition, he wrote a few cantatas, revised some of his Weimar organ works, and published the so-called *Schübler Chorale Preludes* in or after 1746.

Last years. In May 1747 he visited his son Emanuel at Potsdam and played before Frederick II the Great of Prussia; in July his improvisations, on a theme proposed by the King, took shape as *The Musical Offering.* In June 1747 he joined a Sozietät der Musikalischen Wissenschaften (Society of the Musical Sciences) that had been founded by his former pupil Lorenz Christoph Mizler; he presented the canonic variations on the chorale *Vom Himmel hoch da komm' ich her* (*From Heaven Above to Earth I Come*) to the society, in manuscript, and afterward published them.

Of Bach's last illness little is known, except that it lasted several months and prevented him from finishing *The Art of the Fugue.* His constitution was undermined by two unsuccessful eye operations performed by John Taylor, the itinerant English quack who numbered Handel among his other failures; and he died on July 28, 1750, at Leipzig. His employers proceeded with relief to appoint a successor; Burgomaster Stieglitz remarked, "The school needs a cantor, not a musical director—though certainly he ought to understand music." Anna Magdalena was left badly off. For some reason, her stepsons did nothing to help her, and her own sons were too young to do so. She died on February 27, 1760, and was given a pauper's funeral.

Unfinished as it was, *The Art of the Fugue* was published in 1751. It attracted little attention and was reissued in 1752 with a laudatory preface by Friedrich Wilhelm Marpurg, a well-known Berlin musician, who later became director of the royal lottery. In spite of Marpurg and of some appreciative remarks by Johann Mattheson, the influential Hamburg critic and composer, only about 30 copies had been sold by 1756, when Emanuel Bach offered the plates for sale. As far as is known, they were sold for scrap.

Publication of *The Art of the Fugue*

Emanuel Bach and the organist-composer Johann Friedrich Agricola (a pupil of Sebastian's) wrote an obituary; Mizler added a few closing words and published the result in the journal of his society (1754). There is an English translation of it in *The Bach Reader.* Though incomplete and inaccurate, the obituary is of very great importance as a firsthand source of information.

Bach appears to have been a good husband and father. Indeed, he was the father of 20 children, only 10 of whom survived to maturity. There is amusing evidence of a certain thriftiness, a necessary virtue; for he was never more than moderately well off, and he delighted in hospitality. Living as he did at a time when music was beginning to be regarded as no occupation for a gentleman, he occasionally had to stand up for his rights both as a man and as a musician; he was then obstinate in the extreme. But no sympathetic employer had any trouble with Bach, and with his professional brethren he was modest and friendly. He was also a good teacher and from his Mühlhausen days onward was never without pupils.

REPUTATION AND INFLUENCE

For about 50 years after Bach's death, his music was neglected. This was only natural; in the days of Haydn and Mozart, no one could be expected to take much interest in a composer who had been considered old-fashioned even in his lifetime—especially since his music was not readily available, and half of it (the church cantatas) was fast becoming useless as a result of changes in religious thought.

At the same time, musicians of the late 18th century were neither so ignorant of Bach's music nor so insensitive to its influence as some modern authors have suggested. Emanuel Bach's debt to his father was considerable and Bach exercised a profound and acknowledged influence directly on Haydn, Mozart, and Beethoven.

Revival of music. After 1800 the revival of Bach's music gained momentum. The German writer Johann Nikolaus Forkel published a *Life, Genius and Works* in 1802 and acted as adviser to the publishers Hoffmeister and Kühnel, whose collected edition, begun in 1801, was cut short by the activities of Napoleon. By 1829 a representative selection of keyboard music was nonetheless available, although very few of the vocal works were published. But in that year the German musician Eduard Devrient and the German composer Felix Mendelssohn took the next step with the centenary performance of the *St. Matthew Passion.* It and the *St. John Passion* were both published in 1830; the *Mass in B Minor* followed (1832–45). The Leipzig publisher Peters began a collected edition of "piano" and instrumental works in 1837; the organ works followed in 1844–52.

Publication of the *Mass in B Minor*

Encouraged by Robert Schumann, the Bach-Gesellschaft (BG) was founded in the centenary year 1850, with the purpose of publishing the complete works. By 1900 all the known works had been printed, and the BG was succeeded by the Neue Bach-Gesellschaft (NBG), which exists still, organizing festivals and publishing popular editions. Its chief publication is its research journal, the *Bach-Jahrbuch* (from 1904). By 1950 the deficiencies of the BG edition had become painfully obvious, and the Bach-Institut was founded with headquarters at Göttingen (West Germany) and Leipzig, to produce a new standard edition (the *Neue Bach-Ausgabe* or NBA) expected to comprise 84 volumes.

In retrospect, the Bach revival, reaching back to 1800, can be recognized as the first conspicuous example of the deliberate exhumation of old music, accompanied by biographical and critical studies; and it served as an inspiration and a model for subsequent work of that kind.

Among the biographical and critical works on Bach, the most important was the monumental study *Johann Sebastian Bach* (2 vol., Leipzig, 1873–80), by the German musicologist Philipp Spitta, covering not only Bach's life and works but also a good deal of the historical background. Although wrong in many details, the book is still indispensable to the Bach student.

Editions of Bach's works. The word *Urtext* (original text) may lead the uninitiated to suppose that they are being offered an exact reproduction of what Bach wrote. It must be understood that the autographs of many important works no longer exist. Therefore, Bach's intentions often have to be pieced together from anything up to 20 sources, all different. Even first editions and facsimiles of autograph manuscripts are not infallible guides to Bach's intentions. In fact, they are often dangerously misleading, and practical musicians should take expert advice before consulting them. Editions published between 1752 and *c.* 1840 are little more than curiosities, chiefly interesting for the light they throw on the progress of the revival.

No comprehensive edition is trustworthy throughout: neither Peters nor the BG nor even the NBA. Nevertheless, it is advisable to begin by finding out whether the music desired has been published by the NBA.

MAJOR WORKS

Vocal music (sacred)

MASSES: *Mass in B Minor,* BWV 232 (1724–46); 4 Lutheran masses (*i.e.,* containing only settings of the Kyrie and the Gloria).

ORATORIOS: *Christmas Oratorio,* BWV 248 (1734); *Easter Oratorio* (*Kommt, eilet und laufet,* BWV 249; 1725); *Ascension Oratorio* (1735).

PASSIONS: *Passion According to St. John,* BWV 245 (1724); *Passion According to St. Matthew,* BWV 244 (1729).

CANTATAS: About 200 for different Sundays in the church year (1707–after 1735; mainly 1714–16, 1723–27), mostly for soloist(s), chorus, and orchestra.

OTHER WORKS: *Magnificat in D Major,* BWV 243; 7 motets; 2 Sanctus settings (3 others based on works by other composers); 186 independent chorale harmonizations.

Vocal music (secular)

CANTATAS: 24, mostly for soloists, chorus, and orchestra—all on German texts, except two Italian. They include the *Coffee Cantata* (*Schweigt stille, plaudert nicht,* BWV 211; *c.* 1732) and the *Peasant Cantata* (*Mer hahn en neue Oberkeet,* BWV 212; 1742).

OTHER WORKS: 5 songs for voice and continuo and 1 quodlibet for four voices and continuo.

Orchestral music

CONCERTI: 6 *Brandenburg Concertos* (pre-1721); 2 concertos for violin and orchestra and one for two violins (1717–23); 7 for one harpsichord, 3 for two harpsichords, 2 for three, and 1 for four harpsichords; 1 concerto for harpsichord, flute, and violin.

OTHER ORCHESTRAL WORKS: 4 overtures (suites); *Sinfonia in D Major* (incomplete).

Chamber music

SONATAS: 2 for violin and continuo; 2 for flute and continuo; 1 for two flutes and harpsichord; 2 for flute, violin, and continuo; 3 for harpsichord and flute; 3 for harpsichord and viola da gamba; 6 for harpsichord and violin.

OTHER CHAMBER MUSIC: *Das musikalisches Opfer* (1747) for strings, flute, and continuo; 6 unaccompanied sonatas (partitas) for violin (*c.* 1720); 6 unaccompanied suites (sonatas) for cello (*c.* 1720).

Organ music

CHORALE PRELUDES: 140 chorale preludes including the *Orgelbüchlein* (mainly 1714–16); *Clavierübung,* vol. 3 (1739), and *Schübler Chorale Preludes* (1746 or later).

FUGUES: 18 preludes and fugues (1708–17, 1729–39), including the "St. Anne" in E flat major and the "Wedge" in E minor; 5 toccatas and fugues (1700–17), including the "Dorian" in D minor; 3 fantasies and fugues; 4 other fugues.

OTHER ORGAN COMPOSITIONS: Variations on the chorale *Vom Himmel hoch* (1747); *Passacaglia in C Minor,* BWV 582 (1708–17); 4 concertos; 7 fantasies; 4 preludes; 6 sonatas (trios); 3 trios.

Harpsichord music

COLLECTIONS: *Clavierübung*: vol. 1 (1726–31), 6 partitas; vol. 2 (1735), *French Overture in B Minor* and *Concerto in the Italian Style;* vol. 3 (1739) is organ music with 4 "duets" for harpsichord; and vol. 4 (1742), *Goldberg Variations; The Well-Tempered Clavier,* 2 vol. (1722 and 1742), containing 48 preludes and fugues, one in each key in each book; *Clavierbüchlein* (1720), for Wilhelm Friedemann Bach, containing 15 two-part and 15 three-part inventions, 20 preludes, 2 chorale preludes, 2 allemandes, 4 minuets, a fugue, and an "applicatio"; *Clavierbüchlein* (1722) and *Notenbuch* (1725), both for Anna Magdalena Bach, containing marches, minuets, a musette, polonaises, etc.; 6 *French Suites* and 6 *English Suites.*

OTHER HARPSICHORD WORKS: *Aria variata* in A minor; 2 capriccios; *Chromatic Fantasy and Fugue;* 5 fantasies, 2 with fugues; 12 *Little Preludes;* 4 preludes and 6 for beginners; 4 preludes and fughettas, 3 preludes and fugues; 2 sonatas; 4 miscellaneous suites; 7 toccatas and arrangements.

For unspecified instrument(s)

Die Kunst der Fuge (1749); 16 fugues and 4 canons.

(W.Em/Ro.Ma.)

BIBLIOGRAPHY

Catalogs: WOLFGANG SCHMIEDER, *Thematisch-systematisches Verzeichnis der musikalischen Werke von Johann Sebastian Bach. Bach-Werke-Verzeichnis* (BWV), (1950, reprinted 1981), the standard catalog of Bach's music, including a bibliography for each work; PAUL KAST, *Die Bach-Handschriften der Berliner Staatsbibliothek* (1958), a descriptive catalog of the Bach manuscripts in the possession of the Deutsche Staatsbibliothek, East Berlin, the largest single repository, with more than 75 percent of the surviving Bach sources; MAY DEFOREST MCALL (comp.), *Melodic Index to the Works of Johann Sebastian Bach,* rev. and enl. ed. (1962), containing some 3,872 themes; WALTER KOLNEDER, *Lübbes Bach Lexikon* (1982), an illustrated dictionary.

Collections of correspondence, sketchbooks, and reminiscences: Schriftstücke von der Hand Johann Sebastian Bachs (1963), a critical edition of all surviving nonmusical documents, such as letters and receipts, in Bach's hand, and *Fremdschriftliche und gedruckte Dokumente zur Lebensgeschichte Johann Sebastian Bachs 1685–1750* (1969), a critical edition of all known printed and handwritten discussions of and references to Bach dating from his lifetime, both edited by WERNER NEUMANN and HANS-JOACHIM SCHULZE and published as supplements to the *Neue Ausgabe sämtlicher Werke* (hereafter referred to as *Neue Bach-Ausgabe*), are vol. 1 and 2 in the series *Bach-Dokumente.* Volume 3 of the series, ed. by HANS-JOACHIM SCHULZE, is *Dokumente zum nachwirken Johann Sebastian Bachs: 1750–1800* (1972); and vol. 4, ed. by WERNER NEUMANN, is *Bilddokumente zur Lebensgeschichte Johann Sebastian Bachs* (1979), with text and captions in both English and German. See also HANS T. DAVID and ARTHUR MENDEL (eds.), *The Bach Reader: A Life of Johann Sebastian Bach in Letters and Documents,* rev. ed. (1966, reprinted 1972); and ROBERT L. MARSHALL, *The Compositional Process of J.S. Bach,* 2 vol. (1972), a study of the autograph scores of the vocal works, with transcriptions of all surviving musical sketches and drafts included in vol. 2.

Biography and criticism: PHILIPP SPITTA, *Johann Sebastian Bach: His Work and Influence on the Music of Germany, 1685–1750,* 3 vol. (1884, reprinted 1951; originally published in German, 2 vol., 1873–80, reprinted 1979), a monumental study that is still the standard biography, although no longer valid in many particulars. Further important full-length studies are ALBERT SCHWEITZER, *J.S. Bach,* 2 vol. (1911, reprinted 1966; originally published in French, 1905), an influential, if highly subjective and personal, interpretation; CHARLES SANFORD TERRY, *Bach: A Biography;* 2nd rev. ed. (1933, reprinted 1972), a useful supplement (based on new archival researches) to the biographical portions of Spitta's work; KARL GEIRINGER, *Johann Sebastian Bach: The Culmination of an Era* (1966), a full-length account of the life and works that uses results of research in the 1950s by Alfred Dürr and Georg von Dadelsen bearing on the chronology of Bach's works, and *The Bach Family: Seven Generations of Creative Genius* (1954, reprinted 1981); PERCY M. YOUNG, *The Bachs: 1500–1850* (1970). Other useful sources include ALEC ROBERTSON, *Bach* (1977), a biography, with a survey of books, published editions of the works, and recordings; NORMAN CARRELL, *Bach the Borrower* (1967, reprinted 1980), on Bach's use of preexisting material; EVA MARY GREW and SYDNEY GREW, *Bach* (1947, reprinted 1977); C. HUBERT H. PARRY, *Johann Sebastian Bach: The Story of the Development of a Great Personality,* rev. ed. (1934, reprinted 1977); ROBERT L. WEAVER (ed.), *Essays on the Music of J.S. Bach and Other Divers Subjects* (1981).

On the vocal music: ALFRED DÜRR, *Die Kantaten von Johann Sebastian Bach,* 2 vol. (1971, reprinted 1979), a general survey plus individual essays on each cantata by one of the principal editors of the *Neue Bach-Ausgabe;* WERNER NEUMANN, *Handbuch der Kantaten, Johann Sebastian Bachs,* 4th rev. ed. (1971), a handbook of useful factual data and schematic analyses of all the cantatas, which is complemented by WERNER

NEUMANN (ed.), *Sämtliche von Johann Sebastian Bach vertonte Texte* (1974), complete texts of the works set to music by Bach, and *Sämtliche Kantatentexte* (1956, reissued 1967), a complete critical edition of the cantata texts; WILLIAM G. WHITTAKER, *The Cantatas of Johann Sebastian Bach, Sacred and Secular*, 2 vol. (1959, reprinted 1978), a stimulating appreciation, but one that should be used with caution, and *Fugitive Notes on Certain Cantatas and the Motets of J.S. Bach* (1924, reprinted 1976). Detailed research is given in CHARLES SANFORD TERRY, *Bach's Chorals*, 3 vol. (1915–21, reprinted in 2 vol., 1979), *Bach: The Cantatas and Oratorios*, 3 vol. (1925–29, reprinted in one vol., 1972), and *Bach: The Passions*, 2 vol. (1926, reprinted 1980); BASIL SMALLMAN, *The Background of Passion Music: J.S. Bach and His Predecessors*, 2nd rev. ed. (1970); PAUL STEINITZ, *Bach's Passions* (1978), with an overview of the history of performances of the Passions; JAMES DAY, *The Literary Background to Bach's Cantatas* (1961, reprinted 1966); HOWARD E. SMITHER, *A History of the Oratorio*, 2 vol. (1977), a survey of sacred dramatic music of the 17th century; ALEC ROBERTSON, *The Church Cantatas of J.S. Bach* (1972), with information on the religious significance of Bach's treatment of the texts; AUGUSTA RUBIN, *J.S. Bach: The Modern Composer* (1976), an analysis of his harmonic methods, with more than 1,200 quotations from the chorales.

On the instrumental music: HERMANN KELLER, *The Organ Works of Bach* (1967; originally published in German, 1948), *Die Klavierwerke Bachs* (1950), and *The Well-Tempered Clavier by Johann Sebastian Bach* (1976; originally published in German, 1965, reprinted 1981), the historical context of Bach's organ and keyboard works, and individual analyses of the compositions; DONALD F. TOVEY, *A Companion to "The Art of Fugue"* (1931, reprinted 1960), an analysis; HANS T. DAVID, *J.S. Bach's Musical Offering: History, Interpretation, and Analysis* (1945, reissued 1982); CHARLES SANFORD TERRY, *The Music of Bach* (1933, reissued 1963), and *Bach's Orchestra* (1932, reprinted 1972); ANDRÉ PIRRO, *J.S. Bach* (1957; originally published in French, 1907), and *Johann Sebastian Bach: The Organist and His Works for the Organ* (1902, reprinted 1978; trans. from French); WERNER MENKE, *History of the Trumpet of Bach and Handel* (1934, reprinted 1972; originally published in German, 1934); CECIL GRAY, *The Forty-Eight Preludes and Fugues of J.S. Bach* (1948); ALAN E.F. DICKINSON, *Bach's Fugal Works, with an Account of Fugue Before and After Bach* (1956, reprinted 1979); NORMAN CARRELL, *Bach's Brandenburg Concertos* (1963, reprinted 1977).

On performance: ERWIN BODKY, *The Interpretation of Bach's Keyboard Works* (1960, reprinted 1976), a controversial but stimulating approach; WALTER EMERY, *Bach's Ornaments* (1953), a discussion of the problems and suggested solutions, and *Notes on Bach's Organ Works*, 2 vol. (1952–57), with facsimiles of scores; ROBERT DONINGTON, *Tempo and Rhythm in Bach's Organ Music* (1960); THOMAS HARMON, *The Registration of J.S. Bach's Organ Works*, 2nd ed. (1981); HARVEY GRACE, *The Organ Works of Bach* (1922); FRITZ ROTHSCHILD, *The Lost Tradition in Music: Rhythm and Tempo in J.S. Bach's Time* (1953, reprinted 1979); FREDERICK NEUMANN, *Ornamentation in Baroque and Post-Baroque Music: With Special Emphasis on J.S. Bach* (1978), with a glossary of terms and symbols and a bibliography of primary sources. See also ARTHUR MENDEL, the preface of his edition of the vocal score of *The Passion According to St. John* (1951).

Bach's place in history is discussed in WILFRID MELLERS, *Bach and the Dance of God* (1980), focussing on the creative process and the relationship of music, word, and drama in his music; JAN CHIAPUSSO, *Bach's World* (1968, reprinted 1980), a historical study, with musical analyses; DOUGLAS R. HOFSTADTER, *Gödel, Escher, Bach: An Eternal Golden Braid* (1979, reprinted 1980), a metaphorical, philosophical work for the reader interested in the structure of Bach's music.

(W.Em./Ro.Ma./Ed.)

Francis Bacon

Francis Bacon, lawyer, courtier, statesman, philosopher, and master of the English tongue, is remembered in literary terms for the sharp worldly wisdom of a few dozen essays; by students of constitutional history for his power as a speaker in Parliament and in some famous trials and as James I's lord chancellor; and intellectually as a man who claimed all knowledge as his province and, after a magisterial survey, proceeded urgently to advocate new ways by which men might establish a legitimate command over nature for the relief of man's estate.

Francis Bacon, oil painting by an unknown artist. In the National Portrait Gallery, London.

LIFE

Bacon's family

Youth and early maturity. Bacon was born Jan. 22, 1561, at York House off the Strand, London, the younger of the two sons of the lord keeper, Sir Nicholas Bacon, by his second marriage. Nicholas Bacon, born in comparatively humble circumstances, had risen to become lord keeper of the great seal. Francis' cousin through his mother was Robert Cecil, later earl of Salisbury and chief minister of the crown at the end of Elizabeth I's reign and the beginning of James I's. From 1573 to 1575 Bacon was educated at Trinity College, Cambridge, but his weak constitution caused him to suffer ill health there. His distaste for what he termed "unfruitful" Aristotelian philosophy began at Cambridge. From 1576 to 1579 Bacon was in France as a member of the English ambassador's suite. He was recalled abruptly after the sudden death of his father, who left him relatively little money. Bacon remained financially embarrassed virtually until his death.

Early legal career and political ambitions. In 1576 Bacon had been admitted as an "ancient" (senior governor) of Gray's Inn, one of the four Inns of Court that served as institutions for legal education, in London. In 1579 he took up residence there and after becoming a barrister in 1582 progressed in time through the posts of reader (lecturer at the Inn), bencher (senior member of the Inn), and queen's (from 1603 king's) counsel extraordinary to those of solicitor general and attorney general. Even as successful a legal career as this, however, did not satisfy his political and philosophical ambitions.

Bacon occupied himself with the tract "Temporis Partus Maximus" ("The Greatest Part of Time") in 1582; it has not survived. In 1584 he sat as member of Parliament for Melcombe Regis in Dorset and subsequently represented Taunton, Liverpool, the County of Middlesex, Southamp-

ton, Ipswich, and the University of Cambridge. In 1589 a "Letter of Advice" to the Queen and *An Advertisement Touching the Controversies of the Church of England* indicated his political interests and showed a fair promise of political potential by reason of their levelheadedness and disposition to reconcile. In 1593 came a setback to his political hopes: he took a stand objecting to the government's intensified demand for subsidies to help meet the expenses of the war against Spain. Elizabeth took offense, and Bacon was in disgrace during several critical years when there were chances for legal advancement.

Relationship with Essex. Meanwhile, sometime before July 1591, Bacon had become acquainted with Robert Devereux, the young earl of Essex, who was a favourite of the Queen, although still in some disgrace with her for his unauthorized marriage to the widow of Sir Philip Sidney. Bacon saw in the Earl the "fittest instrument to do good to the State" and offered Essex the friendly advice of an older, wiser, and more subtle man. Essex did his best to mollify the Queen, and when the office of attorney general fell vacant, he enthusiastically but unsuccessfully supported the claim of Bacon. Other recommendations by Essex for high offices to be conferred on Bacon also failed.

By 1598 Essex' failure in an expedition against Spanish treasure ships made him harder to control; and although Bacon's efforts to divert his energies to Ireland, where the people were in revolt, proved only too successful, Essex lost his head when things went wrong and he returned against orders. Bacon certainly did what he could to accommodate matters but merely offended both sides; in June 1600 he found himself as the Queen's learned counsel taking part in the informal trial of his patron. Essex bore him no ill will and shortly after his release was again on friendly terms with him. But after Essex' abortive attempt of 1601 to seize the Queen and force her dismissal of his rivals, Bacon, who had known nothing of the project, viewed Essex as a traitor and drew up the official report on the affair. This, however, was heavily altered by others before publication.

The traitorous actions of Essex

After Essex' execution Bacon, in 1604, published the *Apologie in Certaine Imputations Concerning the Late Earle of Essex* in defense of his own actions. It is a coherent piece of self-justification, but to posterity it does not carry complete conviction, particularly since it evinces no personal distress.

Career in the service of James I. When Elizabeth died in 1603, Bacon's letter-writing ability was directed to finding a place for himself and a use for his talents in James I's services. He pointed to his concern for Irish affairs, the union of the kingdoms, and the pacification of the church as proof that he had much to offer the new king.

Through the influence of his cousin Robert Cecil, Bacon was one of the 300 new knights dubbed in 1603. The following year he was confirmed as learned counsel and sat in the first Parliament of the new reign in the debates of its first session. He was also active as one of the commissioners for discussing a union with Scotland. In the autumn of 1605 he published his *Advancement of Learning,* dedicated to the King, and in the following summer he married Alice Barnham, the daughter of a London alderman. Preferment in the royal service, however, still eluded him, and it was not until June 1607 that his petitions and his vigorous though vain efforts to persuade the Commons to accept the King's proposals for union with Scotland were at length rewarded with the post of solicitor general. Even then, his political influence remained negligible, a fact that he came to attribute to the power and jealousy of Cecil, by then earl of Salisbury and the King's chief minister. In 1609 his *De Sapientia Veterum* ("The Wisdom of the Ancients"), in which he expounded what he took to be the hidden practical meaning embodied in ancient myths, came out and proved to be, next to the *Essayes,* his most popular book in his own lifetime. In 1614 he seems to have written *The New Atlantis,* his far-seeing scientific utopian work, which did not get into print until 1626.

Political advancement

After Salisbury's death in 1612, Bacon renewed his efforts to gain influence with the King, writing a number of remarkable papers of advice upon affairs of state and, in particular, upon the relations between Crown and Parliament. The King adopted his proposal for removing Coke from his post as chief justice of the common pleas and appointing him to the King's Bench, while appointing Bacon attorney general in 1613. During the next few years Bacon's views about the royal prerogative brought him, as attorney general, increasingly into conflict with Coke, the champion of the common law and of the independence of the judges. It was Bacon who examined Coke when the King ordered the judges to be consulted individually and separately in the case of Edmond Peacham, a clergyman charged with treason as the author of an unpublished treatise justifying rebellion against oppression. Bacon has been reprobated for having taken part in the examination under torture of Peacham, which turned out to be fruitless. It was Bacon who instructed Coke and the other judges not to proceed in the case of commendams (*i.e.,* holding of benefices in the absence of the regular incumbent) until they had spoken to the King. Coke's dismissal in November 1616 for defying this order was quickly followed by Bacon's appointment as lord keeper of the great seal in March 1617. The following year he was made lord chancellor and baron Verulam, and in 1620/21 he was created viscount St. Albans.

The main reason for this progress was his unsparing service in Parliament and the court, together with persistent letters of self-recommendation; according to the traditional account, however, he was also aided by his association with George Villiers, later duke of Buckingham, the King's new favourite. It would appear that he became honestly fond of Villiers; many of his letters betray a feeling that seems warmer than timeserving flattery.

Among Bacon's papers a notebook has survived, the *Commentarius Solutus* ("Loose Commentary"), which is revealing. It is a jotting pad "like a Marchant's wast booke where to enter all maner of remembrance of matter, fourme, business, study, towching my self, service, others, eyther sparsim or in schedules, without any maner of restraint." This book reveals Bacon reminding himself to flatter a possible patron, to study the weaknesses of a rival, to set intelligent noblemen in the Tower of London to work on serviceable experiments. It displays the multiplicity of his concerns: his income and debts, the King's business, his own garden and plans for building, philosophical speculations, his health, including his symptoms and medications, and an admonition to learn to control his breathing and not to interrupt in conversation. Between 1608 and 1620 he prepared at least 12 draftings of his most celebrated work, the *Novum Organum,* and wrote several minor philosophical works.

The major occupation of these years must have been the management of James, always with reference, remote or direct, to the royal finances. The King relied on his lord chancellor but did not always follow his advice. Bacon was longer sighted than his contemporaries and seems to have been aware of the constitutional problems that were to culminate in civil war; he dreaded innovation and did all he could, and perhaps more than he should, to safeguard the royal prerogative. Whether his policies were sound or not, it is evident that he was, as he later said, "no mountebank in the King's services."

Fall from power. By 1621 Bacon must have seemed impregnable, a favourite not by charm (though he was witty and had a dry sense of humour) but by sheer usefulness and loyalty to his sovereign; lavish in public expenditure (he was once the sole provider of a court masque); dignified in his affluence and liberal in his household; winning the attention of scholars abroad as the author of the *Novum Organum,* published in 1620, and the developer of the *Instauratio Magna* ("Great Instauration"), a comprehensive plan to reorganize the sciences and to restore man to that mastery over nature that he was conceived to have lost by the fall of Adam. But Bacon had his enemies. In 1618 he fell foul of George Villiers when he tried to interfere in the marriage of the daughter of his old enemy, Coke, and the younger brother of Villiers. Then, in 1621, two charges of bribery were raised against him before a committee of grievances over which he himself presided. The shock appears to have been twofold because Bacon,

Charges of bribery

who was casual about the incoming and outgoing of his wealth, was unaware of any vulnerability and was not mindful of the resentment of two men whose cases had gone against them in spite of gifts they had made with the intent of bribing the judge. The blow caught him when he was ill, and he pleaded for extra time to meet the charges, explaining that genuine illness, not cowardice, was the reason for his request. Meanwhile, the House of Lords collected another score of complaints. Bacon admitted the receipt of gifts but denied that they had ever affected his judgment; he made notes on cases and sought an audience with the King that was refused. Unable to defend himself by discriminating between the various charges or cross-examining witnesses, he settled for a penitent submission and resigned the seal of his office, hoping that this would suffice. The sentence was harsh, however, and included a fine of £40,000, imprisonment in the Tower of London during the King's pleasure, disablement from holding any state office, and exclusion from Parliament and the verge of court (an area of 12 miles radius centred on where the sovereign is resident). Bacon commented to Buckingham: "I acknowledge the sentence just, and for reformation's sake fit, *the justest Chancellor that hath been in the five changes since Sir Nicolas Bacon's time.*" The magnanimity and wit of the epigram sets his case against the prevailing standards.

Bacon did not have to stay long in the Tower, but he found the ban that cut him off from access to the library of Charles Cotton, an English man of letters, and from consultation with his physician more galling. He came up against an inimical lord treasurer, and his pension payments were delayed. He lost Buckingham's goodwill for a time and was put to the humiliating practice of roundabout approaches to other nobles and to Count Gondomar, the Spanish ambassador; remissions came only after vexations and disappointments. Despite all this his courage held, and the last years of his life were spent in work far more valuable to the world than anything he had accomplished in his high office. Cut off from other services, he offered his literary powers to provide the King with a digest of the laws, a history of Great Britain, and biographies of Tudor monarchs. He prepared memorandums on usury and on the prospects of a war with Spain; he expressed views on educational reforms; he even returned, as if by habit, to draft papers of advice to the King or to Buckingham and composed speeches he was never to deliver. Some of these projects were completed, and they did not exhaust his fertility. He wrote: "If I be left to myself I will graze and bear natural philosophy." Two out of a plan of six separate natural histories were composed—*Historia Ventorum* ("History of the Winds") appeared in 1622 and *Historia Vitae et Mortis* ("History of Life and Death") in the following year. Also in 1623 he published the *De Dignitate et Augmentis Scientiarum,* a Latin translation, with many additions, of the *Advancement of Learning.* He also corresponded with Italian thinkers and urged his works upon them. In 1625 a third and enlarged edition of his *Essayes* was published.

Profuse literary production of his last years

Bacon in adversity showed patience, unimpaired intellectual vigour, and fortitude. Physical deprivation distressed him but what hurt most was the loss of favour; it was not until Jan. 20, 1622/23, that he was admitted to kiss the King's hand; a full pardon never came. Finally, in March 1626, driving one day near Highgate (a district to the north of London) and deciding on impulse to discover whether snow would delay the process of putrefaction, he stopped his carriage, purchased a hen, and stuffed it with snow. He was seized with a sudden chill, which brought on bronchitis, and he died at the Earl of Arundel's house nearby on April 9, 1626. (K.M.L./A.M.Q.)

THOUGHT AND WRITINGS

The intellectual background. Bacon appears as an unusually original thinker for several reasons. In the first place he was writing, in the early 17th century, in something of a philosophical vacuum so far as England was concerned. The last great English philosopher, William of Ockham, had died in 1347, two and a half centuries before the *Advancement of Learning;* the last really important philosopher, John Wycliffe, had died not much later, in 1384.

The 15th century had been intellectually cautious and torpid, leavened only by the first small importations of Italian humanism by such cultivated dilettantes as Humphrey Plantagenet, duke of Gloucester, and John Tiptoft, earl of Worcester. The Christian Platonism of the Renaissance became more established at the start of the 16th century in the circle of Erasmus' English friends: the so-called Oxford Reformers—John Colet, William Grocyn, and Thomas More. But that initiative succumbed to the ecclesiastical frenzies of the age. Philosophy did not revive until Richard Hooker in the 1590s put forward his moderate Anglican version of Thomist rationalism in the form of a theory of the Elizabethan church settlement. This happened a few years before Bacon began to write.

In England three systems of thought prevailed in the late 16th century: Aristotelian Scholasticism, scholarly and aesthetic humanism, and occultism. Aristotelian orthodoxy had been reanimated in Roman Catholic Europe after the Council of Trent and the Counter-Reformation had lent authority to the massive output of the 16th-century Spanish theologian and philosopher Francisco Suárez. In England learning remained in general formally Aristotelian, even though some criticism of Aristotle's logic had reached Cambridge at the time Bacon was a student there in the mid-1570s. But such criticism sought simplicity for the sake of rhetorical effectiveness and not, as Bacon's critique was to do, in the interests of substantial, practically useful knowledge of nature.

Prevailing systems of thought in England

The Christian humanist tradition of Petrarch, Lorenzo Valla, and, more recently, of Erasmus was an active force. In contrast to orthodox asceticism, this tradition, in some aspects, inclined to glorify the world and its pleasures and to favour the beauty of art, language, and nature, while remaining comparatively indifferent to religious speculation. Attraction to the beauty of nature, however, if it did not cause was at any rate combined with neglect and disdain for the knowledge of nature. Educationally it fostered the sharp separation between the natural sciences and the humanities that has persisted ever since. Philosophically it was skeptical, nourishing itself, notably in the case of Montaigne, on the rediscovery in 1562 of Sextus Empiricus' comprehensive survey of the skepticism of Greek thought after Aristotle.

The third important current of thought in the world into which Bacon was born was that of occultism, or esotericism, that is, the pursuit of mystical analogies between man and the cosmos, or the search for magical powers over natural processes, as in alchemy and the concoction of elixirs and panaceas. Although its most famous exponent, Paracelsus, was German, occultism was well rooted in England, appealing as it did to the individualistic style of English credulity. Robert Fludd, the leading English occultist, was an approximate contemporary of Bacon. Bacon himself has often been held to have been some kind of occultist, and, even more questionably, to have been a member of the Rosicrucian order, but the sort of "natural magic" he espoused and advertised was altogether different from that of the esoteric philosophers.

There was a fourth mode of Renaissance thought outside England to which Bacon's thinking bore some affinity. Like that of the humanists it was inspired by Plato, at least to some extent, but by another part of his thought, namely its cosmology. This was the boldly systematic nature-philosophy of Nicholas of Cusa and of a number of Italians, in particular Bernardino Telesio, Francesco Patrizzi, Tommaso Campanella, and Giordano Bruno. Nicholas of Cusa and Bruno were highly speculative, but Telesio and, up to a point, Campanella affirmed the primacy of sense perception. In a way that Bacon was later to elaborate formally and systematically, they held knowledge of nature to be a matter of extrapolating from the findings of the senses. There is no allusion to these thinkers in Bacon's writings. But although he was less metaphysically adventurous than they were, he shared with them the conviction that the human mind is fitted for knowledge of nature and must derive it from observation, not from abstract reasoning.

Related Renaissance thought outside England

Bacon's scheme. Bacon drew up an ambitious plan for a comprehensive work that was to appear under the title of *Instauratio Magna* ("The Great Instauration"), but like many of his literary schemes, it was never completed. Its first part, *De Augmentis Scientiarum,* appeared in 1623 and is an expanded, Latinized version of his earlier work the *Advancement of Learning,* published in 1605 (the first really important philosophical book to be written in English). The *De Augmentis Scientiarum* contains a division of the sciences, a project that had not been embarked on to any great purpose since Aristotle and, in a smaller way, since the Stoics. The second part of Bacon's scheme, the *Novum Organum,* which had already appeared in 1620, gives "true directions concerning the interpretation of nature," in other words, an account of the correct method of acquiring natural knowledge. This is what Bacon believed to be his most important contribution and is the body of ideas with which his name is most closely associated. The fields of possible knowledge having been charted in *De Augmentis Scientiarum,* the proper method for their cultivation was set out in *Novum Organum.*

Instauratio Magna

Third, there is natural history, the register of matters of observed natural fact, which is the indispensable raw material for the inductive method. Bacon wrote "histories," in this sense, of the wind, of life and death, and of the dense and the rare, and, near the end of his life, he was working on his *Sylva Sylvarum: Or A Natural Historie* ("Forest of Forests"), in effect, a collection of collections, a somewhat uncritical miscellany.

Fourth, there is the "ladder of the intellect," consisting of thoroughly worked out examples of the Baconian method in application, the most successful one being the exemplary account in *Novum Organum* of how his inductive "tables" show heat to be a kind of motion of particles. Fifth, there are the "forerunners," or pieces of scientific knowledge arrived at by pre-Baconian, common sense methods. Sixth and finally, there is the new philosophy, or science itself, seen by Bacon as a task for later generations armed with his method, advancing into all the regions of possible discovery set out in the *Advancement of Learning.* The wonder is not so much that Bacon did not complete this immense design but that he got as far with it as he did.

The idols of the mind. In the first book of *Novum Organum* Bacon discusses the causes of human error in the pursuit of knowledge. Aristotle had discussed logical fallacies, commonly found in human reasoning, but Bacon was original in looking behind the forms of reasoning to underlying psychological causes. He invented the metaphor of "idol" to refer to such causes of human error.

Causes of human error

Bacon distinguishes four idols, or main varieties of proneness to error. The idols of the tribe are certain intellectual faults that are universal to mankind, or, at any rate, very common. One, for example, is a tendency toward oversimplification, that is, toward supposing, for the sake of tidiness, that there exists more order in a field of inquiry than there actually is. Another is a propensity to be overly influenced by particularly sudden or exciting occurrences that are in fact unrepresentative.

The idols of the cave are the intellectual peculiarities of individuals. One person may concentrate on the likenesses, another on the differences, between things. One may fasten on detail, another on the totality.

The idols of the marketplace are the kinds of error for which language is responsible. It has always been a distinguishing feature of English philosophy to emphasize the unreliable nature of language, which is seen, nominalistically, as a human improvisation. Nominalists argue that even if the power of speech is given by God, it was Adam who named the beasts and thereby gave that power its concrete realization. But language, like other human achievements, partakes of human imperfections. Bacon was particularly concerned with the superficiality of distinctions drawn in everyday language, by which things fundamentally different are classed together (whales and fishes as fish, for example) and things fundamentally similar are distinguished (ice, water, and steam). But he was also concerned, like later critics of language, with the capacity of words to embroil men in the discussion of the meaningless (as, for example, in discussions of the deity Fortune). This aspect of Bacon's thought has been almost as influential as his account of natural knowledge, inspiring a long tradition of skeptical rationalism, from the Enlightenment to Comtian positivism of the 19th and logical positivism of the 20th centuries.

The fourth and final group of idols is that of the idols of the theatre, that is to say mistaken systems of philosophy in the broadest, Baconian sense of the term, in which it embraces all beliefs of any degree of generality. Bacon's critical polemic in discussing the idols of the theatre is lively but not very penetrating philosophically. He speaks, for example, of the vain affectations of the humanists, but they were not a very apt subject for his criticism. Humanists were really anti-philosophers who not unreasonably turned their attention to nonphilosophical matters because of the apparent inability of philosophers to arrive at conclusions that were either generally agreed upon or useful. Bacon does have something to say about the skeptical philosophy to which humanists appealed when they felt the need for it. Insofar as skepticism involves doubts about deductive reasoning, he has no quarrel with it. Insofar as it is applied not to reason but to the ability of the senses to supply the reason with reliable premises to work from, he brushes it aside too easily.

Bacon's attack on Scholastic orthodoxy is surprisingly rhetorical. It may be that he supposed it to be already sufficiently discredited by its incurably contentious or disputatious character. In his view it was a largely verbal technique for the indefinite prolongation of inconclusive argument by the drawing of artificial distinctions. He has some awareness of the central weakness of Aristotelian science, namely its attempt to derive substantial conclusions from premises that are intuitively evident, and argues that the apparently obvious axioms are neither clear or indisputable. Perhaps Bacon's most fruitful disagreement with Scholasticism is his belief that natural knowledge is cumulative, a process of discovery, not of conservation. Living in a time when new worlds were being found on Earth, he was able to free himself from the view that everything men needed to know had already been revealed in the Bible or by Aristotle.

Bacon's criticism of Scholasticism

Against the fantastic learning of the occultists Bacon argued that individual reports are insufficient, especially since men are emotionally predisposed to credit the interestingly strange. Observations worthy to substantiate theories must be repeatable. Bacon defended the study of nature against those who considered it as either base or dangerous. He argued for a cooperative and methodical procedure and against individualism and intuition.

The classification of the sciences. Book II of the *Advancement of Learning* and Books II to IX of the *De Augmentis Scientiarum* contain an unprecedentedly thorough and detailed systematization of the whole range of human knowledge. Bacon begins with a distinction of three faculties—memory, imagination, and reason—to which are respectively assigned history, "poesy," and philosophy. History has an inclusive sense and means all knowledge of singular, individual matters of fact. "Poesy" is "feigned history" and not taken to be cognitive at all and so really irrelevant. After subdividing poesy perfunctorily into narrative, representative (or dramatic), and allusive (or parabolical) forms, Bacon gives it no further consideration.

History is divided into natural and civil, the civil category also including ecclesiastical and literary history (which for Bacon is really the history of ideas). History supplies the raw material for philosophy, in other words for the general knowledge that is inductively derived from it. Although Bacon proclaims the universal applicability of induction, he himself treats it almost exclusively as a means to natural knowledge and ignores its civil (or social) application.

Two further general distinctions should be mentioned. The first is between the divine and the secular. Most divine knowledge must come from revelation, and reason has nothing to do with it. There is such a thing as divine philosophy (what was later called rational, or natural, theology), but its sole task and competence is to prove that there is a God. The second, more pervasive distinction is between theoretical and practical disciplines, that is, between sciences proper and technologies, or "arts."

Bacon acknowledges something he calls first philosophy, which is secular but not confined to nature or to society. It is concerned with the principles, such as they are, that are common to all the sciences. Natural philosophy divides into natural science as theory on the one hand and the practical discipline of applying natural science's findings to "the relief of man's estate" on the other, which he misleadingly describes as natural magic. The former is "the inquisition of causes," the latter, "the production of effects."

To subdivide still further, natural science is made up of physics and metaphysics, as Bacon understands it. Physics, in his interpretation, is the science of observable correlations; metaphysics is the more theoretical science of the underlying structural factors that explains observable regularities. Each has its practical, or technological, partner; that of physics is mechanics, that of metaphysics, natural magic. It is to the latter that one must look for the real transformation of the human condition through scientific progress. Mechanics is just levers and pulleys.

The function of mathematics in science

Mathematics is seen by Bacon as an auxiliary to natural science. Many subsequent philosophers of science would agree, understanding it to be a logical means of expressing the content of scientific propositions or of extracting part of that content. But Bacon is not clear about how mathematics was to be of service to science and does not realize that the Galilean physics developing in his own lifetime was entirely mathematical in form. Although one of his three inductive tables is concerned with correlated variations in degree (while the others concern likenesses and differences in kind), he really has no conception of the role, already established in science, of exact numerical measurement.

Bacon is fairly cursory about "human philosophy." Four somewhat quaint sciences of body are sketched—medicine, cosmetic, athletic, and "the voluptuary arts." The sciences of mind—logic and ethics—are practical, consisting of sets of rules for the correct management of reasoning or conduct, with no suggested theoretical counterpart. Bacon is unreflectively conventional about moral truth, content to rely on the deliverances of the long historical sequence of moralists, undisturbed by their disagreements with one another.

Bacon represents civil philosophy in the same uninquiringly practical way. It comprises not only the art of government but also "conversation," or the art of persuasion, and "negotiation," or prudence, the topic of proverbs and, to a considerable extent, of his own *Essayes.*

In principle, Bacon is committed to the view that human beings and society are as well fitted for inductive, and, in 20th-century terms, scientific study as the natural world. Yet he depicts human and social studies as the field of nothing more refined than common sense. It was, of course, an achievement to extricate them from religion, and to do so without unnecessary provocation. But in his conception they remain practical arts with no sustaining body of scientific theory to ratify them. It was left to Thomas Hobbes, for a time Bacon's amanuensis, to develop complete systems of human and social science. Bacon's practice, however, was better than his program. In his writings on history and law he went beyond the commonplaces of chronicle and precedent and engaged in explanation and theory.

Novum Organum

The new method. The core of Bacon's philosophy of science is the account of inductive reasoning given in Book II of *Novum Organum.* The defect of all previous systems of beliefs about nature, he argued, lay in the inadequate treatment of the general propositions from which the deductions were made. Either they were the result of precipitate generalization from one or two cases, or they were uncritically assumed to be self-evident on the basis of their familiarity and general acceptance.

In order to avoid hasty generalization Bacon urges a technique of "gradual ascent," that is, the patient accumulation of well-founded generalizations of steadily increasing degrees of generality. This method would have the beneficial effect of loosening the hold on men's minds of ill-constructed everyday concepts that obliterate important differences and fail to register important similarities.

The crucial point, Bacon realized, is that induction must work by elimination not, as it does in common life and the defective scientific tradition, by simple enumeration. Thus he stressed "the greater force of the negative instance"—the fact that while "all A are B" is only very weakly confirmed by "this A is B," it is shown conclusively to be false by "this A is not B." He devised tables, or formal devices for the presentation of singular pieces of evidence, in order to facilitate the rapid discovery of false generalizations. What survives this eliminative screening, Bacon assumes, may be taken to be true.

Bacon's tables

Bacon presents tables of presence, of absence, and of degree. Tables of presence contain a collection of cases in which one specified property is found. They are then compared to each other to see what other properties are always present. Any property not present in just one case in such a collection cannot be a necessary condition of the property being investigated. Second, there are tables of absence, which list cases that are as alike as possible to the cases in the tables of presence except for the property under investigation. Any property that is found in the second case cannot be a sufficient condition of the original property. Finally, in tables of degree proportionate variations of two properties are compared to see if the proportion is maintained.

Bacon rightly showed some hesitation in arriving at the goal he had prescribed for himself, namely constructing a method that would yield general propositions about substantial matters of natural fact that were certain and beyond reasonable doubt. But he hesitated for an insufficient, secondary reason. The application of his tables to a mass of singular evidence, he said, would give only a "first vintage," a provisional approximation to the truth, because of the defects of natural history, that is to say, the defects inherent in the formulation of the evidence.

There are, however, more serious difficulties. An obvious one is that Bacon assumed both that every property natural science can investigate actually has some other property which is both its necessary and sufficient condition (a very strong version of determinism) and also that the conditioning property in each case is readily discoverable. What he had himself laid down as the task of metaphysics in his sense (theoretical natural science in 20th-century terms), namely the discovery of the hidden "forms" that explain what is observed, ensured that the tables could not serve for that task since they are confined to the perceptible accompaniments of what is to be explained. This point is implied by critics who have accused Bacon of failing to recognize the indispensable role of hypotheses in science. In general he adopted a naive and unreflective view about the nature of causes, ignoring their possible complexity and plurality (pointed out by John Stuart Mill) as well as the possibility that they could be at some distance in space and time from their effects.

Another weakness, not sufficiently emphasized, is Bacon's preoccupation with the static. The science that came to glorious maturity in his own century was concerned with change, and, in particular, with motion, as is the natural science of the 20th century. It was with this aspect of the natural world that mathematics, whose role Bacon did not see, came so fruitfully to grips.

In the end it may be that the conception of a scientific research establishment, which Bacon developed in his utopia, *The New Atlantis,* was a more important contribution to science than his theory of induction. Here the idea of science as a collaborative undertaking, conducted in an impersonally methodical fashion and animated by the intention to give material benefits to mankind, is set out with literary force.

Human philosophy. Although, as was pointed out above, Bacon's programmatic account of "human and civic philosophy" (*i.e.,* human and social science) treats it as a matter of practical art, or technique, his own ventures into history and jurisprudence, at any rate, were of a strongly theoretical cast. His *Historie of the Raigne of King Henry the Seventh* is explanatory, interpretative history, making sense of the King's policies by tracing them to his cautious, economical, and secretive character. Similarly his reflections on law, in *De Augmentis Scientiarum*

and in *Maxims of the Law* (Part I of *The Elements of the Common Lawes of England*), are genuine jurisprudence, not the type of commentary informed by precedent with which most jurists of his time were content. In politics Bacon was as anxious to detach the state from religion as he was to disentangle science from it—both concerns being indicative of very little positive enthusiasm for religion, despite the formal professions of profound respect convention extracted from him. He endorsed the Tudor monarchy and defended it against Coke's legal obstruction because it was rational and efficient. He had no patience with the inanities of divine right with which James I was infatuated. Bacon wrote little about education, but his memorable assault on the Scholastic obsession with words—an obsession largely carried over, if to different words, by the humanists—bore fruit in the educational theory of Comenius, who acknowledged Bacon's influence in his argument that children should study actual things as well as books.

Political views

Assessment and influence. Bacon's personality has usually been regarded as unattractive: he was cold-hearted, cringed to the powerful, and took bribes, and then had the impudence to say he had not been influenced by them. There is no reason to question this assessment in its fundamentals. It was a hard world for someone in his situation to cut a good figure in, and he did not try to do so. The grimly practical style of his personality is reflected in the particular service he was able to provide of showing a purely secular mind of the highest intellectual power at work. No one who wrote so well could have been insensitive to art. But no one before him had ever quite so uncompromisingly excluded art from the cognitive domain.

Bacon was a hero to Robert Hooke and Robert Boyle, founders of the Royal Society. Jean d'Alembert, classifying the sciences in the *Encyclopédie,* saluted him. Kant, rather surprisingly for one so concerned to limit science in order to make room for faith, dedicated the *Critique of Pure Reason* to him. He was attacked by Joseph de Maistre for setting man's miserable reason up against God but glorified by Auguste Comte.

It has been suggested that Bacon's thought received proper recognition only with 19th-century biology, which, unlike mathematical physics, really is Baconian in procedure. Darwin undoubtedly thought so. Bacon's belief that a new science could contribute to the relief of man's estate also had to await its time. In the 17th century the chief inventions that flowed from science were of instruments that enabled science to progress further. Today Bacon is best known among philosophers as the symbol of the idea, widely held to be mistaken, that science is inductive. Although there is more to his thought than that, it is, indeed, central; but even if it is wrong, it is as well to have it so boldly and magnificently presented. (A.M.Q.)

MAJOR WORKS

PHILOSOPHICAL WORKS: *The Twoo Bookes of Francis Bacon. Of the Proficience and Advancement of Learning Divine and Humane* (1605); *Instauratio Magna* (1620), also known as *Novum Organum; Historia Naturalis et Experimentalis ad Condendam Philosophiam: Sive Phaenomena Universi* (1622), also known as *Historia Ventorum; Historia Vitae & Mortis* (1623); *De Dignitate et Augmentis Scientiarum* (1623).

LITERARY AND HISTORICAL WORKS: *Essayes* (1597), 10 essays enlarged to 38 as *The Essaies of Sr Francis Bacon Knight* (1612), and to 58 as *The Essayes or Counsels, Civill and Morall* (1625); *Francisci Baconi De Sapientia Veterum Liber* (1609); *The Historie of the Raigne of King Henry the Seventh* (1622).

POLITICAL WORKS: *A Declaration of the Practices & Treasons Attempted and Committed by Robert, Late Earle of Essex* (1601); *Certain Considerations Touching the Better Pacification, and Edification of the Church of England* (1604); *Sir Francis Bacon His Apologie, in Certaine Imputations Concerning the Late Earle of Essex* (1604).

LEGAL WORKS: *The Elements of the Common Lawes of England* (1630); *Cases of Treason* (1641); *The Learned Reading of Sir Francis Bacon, One of Her Majesties Learned Counsell at Law, upon the Statute of Uses* (1642).

POSTHUMOUSLY PUBLISHED WORKS: *Sylva Sylvarum: Or A Naturall Historie* (1627, with the unfinished *The New Atlantis*).

The standard edition, containing most of Bacon's writings, is James Spedding, Robert Leslie Ellis, and Douglas Denon Heath (eds.), *The Works of Francis Bacon,* 14 vol. (1857–74), which also contains English translations of many of the works and learned commentaries. The purely philosophical works were extracted from this in John M. Robertson (ed.), *The Philosophical Works of Francis Bacon* (1905, reprinted 1970). Benjamin Farrington, *The Philosophy of Francis Bacon: An Essay on Its Development from 1603 to 1609* (1964, reprinted 1966), contains English translations of several of Bacon's lesser known essays that, nonetheless, shed important light on his philosophy. A comprehensive, critical edition of Bacon's essays is Michael Kiernan (ed.), *The Essayes or Counsels, Civill and Morall* (1985).

BIBLIOGRAPHY. JAMES SPEDDING, *An Account of the Life and Times of Francis Bacon,* 2 vol. (1878, reprinted 1880), is a comprehensive biography based on the second half of the above-mentioned *Works of Francis Bacon,* titled *The Letters and the Life of Francis Bacon,* 7 vol. (1861–74). Spedding also produced *Evenings with a Reviewer: or, A Free and Particular Examination of Mr. Macaulay's Article on Lord Bacon: In a Series of Dialogues,* 2 vol. (1848, reissued 1881 as *Evenings with a Reviewer; or, Macaulay and Bacon*), which is a detailed and illuminating rebuttal of a famous attack made on the moral character of Bacon. There is a valuable section devoted to Bacon in JOHN AUBREY, *Brief Lives,* ed. by OLIVER LAWSON DICK (1949, reissued 1982). Also valuable is a memoir by Bacon's chaplain, WILLIAM RAWLEY, "The Life of the Right Honourable Francis Bacon, Baron of Verulam, Viscount St. Alban," which can be found in vol. 1 of the Spedding, Ellis, and Heath edition of *The Works of Francis Bacon* mentioned above. Other more recent works include FULTON H. ANDERSON, *Francis Bacon: His Career and His Thought* (1962, reprinted 1978); and JOEL J. EPSTEIN, *Francis Bacon: A Political Biography* (1977), a survey of his public career.

Critical studies (philosophy): THOMAS FOWLER, *Bacon* (1881); C.D. BROAD, *The Philosophy of Francis Bacon* (1926, reprinted 1976), an excellent lecture; FULTON H. ANDERSON, *The Philosophy of Francis Bacon* (1948, reissued 1971), a major, influential study; BENJAMIN FARRINGTON, *Francis Bacon: Philosopher of Industrial Science* (1949, reprinted 1979), which interprets Bacon's aims as primarily practical and industrial; LISA JARDINE, *Francis Bacon: Discovery and the Art of Discourse* (1974), an attempt to unify Bacon's method in scientific, political, and literary areas; ANTHONY QUINTON, *Francis Bacon* (1980), a short and readable exposition of Bacon's philosophy; PETER URBACH, *Francis Bacon's Philosophy of Science: An Account and a Reappraisal* (1987); RICHARD FOSTER JONES, *Ancients and Moderns,* 2nd ed. (1961, reprinted 1982), a study of the rise of the scientific movement in 17th-century England, seen largely as a movement inspired by Bacon's writings; MARY B. HESSE, "Francis Bacon," in D.J. O'CONNOR (ed.), *A Critical History of Western Philosophy* (1964, reissued 1985), pp. 141–153, an excellent and influential article on Bacon's scientific method; MARY HORTON, "In Defence of Francis Bacon: A Criticism of the Critics of the Inductive Method," *Studies in History and Philosophy of Science,* 4(2):241–278 (August 1973), a good exposition of some of Bacon's experimental principles; JOSHUA C. GREGORY, "Chemistry and Alchemy in the Natural Philosophy of Sir Francis Bacon, 1561–1626," *Ambix,* 2(2):93–111 (September 1938), a good account of some of Bacon's cosmological views; DOUGLAS BUSH, *English Literature in the Earlier Seventeenth Century, 1600–1660,* 2nd ed. rev. (1962, reprinted 1976), which contains a good critique of Bacon's historical, political, and legal writings; and ROBERT LESLIE ELLIS, "General Preface to Bacon's Philosophical Works," in vol. 1 of the Spedding, Ellis, and Heath edition of *The Works of Francis Bacon,* a notable and influential interpretation of Bacon's philosophy. For further research, consult REGINALD WALTER GIBSON, *Francis Bacon: A Bibliography of His Works and Baconiana to the Year 1750* (1950), and *Francis Bacon: Supplement* (1959).

Miscellaneous critical studies: CHARLES W. LEMMI, *The Classic Deities in Bacon: A Study in Mythological Symbolism* (1933, reprinted 1978), an important study of *De Sapientia Veterum.* See also GEOFFREY BULLOUGH, "Bacon and the Defense of Learning," pp.1–20, and RUDOLPH METZ, "Bacon's Part in the Intellectual Movement of His Time," pp. 21–32, both essays in *Seventeenth Century Studies Presented to Sir Herbert Grierson* (1938, reprinted 1967); KARL R. WALLACE, *Francis Bacon on Communication & Rhetoric; or, The Art of Applying Reason to Imagination for the Better Moving of the Will* (1943); VIRGIL K. WHITAKER, *Francis Bacon's Intellectual Milieu* (1962); BRIAN VICKERS, *Francis Bacon and Renaissance Prose* (1968); JAMES STEPHENS, *Francis Bacon and the Style of Science* (1975), a study of his rhetorical methods of communicating scientific knowledge; and BRIAN VICKERS (comp.), *Essential Articles for the Study of Francis Bacon* (1968).

(K.M.L./P.M.U.)

Bacteria

Bacteria are microscopic organisms present in almost all natural environments, often in extremely large numbers: billions in a gram of rich garden soil and millions in one drop of saliva. They constitute the class Schizomycetes, of the division Schizomycophyta. The influence of bacteria in the biosphere is incalculable. Without them, the soil would not be fertile and thus could not sustain plants, on which animals ultimately depend for food. Although some bacteria cause disease, most species are benign, and many are involved in processes of direct benefit to man. For the history and methodology of the study of bacteria, see BIOLOGICAL SCIENCES: *Microbiology.* See also DISEASE and INFECTIOUS DISEASES for coverage of bacterial diseases.

This article is divided into the following sections:

GENERAL FEATURES

Diversity of structure. Bacteria are unicellular microorganisms, among the smallest living creatures known (only the related rickettsias and the viruses are smaller). One of the periods on this page would cover about 250,000 average-sized bacteria, which are measured in microns (one micron, μ, equals $^1/_{1,000}$ millimetre, or $^1/_{25,000}$ inch). There are three bacterial cell types on the basis of shape (see Figure 1): spherical (coccus), rodlike (bacillus), and spiral (spirillum). Each type retains its character under standard conditions of laboratory cultivation but may show changes in appearance under different environments. When conditions are favourable, bacteria grow rapidly (some can reproduce every 15 minutes), forming visible colonies on culture plates in the laboratory. The colonies are distinctive in colour, shape, and texture for certain species and in some cases for the different varieties, or strains, within a single species.

Cell shapes

Distribution and abundance. Bacteria are ubiquitous, occurring in virtually every conceivable environment: from polar ice to hot springs; from mountain tops to the ocean deeps; from plant and animal bodies to forest soils. Most bacteria are active in environments in which the temperature is above 5° C (about 40° F); some marine and soil types are exceptional in being active at temperatures near or slightly below 0° C (32° F). The upper limit is around 30° C (86° F) for soil bacteria and 37° C (99° F) for animal parasites; the maximum temperature, above which growth does not occur, is about 70° C (160° F). Beyond these limits bacteria become inactive. Some survive in a dormant (or spore) state, reviving when conditions become more favourable. This capability has allowed bacteria to become perhaps the most widespread organisms on Earth.

Ecological significance

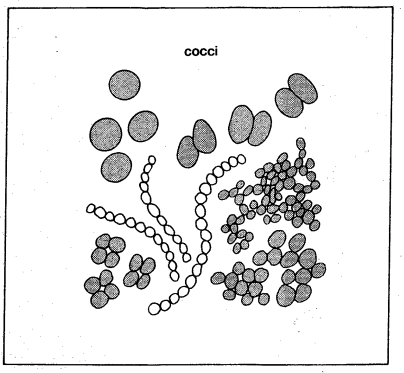
Importance. Bacteria are instrumental in performing numerous critical biochemical transformations of substances in nature, changing them from complex to simple compounds that can be used by plants, man, and other animals. Bacteria in the rumen (largest compartment of the stomach) of the cow digest the cellulose in grasses and animal feed, thus making this matter available as a nutrient for the animal. The organic waste substances in sewage are degraded by bacteria and transformed into compounds that are suitable nutrients for plant growth. In fact, all of the remains of animals and plants are eventually converted to soil through the activities of bacteria and other microorganisms and thus made available again to growing plants.

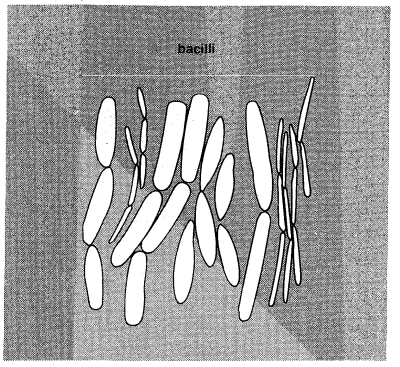
It can be assumed—until evidence disproves it—that any naturally occurring substance can be degraded (metabolized) by some species of bacteria. In some instances, these biochemical transformations are judged by man to be beneficial: as when *Streptomyces griseus* produces the antibiotic streptomycin as a by-product of its metabolism; or when certain strains of bacteria produce cheese and other dairy products by metabolizing constituents of milk; or when certain nitrogen-accumulating bacteria add needed nitrogen to the soil. Other transformations, however, may be detrimental to man's interests, as when *Clostridium botulinum* excretes a toxin responsible for botulism (a type of food poisoning), or when certain strains of bacteria excrete substances that cause disease. Less detrimental are the effects of bacterial deterioration: spoilage of food, corrosion of metals, decay of wood, and other undesirable alterations of substances. Certain strains of bacteria that can attack and partially decompose oil, tar, and related petroleum products may someday be useful as controls for these potential pollutants.

Higher animals, including man, live in constant intimacy with large numbers and a great variety of bacteria. The oral cavities, intestinal tracts, and skin are inhabited by bacteria that, under normal circumstances, create no problems (Figure 2). There are occasions, however, when bacteria break through the normal body barriers and cause an infection. Certain bacteria are more prone to this behaviour than others and are called pathogens, or disease producers (Figure 2). Some pathogens have an affinity for specific parts of the body: meningococcal bacteria infect the meninges, or brain membranes; tubercle bacteria invade the lungs; and diphtheria-causing bacteria establish themselves in the throat. Other bacterial pathogens exhibit less specificity: staphylococcal bacteria, for example, may infect the skin, causing boils or furuncles; the bloodstream, causing septicemia (blood poisoning); or the bones, establishing a condition known as osteomyelitis.

In some cases the biochemical transformations of bacteria are actually exploited industrially to convert raw materials into products that are economically valuable. When the substance is abundant and cheap and the product is valuable and in demand, a bacterial industrial process is likely to be established. Selected examples of products manufactured on an industrial scale through the utilization of bacteria are shown in Table 1. Other industrial processes are developed by man to combat the deterioration of materials by microorganisms (see FOOD PROCESSING).

Bacteria represent a form of life that can be conveniently studied under laboratory conditions. Furthermore, and more importantly, many of the biological processes that take place in the bacterial cell are closely related, if not





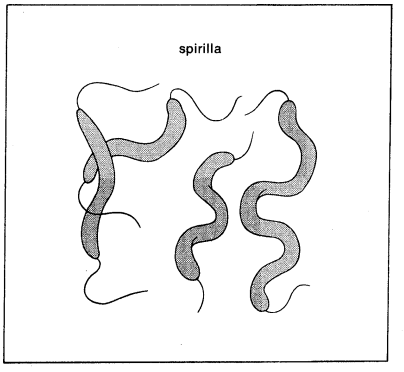


Figure 1: The three major bacterial cell types.

Bacteria as experimental subjects

identical, to processes that take place in higher organisms, including man. Thus, the bacterial cell provides an extremely useful model for the study of intricate biological, physiological, and biochemical processes. Indeed, much of the knowledge that has been acquired since the end of World War II in biochemical genetics, enzymes, and the synthesis of vitamins and their functions has resulted from investigations of bacteria.

NATURAL HISTORY

In view of the widespread occurrence of bacteria, it is not surprising that measures are taken by man to reduce or control their numbers in habitats that are exploited for human welfare. In the following sections, therefore, emphasis is on those particular environments of bacteria that impinge on man's needs.

Growth and reproduction. The life cycle of bacteria involves growth and reproduction, as in other organisms; certain features, however, are unique to microorganisms.

The term growth, in the microbiological sense, refers to increase in a given population rather than to increase in the size of an individual microorganism, or bacterium, in this context. There are, to be sure, changes in the size of an individual bacterial cell at certain stages of the multiplication process, as is shown below.

Generation time

Reproduction. Bacteria characteristically reproduce by an asexual process called binary fission, in which one cell divides into two new cells (Figure 3). A single bacterial cell, under optimum physical conditions for growth, performs metabolic functions including synthesis of intracellular substances. The cell elongates, and the cell wall becomes pinched in at the midpoint: finally, a transverse cell wall separates the parent cell into two new cells (daughter cells) that separate, and the process commences again. The reproduction and multiplication process is by geometric progression: one cell forms two, two cells form four, four form eight, eight form 16, 16 form 32, and so forth. The time required for the populations to double—*i.e.*, for one cell to divide in two—is the generation time (G); it can be calculated from the following formula:

$$G = \frac{t}{n} = \frac{t}{3.3 \log b/B}.$$

In the formula, B is the number of bacteria at the start of the investigation; b is the number of bacteria at the end of the time period; t is the time period; and n is the number of generations. The experimental data—that is, the values for B, b, and t—must be obtained during the period of the total growth cycle known as the log phase of growth (described below). The generation times of bacterial species vary over a wide range. *Escherichia coli,* one of the most rapidly growing bacteria, has a generation time of approximately 15 minutes; *Mycobacterium tuberculosis,* a slow-growing bacterium, can have a generation time as long as 16 hours.

Although binary fission is the characteristic and typical mode of reproduction for the true bacteria (order Eubacteriales), among some bacterial species, particularly those of the higher orders of bacteria, other processes of reproduction occur. *Rhodomicrobium vannielii* (order Hyphomicrobiales), for example, exhibits a budding type of reproduction; *Streptomyces* (order Actinomycetales) species produce chains of spores; *Mycoplasma* (order Mycoplasmatales) reproduce by the segmentation of elementary units within a body surrounded by a membrane.

Sexual reproduction

There are also instances of sexual reproduction (conjugation) among bacterial species. It occurs at low frequency among bacteria found in the intestine (enteric, or coliform, bacteria—*Escherichia, Shigella,* and *Salmonella*). In this process, conjugal pairs, or mating types, of bacteria make transient physical contact. Conjugal pairs consist of a donor (male) and a recipient (female) cell. In conjugation, a piece of chromosome from the donor cell is transferred into the recipient cell, in which it becomes a part of the recipient's chromosome. This is one way by which genetic material is exchanged in bacteria.

The bacterial growth curve. When bacterial cells are placed in a medium providing all of the nutrients necessary for growth (growth medium), the population increases according to a pattern identified as the bacterial growth curve (Figure 4). The four stages are the lag phase, log phase, stationary phase, and decline phase.

After their introduction into a medium, bacterial cells do not immediately reproduce according to their characteristic generation time; instead, the population remains constant for a period longer than the generation time. During

Table 1: Examples of Compounds Produced by Bacteria on an Industrial Scale

product	bacterium	substrate
Lactic acid	*Lactobacillus delbrueckii*	acid-hydrolyzed cornstarch, or whey, plus nutrient and $CaCO_3$
Bacterial amylase	*Bacillus subtilis*	vegetable protein plus sugar for surface cultivation; starch, cereal, grain, and protein for subsurface cultivation
Bacterial protease	*B. subtilis*	protein, carbohydrate, salts
Dextran	*Leuconostoc mesenteroides*	sucrose plus nutrients
Cobalamin (vitamin B_{12})	*Streptomyces olivaceus*	distiller's solubles, dextrose, $CaCO_3$
	Propionibacterium freudenreichii	$CoCl_2$
Vinegar	*Acetobacter* species	alcohol
Streptomycin	*Streptomyces griseus*	hydrolyzed protein and sugar
Monosodium glutamate	*Micrococcus* species	sugar

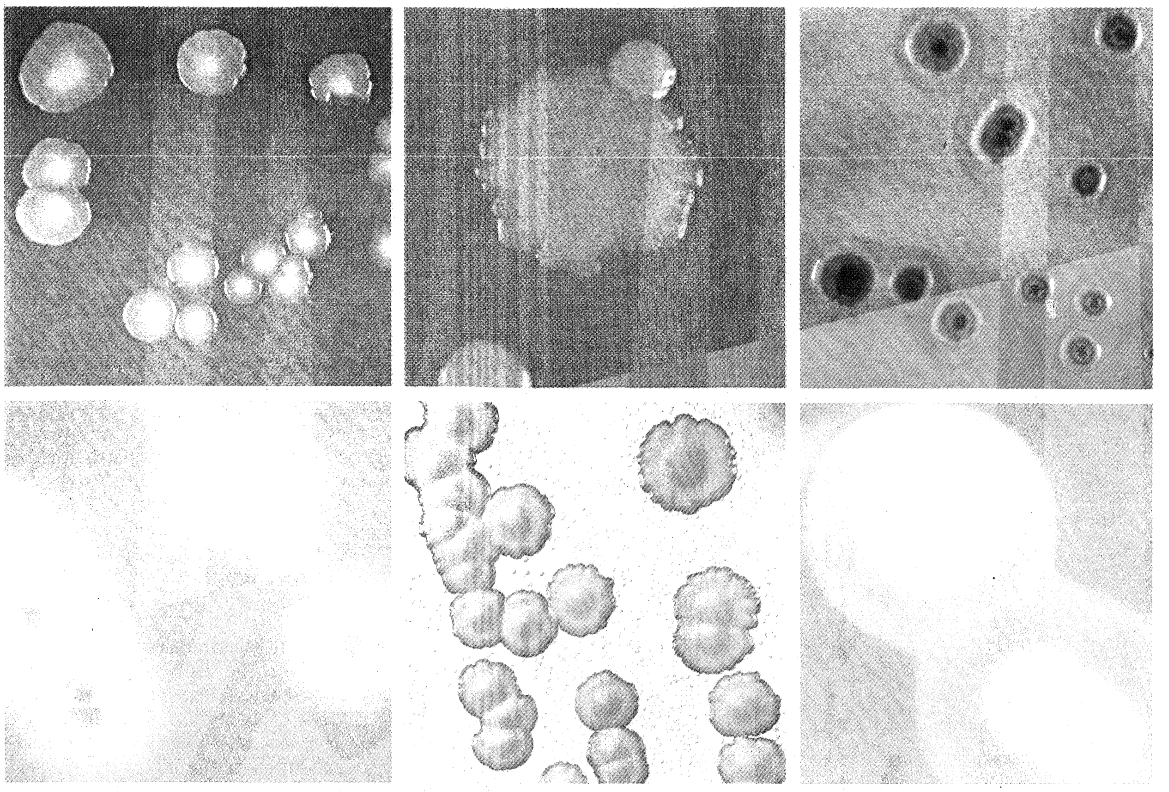

Figure 2: *Typical body flora (top row) and bacteria from infections (bottom row).* (Top left) *Neisseria flava* from the human nasal passage (magnified about 7 ×). (Top centre) Aerobic *Lactobacillus* (large colony) and *Staphylococcus albus* (small colony) from the human vagina (magnified 11 ×). (Top right) *Escherichia coli,* grown on eosin methylene blue dye, from a normal stool (magnified about 7 ×). (Bottom left) Colonies of beta-hemolytic streptococci on blood agar show zones cleared of blood cells surrounding each colony; these bacteria were isolated from the sore throat of a child who later developed rheumatic fever (magnified about 19 ×). (Bottom centre) *Hemophilus influenzae* (small colonies) isolated from a child suffering from spinal meningitis. Position of the *H. influenzae* colonies around larger *Staphylococcus* colonies, which provide a factor necessary for their growth, illustrates the "satellite phenomenon" (magnified about 14 ×). (Bottom right) *Clostridium perfringens,* isolated from infected human gallbladder, as grown under strict anaerobic conditions on blood agar. Zones of complete and partial clearing are characteristic of this species of *Clostridium* (magnified 8.5 ×).

A.W. Rakosy—EB Inc.

this period individual cells actively metabolize (synthesize new cytoplasmic material) and increase in size. After the cells have undergone a rigorous physiological adjustment to the new medium, they divide.

The first cell division initiates the log phase, during which repeated division occurs at a rate consistent with the generation time. Theoretically, this stage describes a logarithmic progression, the population doubling with each new generation of cells. In theory, also, all cells grow at the same rate and reproduce at the same time. This synchronous growth period eventually terminates as cells phase out of the regular reproduction pattern, and some actually die.

Under optimum conditions, in terms of the nutrients available and the physical environment, the maximum viable population is attained at the end of the log phase, with some vigorous bacterial species achieving a density of 10,000,000,000 cells per millilitre.

For a period of time, the length of which depends on the species, the population is stationary. Among the factors responsible for this levelling off of the population are the following, which generally occur in some combination: production of inhibitory substances, depletion of nutrients, and death of cells.

The stationary phase terminates as the death rate of the population exceeds that of formation of new cells. The population steadily decreases until, eventually, all of the cells die.

The coliform bacteria

Ecology. *Bacteria in water.* Good quality drinking water contains very few bacteria per millilitre and no coliform bacteria. The coliform bacteria, including *Escherichia coli* and *Aerobacter aerogenes,* are found in the intestinal tract of man and other animals. Their presence in water indicates that the water has been polluted with fecal material and hence may contain pathogens. The usual procedures employed in municipal water-purification plants—settling, filtration, and chlorination—are designed to remove or destroy these and other microorganisms.

Sewage, defined as the used water supply of a community, contains wastes produced by domestic and industrial sources. Bacteria in sewage are of importance for two reasons. First, as pollutants: human excrement in sewage may contain pathogenic bacteria, which, if not removed or killed, may enter domestic water sources or supplies (Figure 5). Second, as cleansers: the treatment of sewage, particularly the breakdown (dissimilation) of organic material (*e.g.,* proteins, carbohydrates, and fats) requires the activity of certain types of bacteria. Sewage treatment facilities, including residential septic tanks, municipal sludge digesters, activated sludge digesters, and trickling filter and sand filter processes, are all designed to utilize bacteria to break down organic matter in sewage.

The breakdown of organic matter, however, imposes a biochemical oxygen demand (BOD) on the environment into which sewage is dumped (*e.g.,* a body of water). The greater the amount of organic matter, the greater is the amount of oxygen required for its oxidation and, hence, the greater the BOD. This process can be very disruptive to aquatic life in natural streams and lakes. One of the objectives in sewage treatment is to oxidize organic matter as completely as possible and thereby reduce the BOD prior to the discharge of the sewage (effluent) into natural bodies of water. Sewage digestion tanks and aeration devices are designed to exploit the metabolic capacity of bacteria to accomplish this objective.

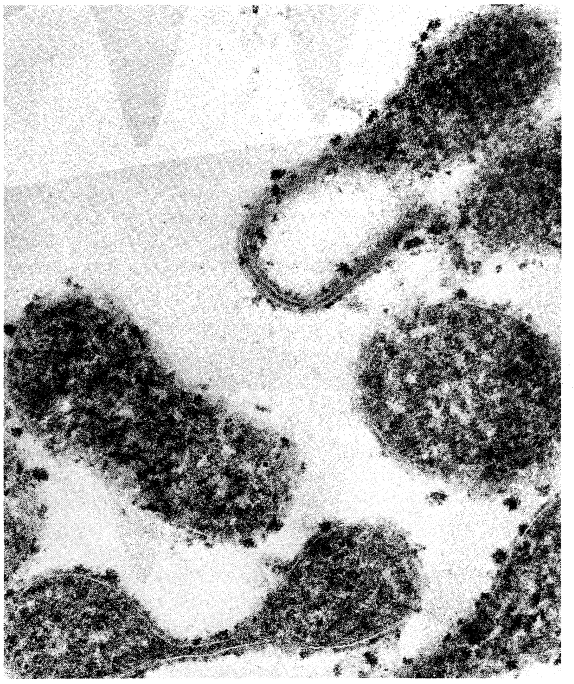

Figure 3: *An electron micrograph of cells of Mycoplasma hominis in several stages of reproduction.*

From Jack Maniloff, "Electron Microscopy of Small Cells: *Mycoplasma hominis*," *Journal of Bacteriology* (December 1969)

The microbial population of the sea consists of bacteria, algae, protozoans, and fungi. Bacteria of all physiological and metabolic types inhabit the various regions, extending from the surface layer of the sea to the bottom mud. They are responsible for transformations of both organic and inorganic compounds that serve as nutrients for marine life. The dissimilation of organic compounds, under aerobic (oxygenated) conditions, yields ammonia, carbon dioxide, and sulfate and phosphate salts. These products serve as the nutrients for algae and other planktonic life, which, in turn, synthesize organic compounds that may eventually serve as food for mollusks and fishes.

Bacteria in air. Air contains bacteria and other microorganisms that are suspended and circulated for varying periods of time, depending upon atmospheric conditions and the size of the particles that carry the microorganisms.

Extremes of bacterial concentration

Generalizations about the microbial component of air can be made only with reference to a particular environment and the circumstances that prevail at a given time: for example, a hospital ward during bed-making time (agitation of bed linens and movements of personnel stir dust that may bear large numbers of bacteria into the air); a city street following a heavy rain (the air is washed and relatively free from bacteria). Air at an altitude of 10,000 feet (3,000 metres) usually has relatively few dust particles and, therefore, considerably fewer bacteria than are common in air at lower altitudes.

Tremendous numbers of bacteria are ejected into the atmosphere by a sneeze or cough. They remain suspended in air on particles referred to as droplet nuclei, which may consist of a single bacterium—in which case the particle remains airborne for a long period of time. When the particles consist of aggregates of bacteria coated with mucus or affixed to other cells, they settle out on surfaces in a short time. Airborne bacteria from the respiratory tract of man are potentially hazardous; they include *Mycobacterium tuberculosis,* which causes tuberculosis; *Neisseria meningitidis,* which causes meningitis; *Streptococcus pyogenes,* which causes strep infections; and *Diplococcus pneumoniae,* which causes pneumonia.

Bacteria occur on plant surfaces and will grow if conditions are favourable. They also invade and infect plant tissues, from which they are dispersed periodically into the atmosphere. Soil, particularly rich garden soil, contains countless bacteria per gram; soil dust dispersed into the air contributes a multitude of bacteria and resistant bodies formed by them (spores).

Airborne bacteria, as already mentioned, are important in the dissemination of diseases of man, of other animals, and of plants. They are also important as the source of contamination of many materials—*e.g.,* pharmaceutical preparations, surgical devices, and foods—thus necessitating precautionary procedures when "bacteria-free" conditions are desired (see below *Control*).

Bacteria in soil. Soil bacteria are extremely active in effecting biochemical changes in soil, which is the repository of the remains of plant and animal life; through microbial attack, materials are eventually transformed into the very substances that characterize soil—humus and minerals.

It is customary to view the chemical changes performed by bacteria in the soil as cyclic processes of the various elements; *e.g.,* the nitrogen, carbon, and sulfur cycles. At some stage of each cycle the element exists in its elemental form; *i.e.,* uncombined with any other elements. Certain species of bacteria are capable of converting the element into an inorganic compound that can be utilized as a plant nutrient and thereby transformed into an organic compound. The plant is consumed by animals, and the organic compound is incorporated into animal tissue. Eventually, animal and plant tissues return to the soil, where bacteria decompose them and thereby again release the elements as well as other products (see BIOSPHERE).

Nitrogen fixers

The nitrogen cycle serves to illustrate the role of bacteria in performing various chemical changes. Nitrogen fixation, one of the key transformations in the nitrogen cycle, is performed by bacteria of several physiological types. Nitrogen-fixing bacteria are capable of transforming raw nitrogen into a form suitable for use by plants. They live in intimate association with a leguminous plant, in which case they are designated symbiotic nitrogen fixers; this type lives within lumps (nodules) on the plant's root system. Species of bacteria that can fix nitrogen in soil that is free from the plant-root system are referred to as nonsymbiotic

A.W. Rakosy—EB Inc.

nitrogen fixers. The best known genera are *Azotobacter* and *Clostridium,* although many others are now known to be capable of nonsymbiotic nitrogen fixation.

Bacteria in food. Milk drawn from a healthy cow contains relatively few bacteria per millilitre, but it is not sterile (free of living bacteria). Furthermore, procedures for handling the milk may add additional bacteria through contamination. Because milk is an excellent medium for the growth of bacteria, an initial small population (inoculum) can increase rapidly if the milk is not properly processed. Bacteria may merely cause spoilage or may present a serious health hazard if they are pathogenic. Bacterial pathogens transmitted through milk may originate in the cow or in man. A cow infected with the tubercle bacillus may transmit this organism, through milk, to man. Brucellosis, or undulant fever, also can be transmitted from cows to man via milk. Alternatively, an infected milk handler can contaminate the milk; outbreaks of typhoid fever, scarlet fever, and diphtheria have been known to occur in this fashion. Proper treatment of milk by the process of pasteurization—either the low-temperature, holding method (63° C [145° F] for 30 minutes) or the high-temperature, shorttime method (72° C [161° F] for 15 seconds)—destroys all pathogens.

Bacterial conversion of milk

On the credit side, however, selected species and strains of bacteria convert milk and casein (milk protein) into such desirable products as buttermilk, yogurt, and cheese. Commercial cultured buttermilk is prepared from skim milk that has been inoculated with a starter culture and allowed to incubate until the desired changes occur. The starter culture consists of *Streptococcus lactis* or *Streptococcus cremoris,* together with *Leuconostoc citrovorum* or *Leuconostoc dextranicum.* Yogurt and other fermented milk products are produced in a similar manner but through the activities of different selected cultures of bacteria.

The formation of cheeses is likewise dependent upon the activity of microorganisms. The curd from which cheese is made is precipitated (made to settle out) from milk by an acid-producing bacterium, such as *Streptococcus lactis.* Following removal of moisture and the addition of salt, the curd is allowed to ripen by the action of selected bacteria. Lactobacilli, streptococci, and propionibacteria are important for the ripening of Swiss cheese; *Brevibacterium linens* is responsible for the flavour of Limburger cheese; and molds (*Penicillium* species) are used in the manufacture of Roquefort and Camembert cheeses.

Bacteria in nondairy foods are as significant as those in milk and dairy products. The variety of bacteria that contaminate foods and the diversity of foods can result in a wide array of types of food spoilage. When allowed to grow in food, certain bacteria can cause food poisoning; they secrete a toxin that, when ingested by humans, can cause either a severe gastrointestinal upset—as in *Staphylococcus aureus* food poisoning—or death—as in botulism (caused by the toxin of *Clostridium botulinum*). It follows that one of the major concerns of food microbiology is the development and assessment of techniques to preserve foods from spoilage and contamination.

Food may be the carrier of pathogenic bacteria and thus be responsible for food-borne infections, among which the more frequently occurring are typhoid fever (*Salmonella typhosa*); salmonellosis (*Salmonella* species other than *S. typhosa*); and shigellosis, or dysentery (*Shigella dysenteriae*).

Notwithstanding the detrimental effects of food contamination, other bacterial populations are responsible for a variety of special foods, produced through bacterial fermentation; these include pickles and other pickled products, sauerkraut, and olives.

Degrees of control

Control. Many materials and products, as well as certain environmental areas, require either the reduction or destruction of microbial populations. In a hospital operating room, for example, procedures are observed that reduce the microbial contents of the air to a very low level; on the other hand, the glucose solution used for intravenous injection is processed to be sterile—absolutely free of any form of life.

Physical and chemical means are available to accomplish sterilization. The method of choice depends upon several considerations, not the least of which is the effect of the sterilizing procedure on the object being sterilized. If the material being sterilized is to be discarded following sterilization, such as used bacteriological media from a laboratory, then there is no problem except effectiveness of the sterilization procedure; however, if the material to be sterilized is a vitamin solution, for example, the procedure must be effective enough to sterilize without affecting the quality of the vitamin product.

Heat. High temperature, applied in a variety of ways, is one of the most effective sterilizing agents. Heat may be applied in the form of incineration, steam under pressure (autoclave), or dry heat (hot-air oven).

Incineration procedures range from the passing of an object through a bunsen burner flame in the laboratory to the burning of infected animal carcasses or contaminated bedding in large furnaces.

Steam under pressure, which is the principle of operation of the autoclave (an elaborate pressure cooker), is perhaps the most widely used sterilization procedure. The autoclave is a standard item of equipment in laboratories, hospitals, industries involved in food processing, and enterprises concerned with sterilization procedures and the manufacture of sterile products.

Dry heat, as in hot-air ovens, also accomplishes sterilization, but, in contrast to steam heat, higher temperatures and longer exposure times are required. Equipment that can be sterilized in an autoclave at 121° C (250° F) within ten to 15 minutes requires 160° C (320° F) for a period of two hours in a hot-air oven. Hot-air sterilization is used

for materials that might be adversely affected by moist heat or that should not be directly exposed to moist heat because of necessary packaging.

The heat afforded by boiling water and pasteurization processes markedly reduces the bacterial flora but does not truly sterilize. Pasteurization, as previously mentioned, is designed to kill only the serious pathogens that might occur in milk; some bacteria and, in particular, bacterial spores are not killed. Similarly, boiling water kills the vegetative (active) bacterial cells but not necessarily the spores.

Anti-bacterial action of ultra-violet radiation

Radiation. Ultraviolet radiation (in the 2650-angstrom region [one angstrom = 10^{-8} centimetre]) is extremely bactericidal; that is, capable of killing bacteria. When properly used—namely, under conditions that allow direct exposure of organisms to the radiation—the microbial population can be effectively reduced. Ultraviolet rays, however, have a very low order of penetration; a thin film of glass filters out most of the rays.

Gamma radiations, which are emitted from radioactive isotopes, have great penetrating power as well as a high lethal effect. This combination of characteristics—high penetration and high bactericidal activity—makes them extremely effective as sterilizing agents. But several technical problems are associated with practical applications of gamma radiations: the development of an adequate supply of radiation sources and the availability of equipment designed to guarantee safety to its operators.

Certain materials cannot be exposed to physical agents without being adversely altered in some manner. Many medicines, including antibiotics, and other biological solutions may be destroyed or inactivated by any of the methods described so far. In such cases filtration is the appropriate method for sterilization. A wide variety of filters are available that are porous enough to allow fluids to pass through but not microorganisms.

Ethylene oxide as a sterilizing agent

Chemicals. Sterilization can also be accomplished with such chemicals as the gas ethylene oxide. With the appropriate concentration, humidity, and temperature, ethylene oxide is a powerful sterilizing agent. In addition, it has the ability to penetrate considerably through materials. Ethylene oxide is widely used for the sterilization of many materials, including plastic devices, that could not undergo the other procedures.

Many chemicals for the control of microorganisms are available for application to environmental surfaces or materials; they are not intended to effect sterilization, but they do reduce the microbial population or eliminate certain types of microorganisms. These chemical agents are variously termed antiseptics, germicides, disinfectants, and sanitizers on the basis of their action.

FORM AND FUNCTION

In normal environments bacteria exist not only in large numbers but also in great diversity. In order to understand the characteristics of the individual species comprising these mixed populations, it is necessary to study each species as a pure culture, by isolating bacterial cells from colonies on a specific nutrient referred to as the medium. This isolation from the colony can be maintained as a pure culture by periodic transfer to fresh medium. Alternatively, a pure culture can be lyophilized (dried while frozen and sealed under vacuum) and kept viable (capable of dividing) in this condition for many years. Characterization of a pure culture requires a study of cell morphology, cultural and physiological characteristics, biochemical (or metabolic) processes, antigenic characteristics, and pathogenicity.

Morphological features. *The bacterial cell.* The typical cell of a species of Eubacteriales, or "true" bacteria, is a bacillus approximately one micron in diameter and a few microns in length. Coccoid cells may occur in characteristic arrangements: *e.g., Diplococcus pneumoniae* occurs in pairs; *Staphylococcus aureus* occurs in grapelike clusters; *Streptococcus pyogenes* occurs in chains; *Sarcina lutea* occurs as a cuboidal arrangement of cells; and *Micrococcus tetragenus,* as the name suggests, occurs in tetrads, or groups of four cells.

In contrast to the true bacteria are the "higher" bacteria, whose appearance suggests some primitive or abortive attempt toward cellular differentiation. They are usually much larger than the true bacteria and often bear some resemblance to yeasts, molds, algae, or protozoans.

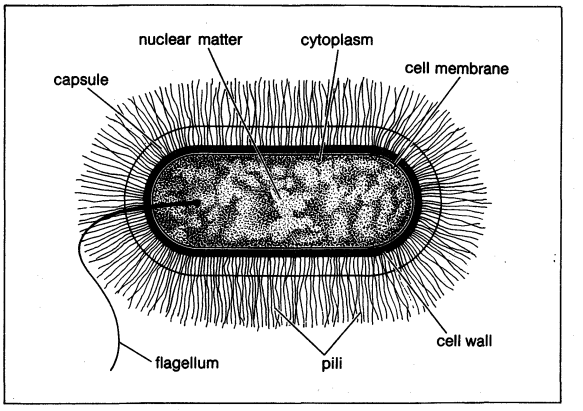

Figure 6: Schematic drawing of structure of a typical bacterial cell of the bacillus type.

The typical bacterium

A typical bacterial cell is shown in Figure 6; not all bacterial species possess all of the structures shown. All bacterial cells contain nuclear substance, but it is not organized into a discrete nuclear structure as in higher organisms; there is no nuclear membrane, and mitotic division, the mechanism by which the cells of plants and animals divide, does not occur. The blue-green algae are akin to bacteria in this respect; together they are characterized as procaryotes, in contrast to eucaryotes, the cells of which possess a discrete nuclear structure.

All bacterial cells possess a membrane and a cell wall. There are distinct differences among species in terms of the chemical composition of these structures, however. The cells of some bacterial species possess whiplike structures called flagella, the number and arrangement of which are typical for a species. Shorter, rigid appearing, spikelike projections known as pili, or fimbriae, appear on some cells. Certain cells are surrounded with a gelatinous or slimy material, the capsule (Figure 7). Many bacteria can assume a dormant state as a spore; in fact, during sporulation the entire vegetative cell, in essence, is transformed into the spore body.

From W.H. Taylor and E. Juni, "Pathways for Biosynthesis of a Bacterial Capsular Polysaccharide," *Journal of Bacteriology* (May 1961)

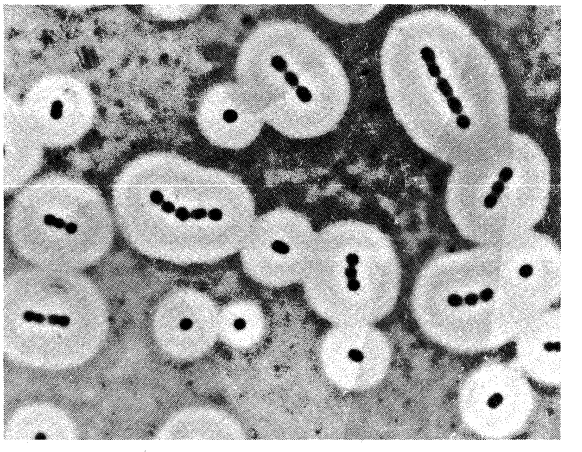

Figure 7: Capsular material surrounding these bacteria (*Acinetobacter calcoaceticus*) is revealed in a suspension of India ink and viewed through the light microscope (magnified about 2500 ×).

Staining techniques are used to demonstrate the various bacterial cell structures. One of the most important staining procedures involves the gram stain (named after its inventor, H.C.J. Gram, a Danish physician). This is a differential stain; *i.e.,* bacteria are said to be gram positive or gram negative depending upon whether they retain the purple colour of the original stain (crystal violet) at the end of the procedure, or whether it is washed out and the

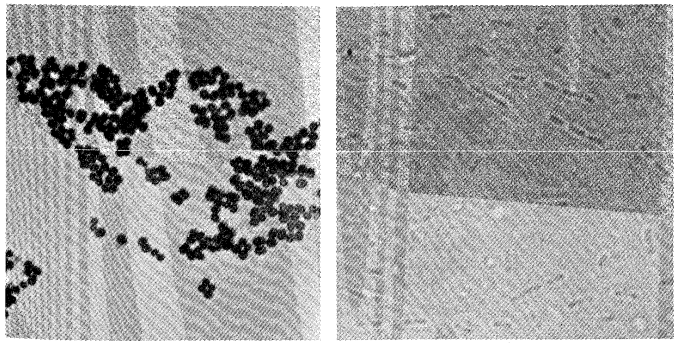

Figure 8: *Bacteria isolated and coloured with gram stain.*

red colour of the counterstain (safranin) shows (Figure 8).

More refined characterization of the anatomy of a bacterial cell can be accomplished by electron microscopy, in which bacterial cells are sliced into very thin sections and then viewed under very high magnification; electron micrographs reveal a great deal of complex detail: layers in the cell surface, internal structures, as well as connections or continuity between certain structures.

The bacterial colony. The gross appearance of bacterial growth in or on media defines the cultural characteristics of a species. When a specimen containing bacteria is inoculated onto an agar medium (a standard preparation of nutrients with a gel-like consistency), colonies develop, each from an isolated bacterial cell. Such colonies (Figure 9) vary in characteristics depending upon the species. They may be pinpoint in size or several millimetres across; flat or raised and convex; smooth or broken edged; stringy, brittle, or buttery in consistency; coloured internally or excreting substances that colour the surrounding medium; and opaque, transparent, or translucent.

Bacteria cultivated as agar slant cultures (slanted medium in test tubes) exhibit differences in characteristics much like those described for colonial appearance (Figure 10). In liquid media (broth), growth may be confined to the surface as a film (pellicle); uniformly distributed throughout the liquid; or particulate, with a tendency to form a sediment.

Physiological features. *Physical requirements.* On the basis of temperature requirements for growth, bacteria are grouped into three categories: psychrophiles, 0° to 30° C (32° to 86° F); mesophiles, 15° to 45° C (59° to 113° F), with best growth in the range 25° to 40° C (77° to 104° F); and thermophiles, 45° to 60° C (113° to 140° F) and above. Bacteria within each group exhibit specific minimum, maximum, and optimum temperatures for growth; for example, *Pseudomonas delphinii* grows at 1° C and 30° C (34° F and 86° F), with optimum growth occurring at 25° C (77° F), and *Bacillus thermoliquefaciens* grows at 37° C and 70° C (99° F and 158° F), with optimum growth occurring at 60° C (140° F).

Temperature categories of bacteria

Atmospheric oxygen is required by some, but not all, bacteria; others are inhibited by its presence. Bacteria are classified as aerobes when they require oxygen to grow and as anaerobes when they cannot grow in the presence of oxygen; facultative anaerobes do not require oxygen and can grow in its presence.

Some bacteria grow in a wide range of salt concentrations; others, such as marine bacteria, require salt levels of 10 to 15 percent for optimal growth. Most bacteria grow best in an environment near neutrality (neither acidic nor alkaline); some, however, grow under strongly acid conditions (*Thiobacillus thiooxidans*) and others under strongly alkaline conditions (*Nitrobacter* species). Most bacteria, especially those intimately associated with man, grow best without light. Photosynthetic bacteria, however, require light.

Nutritional requirements. The establishment of the specific nutritional requirements for various bacterial species required the development of media consisting of known chemical compounds in prescribed amounts, on which the bacteria could be cultivated in the laboratory. In a broad sense, bacteria, on the basis of nutritional requirements, can be divided into two groups: autotrophs and heterotrophs. Autotrophs are capable of growing entirely on inorganic ingredients, with atmospheric carbon dioxide as the exclusive source of carbon. Heterotrophs require an organic form of carbon and, in addition, may require other organic substances, such as amino acids and vitamins.

The autotrophic sulfur-oxidizing bacteria can grow on powdered sulfur, ammonium sulfate, potassium phosphate, calcium chloride, magnesium sulfate, ferric sulfate, water, and carbon dioxide. From these relatively simple chemical substances the autotrophic bacterium can synthesize and organize the vast array of complex organic substances of which it is made.

Heterotrophs exhibit great diversity in their nutritional requirements. *Escherichia coli,* the most frequently studied heterotrophic species, can grow on the ingredients listed above for autotrophic sulfur-oxidizing bacteria, except that carbon from an organic source (such as the sugar glucose) is also essential. *Salmonella typhosa* has a requirement slightly different from that of *E. coli* in that not only glucose but also an amino acid (tryptophan) is required. *Staphylococcus aureus,* another typical heterotroph, requires several amino acids and at least one vitamin, thiamin. *Lactobacillus* species are considerably more fastidious; they require many amino acids, several vitamins, and purine and pyrimidine compounds.

Some bacteria, especially certain pathogens, such as the syphilis bacterium (*Treponema pallidum*), require a complex medium that is provided only by living animal tissue. Such bacteria have so far not been cultivated even in a complex bacteriological medium of peptone (a digest of animal protein) and meat extract (or meat broth), with supplemental substances such as blood, serum, and other animal fluids.

Biochemical activities. Bacteria are capable of carrying out many chemical changes, both in the breakdown of complex substances and in the synthesis of new products. A compound may be degraded to different end products by different bacterial species, just as the same nutrients may be synthesized into different substances by different species.

Decomposition of carbohydrates

Dissimilation. Complex organic carbon compounds, such as pectin, cellulose, and starch, are readily degraded by many bacteria. Pectins are complex carbohydrates that occur in plants. Enzymes produced by species of *Erwinia, Bacillus,* and *Clostridium* are capable of converting pectin to galacturonic acid and further to sugar and other products. Cellulose, the major constituent of plant tissue, is transformed to dextrins and then to glucose by species of *Cellulomonas, Cytophaga, Streptomyces,* and *Clostridium.* Several *Bacillus* and *Clostridium* species produce enzymes that convert starch to sugar.

After the complex carbohydrates have been broken down into their constituent units (*e.g.,* glucose), these units are utilized in a variety of ways—*e.g.,* to produce a variety of other compounds. Bacterial species are characterized in part on the basis of the characteristic products they form from glucose. Table 2 lists several genera of bacteria, together with representative products of their glucose dissimilation.

Proteinases

The process of protein dissimilation (proteolysis) is accomplished by enzymes known as proteinases, which are produced by species of such genera as *Clostridium, Bacillus, Proteus,* and *Pseudomonas.* The proteinases decompose the protein molecules, hydrolyzing (breakdown involving water) the linkages (peptide bonds) between the amino acids that constitute the molecule. The result is the formation of peptides, chains of amino acids. Enzymes called peptidases then break down the peptides into individual amino acids. In turn, the amino acids may be degraded through several processes; deamination, the removal of the amino group ($-NH_2$) by enzymes called deaminases, the end products being ammonia (NH_3) and a fatty acid; decarboxylation, the removal of the carboxyl group ($-COOH$) by enzymes called decarboxylases, the end products being carbon dioxide and an amine; or amino acid fermentation, a breakdown more extensive than either deamination or decarboxylation, and resulting in more complex and varied end products, depending on the amino acid being degraded.

Table 2: Bacteria Grouped According to Major Products of Glucose Dissimilation

groups (with examples of some genera)	representative products
Lactic acid bacteria	
Streptococcus *Lactobacillus* *Leuconostoc*	lactic acid only or lactic acid plus acetic acid, formic acid, and ethyl alcohol; those species producing only lactic acid are *homofermentative;* those producing lactic acid plus other compounds are *heterofermentative*
Propionic acid bacteria	
Propionibacterium *Veillonella*	propionic acid plus acetic acid and carbon dioxide
Coli–aerogenes–typhoid bacteria	
Escherichia *Aerobacter* *Salmonella*	formic acid, acetic acid, lactic acid, succinic acid, ethyl alcohol, carbon dioxide, hydrogen, 2,3-butylene glycol (produced in various combinations and amounts depending on genus and species)
Acetone, butyl-alcohol bacteria	
Clostridium *Butyribacterium* *Bacillus*	butyric acid, butyl alcohol, acetone, isopropyl alcohol, acetic acid, formic acid, ethyl alcohol, hydrogen, and carbon dioxide (produced in various combinations and amounts depending on species)
Acetic acid bacteria	
Acetobacter	acetic acid, gluconic acid, kojic acid

Source: M.J. Pelczar, Jr., and R.D. Reid, *Microbiology* (1972).

Fats, or lipids, composed of fatty acids and glycerol (*i.e.,* triglycerides), can be degraded by such bacteria as *Pseudomonas, Proteus, Achromobacter, Alcaligenes, Bacillus, Micrococcus,* and *Clostridium.* The end products of the dissimilation of fats are glycerol and fatty acids, which can be broken down further.

Synthesis. The extensive capacity of a bacterium to synthesize complex molecules is shown when the simple chemical substances upon which an autotroph grows are compared to the complex chemical composition of the bacterial cells that are produced. In addition to the large, complex molecules that constitute cell structure, other substances of significance are elaborated by bacterial cells, including antibiotics, pigments, toxins, and polysaccharides (complex carbohydrates).

Virulence

Pathogenicity. It was implied above that a pathogen has the potential to produce a disease in a given host species—a plant, an animal, or even another bacterium species. The power of a bacterium to cause a disease, termed virulence, varies within a species. Some strains are highly virulent; *i.e.,* a small number of cells can establish the infection. Other strains have a low degree of virulence and produce infection only when transmitted in massive numbers. Furthermore, some strains of a pathogen may lose their virulence. A quantitative expression of virulence can be determined by performing laboratory experiments to establish the number of bacterial cells required to infect or kill a standard experimental animal. The expression lethal dose$_{50}$ (LD_{50}) refers to the number of bacteria necessary to kill 50 percent of the organisms inoculated.

Factors that contribute to the virulence of a bacterial pathogen are not yet completely understood, except in those instances in which the pathogen causes damage by secreting a potent toxin (an exotoxin). Diphtheria bacteria (*Corynebacterium diphtheriae*), for example, establish themselves in the mucous membrane of the upper respiratory tract of man; as they grow, they produce an exotoxin that is absorbed by the mucous membranes and causes the death of cells in the host. It is the exotoxin that does the damage to the host; a strain of *C. diphtheriae* that does not produce the exotoxin cannot cause diphtheria.

Not all virulent pathogens produce an exotoxin; most,

in fact, do not. *Salmonella typhosa,* the typhoid fever bacterium, produces an endotoxin, a complex substance associated with, or bound to, the surface structures of the bacterial cell. Endotoxins damage host tissues and host metabolism in ways not clearly understood. Other substances that contribute to the virulence of various pathogens are described in Table 3. (M.J.P.)

Table 3: Substances Contributing to the Virulence of Pathogenic Bacteria

substance	action
Hyaluronidase	increases permeability of tissue spaces to bacterial cells
Coagulase	increases resistance of bacteria to phagocytosis (engulfment by defense cells, or phagocytes)
Hemolysins	destroy red blood cells
Collagenase	dissolves collagen, a connective tissue protein
Leucocidin	kills white blood cells (specifically leucocytes) and hence decreases phagocytic action
Exotoxins and endotoxins	interfere with normal metabolic processes

Antigenic features. When bacterial cells enter the tissues of an animal, it is likely that they will act as antigens, agents that evoke the production of substances called antibodies. Antibodies are produced by an animal as part of its immunological defense against any foreign substance that can threaten its welfare.

Antigen–antibody reactions are highly specific and highly sensitive. A bacterial cell consists of many different antigens (*e.g.,* flagellar, capsular, and cell wall antigens). The antigen pattern in one bacterial species differs from that in another. Although it is not uncommon for related species (*e.g., Salmonella typhosa* and *Salmonella paratyphi*) to share certain antigens, each also contains other antigens that are unique.

Variability. The characteristics of one bacterial species are sufficiently definitive and constant to delineate it from other species. This distinctiveness does not mean, however, that each characteristic is evident and manifest by all strains of all species under all conditions.

nviron-
ientally
nduced
ariation

Reversible changes. Bacteria, under uniform conditions, will manifest a constancy of characteristics. If the same species of bacteria is placed in different environments—different physical conditions or different chemical composition of medium—the resultant growth may differ. In fact, the morphological and physiological characteristics are not identical at all stages of the growth curve of a bacterium. The morphology of cells from an "old" culture differs from that of "young" cells. In addition, the formation of a capsule is significantly influenced by the composition of the medium; bacteria that, in a nutrient broth, exhibit no capsules may produce large capsules when grown in milk. Some of the enzymes produced by bacteria are produced only when the compound on which the enzyme acts (substrate) is present; they are called adaptive enzymes, in contrast to constitutive enzymes, which are produced irrespective of the substrate.

Changes of the types just described are transient; they reflect what occurs during a stage of growth or in response to a change in the environment. The genetic endowment (genotype) of the organism remains the same, regardless of the different expressions (phenotype) that are seen under different environmental circumstances.

Permanent changes. Daughter cells that contain genetic information different from that of the parent cell constitute a new genotype. Such permanent-type genotypic changes may occur through four different processes: mutation, conjugation, transformation, and transduction.

Mutation involves a sudden alteration of a gene that is inherited by subsequent generations. Some bacterial cells in the process of normal growth undergo mutation; however, the ratio of mutant cells to unchanged cells is very small. The number of mutants in a population can be greatly increased by exposing the bacteria to certain physical agents (for example, ultraviolet rays and X-rays) or to chemicals (for example, mustard gas and organic peroxides). Bacterial mutants exhibit alterations in nutrition, drug resistance, pigmentation, and colonial form, among other characteristics.

Conjugation (sexual reproduction), a rarity in bacteria, results in recombinations of genes in the cells that pair (see above *Reproduction*).

Transformation also involves the transfer of genetic information from one cell to another, but pairing does not occur. Deoxyribonucleic acid (DNA) that is released from one cell (the donor) is taken up by another cell (the recipient) and incorporated into the genetic apparatus of the latter.

Changes caused by viruses

Transduction involves the transfer of genetic substance from one cell to another via a bacteriophage, a virus that infects bacteria. The bacteriophages produced in a host cell are released when the cell is destroyed by the infection. Some virus particles may carry fragments of DNA from the host bacterium, which, under certain circumstances, may become incorporated into the DNA of the recipient cell, thus changing the genetic constitution of the latter.

EVOLUTION

Bacteria have existed from very early periods in the history of life on Earth. They have been detected as fossils in rocks dating from at least Devonian times (as early as 395,000,000 years ago). On the basis of their indistinct nuclear matter, bacteria are assumed to be closely related to the blue-green algae. It has been speculated that a photosynthetic ancestor may have given rise to both the bacteria and the blue-green algae.

Relationship to other microorganisms

Several groups of bacteria show features that suggest relationships to other classes of organisms: these features do not necessarily indicate a close relationship, however. Actinomycetes form branching units and reproductive stages similar to the fungi. Mycoplasmas (formerly called PPLO and L forms) are variable organisms that seem to lack in organization. Myxobacteria resemble, in some ways, the slime molds.

CLASSIFICATION

Distinguishing taxonomic features. Shape and size of the bacterial cell are aids in classifying bacteria, as is the appearance of the colonies that are formed. Other characteristics, however, assume even greater significance because they are more consistent under different environmental conditions. These include the kinds of foods utilized, the products of metabolism, reactions to specific chemicals, antigenic composition, and degree of tolerance to environmental change.

The 10 orders listed in this classification are distinguished primarily on the shape and rigidity of the bacterial cell and on locomotor ability; on the capacity of individual bacteria to aggregate in chains or clusters of special shape; and on special physiological characteristics.

Annotated classification. The following classification is based on an edition of *Bergey's Manual of Determinative Bacteriology.*

CLASS SCHIZOMYCETES

Unicellular microorganisms generally ranging from 1 to 5 microns in size; variable in shape and in nutritional needs; lacking a distinct nucleus; most species without chlorophyll; occur singly or in chains or clusters and form distinctive colonies; about 1,500 species; worldwide distribution.

Order Pseudomonadales

Rigid-walled cells of variable shape, in some species forming chains; photosynthetic pigment present in certain species; cells usually motile by means of a single flagellum. Species in soil and in freshwater and saltwater. Examples of genera: *Vibrio comma* (cholera bacteria), *Pseudomonas, Nitrosomonas, Thiobacillus.*

Order Chlamydobacteriales

Rigid-walled cells in many-celled filaments (trichomes), frequently ensheathed; occasionally produce motile spores; trichomes often attached to a surface; species in freshwater and marine habitats. *Sphaerotilus natans* common in polluted water.

Order Hyphomicrobiales

Rigid-walled cells often attached to surface by a stalk; reproduction by budding (as in yeasts) rather than by ordinary division. Genera include *Rhodomicrobium* and *Hyphomicrobium.*

Order Eubacteriales

Rigid-walled cells, coccoid or bacilloid, sometimes in chains; motile forms move by means of laterally emergent flagella; not acid-fast (*i.e.,* retaining a bacterial dye when treated with an

acidic solution); includes the largest number of genera of concern to man—*e.g., Escherichia, Diplococcus, Staphylococcus, Streptococcus, Bacillus, Lactobacillus.*

Order Caryophanales
Rigid-walled cells in trichomes; motile by means of lateral flagella; very large cells (up to 30μ long and 3μ across); occur in water and decomposing matter as well as in the intestines of arthropods and vertebrates. *Caryophanon latum,* common in cow dung, and *Simonsiella muelleri,* found in the mouths of humans and domestic animals.

Order Actinomycetales
Rigid-walled cells that may grow out in a branching system, resembling mold colonies; includes *Mycobacterium tuberculosis* (tuberculosis bacterium), *Streptomyces.*

Order Beggiatoales
Rigid-walled cells, usually large and often in trichomes that move by gliding motion as do some blue-green algae; genera include *Beggiatoa, Thiothrix.*

Order Myxobacteriales
Flexible-walled cells that creep on surfaces. Stalked fruiting bodies usually develop from a spreading colony, like slime molds. Found in soil, compost, manure, and rotting wood; genera include *Myxococcus, Chondrococcus, Sorangium.*

Order Spirochaetales
Spiral cells that swim by flexion; found in water and in the bodies of vertebrates; genera include *Borrelia, Treponema,* and *Leptospira,* all parasites of man and other animals.

Order Mycoplasmatales
Flexible-walled cells, nonmotile, highly variable in shape at different life stages; includes *Mycoplasma* and forms once known as pleuropneumonia-like organisms (PPLO) and L forms, which are apparently intermediate between true bacteria and rickettsias.

Critical appraisal. The classification of bacteria, as given above, encompasses 10 orders. The question of higher categories, however, remains a subject of study and debate. Some biologists favour a taxonomic system in which the bacteria (class Schizomycetes) are grouped with the rickettsias and viruses (class Microtatobiotes) as the division Schizomycophyta, which, in turn, is grouped with the Phylum Cyanophyta (blue-green algae) as a subkingdom, Monera, of the kingdom Protista (of equal rank with the kingdoms of Plantae and of Animalia). Such a scheme obviates the need for assigning these procaryotic organisms (*i.e.,* without distinct nuclei) to the kingdom Plantae, which is not quite suitable.

For many years the actinomycetes, myxobacteria, and mycoplasmas were listed as bacteria even though they have unusual life cycles and variable structure. It is now fairly well established, however, that they do belong in the class Schizomycetes. The rickettsias, which were occasionally grouped with the bacteria, are now considered an order, Rickettsiales, of the class Microtatobiotes. A completely revised taxonomic scheme appears in the latest edition of *Bergey's Manual of Determinative Bacteriology* (see *Bibliography* below).

(M.J.P./Ed.)

Baghdad

Baghdad (also spelled Bagdad, Arabic Baghdād) is the capital of Iraq and one of the largest cities in the Middle East. Located near the centre of Iraq, about 330 miles (530 kilometres) from the head of the Persian Gulf, Baghdad is famous as the capital of the ʿAbbāsid caliphs and the setting of many of the stories in *The Thousand and One Nights.* Baghdad exhibits marked contrasts in architecture and life-styles, combining Oriental bazaars, shrines, and mosques with riverfront cafés, Western-style luxury hotels, and modern high-rise apartments. With almost a third of the country's population, Baghdad is the centre of Iraq's political, economic, and cultural life.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Baghdad is situated on the Tigris River at the river's closest point to the Euphrates, 25 miles to the west. The Diyālā River joins the Tigris just southeast of the city and borders its eastern suburbs. The terrain surrounding Baghdad is a flat alluvial plain 112 feet (34 metres) above sea level. Historically the city has been inundated by periodic floods from the Tigris' tributaries to the north and east. These ended in 1956 with the completion of a dam on the Tigris at Sāmarrā', north of Baghdad, and the ending of the floods has permitted extensive expansion of the city to the east and west. To the north, urban expansion has absorbed the medieval townships of al-Aʿẓamīyah on the east bank and al-Kāẓimīyah on the west bank.

Climate. The climate is hot and dry in summer, cool and damp in winter. Spring and fall are brief but pleasant. Between May and September the average daily maximum temperature is 105° F (41° C), and the high may reach 120° F (49° C) at midday in July and August. Intense daytime heat is mitigated by low relative humidity (10 to 50 percent) and a temperature decline of 30° F (17° C) or more at night. In winter the average daytime temperature is about 55° F (13° C), and the temperature occasionally drops below freezing. Rainfall is sparse (six inches, or 150 millimetres, annually) and mainly occurs between December and April. There is no rain in summer. In spring and early summer the prevailing northwesterly winds (shamals) bring sandstorms that frequently bathe the city in a dusty mist.

The city layout. *The districts.* The city extends along both banks of the Tigris. The east-bank settlement is known as Ruṣāfah, the west-bank as al-Karkh. A series of modern bridges, including one railroad trestle, links the two banks. From a built-up area of about four square miles (10 square kilometres) at the beginning of the 20th century, Baghdad has expanded into a bustling metropolis with suburbs spreading north and south along the river and east and west onto the surrounding plains.

'he city entre

The older core of the city consists of a rectangle about two miles long and one mile wide located on the east bank. Its length extends between two former city gates, al-Muʿaẓẓam Gate, now al-Muʿaẓẓam Square, in the north and ash-Sharqī Gate, now Taḥrīr Square, in the south. From the Tigris the rectangle runs eastward to the inner bund, or dike, built by the Ottoman governor Nāẓim Pasha in 1910. Rashīd Street in downtown Baghdad is the heart of this area and contains the city's financial district, many government buildings, and the copper, textile, and gold bazaars. South of Rashīd Street a newer commercial area with shops, cinemas, and business offices has spread along Saʿdūn Street. Parallel to Saʿdūn, Abū Nuwās Street on the riverfront is the city's showpiece and its entertainment centre, featuring cafés, restaurants, luxury hotels, and, along its southern reaches, rows of ultramodern townhouses.

Adjacent to these commercial districts are older, middle-class residential areas, such as as-Sulaykh to the north, al-Wizarīyah to the west, and al-Karrādah to the south, now densely settled. Baghdad University and a fashionable new residential area are located on al-Jādrīyah, a peninsula formed by a bend in the Tigris.

'lanned eighbour- oods

Since the late 1950s the city has expanded eastward beyond the bund. Planned middle-class neighbourhoods are located between the bund and the Army Canal, which connects the Tigris and Diyālā rivers. Beyond the canal, at the eastern edge of the city, is a sprawling low-income housing development inhabited by more than 1,000,000 urban migrants.

On the west bank are a number of residential quarters, including al-Karkh (an older quarter) and several upper middle-class districts with walled villas and green gardens. Chief among these is al-Manṣūr, surrounding the racetrack, which provides boutiques, fast-food restaurants, and sidewalk cafés that appeal to its affluent professional residents.

Architecture and monuments. The architecture of the city ranges from traditional two- or three-story brick houses to modern steel, glass, and concrete structures. The traditional Baghdad house, usually located in a crowded narrow street, has latticed windows and an open inner courtyard; a few fine specimens from the late Ottoman period are tucked away in traditional quarters of al-Karkh, Ruṣāfah, and al-Kāẓimīyah. The typical modern middle-class dwelling is built of brick and mortar and has a garden and wall.

Traditional and modern houses

While no monuments survive from the early ʿAbbāsid period, examples of late ʿAbbāsid architecture include the ʿAbbāsid Palace (late 12th or early 13th century) and the Mustanṣirīyah (an Islāmic law college built by the caliph al-Mustanṣir in 1233), both restored as museums, and the Sahrāwardī Mosque (1234). The Wasṭānī Gate, the only remnant of the medieval wall, has been converted into the Arms Museum.

Another group of buildings dates from the late 13th and 14th centuries (the Il-Khanid and Jalāyirid periods). These include the minaret of the caliph's mosque (1289); the ʿAqūlī Mosque (1328); and two superb buildings constructed by the Jalāyirid governor Marjān ibn ʿAbd Allah: the Marjān Mosque (1356), partly demolished in 1946, and the Marjān Khān (1359), a restored caravansary (inn). A number of mosques, bazaars, and public baths survive from the Ottoman period.

A cultural revival in the post-1958 period has produced many modern monuments, the work of contemporary artists and sculptors. Among the best known are Jawād Salīm's Liberation Monument in Taḥrīr ("Liberation") Square, depicting the struggle of the Iraqi people to achieve liberty before the 1958 revolution, and Muḥammad Ghānī's "Murjāna Monument," which depicts Murjāna, Ali Baba's housekeeper in *The Thousand and One Nights*, pouring boiling oil on the 40 thieves. Two monuments are dedicated to the war dead. A large, modernistic shield, built by Khālid ar-Raḥḥāl in 1982, commemorates the Unknown Soldier. The Martyr's Monument, a 150-foot split dome built in 1983, commemorates the casualties of the Iraqi-Iranian war.

Commemorative sculpture

THE PEOPLE

The population of greater Baghdad has grown tremendously since World War II, exceeding 4,000,000 by 1987. The vast majority of the population is Muslim and Arab. The Muslims are divided, however, between the two main sects of Islām, the Sunnites and the Shīʿites. Other ethnic and linguistic groups include Kurds, Armenians, and people of Indian, Afghan, or Turkish origin. A substantial Persian-speaking population departed for Iran in the 1970s and '80s in the wake of troubles between Iran and Iraq. There are several Eastern-rite Christian communities, notably the Chaldeans and Assyrians, and a small Jewish community with ancient roots in Mesopotamia; most Jews left the country for Israel at the beginning of the 1950s.

Baghdad has a large community of foreign Arabs, including hundreds of thousands of Egyptian workers and a sizable number of Palestinians, many of whom are the second generation to live in the city. The Western community, once substantial, has been reduced since 1958 and is limited mainly to businessmen, members of the diplomatic corps, and executives of foreign companies.

Changes in neighbourhood patterns

Traditionally, people of the same sect, ethnic group, or craft lived together in separate quarters or neighbourhoods, but oil wealth and massive migration from rural areas to the city have resulted in distribution based on socioeconomic stratification. Some patterns persist, however. As the city expanded physically, the government offered parcels of land for a minimal fee to various professional associations. Thus doctors, lawyers, army officers, and those of other occupational groups have tended to concentrate in new neighbourhoods, each with its own mosques, shops, and schools, creating a pattern of cities within the city. In the 1970s the government attempted to curb "horizontal" expansion, and a new phenomenon, high-rise apartments, appeared.

Baghdadis have an affinity for gardens and family recreation. On weekends the city's restaurants, cafés, and public parks are filled with people, particularly along Abū Nuwās Street, where restaurants serve the local delicacy *masgūf,*

Tigris fish roasted over an open fire. Other recreational centres include two islands in the Tigris that have swimming pools and cafés, the Lunar Amusement Park, and az-Zawrā' Public Park and Zoo.

THE ECONOMY

Industry. Most of Iraq's industry, finance, and commerce is concentrated in and around Baghdad. At least half of the country's large-scale industry and much of its smaller industry is located in the Baghdad governorate. The exception is heavy industry (petroleum, iron, steel, and petrochemicals), which is situated near the oil fields in the north (Kirkūk) and the south (in Baṣrah and az-Zubayr). Most economic activities are owned or controlled by the government, which both stimulates and monopolizes the country's economic activities.

Baghdad's modern industry

Modern industry began in the interwar period, spurred by the Law for the Encouragement of Industry in 1929. Early factory production centred on textiles (cotton ginning, spinning, and weaving), food processing, brick making, and cigarettes. Beginning in the 1950s, the government used increased oil revenues to develop industries. The city now produces a wide variety of consumer and industrial goods, including processed foods and beverages, tobacco, textiles, clothes, leather goods, wood products, furniture, paper and printed material, bricks and cement, chemicals, plastics, electrical equipment, and metal and nonmetallic products. Despite the growth of modern industry, however, a large percentage of Baghdad's labour force still works in traditional economic activities, such as retail trade, production of handmade consumer goods, auto and mechanical repairs, and personal services.

The most important industry in Baghdad is the government, the city's principal employer. Hundreds of thousands of citizens work for the government, directly or indirectly, in the civil service, in government-run educational institutions, and in government-owned industrial and commercial enterprises.

Commerce and finance. The main offices of the Central Bank of Iraq, which has the sole right to issue currency, and the commercial Rafidayn Bank are in Baghdad. No foreign banks are allowed. The main offices of the government companies for commerce, trade, and industry are located in Baghdad, as are the branches of foreign companies operating in Iraq.

Transportation. Baghdad is the hub of the country's transportation system. Saddam International Airport, west of Baghdad, serves numerous international airlines, including Iraqi Airways. The major railway lines of the state-owned railway meet at Baghdad. These connect Baghdad with Baṣrah and Umm Qaṣr near the Persian Gulf, with Kirkūk and Irbīl in the northeast, with Mosul in the north, and with al-Qā'im near the Syrian border in the northwest.

Baghdad is also the centre of a regional road network, connecting the city by overland routes with Turkey, Syria, Jordan, Iran, Kuwait, and Saudi Arabia. Baghdad is also connected by road with Europe. Within the city, a network of expressways completed in the 1980s relieves traffic congestion and links the city centre with its suburbs. The main means of public transportation are the red double-deck bus (introduced by the British) and the public taxi.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Baghdad is both a national and a provincial capital. The governor (*muḥāfiẓ*) of the Baghdad province is nominated by presidential decree but is responsible to the minister of interior. The city is governed by a mayor, who is appointed by the president. As the seat of the national government, Baghdad contains the offices of the president, the Council of Ministers, the National Assembly, and the headquarters of the governing party.

Public services. Since the 1950s the government has greatly expanded public services in Baghdad, providing low-income housing for poor and middle-income families, as well as electricity, water, sewage, and medical facilities. Baghdad has numerous hospitals and clinics, many of them specialized, and a major medical complex, Madīnat aṭ-Ṭub ("Medical City").

Education. Public school facilities have expanded rapidly since the 1950s. Education is compulsory through primary school, and statistics show nearly total compliance in Baghdad. The Baghdad governorate has more than 1,000 primary schools, several hundred intermediate and secondary schools, and a number of vocational schools, as well as numerous technical institutes and teachers' training schools. Baghdad is the centre of higher education in Iraq. The University of Baghdad was established in 1957, although some of its faculties were founded much earlier. There are, in addition, three other institutions of higher learning: al-Mustanṣirīyah University, the University of Technology, and al-Bakr Military Academy. Education is free up to and including the university level.

CULTURAL LIFE

Baghdad has become an active cultural centre for the Arab world, producing some of the most prominent modern sculptors, painters, poets, and writers. Iraqi poets, for example, pioneered the free-verse movement in Arabic.

Among the most important of Baghdad's museums are the Iraqi Museum, containing important archaeological treasures from ancient Mesopotamian history; the National Museum of Modern Art, containing a permanent collection of painting, sculpture, and ceramics by Iraqi artists; and the Museum of Iraqi Art Pioneers, holding the works of Iraqi artists who laid the foundation of the modern Iraqi art movement.

The city's Muslim shrines

Several of the most important mosques and shrines in the Islāmic world are found in Baghdad, including the shrine of the Shī'ite imams Mūsā al-Kāẓim and Muḥammad al-Jawād, in al-Kāẓimīyah; the shrine of the Sunnite jurist Abū Ḥanīfah, in al-A'ẓamīyah; and the shrine of 'Abd al-Qādir al-Jīlānī, founder of the Qādirīyah Ṣūfī order, in Ruṣāfah. All contain libraries and are centres of Muslim pilgrimages.

All mass media are controlled by the government. Two major daily newspapers are published in Arabic, and a variety of political, cultural, and professional journals are published. English is the most widely used foreign language, but publications in European and Asian languages can be found. Radio Baghdad broadcasts to the entire country over several frequencies and in several languages. Baghdad's television station began operation in 1956.

The National Theatre, one of the best equipped in the Arab world, has a regular schedule of plays, concerts, musical productions, and cinema. The National Troupe for Popular Arts presents Iraqi dance and folklore and tours world capitals. Cinema plays an important role as a source of popular entertainment in Baghdad. The Baghdad International Fair, held annually in October, includes industrial displays, theatrical productions, and other cultural activities.

History

FOUNDATION AND EARLY GROWTH

Archaeological evidence shows that the site of Baghdad was occupied by various peoples long before the Arab conquest of Mesopotamia in AD 637, and several ancient empires had capitals located in the vicinity. The true founding of the city, however, dates from 762, when the site, then occupied by a Persian village called Baghdad, was selected by al-Manṣūr, the second caliph of the new 'Abbāsid dynasty, for his capital. His city, built within circular walls and called Madīnat as-Salām ("City of Peace")—and known as the Round City—was located between present-day al-Kāẓimīyah and al-Karkh. More a government complex than a residential city, it was about 3,000 yards (2,700 metres) in diameter and had three concentric walls. Its four equal quarters were used mainly to house the caliph's retinue. Four main roads led from the caliph's palace and the grand mosque at the centre to various parts of the empire.

Baghdad's founding in 762

The limited size of this city resulted in rapid extramural expansion. Merchants built bazaars and houses around the southern gate and formed a district called al-Karkh. From the northeast gate the Khurāsān road was joined by a bridge of boats to the east bank of the Tigris. There, around the palace of al-Manṣūr's heir apparent, al-Mahdī,

grew up the three suburbs of Ruṣāfah, ash-Shammāsīyah, and al-Mukharrim, the forerunners of the modern city. By 946 the seat of the caliphate was fully established on the east bank, and Ruṣāfah grew to rival the Round City.

Baghdad reached the zenith of its economic prosperity and intellectual life in the 8th and early 9th centuries, under al-Mahdī, who reigned from 775 to 785, and his successor, Hārūn ar-Rashīd (786–809). It was then considered the richest city in the world. Its wharves were lined with ships from China, India, and East Africa. The caliph al-Ma'mūn (813–833) encouraged the translation of ancient Greek works into Arabic, founded hospitals and an observatory, and attracted poets and artisans to his capital. The glory of Baghdad in this period is reflected in stories in *The Thousand and One Nights.*

From the mid-9th century onward the 'Abbāsid caliphate was gradually weakened by internal strife, by failure of crops caused by neglect of the irrigation system, and finally, in the 10th century, by the intrusion of nomadic elements. A civil war between Hārūn ar-Rashīd's two sons resulted in destruction of much of the Round City. Between 836 and 892 the caliphs abandoned Baghdad for Sāmarrā' in the north, and the city was taken over by the unruly Turks they had imported as bodyguards. When the caliphs returned to Baghdad they made their capital on the east bank. Invasions and rule by alien elements (the Būyids from 945 to 1055 and the Turkish Seljuqs from 1055 to 1152) left parts of the city in ruins.

CENTURIES OF DECLINE

This long, slow decline was merely a prelude to the devastating attacks from which Baghdad would not recover until the 20th century. In 1258 Hülegü, the Mongol conqueror, overran Mesopotamia, sacked Baghdad, killed the Caliph, and massacred hundreds of thousands of residents. He destroyed the surrounding dikes and headworks, making restoration of the irrigation system impossible and thereby destroying Baghdad's potential for future prosperity.

The Mongol sack of Baghdad

Thereafter Baghdad became a provincial capital, first of the Mongol emperors of Iran, the Il-Khanids (1258–1339), and then of their vassals, the Jalāyirids (1339–1410). In 1401 the city underwent yet another Mongol sack by Timur (Tamerlane), after which it fell under the sway of two successive Turkmen dynasties (1410–1508), both of which did little to restore its fortunes.

In 1508 Baghdad was temporarily incorporated into the new Persian empire created by the Ṣafavid shah Ismā'īl I. The city was not to remain under the Persians, however. In 1534 the Sunnite Ottoman sultan Süleyman I retook the city. Despite repeated Persian attacks, it remained under Ottoman rule until World War I, except for a brief period (1623–38) when it was taken and held by the Persians.

BEGINNINGS OF MODERNIZATION

In the 19th century European influence grew in Baghdad with the establishment of French religious orders and increased European trade. In 1798 a permanent British diplomatic residency was established there, and the British residents soon acquired a power and prestige second only to that of the governor.

Prosperity began to be restored to Baghdad with the opening of steamship travel on the Tigris in the 1860s. Between 1860 and 1914 several energetic, reforming Ottoman governors improved the city, especially Midhat Paşa. During his tenure (1869–72), he destroyed the city walls, reformed the administration, started a newspaper, and set up a modern printing press. The telegraph, military factories, and modern hospitals and schools were also established, along with a municipal council.

THE MODERN CITY

In 1920 Baghdad became the capital of the newly created state of Iraq. Recognizing British conquest of the state in World War I, the League of Nations granted Great Britain a mandate to govern Iraq, and it did so until 1932. British influence remained dominant until 1958, when the Hashemite monarchy that Britain had helped to establish was overthrown in a military coup d'état. For a decade after 1958 Baghdad underwent a period of political turbulence, with a succession of coups and military regimes. In 1968 the Arab Socialist Ba'th Party came to power. The Ba'thist government achieved relative stability and internal development, particularly after 1973, when rises in oil prices greatly increased revenues to the government and the populace. It was in this period that Baghdad saw its greatest expansion and development. Both were curtailed, however, by the eruption in 1980 of a bitter war with neighbouring Iran.

British influence

BIBLIOGRAPHY. GUY LE STRANGE, *Baghdad During the Abbasid Caliphate* (1900, reprinted 1983), remains the standard work on the city's history to 1258. GASTON WIET, *Baghdad: Metropolis of the Abbasid Caliphate,* trans. from French (1971), is a general, more anecdotal account. A.A. DURI, "Baghdad," in *Encyclopaedia of Islam,* new ed., vol. 1 (1960), pp. 894–908, brings the history to the middle of the 20th century and includes a bibliography of original sources. A collection of scholarly articles on the history and culture of the city (in French) can be found in a special issue of *Arabica,* vol. 9 (1962). JACOB LASSNER, *The Topography of Baghdad in the Early Middle Ages* (1970), offers a detailed analysis of the city's early geography and development. ROBERT M. ADAMS, *Land Behind Baghdad: A History of Settlement on the Diyala Plains* (1965), studies the area around the city. A discussion of the architectural monuments of Baghdad, with beautiful photographs, is presented in IHSAN FATHI, *The Architectural Heritage of Baghdad* (1964); and JOHN WARREN and IHSAN FATHI, *Traditional Houses in Baghdad* (1982), is an account of domestic architecture. Modern Baghdad is sparsely covered. FREYA STARK, *Baghdad Sketches* (1937), is a personal account of life and customs, now somewhat dated. Later impressions and good photographs are found in the chapter "Baghdad" in GAVIN YOUNG, *Iraq, Land of Two Rivers* (1980), pp. 25–67; and WILLIAM ELLIS, "The New Face of Baghdad," *National Geographic,* 167 (1):80–109 (January 1985). Useful information and detailed city maps are offered in the guidebook prepared by the BAGHDAD WRITERS GROUP, *Baghdad and Beyond* (1985).

(P.A.Ma./L.Y.B.)

Balkans

Since the early 19th century, the name Balkan, a Turkish word meaning mountain, has been applied to the easternmost of the three great southern peninsulas of Europe. The peninsula shades gradually into the European mainland, and it is therefore difficult to assign its exact geographical boundaries; but for the purpose of this article the Balkans are taken to mean the territory of the modern states of Greece, Albania, Yugoslavia, Bulgaria, and Romania. (For further treatment of the physical and human geography and the history of these states, see the articles ALBANIA; BULGARIA; GREECE; ROMANIA; and YUGOSLAVIA.) Western Turkey is often included because of historical considerations and will be discussed here where appropriate. The area possesses certain basal resemblances to the Iberian and Italian peninsulas, particularly in its relation to the folded mountain chains of southern Europe and in its structural elements. During the 19th century, when geographers and geologists were acquiring new knowledge of the interior of the region and were coming to regard it as an entity, not merely as a background to Greece and Byzantium, great political changes were taking place within it. The people, submerged by the Turkish advance, began to organize themselves into national states and, as the Turkish empire contracted, new names appeared on the map. The growth of the new states was accompanied by much turmoil, which had reflex ef-

fects outside the peninsula limits, however these be drawn; but the essential point is that it drew general attention to the region. It became increasingly clear that all the older European states, if in varying degree, were interested in the delimiting of Balkan boundaries, and thus the facts disclosed by detailed geographical study had more than purely technical importance.

No mountain barrier separates the peninsula from the continental mainland. There is thus no sharp break of continuity such as is experienced when the Alps are crossed and a new world is disclosed in Italy. This physical continuity is accentuated by a notable increase in the width of the peninsula toward the north. The line of the Danube and its tributary the Sava has sometimes been chosen as a convenient northern limit (east to west). This limit has a certain justification. The Danube–Sava line, easily recognized on a map, served for a period as a boundary to the Turkish empire and thus as the frontier of Christendom. However, a geographically satisfactory frontier in this northwestern section is difficult to draw. Even the Danube–Sava line, at least to the west of the Danube's Iron Gate, has never been a limit so far as people are concerned; it bears no relation to political frontiers, and the post-1918 state of Yugoslavia extends well beyond it.

The second outstanding feature is the peculiar structure that causes the peninsula to fall into two very unequal and very dissimilar parts. To the south is Greece, a secondary peninsula, with an average width of only about 125 miles (200 kilometres). Although both sections are highly mountainous, not only is the Greek section much narrower but also it has a peculiarly dissected coastline that brings sea influences within easy reach of nearly every part. The broad, continental northern section, on the other hand, is largely removed from the surrounding seas because of its width, the nature of its shorelines and, in part, of the direction of its mountains. In climate, in vegetation, and in possible crops, it differs profoundly from Greece. No less profound was the effect of the actual remoteness from the sea routes so freely open to the people of the south. It is this division into two parts—one sharing in the full life of the Mediterranean peoples, the other cut off from it—rather than the absence of a definite northern limit that made the European world so slow to recognize the existence of a Balkan peninsula. Until the peoples of the continental segment awoke, the whole northern area tended to be regarded only as a broader equivalent of the Alps or Pyrenees: the real peninsula was the Grecian one.

The article is divided into the following sections:

Physical and human geography

THE LAND

Relief. It is the presence within the peninsula of young fold mountains that makes it essentially similar to the Iberian and Italian peninsulas. Two separate series of these can be recognized, one, of transverse direction, lying to the east, and the other, which is longitudinal, in the west. The Transylvanian Alps swing around in a great curve, the Danube breaking through at the Iron Gate at the western apex of the curve, and are continued in the Balkan Mountains (Stara Planina), which have a roughly parallel direction. Fingering out eastward into several separate ranges and breaking off steeply on the shores of the Black Sea, these rise to a maximum height of nearly 8,000 feet (2,440 metres), and the most noted of their passes, the Shipka Pass, has a summit level well above 4,000 feet. Northward these mountains sink gradually to a limestone tableland, presenting a marked contrast to the alluvial Walachian plain (Cîmpia Romînă) beyond the river, and the presence of this tableland means that the northern slopes as far as the passes, relatively high though these are, are gentle.

Just as the Balkans are a continuation of the Carpathian branch of the Alpine chain, so the main chain itself bends down the western side of the peninsula. From the Julian Alps north of Trieste a series of mountains runs in a southeasterly direction close to the coast and parallel with it. These, to which the general name of Dinaric Alps may be given, rise to 8,274 feet in the peak Bolotov Kuk of Durmitor; but their significance as a barrier does not depend upon their height. They are characterized by the great development of massive limestones, particularly extensive in the area lying behind the peninsula of Istria. These limestone areas, called karst, display to a very marked extent certain peculiar relief features, dependent on the effect of rainwater on their constituent rocks. Thus the surface soil is very thin, bare rock being frequently exposed; running water is usually absent at the surface, most of the rivers sinking, after a short course, into cavities of the rocks; and caves and sinks are common, as well as elongated depressions called locally *polje*, or fields, because only in them as a rule is there sufficient depth of soil to permit cultivation.

In places the limestone mountains rise steeply from the shore of the Adriatic, but a certain amount of subsidence has occurred, with the result that numerous islands fringe the coast. Because the mountain folds run parallel to the shore, the islands tend to be elongated in the direction of the coastline, and the straits and inlets tend to have the same direction.

The Dinaric Alps may be said to extend to the neighbourhood of the mouth of the Drin in Albania. There the coast changes in direction, trending almost north–south, and the mountain belt thins out and draws back from the coast, so that the Albanian lowland invervenes between it and the sea. This triangular area, with its inland apex at Elbasan, extends southward to Vlorë (formerly Valona); it shows another contrast with the Dalmatian area farther north in that several large and permanent rivers flow from the mountains across the lowland to the sea; there, then, access to the interior becomes at least relatively easy.

Vlorë, with the adjacent sheltering peninsula ending in Cape Linguetta (Albanian Kep i Gjuhëzës), marks the beginning of a new change. The coast resumes a southeasterly direction and the fold mountains become more conspicuous as the Pindus range, which extends through peninsular Greece. Beyond the down-faulted Gulf of Corinth, in the Peloponnese, the ranges diverge like fingers, leaving narrow triangular plains in between. In the eastern part of the Greek peninsula several ranges diverge eastward or southeastward from the Pindus, and between them lie the well-watered open plains which, like those of the Peloponnese, nourished early centres of civilization.

The Balkan Peninsula's central core

The central core of the Balkan Peninsula is an old crust block, roughly triangular in shape, with its apex pointing

toward Belgrade and its broad base approaching the shore of the Aegean Sea. That sea is believed to overlie a former extension of the crust block that has sunk beneath its waters. The numerous Greek islands represent fragments of the surface of this lost land that remained above sea level when the remainder sank. The narrow staits of the Bosporus and Dardanelles are also regarded as flooded parts of the courses of rivers which crossed the old land.

The central core of the peninsula, though it has retained a position above sea level, has been greatly modified as a result of the formation of the fold mountains on its margins. The narrowed northern region, constricted between the Dinaric Alps and the curve of the Balkans, is a broken hilly country traversed by a continuous longitudinal depression through which the Morava River flows on its way to the Danube. South of Niš (Nish), Yugoslavia, however, and extending to the Gulf of Salonika is a region of great structural complexity which seems to have received the full force of the thrust. Faults are innumerable, and closed basins alternate with short and steep highland belts. The basins tend to be elongated in a longitudinal direction, and the major river courses—for example the Vardar—consist of alternating basins and gorges. Many of the basins have formerly been lakes, and since they are floored with fertile soil, they are fitted to become centres of population; but their isolation from each other has had very important human effects.

In contrast with this fractured and much subdivided region, the southeastern part of the triangle, that lying between the Balkans and the Aegean, shows relative simplicity. There the core reaches its greatest height (9,596 feet in the Rila Mountains), and there also is the broadest unbroken mass of elevated ground. The general name of Rhodope (Rodopi) may be given to the whole block, though the separate parts have local names. The Rhodope upland is separated from the Balkan Mountains by a considerable lowland, the Rumelian plain. This is one of the most considerable tracts of lowland within the peninsula and continues to the shores of the Sea of Marmara. There is also an interrupted belt of plain in Thrace, between the Rhodope and the Aegean, the total result being to make the southeastern part of the peninsula much less continuously hilly than the northwest, where lowlands are virtually absent.

Settlement patterns. The build of the peninsula has influenced the routes and the areas of settlement within and the zones of effective contact with adjacent lands outside. The Balkans have indeed proved in practice much less of a barrier to human movement than would appear from a map.

Yugoslavia. An orographical map shows an almost continuous area of high ground on the west, continued into the Grecian peninsula, which is mostly mountainous. In the northwest the way in which the high ground within the peninsula passes into the Alps proper means that the Danubian plains have no natural, easy exit to the Adriatic. But the mountain belt thins out in the karst of the Slovenian Julijske (Julian) Alps. Although this belt is neither wide or lofty—it does not rise much above 5,000 feet—because of its karstic nature it forms a very effective barrier. The chief elements of the belt are the Velika Kapela and Velebit mountains, both remarkably waterless and barren. Continuous river valleys to serve as natural routes are generally absent and, where they do occur, the stream tends to flow in steepsided canyonlike gorges that form a great obstacle to transverse movement. Further, not only do these lands form a barrier between the sea and the interior but also they can as a rule support only a scanty and scattered population, for the local resources are small.

Beyond the karst areas lies a tract of undulating country. This area is a continuation of the plains of the Danube and, where the Drava and Sava converge toward one another in Slavonija, it includes a considerable area of true plain. This whole area of mountain and plain was once the kingdom of Croatia-Slavonia; from a physical standpoint it is a transition region between central Europe and the Balkan Peninsula. Until the creation of Yugoslavia it had little direct relation to the Adriatic, though economic and political causes led to Hungary's making great efforts to develop Rijeka (Fiume) as a grain port during the late 19th century. In the past, Croatia-Slavonia was politically, economically, and culturally attached to central Europe, but ethnically it belongs to the Balkan Peninsula.

Dalmatian coast islands

The islands off the Dalmatian coast to the south are usually fertile and there is often a strip of productive land fringing the inlets. Water is also easy to obtain, for the streams which were lost on the heights above emerge as full-grown rivers where the rocky hills descend in cliffs to the sea margin, or springs even bubble up on the seafloor itself. In contrast with the dry and barren lands above, therefore, there is possibility of cultivation and settlement on the shore. But the coastal areas are too narrow and the difficulties of communicating with the interior too great to have allowed for the rise of indigenous civilizations there. The scattered towns on this Dalmatian coast represent islets of ancient but alien (Venetian) culture and, until relatively recent times, scarcely influenced the interior of the peninsula. They arose as offshoots of areas enjoying much greater advantages.

To the south of the Velebit mountains a narrow strip of coastline, with the mountain crest behind, forms Dalmatia. But the historic Dalmatia is really an interrupted series of maritime towns, Zadar, Šibenik, Trogir, Split, and Dubrovnik (respectively the former Zara, Sebenico, Trau, Spalato, and Ragusa) being among the most important. Until the creation of Yugoslavia these towns had little connection with the interior.

The actual mountain belt, from the borders of Croatia-Slavonia to the confines of Greece, extends through the Yugoslav republics of Bosnia-Hercegovina and Montenegro, to Albania. In Bosnia the limestone rocks of the coastal area give place to others, including sandstones, which allow for the development at once of deeper soils and of a more normal drainage system. Numerous rivers drain into the Sava, and Bosnia can be reached from that river, and thus from the Danubian plains, with relative ease. Other route lines connect it with the interior. Hercegovina is a karstic area with only one important river, the Neretva, which flows to the Adriatic. Montenegro is essentially a mountain aerie, a refuge that withstood invasion in the past as much perhaps because of its worthlessness as of the difficulty of conquest.

Eastern Yugoslavia comprises the western part of the crust block, with its marked contrast between the northern section, draining into the Danube mainly by the Morava, and its complex southern section, draining into the Gulf of Salonika by the Vardar. West of the Morava the country is undulating, and lowlands fringe the southern bank of the Sava. The Western Morava, a tributary entering the main stream from the west, also helps to define a block of land which affords possibilities of settlement. This was the nucleus of 19th-century Serbia, with Belgrade, at the junction of the Sava and Danube, as its capital. The complex southern region is Macedonia, with its jumble of people and its long history of turmoil and disorder.

Albania. Albania, with its coastal lowland, formerly malarial, and its mountainous hinterland, is a region of much interest. As already seen, it affords the possibilities of routes to the interior by the Drin, Shkumbin, and Vijosë valleys.

Greece. Peninsular Greece comprises three relief elements: (1) the Pindus ranges in the centre and in the west, continuing southward beyond the Gulf of Corinth into the four-fingered Peloponnese; (2) the western coastal belt, which is more broken than that of Dalmatia, while the offlying Ionian Islands are larger and exhibit less parallelism to the coast; (3) the eastern ranges and plains, which in the north belong (including Mt. Olympus, 9,570 feet) to the old crust block and farther south are offshoots of the Pindus. The continental or truly Balkan portion of Greece comprises the uplands and plains of southern Macedonia and Thrace, which provide an east–west passageway between the Rhodope and the sea. The plains are largely spread around the lower courses of the major rivers—the Vardar (Axiós), Struma (Strimón), Néstes, and Maritsa (Évros). They were formerly swampy, but many drainage works were executed between World Wars I and II.

Bulgaria. Bulgaria has as its northern frontier the Dan-

ube, except where the river takes its great bend to the north; there the frontier leaves it and runs slightly south of east to the Black Sea, much of the steppelike Dobruja being included in Romania. Southward Bulgaria extends to the Rhodope crest, and it is thus nearly bisected by the Balkan Mountains. Sofia, the capital, lies in a small basin between the Balkan Mountains and a northwesterly prolongation of the Rhodope, the basin being drained by the Iskŭr River, which breaks through the Balkans to enter the Danube. South of the range, and separated from it by a longitudinal depression, lies a parallel upland, the Sredna Gora (Middle Forest). The invervening depression (known, from its principal product, as the "Valley of Roses") is watered by the Tundzha River, which seems to be making for the Black Sea near the port of Burgas, but turns instead sharply southward, breaks through the western end of the Istranca and joins the Maritsa at Edirne.

Bulgaria's "Valley of Roses"

The upper Maritsa, on which stands Plovdiv, flows through the wider depression which has been called the Rumelian plain. These two fertile lowlands, with their bounding uplands, form Eastern Rumelia, which was not united politically to northern Bulgaria until 1885. This region, with southern Macedonia, formed the granary of Turkey in Europe, as it did of the earlier Eastern Empire. The Maritsa depression shows certain analogies to the valley of Andalusia in Spain, both in its position between fold mountains and a crust block and in its value to an invader.

Transportation. Greece within its peninsula, Serbia in the Morava region, and Bulgaria astride the Balkan Mountains all became independent states while Turkey still held Thrace, Macedonia, Albania, and, at least nominally, a large part of the northwest. That the progressive contraction of Turkish territory led to such bitter and prolonged conflict was largely the result of the nature of the routes within the continental section of the peninsula, and particularly of the difficult access of both Bulgaria and Serbia to open water. Thus the natural route lines demand careful consideration. But the routeways which were important in the historic or even the recent past are not necessarily those of most value, for the current political subdivision of the peninsula and in particular the interposition of iron curtain frontiers across the routeways materially lessen their significance.

On the northern, southern, and eastern margins of the peninsula, respectively, are situated the three nodal points of Belgrade, Thessaloníki, and Istanbul, all owing their importance to the land and water routes which converge upon them and all linked together by rail.

Belgrade is situated at the junction of four great routes: from the north and the east, the Danube valley; from the south, the Morava–Vardar corridor; from the west, the Sava valley. The Danube is continuously navigable, despite the partial interruption of the Iron Gate, downstream to the Black Sea as well as upstream. The Sava, though not a first-class waterway, can be used by steamers as far as the Kupa confluence at Sisak. Apart from the waterways, no fewer than seven railway routes converge on the city; the most important are the Orient Express routes from western and central Europe to the Aegean and the Bosporus—from France and Italy via Zagreb and the Sava valley, from Belgium and Germany via Budapest and the Danube plain; to Athens via the Morava and Vardar valleys, to Istanbul via the Morava valley and Sofia, and to Bucharest via Vršac. The last-named route lost its international significance after Romania became a Soviet satellite. An important narrow-gauge railway leads southward across the mountains to the Adriatic coast at Dubrovnik.

The port at Thessaloníki

Thessaloníki is the only good port on the northern coast of the Aegean and is the best exit to open water for much of the interior. Three major land routes and some minor ones converge upon it. The first group consists of the meridional furrow indicated by the direction of the Morava and Vardar rivers, the route from Istanbul by the Thracian lowland and the route to Athens.

The Morava–Vardar furrow is followed by the railway from Belgrade to Thessaloníki by way of Niš and Skopje. Although the headstreams of the two rivers, despite their contrary direction, actually interjoin in wet weather, it must not be assumed that a continuous valley line extends from the Danube to the Thermaíkós Kólpos (the Gulf of Thérmai). The Morava, upstream from Niš, and the Vardar, downstream from Skopje, both pass through gorges which offered considerable resistance to through communication in prerailway days. The Morava gorge at Vranje was actually the Serbian frontier at one stage in the development of that state and at the time the railway was built (1887)—a clear indication of the break in the furrow there. The Belgrade–Skopje section of this route was effectively duplicated in 1931 by construction of a railway which leaves the Morava valley at Lapovo and proceeds via Kragujevac, the Ibar valley and the Kosovo Polje.

The second major route entering Thessaloníki runs through the Thracian plains and hills from Istanbul. It dates from 1895 and was essentially strategic in character—it was built at least 12 miles from the coast to be beyond what was then the range of naval bombardment, and the two major ports which it served, Thessaloníki and Dedeağaç (modern Alexandroúpolis), were both provided with bypass lines. It has had relatively little international significance, though it remains a possible route from central Europe to Istanbul, avoiding the crossing of the iron curtain frontier of Bulgaria. The third route is the southward continuation of the Orient Express route, from Thessaloníki to Athens. This, sometimes called the Greek Longitudinal railway, was completed after the Balkan Wars, in 1916, but its functioning as an international route was delayed by World War I and its aftermath until 1920. It is a difficult route, alternately crossing plains and mountain ranges; its ruling gradient is 1:50.

The westward communications of Thessaloníki are less important. A railway runs to the Florina basin and then turns north, crossing the Yugoslav frontier to Bitola and eventually linking with the Vardar valley line at Titov Veles. The road to the Adriatic, though of no significance at all in modern times, was an important Roman route—the Via Egnatia—leading from Bitola, Lake Ohrid, and the Shkumbin valley to Durrës (Italian Durazzo, Roman Dyrrhachium).

The fact that Thessaloníki is politically Greek and not attached either to Yugoslavia, despite the presence of the Morava–Vardar furrow, or to Bulgaria, despite the relative nearness of Sofia, is explicable rather by the strength of a cultural and historical tradition than by purely physical facts. It is an Aegean port of much importance in the modern world, and to the Greeks the idea that control of Aegean trade is their national right is one that admits of no argument. Part of its basis is of course the geographical fact that their somewhat barren land could not support them unless supplemented by the sea trade for which they have always shown natural aptitude.

Istanbul, with a superb natural position where the waterway from the Black to the Aegean sea crosses the land route from Asia Minor to the Balkan peninsula, is connected to Belgrade by a diagonal furrow, certainly as important as the north-to-south one from Belgrade to Thessaloníki. The route follows the Morava valley to Niš, ascends the Nišava tributary and crosses the Dragoman pass (2,550 feet) to the basin of Sofia, then by another pass it reaches the Maritsa valley and follows this past Plovdiv and Edirne until the valley of the Ergene enables it to turn east toward Istanbul.

The main international railway routes through the Balkan peninsula were conceived in central Europe about 1869, when Turkey still held a large part of the peninsula. The wars of 1876–78, which materially altered the political map, upset the plans, but the main lines, Vienna–Belgrade–Sofia–Constantinople and Niš–Thessaloníki, which in any case were to be international and not local avenues of transport, were opened in 1888. Subsequently, the political boundaries changed several times, more notably after the Balkan Wars of 1912–13 and after World War I, and the creation of a railway network thus responded to different national and local stimuli at different times. For its size and economic development, Bulgaria has a fair system, with important lines linking Sofia with the Danube and with the Black Sea ports of Varna and

The opening of international railway routes

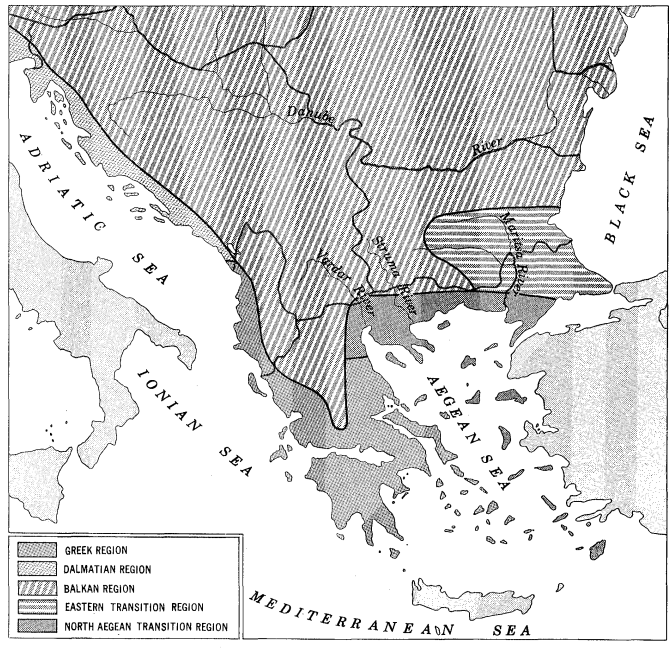
Burgas, an important though difficult route across the Balkan Mountains and many branch lines. After World War II the construction of a bridge across the Danube at Ruse made possible a through route to Moscow. Yugoslavia, assembled like a jigsaw from Serbia, parts of Austria-Hungary, and what remained of Turkey, had to create a national railway system from a series of fragments—and largely succeeded in doing so between World Wars I and II. Its main needs were for better communication between the capital and the Adriatic ports of Split and Dubrovnik, for more railways in the south, and for bridges across the Danube and Tisza rivers.

Climate. A central European climate prevails through the greater part of the broad northern section of the peninsula and even extends into the centre of the northern part of the Greek section, and elsewhere the climate is Mediterranean. No notable difference in climate separates the peninsula proper from the adjacent Danubian lands.

The Mediterranean climate is of peculiar interest because it is so closely linked to a particular type of culture showing a very delicate adaptation to local conditions. Three essential features differentiate the Mediterranean climate: the winters are warm in relation to latitude and the greater part of the rain falls during that period; the summers are hot and dry and one or more months may be practically rainless; throughout the year the skies are clear and there is abundant sunshine, for the winter rains come in heavy showers of short duration. Two regions within the peninsula show typical Mediterranean climate.

One of these is made up by the Greek islands, the Peloponnese, the margins of the northern part of the Greek peninsula, and a narrow strip on the coast of Albania. Even within the region so defined, however, elevation above sea level, as in the mountains, or an upland girdle, as in the plain of Thessaly, may produce local modifications. Athens and Corfu may be taken as representative places within this region. Athens, on the eastern side of a peninsula, largely sheltered from rain-bearing winds, has a much smaller total rainfall than the island of Corfu, which faces the wet winds of winter; but, despite the difference in the amount of rain in the two places, its distribution is closely similar. At both places winter temperatures, as far as monthly averages are concerned, do not fall below 48° to 50° F (9° to 10° C). Summer temperatures range from 78° to 81° F (25° to 27° C; July averages), which permits the ripening of subtropical fruits. In Athens, July and August are practically rainless and only about one-fourth of the total fall occurs in the period April to September, so that more than three-quarters of the total falls in the cooler half of the year. More than one-third falls in the two rainy months of November and December. Corfu has a rainfall four times as great as that of Athens, and, although only July can be described as practically rainless, only about 20 percent of the total rainfall occurs in the period April to September.

A narrow strip along the coast of Dalmatia is regarded as forming a second major region. Dubrovnik may be taken as typical, bearing in mind, however, that it is the most southerly of the important towns of Dalmatia. The winter temperatures there are closely similar to those experienced in the Greek region, much of Dalmatia being remarkable for its mild winter climate. The summers are not quite as hot as in Athens or Corfu, but the real distinguishing feature is the less marked periodicity of the rainfall. There is no rainless month, although July continues to be the driest period of the year. More than 30 percent of the total rainfall occurs during the period April to September, so that summer drought is far less marked. Oranges can be grown without irrigation, and their coexistence with the olive is a distinguishing feature. Not only, however, is the strip with this typical Mediterranean climate very narrow, but changes occur with considerable rapidity toward the north. Except where, as in Split, the form of the coastline gives shelter, the more northerly places are often exposed to the blast of the bora, or cold northerly wind of winter, which at once is a danger to shipping and excludes the more delicate Mediterranean fruit trees. When Trieste is reached on this eastern Adriatic coast, the somewhat cold winters (January average below 40° F) and the fact that



Five major climatic regions of the Balkan peninsula.
From W.G. Kendrew, "Climates of the Continents," by permission of the Clarendon Press

the period April to September shows rather more than half the total amount of rain, with a rainfall maximum in October and a secondary one in June, mark the transition from the Mediterranean climate to the central European one. The northerly Dalmatian towns and the coast of Croatia show stages of the transition.

Southern and eastern Macedonia and western Thrace fall into a third region, characterized by notable modifications of the Mediterranean climate. Thessaloníki may be selected as a representative locality. The winters are cold for the latitude (average January temperature 41° F [5° C]) because of the bitterly cold northerly winds which blow down the Vardar valley, and this feature is accentuated as the coast is left. But the summers are hot and the range of temperature between summer and winter is greater than at any of the places already discussed. There is no rainless month, and, though July is still the driest period and November and December are the wettest months, there is a much more even distribution of rain throughout the year, the six colder months having very little more rain than the six warmer ones. The colder winters, especially where there is exposure to wind, again limit the distribution of the more delicate Mediterranean fruit trees, and growth even of hardy plants is checked during winter. On the other hand the high summer temperatures and the fairly heavy summer rainfall, with the possibility of irrigation from the mountain snows, make it possible to grow crops demanding both heat and moisture but being indifferent to winter cold because of their annual nature. Among such are cotton, rice, tobacco, corn (maize), and, historically, the opium poppy.

As one passes northward from Thessaloníki into the interior of the peninsula, the change in this fourth region, from the modified Mediterranean to the true central European climate, is rapid and is accentuated by the relief. The general features of that climate are the cold winters, the temperatures then showing little relation to latitude, the warm summers and a rainfall well distributed throughout the year, but with a tendency toward an early summer maximum. Skopje, in a latitude somewhat lower than that of Dubrovnik, though in a more elevated position, has mean January temperatures well below the freezing point and fully 18° F (10° C) lower than those of Dubrovnik. This means that there is a definite winter stoppage of agricultural activities, December, January, and February all being too cold even for the growth of grass. On the other hand, despite its elevation, the summer temperatures at Skopje are not more than a few degrees lower than those of Dubrovnik. The rainfall is fairly well distributed

thoughout the year but May, June, and October are the rainiest months, the maximum fall coming in May when temperatures are already fairly high (more than 62° F [17° C]). Belgrade, considerably farther north but less elevated than Skopje, has a very similar temperature range, but November is already a winter month. June instead of May is the rainiest month and the summer rainy period lasts for the three months of May, June, and July, again with a second rainfall maximum in October. Broadly speaking, this climate, with summer heat and summer moisture coinciding, is one well suited to corn among cereals. With local variations caused by height above sea level and by degree of exposure, this type of climate prevails throughout the greater part of the interior of the peninsula, which thus falls into a fourth or central major climatic region. The total rainfall shows a tendency to increase toward the northwest, in Bosnia and northwestern Serbia; it diminishes toward the east.

As a fifth major region, eastern Thrace and the plains of Bulgaria may be included. Over much of this region, especially in Thrace, the total rainfall is very small, giving the landscape a steppelike appearance, and the winters are very cold as a result of exposure to winds from the Russian plain. The Maritsa valley allows Mediterranean influences to penetrate into southern Bulgaria, where also the Balkans give a certain amount of shelter from the cold winds of winter. Parts of the valley plains of Bulgaria have in consequence much milder winters than northern Macedonia or Serbia, and, as there is a tendency for the winters to be wetter than the summers, the climate is sometimes described as modified Mediterranean. The dry, sunny summers favour wheat rather than corn, and the vine is grown in sheltered places. Cotton and rice are grown with irrigation.

To this general division of the whole area into five climatic regions, of which the central one covers by far the greatest area, it may be added that the fact that so much of the surface is elevated introduces numerous modifications in detail. Because of the cold winters of the central area, much of the winter precipitation falls as snow. No mountain within the peninsula rises in the strict sense above the snow line, but the higher peaks of the Rhodope are only snow-free for about one month in the year, and even the Balkan Mountains show some snow until July.

Plant life. The flora of the Balkan peninsula is one of the richest in Europe and consists of about 6,600 species of vascular plants. The largest families, on the basis of numbers of species, are the Compositae, Leguminosae, Caryophyllaceae, Labiatae, Gramineae, and Cruciferae. The genera with most species are *Centaurea* (knapweeds), *Silene* (campions), *Dianthus* (pinks), *Trifolium* (clovers), *Campanula* (bellflowers), *Carex* (sedges), *Verbascum* (Mulleins), and *Thymus* (thymes). Floristically, Greece is the richest area. Apart from the actual number of genera and species the flora of the Balkan peninsula is botanically noteworthy for the number of its endemics (plants found nowhere else in the world). The central portion of the Balkan peninsula is geologically old and has been a land surface at least since the advent of the flowering plants. Moreover, the effects of the Ice Age were much less drastic than in northern and central Europe and many plants found a refuge in the peninsula. There are, therefore, a considerable number of old relict types in the flora. Examples are *Ramonda* and *Haberlea* of the Gesneriaceae, related to western Chinese genera, the Serbian spruce (*Picea omorika*), the Balkan yam (*Dioscorea balcanica*), and *Forsythia europaea*, the only native European species of this well-known garden genus. In contrast, there are many species that are most probably of relatively recent origin and may have partly originated by hybridization following the clearance of woody communities by man. Thus many of the pinks, campions, mulleins, and thymes are closely related one to another and appear still to be evolving new microspecies.

Given the old Tertiary basis of the flora, the chief migration routes have been from the north and the east. From the north there was an extension of central European species, especially with the oncoming of the glacial period. The Aegean Sea is of recent geological origin, and plants from Asia Minor undoubtedly contributed to the floristic wealth of the Greek mainland and islands.

The vegetation of the Balkan peninsula clearly demonstrates the controlling influence of climate on plant life. In the northern and central parts the climax communities are deciduous forests up to about 4,900 feet (1,500 metres), then coniferous forests to about 5,900 feet (1,800 metres) and above these are high mountain scrub and herb and mat associations. In the southern and western coastal districts evergreen Mediterranean woods and brushwoods naturally dominate, with oak and conifer forests at the higher altitudes. Throughout the peninsula there has been great destruction of the woody vegetation by man.

Animal life. The distribution of the animal life of the Balkan peninsula is a fusion of three major elements. Mediterranean forms dominate along the southern and western borders of Greece, Albania, and Yugoslavia; eastern steppe species in the lowlands of the east; and central European forms in the interior. Some of them are widely distributed in Europe, mainly in the mountains, whose peaks still have an Alpine element.

Among Mediterranean mammals are wild goat (bezoar), jackal, porcupine, and several kinds of bat. Eastern elements include the ground squirrel (*Citellus*), some forms of hamster, the mole rat (*Spalax*), etc. The mole, lynx and wildcat, marten, wolf and fox, bear, hare, boar, and red and roe deer are some of the central European mammals, while the chamois is an example of the Alpine element. The same types of distribution are found among the breeding birds. In the south and in Dalmatia, Mediterranean forms predominate, with the great cuckoo, the melodious warbler (*Hippolais*), etc.; and these also penetrate some of the great river valleys (*e.g.*, the Vardar) far to the north. Central European forms include chaffinch, creeper, and some thrushes; among eastern types are the little bustard, the lesser gray shrike, and the red-footed falcon; among Alpines are the mountain lark (*Eremophila alpestris*) and the Alpine ptarmigan. The big birds of prey include the golden imperial eagles and several kinds of vulture. The red-legged partridge (*Alectoris*) and the stork are common.

Among reptiles various forms of lizard are known, especially in seaside regions, and a certain number of species of gecko, turtle, and snake, among which are three kinds of poisonous viper. There are amphibians belonging to the Palearctic fauna; *e.g.*, the true toads, while central European fauna include true frogs, spadefoot toads, and salamanders. There are also some Mediterranean forms. The fishes of lakes and rivers include carp, barbel, small salmon, wels or sheatfish (*Silurus*), etc.

The same zoogeographical pattern is found in the invertebrates. Among harmful plant insects are tussock moths and Moroccan, Italian, and migratory locusts. After World War I the San José scale and the Colorado beetle were brought to Europe from America. The Colorado beetle, which did not reach the Balkans until after World War II, spread quickly.

In low-lying land near water, domestic buffaloes are not uncommon. The important meat animal is the pig and the chief milk and meat animals are cattle and sheep. Hens and turkeys are common among domestic birds.

Very special and localized faunas, not discussed here, live in the delta of the Danube, in the islands of the Aegean Sea, and in Crete.

THE PEOPLE

Ethnic distribution. Five major ethnic groups or races are to be found in the Balkan peninsula. These are the Albanians, the Greeks, the Bulgarians, the Southern Slavs (Serbs, Croats, Slovenes, Montenegrins), and the Turks. All of them, with the possible exception of the Southern Slavs, have at one time been spread over wider areas than those they now occupy. This is particularly true of the Turks, who for several centuries were primarily the governing occupiers of most of the peninsula. They also fairly effectively colonized certain parts of it, particularly in Thrace, Macedonia, and in northeastern Bulgaria, and were finally ousted after World War II. This is also true of the Bulgarians, who at one time extended throughout much of Macedonia and Thrace. World Wars I and

Frontier adjustments

II, and the resultant frontier adjustments and population exchanges, have given the political map a much closer resemblance to the map of nationalities than it has ever had before. Outside of the northwestern fringes of the peninsula, where some Romanians, Hungarians, Austrians, and Italians are included in Yugoslavia, the Albanians of the Kosovo Autonomous Region are probably the most sizeable minority left inside the territory of another country. The most mixed region is undoubtedly Macedonia. There, ethnic differences have been confused by differences of religion, and adherents of the Greek Orthodox Church were long regarded as Greek, whatever their ethnic heritage; similarly, all Muslims were formerly regarded as Turks, whether they were of Bulgarian, Albanian, or Southern Slav stock.

Ethnology. The ethnology of the Balkan peninsula is more involved than that of either the Italian or the Iberian; first, because this peninsula has a more fragmented geography; and second, because it is open to entry from more directions. On the northwest the plains of the middle Danube afford a way to central Europe; on the northeast there is a wide corridor through Moldavia from the steppes of the Ukraine; on the east, an easy passage is possible from Asia Minor across the Bosporus and through Thrace; while the coasts of Greece are accessible to all the eastern Mediterranean basin, and those of Dalmatia, though cut off by mountains from the interior, are easily approached by water from across the Adriatic. People entered the Balkans from all these directions and left vestiges of racial types and customs derived not only from many parts of southern and central Europe but also from wide areas of central Asia and the near east.

The main ethnic divisions of the Balkans are based on linguistic and religious differences rather than on true racial distinctions. Yet it is remarkable that in many cases the cultural group has clearly recognizable physical features which it may have acquired through long isolation and inbreeding. Moreover, despite repeated immigrations into the peninsula from the heart of the continent, certain racial types have persisted there and absorbed the new blood from outside. Thus there is little doubt that the Slav-speaking folk who poured into the Balkans from the 3rd century AD, and particularly after the 6th century, were predominantly of Nordic race; yet the present day Southern Slavs belong principally to the Dinaric race—tall, dark, and with high and broad head and prominent nose—a type that is probably very ancient there and that is also found farther west in a highland zone extending through northern Italy, southern Germany as far as Austria, and Switzerland.

The Southern Slavs. These people, separated by the intrusive Magyars from their linguistic kinsfolk to the north, are united by ties of language and political allegiance. They are, however, subdivided by differences of religion, the Croats and Slovenes being Roman Catholics, the Serbs proper and Montenegrins mostly Greek Orthodox. Moreover, among the Dalmatians, Bosnians, and Hercegovinians, who are normally classed with the Serbs, there are in addition to the Greek Orthodox Christians considerable Roman Catholic minorities, and in the last two cases also a fair proportion of Muslims.

The Slovenes of Carniola are physically very similar to their Austrian neighbours. They are of low height, with small round heads of Alpine type, and include a good number of fair individuals. Among the Croats to the south, however, there are on the average more tall individuals and more broad heads, dark colouring, and prominent noses; and farther south still, among the Serbs, these Dinaric features become pronounced. Among the Serbs there is a preponderance of high broad heads, giving a mean cephalic index of about 85; the face tends to be long, the colouring of eyes and hair to be dark, and the nose to be high-rooted and straight or convex, with a downward-turning tip.

The Bosnians and Hercegovinians are, like the Serbs, on the average tall and broad-headed; but there is an interesting physical difference between the Roman Catholic and Muslim communities, doubtless the result of protracted inbreeding within each group. The former includes a larger proportion of tall, fair, and very broad-headed individuals.

Along the Dalmatian coast, the extreme broad-headedness of the population of the mountainous interior is not found, and among the inhabitants are more long-headed individuals of the Mediterranean race. Farther southeastward along the coast, from Istria to the borders of Albania, the population becomes on the average progressively taller and more dark in complexion.

In physique and culture, the Montenegrins, who live in rugged and isolated limestone mountains, are the most distinctive of the Southern Slavs. Although they speak a Slav Serbian language, they resemble the Albanians in their loyalty to their exogamous clans. They are probably the tallest people in Europe, and at the same time they are thickset and very heavily built. Their heads tend to be broad and high-backed and their noses large and beaked. In these respects they resemble the Dinaric type, which seems to be very old-established in the western Balkans. But they differ from the standard Dinaric type in having broad rather than high faces, a high proportion of light eyes and, in particular, a preponderance of red hair, red beards, and freckling.

Albanians. About half of this group lives outside the boundaries of Albania, for the most part in Yugoslavia. They are distinguished from the Slavs by language in the first place, the Albanian tongue being a mixture of elements from Illyrian, Thracian, Latin, Slavonic, and Turkic. They are also separated from their neighbours by religion and general culture, and there is no doubt that they represent the survivors of the native inhabitants of the Balkans in classical times, the Thracians, Macedonians, and Illyrians, who were driven back into isolation by the invading Slavs. Later, the Albanians became even more alien to the Slavs by adopting Islām from their Turkish conquerors in the late 15th century. Nearly all the Albanians in Yugoslavia and most of those in Albania are Muslim.

Distinctions between Albanians and Slavs

There are two distinct groups of Albanians, each with its own dialect, costume, and customs. These are the Tosks in the south and the Ghegs in the north and on the plain of Kosovo. The Ghegs comprise 10 tribes, each of which is subdivided into political groups known as *bairaks* and on a quite separate system into exogamous patrilineal clans, or *fis*. This *fis* system often leads to inbreeding within small areas, through the institution of cross-cousin marriage, with the result that the physique of the Ghegs varies from district to district. In the north, near the borders of Montenegro, a tall thickset type, like the characteristic Montenegrin, is found, while to the east the population includes more individuals of the Atlanto-Mediterranean strain, tall but not very heavily built, with long head, dark hair, and dark brown eyes. But the most characteristic physical type among the Ghegs, which there as elsewhere is probably by origin a hybrid, is the Dinaric, commonest in the tribe of Dibra. This type is of medium height, with a characteristically narrow and convex nose, light brown eyes, and dark brown hair, and above all with a very broad and flat-backed head. This extreme occipital flattening may be partly artificial, resulting from the use of a hard cradle, but it appears that this is not the whole explanation and that it is also an inherited racial character.

The Tosks, like the Ghegs, are extremely broad-headed; in fact, the mean cephalic index measured in a Tosk district of southwestern Albania, 90.8, is the highest recorded in Europe. But the broad-headed character of the Tosks is of a different type from that of the Ghegs. The head is globular in shape, with high and bulbous forehead, and the back of the head is not flattened. In addition, the nose lacks the high bridge and depression of the tip that are often observed among the Ghegs. The Tosks, in other words, belong to the Alpine variety of the broad-headed people of Europe rather than to the more specialized Dinaric variety, and in this respect resemble closely the inhabitants of southern and central France.

Greeks. Inside Greece the population is by no means homogeneous. Whole districts, even as far south as Attica, still speak Albanian, and wide pastures on the Pindus mountains are still the preserve of Romanian shepherds. The common loyalty of the modern Greeks, therefore, is linguistic and religious rather than territorial.

Variation among Greek communities

Among the Greek-speaking peoples can be traced a variety of communities of different physical types. These physical distinctions are doubtless the result of segregation and inbreeding within the various small compartments into which the territory of Greece is naturally divided, and it is likely that these distinctions were equally noticeable in classical times. Differences of head form from region to region afford a good illustration. In the high western slopes of the Pindus mountains or the district of Epirus, as well as in Macedonia, the Greek population, like their Tosk neighbours in Albania, is extremely broad-headed, with mean cephalic indexes of about 85–88. In the Peloponnese, Attica, and the Ionian Islands, on the other hand, the populations have a mean cephalic index of 81 or 82, while in Thessaly the inhabitants are comparatively long-headed, with a mean cephalic index of 77. There is also a regional variation in the colouring of the complexion, the Macedonian Greeks, for example, being noticeably fairer than those of the Ionian Islands and the Peloponnese.

Briefly, three main types can be traced within the Greek population. The first, with heavy and dark beard, strong brow ridges, and eyebrows which run together, clearly belongs to the Alpine race. The second is taller, with a fairly long head, straight nose, and dark brown hair and eyes, and represents a tall variety (Atlanto-Mediterranean) of the Mediterranean race. Third, much less common than the others, is a Dinaric element, with very dark hair, flat back to the head, and narrow facial features. Very occasionally also a blond Nordic strain can be observed.

The Greek population, therefore, is of mixed ancestry. Yet to judge from measurements taken in a Greek community in Boston, there are certain special physical features which have become characteristic of these people and serve to distinguish them from their neighbours in the Balkans. Such are the broad jaws, high nasal bridge, wide cheeks, and broad nose with a tendency to turn up rather than down at the tip.

Bulgarians. These people were members of a heathen Ugrian tribe who entered the Balkans from eastern Russia in the wake of the Slavs and soon afterward adopted Greek Orthodox Christianity and abandoned their language in favour of the Slavic tongue of their predecessors. Later, the country fell under Turkish rule, and Tatar and Circassian settlers entered in considerable numbers. Despite these repeated incursions, however, the bulk of the population of modern Bulgaria still belongs to the very ancient tall variety of the Mediterranean stock, usually known as the Atlanto-Mediterranean type, which inhabited the territory in Neolithic times. The chief characteristics of this type are dark colouring, moderate to tall stature, narrow face, and, above all, a long head. The Bulgarians, on the average, are among the longest-headed folk of the Balkans, and only in the west, in the region of Macedonia where they come into contact with the Albanians, is there any significant broad-headed element in the population. The second chief racial constituent in the Bulgarian population is the Neo-Danubian, a moderately broad-headed race, generally of light complexion and with a characteristic concave snub-tipped nose. A slight flattening of the face suggests Mongoloid admixture, though the basic element of this type is undoubtedly Nordic. It is found also in central Finland and in the black earth region of Russia, and was probably introduced into Bulgaria during the Slavic and Ugrian invasions.

The Vlachs

Romanians. These people, who are locally called Vlachs, are the most scattered of all the people of the Balkans. They have a common language, of Latin derivation, and a common pastoral nomadic heritage, but their racial type varies widely from region to region. In Walachia, for example, the main element in the population resembles that of Bulgaria to the south, being of medium height, with dark hair and eyes, narrow forehead, and nose and head of medium breadth. These features indicate a tall variety of the Mediterranean race. Farther north in Moldavia, where the Romanian plain abuts on the black earth region, there is a higher proportion of individuals of the Neo-Danubian race, fairer and with flatter and broader faces and more snub noses. To the west, however, just over the crest of the Carpathians in Bukovina, the Vlach population belongs to the Dinaric race. Their heads are appreciably broader and larger than those of the plainsfolk, their stature taller, their faces longer and broader, their noses larger and more prominent, and the backs of their heads much flatter. The Vlachs of Macedonia and Istria appear also to belong substantially to the same tall, dark, prominent-nosed, and broad-headed Dinaric race.

In short, the Vlachs have no racial uniformity but represent the descendants of the aborigines who, during the 150 years of Roman rule in the province of Dacia, in the 2nd and 3rd centuries AD, adopted something of the language and civilization of their rulers. After the withdrawal of Roman rule they were scattered by the various incursions of Goths, Slavs, Bulgars, and Turkic peoples, but survived in isolated mountain districts in many parts of the Balkans, especially in Macedonia, northern Greece, and southern Albania, where they took to a pastoral, seminomadic economy. Their physical features no doubt varied from one district to another at the time when they first came under Roman influence and have since become even more localized as a result of intermixture of the various groups with their immediate neighbours.

The Slavic word *vlach* means "foreigner," and it appears to be related to the terms Welsh and Walloon in western Europe.

Not only are the Vlachs or Romanians proper, as defined by language and culture, widely scattered through the Balkans outside Romania, but the inhabitants of Romania itself are very mixed, and in the district of Dobruja (a small plateau enclosed between the Black Sea and the lower reaches of the Danube), for example, there are besides the Vlachs, representatives of the following peoples: Bulgars, Ottoman Turks, Gaguz, Armenians, Kurds, Circassians, Gypsies, and Jews. These last two groups form important minorities throughout the Balkans, though their numbers were greatly reduced in World War II and, afterward, by emigration. The surviving communities are particularly concentrated in Romania.

Balkan Jews. The Jewish communities in the Balkans are predominantly made up of Sefardim, that is, the descendants of those driven out of Spain in the persecution of 1492. Some still speak a form of Spanish known as Ladino, and until World War II they often preserved a dress and customs that recalled their origins in Spain. After the war, the much-reduced community was largely assimilated into the general urban population of Romania. Physically they must be classed, there as elsewhere in southern Europe and the Near East, as a variety of the small Mediterranean race. The chief type is slender and delicately built and is of moderate stature with fairly long head, long narrow face, straight or convex nose, and dark colouring. A second type has a shorter and broader face, well-developed chin, thicker lips, short and straight nose, heavy eyebrows, and deep-set eyes and is altogether of broader and more muscular build. The Jewish communities have generally preserved their racial characters, which are the outcome of a stable combination of several varieties of the brunette Mediterranean race. Although darker than most of the people of central Europe, they are fairer than their neighbours within Romania. Among the Jews of Thessaloníki a minority are of blond colouring, although in other physical features they are no different from their coreligionists.

Balkan Gypsies. The Gypsies of Europe are especially concentrated in the Balkans, with a majority living in Romania and Hungary, and many in Bulgaria, Greece, and Yugoslavia. A great many have now settled and have intermarried to a varying extent with their neighbours. But wherever they retain their nomadic habit, the original racial type can still be traced. This type is of short stature, with long and low-vaulted head, small and fairly long face, narrow nose, straight black hair, and very dark eyes and complexion. The Balkan Gypsies are characteristic of the dark-complexioned small Mediterranean racial type, which is at home in India, and this identification is confirmed by their language and traditions. Their speech is basically Indian, a derivative of Sanskrit, though it includes words borrowed from the languages of numerous countries, such as Iran, Armenia, and Greece, across

which they travelled on their way through the Near East or during their wanderings in Europe. They appear to be the descendants of pariah tribes of northern India who moved to the west early in the present millennium and entered Europe about AD 1300. In the Balkan countries some of them were made landed serfs, while others were allowed to wander and to practice their traditional trades as tinkers, wood-carvers, gold panners, minstrels, and sorceresses.

Turks. The communities of Turkish-speaking Muslims in the Balkans, relics of the long period of Ottoman control, have been rapidly depleting in the 20th century because of migration back to Turkey. There has been a particularly large exodus from Bulgaria. Away from the small area of European Turkey, it is unlikely that many of these Balkan Turks are racially akin to the Ottoman conquerers. This is shown clearly by the range of physical types that is found among these European Turks. For example, those of Bosnia-Hercegovina belong to the local tall and very high- and broad-headed Dinaric race; while a series of measures taken in Sliven (Slivno) in Bulgarian Rumelia showed, on the contrary, that the Turks there were long-headed and in this and other respects very akin to their Bulgarian neighbours. Manifestly, very many of the Balkan Turks are indigenous folk whose ancestors, from compulsion or self-interest, adopted the Turkish language and religion.

An exception must probably be made for the Yürüks, or seminomadic shepherds, such as inhabit the southern slopes of Mt. Ograzden in Yugoslavia. There, as in Turkey, these people preserve in a very pure form the language, economy, and customs, and probably also the physical type, of the old Turks who emigrated from central Asia.

The Bektāshī communities of Turks, however, are much more clearly of local origin, as is suggested by their doctrines and institutions, many of which are compromises with the practices of Greek Orthodox Christians. Such are their belief in the Trinity and their celebration of Christmas Eve. Since the dissolution of the dervish orders in Turkey in 1925, the Bektāshī communities of the Balkans, in particular of Albania and parts of Yugoslavia such as the district of Strumica, have become the main survivors of this enigmatic sect. A colony was also established in New York City by immigrants. The true Bektāshī are the members of an order of Muslim dervishes, who follow the rule of Ḥājjī Bektāsh Walī, their 13th-century founder; but the villages which take instruction from these dervishes also adopted this name. The chief ways in which the Bektāshī differ from orthodox Muslims—although they arrogate to themselves the title of Sunnī—are in their devotion to ʿAlī and to his children Ḥasan and Ḥusayn, in memory of whose martyrdom they fast for the first 12 days in the month of Muḥarram; in the privileges they accord to their women, who are even allowed to become dervishes; in their religious proceedings; in their custom of worshipping in tekkes (monasteries) and turbehs (mausoleums) rather than in mosques; and in their open compromises with the feasts and customs of their Christian neighbours.

Ethnic survivals in the Balkans. The Bektāshī villages provide an example of the very mixed cultural traditions of the Balkans. In this peninsula people with varied customs and beliefs have come together and though they often preserved their old racial and political differences and rivalries, they have at the same time interchanged ideas, beliefs, crafts, and artistic symbols. These countries may indeed be regarded as a somewhat disorderly ethnological museum, in which traces of numerous people are haphazardly preserved. Mary Durham's studies of Balkan jewelry and tattoo patterns, for example, demonstrate how there are often retained side by side designs from Muslim and Christian sources, and even from ancient Illyrian and Mithraic sun cults.

Demography. Due to the decreasing isolation of rural communities and to the rising standards of living, particularly among the ever-increasing proportion of the population which is urban-dwelling, both birth and death rates have tended to decline.

Population density within the four countries of the peninsula is relatively low, compared with most of central and western Europe. There are, of course, wide differences within the countries, from region to region, which result from differences in altitude, relief, and agricultural productivity. In most of the mountainous areas, but particularly in the Greek Pindus ranges, in northern Albania, and in Montenegro, densities are very low, while high densities are reached in the plains of northern Yugoslavia (particularly the former Serbian area) and in the plains and basins of central Bulgaria.

History

BALKANS TO 1815

The Balkan Peninsula has been inhabited since Lower Paleolithic (Old Stone Age) times (*c.* 200,000–100,000 BC), but how continuously is not yet known. The Mousterian industries of Neanderthal man from the early part of the last glaciation (*c.* 70,000–40,000 BC) are well represented, followed by those of the Upper Paleolithic Aurignacian and Gravettian, *c.* 40,000–*c.* 8000 BC, associated with the physical remains of modern man (*Homo sapiens*). Evidence of habitation layers of postglacial food-gatherers in caves includes the chipped-stone industry developed from the Gravettian, and it continues into the beginning of the food-producing era.

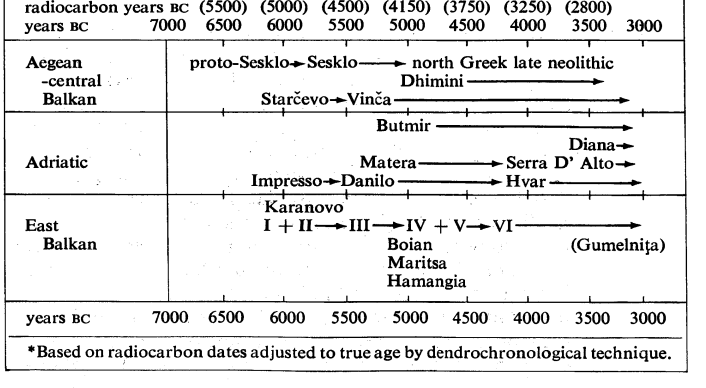
The development of the Neolithic Period around 7000 BC was characterized by increased sedentariness and reliance upon domesticated plants and animals, permitting the existence of larger demographic units. From this period onward, one can speak of the Balkan culture in more detail.

Old European civilization. With east central Europe, the Balkans formed the core of the earliest European civilization, Old Europe, dated to the period 7000–3500 BC. Old Europe is not merely a provincial reflection of the great civilization of the ancient Near East but rather a distinct, unique culture with roots of its own. The Old Europeans discovered the use of copper in the 6th millennium BC and formed population aggregates that often amounted to small townships, which inevitably involved craft specialization and religious and governmental institutions. The Old Europeans also evolved a written script.

Regional groupings

Old European civilization may be divided into five regional groups: (1) the Aegean and central Balkan, (2) the Adriatic, (3) the middle Danube, (4) the east Balkan, and (5) the Moldavian–western Ukrainian. The first region embraces the culture of the Neolithic Period in what is presently Greece, Yugoslavia (except the Adriatic seaboard), southeastern Hungary, and western Romania, succeeded by the Chalcolithic Vinča, Butmir, and Tisza cultures. The second area consists of the painted-pottery complex on either side of the Adriatic, including the Matera-Serra d'Alto in southern Italy and the Danilo in Dalmatia. The third variant includes the Lengyel culture of the middle Danube Basin, which displays similarities to the Adriatic complex. To the eastern bloc belong three cultural groups with individual traditions in art: the Hamangia on the Black Sea coast; the Karanovo in Thrace, and its Chalcolithic successors, and the Boian and Gumelnița complexes, which occupied most of modern Macedonia, Bulgaria, and Romania. In the fifth region, Moldavia and

Chronology of Balkan Neolithic and Chalcolithic Complexes*



*Based on radiocarbon dates adjusted to true age by dendrochronological technique.

Prehistoric Balkan sites.

the western Ukraine, local Neolithic culture was followed by the formation of the Cucuteni (Tripolye in Russian) civilization. On coastal and inland plains, mounds created by the accumulation of cultural debris attest to the permanence of the farming communities, whereas in the Danubian region there is evidence that a wandering agriculture was practiced. Houses were arranged either around a central structure or in parallel rows. The typical house was a rectangular structure of timber posts completed with wattle-and-daub walls, semisubterranean dwellings, trapezoidal structures; cultures living in dry Mediterranean conditions built characteristic houses with mud-brick walls, stone foundations, and internal buttresses.

The Neolithic complex left a remarkably uniform artifactual expression, including polished-stone axes, adzes, and small ornaments; clay stamp seals; bone spatulas; bird-shaped vases; and clay models of shrines. Clay and marble votive figurines reflect several types of goddesses, notably the Snake Goddess, the Bird Goddess, and the Great Goddess, and their epiphanies in the form of a bird, toad, bee, butterfly, deer, bear, and dog. A male god is also represented. Loom weights, spindle whorls, and woven-mat impressions on pot bases attest the production of textiles. Typical of the fine pottery is a highly burnished, hemispherical bowl, often on a ring base; the vessel is commonly coated with a red slip, with red-on-white or white-on-red painted decoration. Cemeteries were unknown and interments are found within the settlement. Infants were buried inside egg-shaped vessels.

Differentiation into regional groups progressed steadily. By the mid-6th millennium BC, there appeared the first traces of metallurgy, the Neolithic thus yielding to the Chalcolithic, the age of a mixed copper and stone technology.

Proto-Sesklo and Starčevo

Central Balkan region. The earliest Neolithic occupation of the Aegean and central Balkans is differently named in each of the modern European countries in which it is distributed—Proto-Sesklo, Starčevo, Körös, Criș—but these are regional variants of a widespread, comparatively uniform cultural complex.

Early Neolithic technology

The subsistence bases relied upon emmer, a primitive variety of wheat, and the domesticated sheep or goat. The identical bone structure of the sheep and goat makes it impossible to distinguish which animal is represented by the remains, but, because neither species was indigenous to Europe in the terminal Pleistocene, or Ice Age, the animals in question must have been introduced from their natural habitat in Anatolia and the Near East. Though their initial introduction was probably a function of ethnic movement across the Aegean, subsequent diffusion may have resulted from acculturation of the Mesolithic population under the stimulus of contact and trade with early farming communities. Radioactive-carbon dates and typological study show the Thessalian and Macedonian pre-pottery and early ceramic sites to be Europe's earliest Neolithic settlements.

Excavations conducted in the late 20th century on the Danube above the Iron Gate provide new insight into the process of economic transition to a Neolithic way of life. The early levels comprise permanent settlements without ceramics; their subsistence was based on fishing and on hunting with the dog, the only domesticated animal. The subsequent phases belong to the characteristic central Balkan Neolithic (Starčevo), with the domesticated sheep or goat and wheat. Starčevo farmers increasingly exploited domestic cattle and pigs and hunted and fished in response to the better forested environment. Two of the systematically excavated sites in this region are Lepenski Vir, excavated by D. Srejović, and Padina, excavated by B. Jovanović.

Sesklo

Sites containing Sesklo materials have been discovered throughout Greece; most of these were newly founded settlements, implying an increase in population density. The beginning of the Sesklo phase is defined by the appearance of fine white-slipped pottery, decorated with flame and stair designs, painted in dark red. Shapes included globular-necked jars, footed bowls, straight-walled bowls, and cups and jugs.

The site of Otzaki, in Thessaly, has disclosed a three-phase development of Sesklo ceramic art. Excavation has uncovered two close-standing rows of square houses constructed of rectangular mud bricks. These houses frequently rest upon a stone foundation and are occasionally strengthened by internal buttresses.

The Vinča sequence is best documented at the eponymous site, situated 14 kilometres (nine miles) east of Belgrade, which has yielded 23 feet of stratified Vinča deposit overlying the Starčevo levels excavated by the Yugoslav archaeologist Miloje Vasić. Fine Vinča ceramic wares are burnished in orange or black and decorated with a shallow linear channeling.

Vinča

The origin of the Vinča black burnished ware need be sought no farther afield than the Maritsa Valley of central Bulgaria. At its greatest extent, the Vinča complex occupied the central Balkans from the Rhodope Mountains north as far as the Banat; west to northeast Bosnia; and eastward to western Bulgaria, southwest Romania, and Transylvania. In architecture and subsistence economy, no marked difference has been discerned between Vinča and the Neolithic Period. Wattle-and-daub architecture continued to be employed, with evidence of the use of split planking in floor and wall construction. Floors were clay plastered. Increasing trade is evidenced by the widespread occurrence of Aegean Spondylus shell, which was used for beads and bracelets. The archaeological data indicate gradual social and economic change and an attendant population increase. Vinča sites occupy as much as 20 acres of river terrace, with houses organized into lined streets.

Concomitant with this expansion was a remarkable artistic development of the Vinča culture, marked by an increase in the quality and number of figurines and other objects that served a ritual function. These symbolic figures testify to an important intensification of spiritual life during the period. Vinča art remained distinct from that of neighbouring groups throughout a millennium or more; and its gradual evolution reflects a remarkably stable and well-organized social structure.

Linear writing

The 1961 discovery at Tărtăria in Transylvania of three clay tablets inscribed with pictographs and linear signs has encouraged the explanation of import from Mesopotamia at about 3000 BC, but this hypothesis has been invalidated by the mutually reinforcing evidence of stratigraphic typologies and radioactive-carbon dating, which locate the early Vinča period in the latter part of the 6th millennium

BC. The Tărtăria tablets were found in a secure Vinča context, and inscribed linear signs on figurines, vases, and spindle whorls of definitively local manufacture appear to confirm that the late 6th and 5th millennia witnessed the development of linear writing. Equivalent inscriptions occur in the east Balkan civilization.

Tisza

Tisza settlements, named after the River Tisza, contemporary to Vinča and distributed in eastern Hungary and the Yugoslav Banat, are smaller than Vinča, consisting of rectangular and semisubterranean dwellings with pitched roofs apparently resting at ground level. Local domestication of cattle on a scale unprecedented in temperate Europe was proved here by S. Bökönyi.

Butmir

The inland Bosnian Butmir variant was strongly influenced by the Vinča culture and was already producing copper. It is best known from the eponymous site at Butmir (Sarajevo), excavated between 1893 and 1896 by W. Radimsky and F. Fiala, which yielded a significant number of sculptures and fine ceramics, including black-polished ones with incised triangle and spiral decoration encrusted with red and white paint. Typical shapes were biconical bowls; high-pedestal, footed "wine" cups; and hole-mouth pyriform vases. At Obre II, a Butmir site in a forested upland environment near the upper Bosna, excavated by A. Benac and M. Gimbutas, faunal analysis revealed that more than half the domestic animals were cattle and that a considerable amount of hunting was practiced. Einkorn wheat was the chief cereal crop, supplemented by barley and lentils; at the Butmir site itself, pear and apple pips have been found.

At Obre II, wattle-and-daub houses of two rooms, about 49 feet long, containing beehive-shaped bread ovens, wooden platforms, ash pits, storage and ritual vases, spindle whorls, loom weights and tools, were revealed. The calibrated radioactive-carbon dates from this site place the three periods of the Butmir culture at 5000–4000 BC.

Impresso

Adriatic. The Early Neolithic culture of the Adriatic region is known as the Impresso complex; it is characterized by grit-tempered wares impressed with shells or with a stabbing tool. The simple ornamented bowls and the farming economy they served are believed to have developed as a result of rapid diffusion, a corollary to maritime movement and trade along the Adriatic littoral. The Impresso culture of western Yugoslavia represents only a part of a complex widely dispersed throughout the Mediterranean world. The initial stimulus to agriculture probably came through eastern seaborne contact with the indigenous Mesolithic peoples of the Mediterranean coastlands. No considerable ethnic migration need be invoked in explanation.

Impresso sites occupy both caves and open settlements. The Dalmatian open-air settlement of Smilčić near Zadar consisted of wattle-and-daub houses and was enclosed by a deep ditch.

Danilo

The beginning of the Danilo period is marked by the appearance of elaborate red-on-cream painted wares, with geometric motifs akin to Sesklo designs. This was a flourishing Neolithic culture of the end of the 6th and 5th millennia BC, with contacts with Greece and southern Italy.

Middle Danube. The local indigenous population of Cro-Magnon type prevailed in the middle Danube until the 5th millennium BC, when the periodically migrating farmers were supplanted by the Lengyel complex, named after a site in western Hungary that displays different architectural and artistic traditions. The Lengyel physical type contrasts markedly with the central European Cro-Magnon and is related, rather, to the people of the Adriatic region. Lengyel settlements are fortified with wide ditches and palisades, and the typical painted piriform vases and "fruit stands" have analogies in the Danilo complex. These similarities may reflect an ethnic infiltration from the Adriatic to the Sava basin and the region east of the Alps. The villagers cultivated wheat, barley, and Italian millet; and in addition to tending sheep or goats, they hunted and locally domesticated both cattle and pigs.

East Balkan area. The east Balkan civilization began around 6000 BC with the first appearance of Neolithic occupation along the Maritsa Valley in Bulgaria. The best known sites are Karanovo, Azmak, and Kazanlŭk. The Karanovo sequence, phases I–VI, has become universally adopted as a chronological yardstick for the development of east Balkan civilization. (Roman numerals are used by archaeologists to designate the successive layers of occupation found at a particular site, in this case phase I representing the earliest known settlement and higher numerals representing later settlements.)

Karanovo I–III

In the villages of the Karanovo I–II period, rectangular one-roomed houses of 20–23 feet to a side, with thick, wattle-and-daub walls, an aligned plank floor, and an internal oven, were arranged in parallel rows. The ceramics show affinities with central Balkan wares, and a rich tool kit includes numerous millstones and sickles of deer antler with flint blades inserted like sawteeth. The plentiful remains of einkorn and emmer wheat, lentils, and bones of domesticated animals confirm the role of mixed farming. Karanovo III pottery typically displays a dark, lustrous black surface, sometimes decorated with plastic bands and knobs or linear incision. The most diagnostic forms are cylindrical and pear-shaped vases with single handles. Karanovo III complex is also known as Veselinovo, after another site in eastern central Bulgaria. Karanovo III corresponds to a considerably increased population; during this phase, elements of the Karanovo III assemblage were carried, probably by a movement of peoples, northwest into the lower Danube region and south beyond the Rhodope Mountains to eastern Macedonia and Thrace. In the north, the intruders came in contact with the Hamangia group on the coast of the Black Sea and with the settlers of the central European Linear Pottery culture. This contact along the lower Danube resulted in the amalgamation of the individual ceramic traditions within the assimilating expansion of the Karanovo III population, bringing about the formation of the "Boian" tradition, a northern variant of east Balkan civilization (the name Boian is derived from an island settlement near the Danube south of Bucharest). The "Vădastra culture" in western Romania represents a sister branch of the same civilization.

Boian

The Boian farmers cultivated einkorn, millet, beans, and flax; they also domesticated and kept cattle, pigs, sheep, and goats, but cattle were by far the most important. Houses arranged in parallel rows in compact villages were fortified by ditches. The Boian pottery was ornamented with excised, white, encrusted spiral and meander designs. There are five subbases of Boian.

During its second phase, Boian material culture spread as far as Moldavia in the northeast, influencing the formation and development of the Cucuteni civilization; it was this vigorous phase that witnessed the first signs of metallurgy. A late Boian temple edifice with trichrome wall decorations and with two exquisitely painted pillars inside has been discovered in the island site of Căscioarele, southeast of Bucharest. Skeletons from a large cemetery at Cernica (near Bucharest) are predominantly of a small-statured Mediterranean type.

East Balkan culture

The advanced stage of east Balkan culture is the Gumelnița civilization, known from at least 500 tells (mounds of cultural debris) in Romania, Bulgaria, and eastern Macedonia. Gumelnița itself lies southeast of Bucharest. Other important sites are: Căscioarele; Tangîru and Hîrșova, in the lower Danube region of Romania; and Ruse and Hotnica, in northern Bulgaria. North of the Aegean, the most noteworthy sites are the mounds of Sitagroí and Dikili Tajh on the plain of Drama. Sedentary Gumelnița communities occupied compact villages or small towns for a millennium or more. Ceramic models of houses show gabled roofs, round windows, and plastered walls with designs painted in red, yellow, and white. These models all attest to the existence of two-story buildings. A model of a temple edifice discovered on the Danube island of Căscioarele shows four shrines standing on a large substructure.

Gumelnița

Gumelnița fine ceramic vessels are distinguished by their technological sophistication. Graphite painting required special kilns to prevent oxidation of the graphite.

Metal production and trade exhibited steady growth during the period: needles, awls, fishhooks, and pins were of copper, and, at the end of the period, axes and adzes were manufactured, a development also found in the

Vinča, Tisza, Lengyel, and Cucuteni civilizations. Workshops of flint, copper, gold, Spondylus shell, and pottery imply craft specialization and increasing division of labour. Gold was obtained from Transylvania and copper from the Carpathian sources. Evidence of linear writing is found on ceramics throughout the duration of Boian–Gumelnița civilization.

Hamangia

The Hamangia settlements and cemeteries are found along the coastal strip between northern Bulgaria and the western Ukraine. Most information comes from the cemetery at Cernavodă, where some 350 graves have been excavated by D. Berciu. Examination of the skeletons has revealed that the population was predominantly Mediterranean; but also found was a distinct local type with a short, broad skull.

The Hamangians practiced mixed farming; they cultivated wheat and vetch and herded sheep and goats, cattle and pigs. Deepsea fishing appears to have been important to early subsistence.

Figurine art characteristically shows a standing female, breasts and buttocks well-developed, with a columnar head and neck, lacking facial features. Less schematic are the exceptional pair of seated figures from Cernavodă—a male "Thinker" and a comfortably relaxed female, both masked. The earliest ceramics were impressed with cardium shell. Ornaments, found abundantly as grave goods, include huge bracelets and beads of Spondylus shell. The Hamangian complex was superseded by the east Balkan Gumelnița civilization.

From the Bronze Age to the coming of the Slavs. *Indo-Europeanization during Bronze Age.* Old Europe was developing into an urban culture, but its power was cut short by a steadily increasing infiltration of the seminomadic pastoralists from the Russian steppes in about 3500 BC.

Kurgan culture

Their culture is called Kurgan because of their burial in tumuli (*kurgan* means "barrow" in Turkic and Russian), covering graves in deep shafts. It reveals elements of the hypothetical mother culture of the Indo-European speakers as reconstructed with the help of common words. In the period *c.* 3500–2300 BC, their presence is traced in Danubian Europe, and, after 2300 BC, their arrival is documented in the Aegean and Adriatic regions. Changes in social structure, economy, and religion show that people of different background imposed their ways of life. Centres of the new power are witnessed by strongholds such as Vučedol (at Vukovar in northern Yugoslavia) and Nagyárpád (at Pécs in southern Hungary). Cultural uniformity is evidenced over the Danubian plain down to Macedonia before 3000 BC. The new culture with persisting elements of Old European substratum is known by the names of Cernavodă in Dobruja, Ezero in Bulgaria, Coțofeni in Transylvania, and Baden in the middle Danube region.

By 2000 BC, nuclear groups parent to Indo-European Illyrian-, Armenian-, Venetan-, Phrygian-, Mysian-, Dacian-, Thracian-, and Greek-speaking units were formed; their cultures were typified by military aristocracies, hill forts, small villages, horses, and vehicles. Their archaeological complexes are dubbed Otomani and Wietenberg in Transylvania; Monteoru in Moldavia; Tei in the lower Danube region and Thrace; and Incrusted Pottery in Pannonia and northwestern Yugoslavia.

The centres of military power and of bronze metallurgy in the mid-2nd millennium were in central Europe and Greece: the Unětice-Tumulus in the upper and middle Danube region; the Otomani-Wietenberg in the Carpathian Basin; and the Mycenaean culture in Greece. Trading of transcontinental Baltic amber and Transylvanian and Mycenaean gold and bronze is richly evidenced from the 17th through the 15th century BC.

Around 1400 BC the Tumulus people extended their influence over the whole middle Danube Basin and to the Adriatic coast. As Urnfield peoples, they caused an upheaval in the Balkans in Anatolia and in the east Mediterranean region before and around 1200 BC. Their graves and pots are found in Macedonia, while their weapons are found in Greece, Crete, Cyprus, Syria, Palestine, and Egypt. The destruction of the Mycenaean culture is attributed to the middle Danubian Urnfield invasion through the Balkan Peninsula and the Adriatic Sea. The Urnfield people were Indo-European speakers, parent to Venetan and perhaps Phrygian, Mysian, and Armenian. In past research they were assumed to be Illyrians, but this name can be used only as a broad cover name and should not be confused with the Illyrians proper, known since the time of Herodotus in Dalmatia, Bosnia, and Hercegovina. This period of raids and migrations, instigated by central European Urnfield peoples (misleadingly called an "Aegean migration"), resulted in a Phrygian, Mysian, and Armenian exodus to Anatolia, the destruction of the Hittite Empire, the Dorian infiltration into Greece, and the introduction of iron technology and a new ethnic configuration in the Balkans.

Illyrians and Thracians during 1st millennium BC. Illyrians proper occupied western Yugoslavia, Albania, and Epirus, with the Morava–Vardar line as their approximate eastern limit; in the northeast they extended into southwest Romania. Tribes north of the Sava River, Venetans and Pannonians, are usually treated as northern Illyrians. The general name for the period from 750 to 450 BC is "Illyrian Hallstatt." The exploitation of iron ores, particularly in northwestern Bosnia, increased commerce. From the 7th to the 5th century BC, strong tribal centres emerged, together with a powerful aristocracy, as witnessed by extravagantly furnished royal burials. Autochthonous traditions were maintained even after an exchange with Greek merchants and colonizers of the Adriatic coast started around 600 BC. Glasinac, an Illyrian centre near Sarajevo, displayed an uninterrupted development until the period of Celtic influence in the 4th century BC.

The Iron Age in Illyria

From the late 6th and early 5th centuries, the Greek influence is evidenced by masterpieces of Greek workmanship, which arrived through southern Italy. To this period belongs the treasure of Trebeništa at Lake Ohrid, which includes a large bronze krater, or mixing bowl. Greek influence increased markedly in the 4th century BC after the foundation of towns on the islands and coast of the Adriatic, among them Issa (Vis), Pharos (Hvar), Corcyra Melaina (Korčula), Salonae (Solin), Epidaurus (Cavtat), Iader (Zadar), and Tragurion (Trogir).

Written evidence of an Illyrian kingdom on the borders of the Greek world appeared at the end of the 5th century BC; its capital was at Skodra (Skoútari). Before Illyria was annexed to the Roman Empire in 168 BC, it was ruled by 15 monarchs carrying Illyrian names.

The Thracian culture formed of the Bronze Age substratum mixed with that of the seminomadic peoples from the Ukraine. The ethnic infiltration is shown by the appearance of an eastern archaeological complex called Noua, dated to the 12th century BC. The cultural melange that produced the Basarabi–Babadag complex of the Hallstatt era is held to be the basic component of the Daco-Thracian culture. Repeated incursion of groups of warriors from the northeast occurred at the end of the 8th century BC, bringing with them Caucasian elements in art and weaponry. This period is called Thraco-Cimmerian; it coincides with the conquest of the Cimmerians north of the Black Sea by the Scythians, but the actual ethnic infiltration of the Cimmerians into the Balkans is not evidenced. The Scythians proper appeared in the middle of the 6th and the beginning of the 5th centuries BC; but it was not until the beginning of the second half of the 4th century BC that the Scythians tried a violent and massive penetration into the territory. Contacts with the Scythian world contributed to the wider diffusion of iron metallurgy and the formation of a distinctive Thraco-Scythian style of art.

At the end of the 7th and in the 6th century BC, the Greeks founded several colonies along the western shore of the Black Sea: Apollonia Pontica (Sozopol), Mesembria (Nesebŭr), Odessus, Callatis (Mangalia), Tomis (Constanța), and Istrus (Hystria). The Greek cultural influx was of fundamental importance. It included the potter's wheel, which was in use by the local inhabitants at the end of the 6th century BC, and the striking of coins, which the Greeks themselves borrowed from the Lydians in Anatolia. The Greeks were interested in timber and wheat from Moldavia and the Ukraine and in silver and gold from the mines of southwestern Thrace. Greek influence steadily increased. At Panagyurishte, in central Bulgaria, a gold

Greek colonies on the Black Sea

service weighing more than 13 pounds (six kilograms) included vessels of superb workmanship by Greek artists of the late 4th century BC. Dionysian festivals and worship of Bendis (Artemis) and Ares are ascribed to Greek influence.

Dacians, the northern Thracians, are known from Greek sources of the 4th and 3rd centuries BC. A good deal about southern Thracian life and manners is revealed by the Greek authors Homer, Herodotus, Thucydides, and Xenophon. Thracian nobles are shown on Greek vases wearing caps of fur, decorated cloaks, and leather boots. The society was classified into chieftains, warriors, commoners, and slaves. In the mid-5th century BC, the first known Thracian state emerged in the Maritsa Valley, ruled over by the Odrysian king Teres. According to Thucydides this state enjoyed a large revenue and general prosperity. The Odrysian king Sitalces allied himself with Athens and in 429 overran Macedonia. The 4th century marks the final flourishing of the Thracian civilization. Before mid-century Philip II of Macedon brought unity to the area between southern Thrace and Albania and a new power—Macedonia—emerged. Philip's son Alexander III the Great crossed the lower Danube in 335 BC and attacked the Getae.

By about 300 BC, the Getae of Dobruja and the lower Danube, a people akin to the Dacians of Transylvania and Moldavia, combined to form what was virtually a state, an evolved type of military democracy having as its leader the *basileus* Dromichaites, who in 292 conquered Lysimachus. Greek cities on the coast of the Black Sea found protectors and allies in the Getian *basileis.*

Arrival of the Celts

About the beginning of the 3rd century BC, bands of Celtic warriors appeared east of the Tisza and advanced toward Oltenia and Transylvania. This movement can be traced by the evidence of their warriors' graves. The military superiority of the Celts, which had at its disposal a developed iron technology, insured their success. The Celtic element, which was present in Romania for several centuries, contributed to the development of iron metallurgy and to the adoption of the iron plowshare, which led to a great expansion in agriculture. Celtic influence left imprints in a novel Getian–Dacian silverwork and coinage. The southern wave of Celtic invasion—toward Thrace, Macedonia, Thessaly, and Greece—was broken at Delphi in the winter of 279–278 BC.

The Dacian state extended between the Tisza River and the lower Danube in the period between 200 and 31 BC, reaching its peak during the reign of Burebistas (60–44 BC).

Roman conquest and barbarian colonization. After Macedonia crumbled, Thracians, Illyrians, and Dacians were left to their own devices until a major Roman irruption at the end of the 3rd century BC. Thracians and Illyrians combined in self-defense, and there followed a struggle for 150 years. The southern Illyrians were conquered and annexed in 168 BC, but hostilities continued until AD 9, when all Illyrians were subjugated by the Roman general Tiberius (later emperor). The territory along the Adriatic, Dalmatia, Iapodes, and Liburnia, was united as the Roman province of Illyricum. In 29 BC the area between the Danube and the Balkan Mountains was conquered by Crassus and became the Roman province of Moesia, while the area further south was incorporated into the province of Thrace. The emperor Domitian's expedition against the Dacians in AD 85 consolidated his position north of the Danube. In 89 the king of Dacia, Decebalus, was forced into a collaboration with Rome against the Germanic Marcomanni, the Quadi, and the Iranian Sarmatians, the latter coming from the Pontic steppe. The complete conquest of Dacia in 106 followed two vigorous campaigns by the emperor Trajan in 101–103 and 105–106. The Dacian capital of Sarmizegethusa was captured and the province of Dacia was established.

The process of Romanization was swift. In Romania, Latin completely supplanted the Dacian and Thracian languages. Trade and handicrafts penetrated deep into the provinces. Trade routes connected the growing cities: the northern road led to Sirmium (Sremska Mitrovica on the Sava), Singidunum, Viminacium, and Ratiaria on the Danube; the southern led to Stobi (south of Titov Veles) and Scupi (now Skopje); and the eastern ran from Sardica (Sofia) via Naissus (Niš) and Margum to Viminacium on the Danube; in the west, the road crossed from Salonae and Narona on the Adriatic through Bosnia to Sirmium. Commercial expansion reached its culmination in the course of the 2nd century. Rome became decentralized and its art cosmopolitan. At the end of the 3rd century, Sirmium became a capital of the empire. Diocletian built his palace near Salonae (near Split), and official art was created in Dalmatia, Pannonia, and Moesia. From the time of Marcus Aurelius, the empire lived under the protection of an Illyrian–Thracian army. When Constantine I established Constantinople as a second Rome, in AD 330, the eastern part of the empire split in two: Thrace was included in the prefecture of the Orient, whereas the rest of the peninsula was in the prefecture of Illyrium.

In the 3rd century there began an infiltration of the Goths into the peninsula. About AD 214 the Goths clashed with the Romans at the Dacian frontier and conquered Dacia. The Goths then attacked Thrace continually through the middle and late 3rd century. The Gothic state flourished for nearly 200 years until the Huns invaded and swept across the country.

The coming of the Slavs

The devastation of the empire by the Huns, followed by that of the Bulgars at the end of the 5th century and that of the Avars in the late 6th century, prepared the ground for a wide Slavic dissemination from their homeland north of the Carpathians in the Ukraine.

In the Middle Ages. With the settlement of the Germanic Ostrogoths in Italy and the disintegration of the Western Roman Empire in the final decades of the 5th century, the Balkans again came under the direct control of the Eastern Empire at Constantinople, at least in theory. But the barbarian invasions of that century had left the Balkan Peninsula a sparsely populated wasteland destined to attract new and more permanent settlers, the Slavs. An Indo-European people, the Slavs had settled in the valley of the upper Vistula in central Poland during the great prehistoric migration that brought most of the ancestors of the modern Europeans from Asia. Basically a sedentary people with a highly developed tradition of agriculture and animal husbandry as well as of hunting and fishing, the Slavs were easy prey to the highly mobile and often strongly united nomadic hordes that swept across eastern Europe. These barbarian tribes easily superimposed their rule over the native Slavic political system of democratically run clans, owing only loose allegiance to a chief, or *župan.* It was as vassals of such nomadic tribes that the Slavs spread into south Russia and Pannonia, a former Roman province that occupied parts of modern Austria, Hungary, and northern Yugoslavia. From these two areas beyond imperial control, the Slavs began their steady movement into the Balkans. By AD 517 groups of Slavs were crossing the lower Danube to raid in Thrace, Macedonia, Thessaly, and even Epirus. Almost simultaneously, others were moving into the northwest corner of the Balkans toward the Dalmatian coast. The massive military endeavours of the Byzantine emperor Justinian I elsewhere in the empire left no troops free to man the fortresses protecting the Danube River boundary of his realm. Imperial officials in Constantinople attempted to neutralize the northeastern arm of the Slavic pincers encircling the Balkans by offering the Slavs on the lower Danube the status of *foederati,* paid border guards for the empire. The Slavs, however, became vassals of the Avars, a new Turkic horde of nomads who appeared on the south Russian steppe.

Slav invasion of the Balkans

The Avars, akin to the Huns, attempted to follow the route of their predecessors. Driving the remaining Germanic tribes from the Pannonian plain, they established there a new state that loosely controlled the Slavs settled in modern Czechoslovakia, the Balkans, and even north of the lower Danube in south Russia. Both the Avars and their Slavic tributaries undertook plundering expeditions throughout the Balkans. Eventually, the invaders took effective control of many areas as far south as the tip of the Peloponnese and as far east as the great wall of Thrace, the first line of defense of Constantinople. Usually, the ravaging of territory was followed by permanent Slavic settlements being made in the devastated villages. It was

only after 591 that the Byzantine army, finally withdrawn from other theatres of war, attacked the Avar–Slavic armies in the Balkan Peninsula; but by then the situation was hopeless. The Byzantine troops committed to driving the Avars back beyond the Danube revolted in 602, and soon the emperor was paying tribute to the Avars while the latter's Slavic vassals moved unimpeded through the Balkan Peninsula, populating it anew. Remnants of the local agricultural population probably remained among the Slavic settlers, but many of the Greek-speaking and Latin-speaking inhabitants took refuge in and around fortified Byzantine cities, particularly along the coasts. The safety of these cities, however, was in no way guaranteed. Thessalonica, the leading city of Macedonia and the second-richest city in the Byzantine Empire, several times came close to falling to the Slavs. In the interior, no imperial islands remained. Singidunum (Belgrade), Naissus (now Niš in Yugoslavia), Sardica (Sofia), Sirmium (now Sremska Mitrovica in Yugoslavia)—the mighty fortresses guarding the middle Danube frontier—fell, with the surrounding countryside, to the Avars and Slavs. Contemporary sources often speak of the Balkans simply as Sclavinia (Slavdom). Byzantine control of this region had been so completely disrupted that the emperor Heraclius omitted the Balkan provinces from the administrative reorganization of the rest of his realm. Rather, to preserve his capital, Constantinople, Heraclius paid massive tribute to the Avar khan (chief) before he dared move against the equally serious Persian threat on the empire's eastern border.

In 626, however, the strength of the fabled walls of Constantinople and Byzantine naval superiority gave the Byzantines a wholly unexpected but decisive victory against a joint attack by the Avars and Persians. From this point on, both the Persian and Avar states began their rapid decline. Already weakened by a revolt of their Slavic subjects in what is now Czechoslovakia, the Avars were further threatened when Emperor Heraclius invited two strong tribes from beyond the Carpathian Mountains, the Croats and the Serbs, to settle in land held by the Avars in the northwest Balkans. Aided by the Byzantine navy and the few fortified imperial cities left on the Dalmatian coast, these tribes took control first of Dalmatia and then of the territory that, after their occupation, bore their names, the Croatia and Serbia of modern Yugoslavia. Once settled, theoretically as vassals of Byzantium, they mingled with the earlier Slavic settlers.

Return of Byzantine power

For the great new empires that emerged in the early Middle Ages from settlement of the invading people, see separate Balkan country articles.

The 11th century saw further invasions of the Balkans by people from the Volga region, namely the Pechenegs and the Kumans. At the beginning of the 13th century, however, Greek Byzantine rule over the south of the peninsula was replaced, except in Epirus, by Latin, through the diversion of the Fourth Crusade to Constantinople.

Under Ottoman rule. *Ottoman conquest.* The Ottoman Empire had its origins in a small Turkish emirate established in the second half of the 13th century in northwest Anatolia, near the Sea of Marmara and close to the borders of the Byzantine Empire. The name Ottoman was derived from Osman I, a Turkish chieftain who ruled the emirate from 1281 to 1324. An active and aggressive military organization of dedicated frontier warriors, this state first established itself on the European mainland in 1354 on the Gallipoli Peninsula. In 1362 the Ottoman armies took Adrianople, which soon became the Ottoman capital. From this centre the Ottoman armies moved up the Maritsa and Vardar valleys against the Christian states of the Balkans.

The early Ottoman successes were made possible by their superior military power that was based on a mobile light cavalry and by excellent leadership and organization. The Christian powers were hampered by their failure either to cooperate among themselves or to secure effective European assistance. Pope Boniface IX's army, sent in an attempt to aid the Hungarians, was crushed by the Ottoman army at Nicopolis in 1396. A second effort in the next century by Pope Eugenius IV collapsed with the defeat of the Christian armies led by János Hunyadi and King Wladyslaw III Warneńezuk of Poland and Hungary at Varna in 1444.

The victorious march of the Ottoman forces into Europe was checked briefly, at the beginning of the 14th century, by internal problems within the empire and by Timur's threat in the east. Under the leadership of Mehmed I (1413–21), who won the struggle for succession, and his successor Murad II (1421–51), the march forward was resumed. The empire at this time also had to develop a navy to deal especially with Venice. Until the end of the 18th century this city-state was a major power in the eastern Mediterranean and waged with the Ottoman Empire a continual duel for control of the islands and the peninsulas of this sea—in particular, Crete, Cyprus, and the Morea.

The greatest single Ottoman military achievement occurred in the reign of Mehmed II the Conqueror (1451–81). Although Ottoman territories now reached far into Europe, the Byzantine Empire, reduced to the city of Constantinople and a small surrounding area, still stood. After long and careful preparation, Mehmed took the city in 1453, a date that compares in Greek history to that of Kosovo in the Serbian national memory. The fall of Constantinople marks also the completion of the process of the subjugation of the Balkan Peninsula to Ottoman rule. The empire now held most of Serbia, Bosnia, Bulgaria, and Greece. Although some isolated areas still resisted, no major centre of opposition remained. With the capture of the imperial city, the Ottoman conquerors made it their capital and developed an administrative system that was to dominate the Balkan region for the next five centuries.

Fall of Constantinople

The Ottoman Empire reached its height in power and prestige during the reign of Supleyman I, known in the West as "the Magnificent" and in Ottoman history as "the Lawgiver" (1520–66). A great military leader and an able administrator, Supleyman extended Ottoman territory far into the centre of Europe. Belgrade fell in 1521; in 1526 Supleyman defeated a Hungarian army at Mohaacs; and in 1529 the Ottoman army reached Vienna and lay siege to that imperial city. With the failure of this attempt, the limits were set to Ottoman westward expansion, but Supleyman's campaigns had left his country with control over most of Hungary and Transylvania. Transylvania, like the principalities of Walachia and Moldavia, taken in the 15th and 16th centuries, became an autonomous tributary province of the empire.

Although some territorial changes occurred in the Balkans during the next century and a half, the Ottoman Empire lost no significant territory to Christian Europe until after 1683. Moreover, it kept at least titular control of the majority of the Balkan lands until 1878. Thus, for almost five centuries the greater portion of the Balkan people lived under an alien Muslim rule. It is the common experience of the peninsula and one that has profoundly shaped its present condition.

Character of Ottoman rule. When the Balkan people first fell under Ottoman control, they became a part of one of the great empires of world history, a worthy successor to the Roman and Byzantine states, which, too, once had their centres at Constantinople. The negative opinion often held of Ottoman civilization is usually based on judgments made of conditions in the 18th and 19th centuries, when the state was in a period of obvious decline. In the 15th and 16th centuries, however, Ottoman institutions may have offered the Balkan Christian a better life than he had led previously under his native feudal governments.

To understand the political conditions in the Balkans in the Ottoman era, it is first necessary to emphasize that the conquering power was a Muslim and not a Turkish national state. The Ottoman leaders regarded their peoples as divided by religious faith rather than by nationality. Any individual could join the ruling group by converting to Islām. Basing the political structure on this concept, the non-Muslim peoples were divided into five religious communities called millets: Orthodox, Gregorian Armenian, Roman Catholic, Jewish, and Protestant. Each group was under the direction of its religious head. Thus for the Balkan people, the vast majority of whom were Orthodox, the titular leader was the patriarch of Constantinople. But

in practice, during the years of Ottoman rule, the Balkan Orthodox church organization became divided into its national components. Constantinople became a Greek centre; the Serbians had their own patriarchate at Peca, and the Bulgarians had a metroplitanate at Ohrid. The Romanians had similar national institutions. Thus national separateness and local tradition were preserved through the ecclesiastical organizations. The Ottoman government expected the church authorities to assume many civil functions, in particular judicial and tax-collecting duties. The Christian churches thus became, in a sense, part of the Ottoman state system.

The Ottoman government had a regularly organized administrative system with its centre in Constantinople and extending over the entire empire. The Balkan lands were part of the region (*beylerbeylik*) of Rumelia; the territories under direct administration were subdivided into provinces and then into lower administrative units. The principal interest of the Ottoman officials was the collection of taxes, which were to pay for the military power and the administration of the empire. Soldiers, policemen, and judges were also present in the administrative centres to maintain conditions beneficial to the proper collection of revenue.

Although most of the Balkan lands were administered by Ottoman officials, some areas enjoyed unusual rights of self-government. The Danubian principalities of Walachia and Moldavia, for instance, as well as Transylvania, being autonomous tributary regions, were governed by their own aristocracy. The merchant city of Dubrovnik was an autonomous republic. Certain other cities and regions either had won special rights or were too remote and primitive to arouse Ottoman concern. They enjoyed almost complete self-government. Even among the areas under direct administration, the Ottoman authorities remained chiefly concerned with taxation and the maintenance of public order. They did not attempt to regulate other details of Balkan Christian life. These fell under the jurisdiction of the local village authorities or the church.

The *devşirme* system

Although only Muslims could hold office in the empire or serve in its military forces, converted Balkan Christians came to occupy the highest positions at this time. In fact, these converts came to form the main basis of the military and administrative apparatus of the state. By the time of Süleyman, the highest state offices were held by slave administrators. These were either purchased, were prisoners of war, or were acquired through the *devşirme* system: from the 14th century to about the middle of the 17th, approximately every five years one out of four boys in the Balkans, aged between 10 and 20, was taken from his parents, brought to Constantinople, and converted to Islām. The most able of these were sent to the palace school, where they were trained as administrators, and then assigned posts throughout the empire. Other children recruited in this manner became members of the Janissary Corps—an elite infantry unit armed with muskets—which became the most effective fighting arm of the Ottoman army. Forbidden at first to marry, this body of new converts proved to be fanatic and dedicated soldiers.

In the first period of Ottoman rule, conditions for the Balkan peasant on the land were probably not overly onerous; in fact, he may have enjoyed a better position than his counterpart in western Europe. In theory, the sultan held all of the land taken in war; he was free to dispose of it at will. In practice, the Balkan lands were used to support cavalry units of the army. The members (spahis) were given grants of land (timars) in return for which they had to provide military service. At first, the amount that the peasant had to contribute in dues and services was carefully regulated. Later, however, the system tended to break down. With the introduction of the wide use of firearms the effectiveness of the cavalry was reduced. The government became more interested in increasing the tax load to pay for new weapons.

Despite the fact that the Ottoman government showed a high degree of toleration for non-Muslim faiths, there was no question of equality between religious groups. To rise in Ottoman society Balkan Christians had to abandon their faith. There were few attempts at forced conversion, but the subordinate position of the Christians was constantly emphasized. They could not wear conspicuous or rich clothes, for instance, or the colour green, sacred to Islām. If when on horseback a Christian passed a Muslim, he was forced to dismount. Old churches could be repaired, but new ones could not be built. They could not have bells or bell towers or be constructed in a place or manner likely to "offend the eyes of the faithful."

Even more important, Balkan Christians were forced to carry an unequal share of the tax burden of the empire. Although Christians were not subject to military conscription, they were assessed a special tax as a replacement. Christians were also liable to other services and payments, particularly in time of war, which were connected to their secondary status within the state. Despite these and other severe disabilities, it is interesting to note that there were relatively few examples of mass conversions among the Balkan people, with the exception of those that occurred in Bosnia, Albania, and Crete, where local conditions were unusual.

Despite the fact that the Ottoman system of government served to maintain the separation of the national groups, great similarities nevertheless existed in the conditions of life of all of the people who lived under direct Ottoman rule. The vast majority of the Balkan population lived as farmers or herdsmen, either on estates or in the less economically valuable hills and mountains on virtually independent family farms. They inhabited small primitive houses, clustered in villages, where their local and personal affairs were managed by the village elders and the church. Larger towns and cities served principally as trading and administrative centres. Ottoman officials usually resided in the largest cities, as did those Muslims who held large estates. Handicrafts and trades, with their centres in these cities, were organized in a guild system.

The average Balkan peasant in these circumstances lived a primitive existence, cut off from the rest of the world. Since education was controlled by the church and was extremely limited, illiteracy was nearly universal. The life of the individual was limited to his village. Nevertheless, in each region a unique peasant culture was retained. Each area and national group had its own style of houses, decorative patterns, and, most important, its traditional songs and stories that substituted for a written literature.

While the smaller Balkan communities reflected the local peasant culture, the Balkan cities, as the military and administrative centres for the Ottoman authorities, were built according to the architectural preferences of the ruling group. Typical of Ottoman architecture were the massive stone bridges, fortresses, mosques, baths, covered markets, and caravansaries.

Although most of the Balkan peoples tended to prefer to remain on the lands of their ancestors, they could, of course, as citizens of one state, move about within the empire. During the four centuries of Ottoman domination, there was not only much internal migration, due to war and similar causes, but certain nationalities tended to specialize in occupations that drew them out of their national area. For instance, Greek merchants could be found in most major Balkan cities; Vlach (Romanian) shepherds roamed the mountains of the entire peninsula. Some Turks moved from Anatolia to areas such as the Black Sea coast, Macedonia, Bosnia, and Thrace. Albanians served as guards or police in many localities. This intermixture of population caused complications later when it became necessary to draw the boundaries of the national states.

The decline of the Ottoman Empire

Despite the long existence of the empire, signs of weakness appeared in its structure as early as the reign of Süleyman. The Ottoman system could not function well without strong direction from the top. Up through Süleyman the state had been remarkably fortunate in its rulers, but among the 17 sultans who followed, few were men of ability. With the lack of firm direction from above, the administration based on slave officials who rose by merit inevitably changed. Born Muslims and sons of officials naturally sought to enjoy the rewards of public office. The *devşirme* system came to an end by the middle of the 17th century. Parallel with these developments was the increasing corruption of all aspects of Ottoman political life. High

offices were regularly sold; the officials who purchased their positions were primarily concerned with recovering their expenses and enriching themselves. The breakdown of the Ottoman administration, which commenced at the centre in Constantinople, spread out to encompass the entire governmental network.

Most dangerous for the future of the empire was the decline of the Janissary Corps. Though its members had gained the right to marry and to enlist their children in its ranks, they were soon forced to earn extra money and many became craftsmen on the side. Thus, this once-powerful military unit degenerated into a weak organization whose chief role in the state was to exert influence on the government. The corps, like the rest of the Ottoman military forces, failed to keep up with Western advances in military technology and organization. The military preeminence and the qualities of leadership that had won for the Ottoman Empire its vast domain were now lost.

The Christian, together with his Muslim neighbour, was directly affected by the decline of Ottoman administration. His chief grievances became the willful and arbitrary manner of the local officials and the grave abuses that were now associated with the collection of taxes. The central government relied for this service on tax farmers who competed yearly in bidding for the position. The tax farmer was chiefly interested in making a profit from his investment. Forceful methods and unfair standards of assessment were regularly used to extract high payments. The system was economically ruinous for the peasant and the central government alike.

The Balkan peasant found his standard of life also deeply affected by a change in the landholding system. As mentioned previously, under the timar system, strictly controlled nonhereditary land grants had been made in return for military service. With the relative decline in importance of the cavalry and the reduction in the number of military campaigns, large estates tended to pass into the hands of those who wished to work them at a profit and who now held them as hereditary rights. The peasant who worked the fields of the estates (now called *chifliks*) was reduced to the position of a sharecropper; his dues in kind and in labour were greatly increased.

Among the most severe consequences of the breakdown of the Ottoman government was the rise of lawlessness throughout the peninsula. As the central authority grew weaker, local Muslim leaders throughout the empire established what were in effect small principalities from which they were able to defy Constantinople and war among themselves. The most important of these for Balkan affairs were Ali Pasha of Janina and Pasvanoglu of Vidin. Christian bands of robbers (haiduks or klephts) also existed in large numbers. Their activities, together with the destruction caused by the Ottoman wars of the 18th century, made certain areas uninhabitable for long periods. These conditions were the direct cause of both the Serbian revolt of 1804 and the Greek revolution in the Morea in 1821.

Although all of the inhabitants of the empire suffered from this situation, certain Balkan Christians nevertheless did benefit from the growing weaknesses in the Ottoman system. Of the non-Muslim people, certainly the Greeks associated with either the Ottoman administration or the commercial world were in a privileged position. By the 18th century a number of Greek families residing in Constantinople, known as Phanariotes, had come to secure regularly certain high appointments in the Ottoman service. Most important were the offices of grand dragoman (secretary of state) and the governorships (*hospodar*) of Walachia and Moldavia. At the same time, through the patriarchate at Constantinople the Greek hierarchy was able to dominate the other national churches. In the middle of the 18th century, it secured control of the Bulgarian and Serbian ecclesiastical centres at Ohrid and Peca. In addition, Greek merchants were established in the cities of the peninsula, and they controlled a large part of the trade of the Black and the Mediterranean seas. These merchant communities were the most susceptible to the influence of Western political and social ideas.

The position of the Greeks in the empire

After the Greek, the Romanian landowner of the privileged provinces of Walachia and Moldavia held a superior position within the empire. These principalities were never under direct Ottoman administration, although they did pay tribute and they were subject to regulation from Constantinople. In both, a native aristocracy held control over an enserfed peasantry. After the Russian invasions of the early 18th century, during which Romanian leaders cooperated with the enemy, the Ottoman government appointed Greek rather than Romanian governors for the provinces. The Phanariote Greek regime, which lasted until 1821, was extremely corrupt and strongly disliked.

In comparison with these groups, the Serbs and Bulgarians—without a native aristocracy and largely peasants—were at a distinct disadvantage. Both nations suffered severely from the corruption and lawlessness of the time. Their lands were the scene of repeated struggles between local Muslim leaders and of battles with the invading great powers. In the 18th century, both found their national churches taken over by Greeks.

A special word must be said concerning the Albanians and the Montenegrins. As the only Balkan people among whom a majority (70 percent) converted to Islām, the Albanians were not subject to many of the problems of their Christian neighbours. Many rose high in the Ottoman state and in military service. Moreover, the central government made little effort to control closely this distant, backward, mountainous region. Relatively content with their status, the Albanians were the last to establish an independent state. Montenegro, too, although a Christian state under a prince-bishop, because of its poverty and the difficulty of access to its lands, was usually able to govern itself.

Increased role of European powers. Although the internal problems had become acute long before, in international affairs the empire was able to preserve its territories almost intact until the end of the 17th century. In the second half of that century, a last great offensive was begun and additional lands in the Ukraine were acquired. The symbolic turning point for the Ottoman offensive against Europe was the second siege of Vienna, in 1683. The failure to take the city marked a reversal in Ottoman fortunes. Henceforth, the European states moved against Ottoman possessions. Russia, Venice, Poland, and Austria now joined in a victorious coalition. In 1699 the empire was forced to sign the Treaty of Carlowitz, the first time that the Ottoman government appeared on the diplomatic stage as a clearly defeated power. By this treaty, Austria gained control of most of Hungary, Transylvania, Croatia, and Slavonia; Venice took Dalmatia and the Morea; Poland gained Podolia. Thus large numbers of Balkan people passed from Ottoman to Austrian and Venetian control. The agreement established what was to be until 1878 a relatively stable Austrian–Ottoman frontier along the Danube and Sava rivers. The main territorial gains at the expense of the Ottoman Empire in the next century were to be made by Russia.

Russian invasions

The Russian advances against Ottoman lands began under Peter I the Great at the end of the 17th century. The major acquisitions were made, however, by Catherine II the Great, who by the end of her reign had won the lands north of the Black Sea to the Dnestr River. For the future of the Balkan Peninsula the most important agreement between Russia and the Ottoman Empire was the Treaty of Küçük Kaynarca (1774). By its terms, Russia gained territory in the Black Sea region and certain trade rights, but, most important, because of the ambiguous wording of the treaty, Russia was later to claim that it had won certain rights to speak in behalf of the Orthodox Christians of the empire. In 1781 Catherine joined with Joseph II of Austria in what was to be the first of numerous partition agreements among the great powers. According to this agreement, both Austria and Russia were to receive territory, but the majority of the lands of the Ottoman Empire in Europe were to be organized into a Kingdom of Dacia, under Russian influence, and a Greek kingdom with its capital at Constantinople and with Catherine's grandson as its ruler. General European events prevented the success of this venture, but, by the end of the century, it was apparent that Russia was both the chief threat to the empire and the major hope of the Balkan people for outside aid.

French Revolution and Napoleonic era. The wars of this period were to have a deep effect on the Balkans, both from the international aspect and because of the response that French Revolutionary ideology evoked within the peninsula. This period also witnessed the entrance of France and Britain actively into the diplomatic and military struggle over the control of the Ottoman Empire. That state, in the midst of another grave internal crisis, now found its lands under attack from France. In 1797 France took the Ionian Islands from Venice. A year later, Napoleon launched an invasion of Egypt and Syria. As a consequence of this action, the empire was in alliance with Britain and Russia from 1798 to 1802.

After a period of peace from 1802 to 1806, the Ottoman government shifted sides and joined France against Russia. This alliance proved disastrous, because in the next year, by the Treaty of Tilsit, France came to terms with Russia. It is interesting to note that at this time these two governments discussed a partition of the Ottoman Empire, but they were unable to agree on the fate of Constantinople. In 1812 Russia, faced with an impending French invasion, signed the Treaty of Bucharest with the Ottoman Empire, which ceded the Romanian territory of Bessarabia to Russia.

The Balkan peoples were affected not only by the wars that were waged in the area, but also by the political arrangements made by the several powers. Most influential for the future was the introduction into the Balkans of French Revolutionary institutions and ideology through the Napoleonic conquests. For example, in the Ionian Islands, which France held from 1797 to 1799 and again from 1807 to 1814, a constitutional government on Western patterns was established. The Septinsular Republic was the first Greek national government in modern times. French political experiments also involved South Slav lands. In 1809 Austria was forced to cede to France its Balkan territories. From Dalmatia, Slovenia, Istria, Trieste, and parts of Croatia a new political entity, the Illyrian Provinces, was formed and became a part of the French Empire. As in the Ionian Islands, the government was based on revolutionary principles. The Illyrian Provinces has been described as the first Yugoslav state, as it included within its boundaries Serbs, Croats, and Slovenes.

This period also brought about important changes in Moldavia and Walachia and in Serbia. The Ottoman Empire was forced to agree to an increase of Russian direct influence in the Danubian principalities; henceforth, no governor of either province could be dismissed without Russian consent. Russia thus acquired what was, in effect, a protectorate over the country. This power also played a major role in the events of the first Serbian revolution (see below).

The defeat of Napoleon in 1815 resulted in the restoration of the political and territorial status quo in the Balkans, with only a few exceptions—Russia, of course, retained Bessarabia; the Ionian Islands were placed under British protection; the Illyrian Provinces disappeared as a political entity; and Austria received back its former land and, in addition, acquired Dalmatia. The Ottoman Empire, which did not attend the Congress of Vienna in the aftermath of the Napoleonic Wars, retained most of its territories intact. It was also to be aided by the conservative reaction that followed in a Europe tired of war and revolutionary upheaval.

In Balkan history the French Revolution and the wars of Napoleon mark the shift from the long period of Ottoman domination into the era of the national revolutions of the 19th century. To some extent, the stage had already been set in the 18th century, when both Russia and Austria appealed to the Balkan subject populations for assistance against the Ottoman Empire. These wars, as well as those of Napoleon, had shown how weak the Ottoman military forces really were. Moreover, Balkan nationals had fought in these wars. They had learned modern military methods and they were armed. Equally important, the period of war and internal upset had opened the area to outside influences. The national and liberal ideology of Revolutionary France provided a program that would allow Balkan leaders to combat not only Ottoman political control but also the stifling cultural influence of their Christian church hierarchies.

Although the Balkans were now ready for revolt, the international situation was to change to the detriment of such actions. After the period of war, which had wasted the resources and energy of Europe before 1815, the powers desired, above all, peace with political and social stability. There occurred in all the European states a conservative reaction directed against revolutionary methods and liberal–national programs. Subject Christian peoples could thus not expect aid or sympathy from abroad. At the same time, it was also apparent to the European powers that the Ottoman Empire was in a dangerous condition of internal decay and military weakness. The question of the fate of the Ottoman territories and of the control of that government became perhaps the most important single diplomatic problem for Europe in the century after the Congress of Vienna. This issue, the so-called Eastern Question, was the direct cause of the two great wars of that period—the Crimean War and World War I—and the occasion of repeated less serious conflicts among the powers.

The basic problem in the disposition of the Ottoman lands was their strategic position across three continents. Because of its past history and its close links with the Balkan people through the Orthodox Church, Russia was in the best position to gain predominant influence in the area. Russia's chief rivals were Austria and Great Britain. The Habsburg monarchy could not afford to allow Russia more political control in lands along its frontiers. The British feared for their communications with their empire, which ran through the eastern Mediterranean, and their control over India. Moreover, despite its favourable relations with the Balkan people, the Russian government, too, because of its abhorrence of revolutionary activity and liberal reform programs, stood after 1815 against national revolt. Thus, although the era of the French wars had prepared the Balkan people for revolution, the international situation was not favourable. Nevertheless, the next 65 years were to witness the establishment of independent, or autonomous, governments for almost all of the Balkan national groups.

BALKANS FROM 1815 TO 1914

The era of national liberation

The 19th century saw the political and social development of the Balkans and the formation of independent states. During this period the Balkans were drawn, economically and culturally, into the orbit of contemporary Europe. While it is somewhat arbitrary to divide this exceedingly complex and dynamic era into segments, it is possible to delineate four general periods.

The first period brought the beginning of the process of national liberation during the first Balkan revolutions, 1800–30. At the beginning of the 19th century the Habsburgs ruled the northwestern part of the Balkans, while the Ottomans dominated the main central and southern regions of the peninsula. The development of a national renaissance of the Balkan peoples varied according to the different political and social conditions prevailing in these areas: political development occurred under the Habsburgs, and revolutionary upheavals predominated under the Ottomans.

Three main factors influenced the national revolutions in the areas under the Ottomans: the decline of the Ottoman Empire, provoked by a general crisis of Ottoman feudalism; the gradual shaping of a new Balkan society, as a result of the economic traffic with Europe and the development of local autonomy; and the influence of the "outer" Balkan world on the "inner" (*e.g.*, the influence of the Greek, Bulgarian, and Albanian trading colonies in the Mediterranean and Black Sea areas, of the Serbs in southern Hungary, etc.). The Balkan revolutions had two general aspects: nationalistic and agrarian. The national aspect was expressed in the drive for national liberation, the creation of national economies and cultures, and the political organization of national states. The agrarian aspect was marked by the endeavours of the peasantry to get rid of the Ottoman landlords and take possession of the land.

Next came a period (1830–78) of political and social

development. A third period saw the inclusion of the Balkans in Europe during the age of imperialism, 1878–1903. Russian designs on the Balkans culminated in the Treaty of San Stefano in 1878, which created a greater Bulgaria extending from the Danube to the Aegean and from the Black Sea to Albania, but at the Congress of Berlin in the same year the other European powers, alarmed at this extension of Russian influence, redrew the map. Bulgaria was limited to the country between the Danube and the Balkan Mountains; Serbia received Nish, Pirot and Vranje; the Dobruja was ceded to Romania; and Austria-Hungary was accorded the right to occupy Bosnia-Hercegovina provisionally. Serbia and Romania at the same time became independent principalities, while the independent status of Montenegro was recognized. In 1881 Greece secured Thessaly and Aarta from Turkey. The Bulgarian occupation of Eastern Rumelia (recognized in 1878 as an autonomous Turkish province) in 1885 was followed by the Serbo-Bulgarian War. The Greco-Turkish War of 1897 led to a rectification of the Thessalian frontier in Turkey's favour. For further history of this era, see separate Balkan country articles.

Imperialism, nationalism, and Balkan unity

Before World War I (1903–14). The fourth period involved the Balkans in European crisis on the eve of World War I. At the beginning of the century the Balkans were increasingly the scene of international conflict. The European powers had clashing military, political, and economic interests in the peninsula. The Baghdad railway project at the turn of the century symbolized German ambitions to push eastward, challenging French financial dominance in the Ottoman Empire. The growing weakness of Russia upset the Austro-Russian balance in the Balkans, while growing Italian strength in the Adriatic stimulated efforts by Austria-Hungary to reach the port of Thessaloníki and the Aegean.

Among the Balkan countries themselves, developing national strength resulted in a general movement toward political and economic emancipation. In the Yugoslav lands the year 1903 marked a turning point. Croatian political forces began to organize against Hungarian repression, and a similar restlessness was apparent in Bosnia. The assassination of King Alexander Obrenovica in Serbia prepared the way for a dynamic, nationalistic foreign policy (under the rule of Peter I Karageorgević). In Macedonia in 1903, the Ilinden uprising displayed to Europe the weakness of Turkey, the "sick man on the Bosphorus." In Croatia and Dalmatia, a coalition of political parties put forward a program calling for Yugoslav unity and social and political reform. The movement received support from Serbia and Montenegro and began to gather impetus. The Balkan states started to arm, buying artillery and ammunition in Europe.

Two tendencies were at work in the Balkans: rivalries among the states for territorial aggrandizement, and a common hostility toward interference from outside powers. A growing inter-Balkan struggle next occurred over Macedonia and was expressed in the activities of armed bands from neighbouring states that brought much suffering to the local populations. The fear of European intervention and the needs of common defense imposed a political rapprochement on Serbia and Bulgaria in 1904, joined later by Montenegro. A peasant revolt in Romania in 1907, put down by the military at the cost of thousands of lives, demonstrated that Romania's agrarian problem was far from solved.

Crisis of 1908–09. A diplomatic struggle among the European powers began in 1908 over railway projects in the Balkans. These projects expressed the political tendencies of the states involved: Austria's push toward the Aegean (the Novi Pazar railway project), Russia's and Serbia's toward the Adriatic (the Danube–Adriatic project), Italy's penetration of southern Albania (the Vlóre–Munushtir railway), and the effort of Greece and Bulgaria to absorb central Macedonia. In July 1908 the Ottoman garrison in Thessaloníki rebelled, as a result of the revolutionary activity of the Young Turks. The officers (among them Mustafa Kemal, the future leader of the Turkish republic), forced the Sultan to proclaim a constitutional era. The Young Turks wanted a regime that would give liberty and equality to all the nationalities within the empire. On October 5 the Bulgarians took advantage of the confusion to proclaim their full independence. On October 6 Austria-Hungary announced its annexation of Bosnia-Hercegovina. Two days later the Cretans proclaimed their union with Greece. The system created by the Congress of Berlin in 1878 had collapsed. The major crisis was over Bosnia-Hercegovina: the Serbs protested vehemently against the annexation; England opposed Austria; Russia backed Serbia and Bulgaria. The Austro-Turkish conflict was settled by an indemnity paid by Austria to the Turks, but the Austro-Serbian conflict brought Europe to the edge of war. Pressure from Berlin in March 1909 forced Russia to yield. Serbia had to follow the Russian example and accept Bosnia's annexation by Austria-Hungary. The crisis of 1908–09 foreshadowed coming events.

Revolt of the Young Turks

Balkan Wars of 1912–13. The situation in the Balkans remained uneasy. The Albanians, after a short-lived collaboration with the Young Turks, revolted against them in 1909–12. The Cretan *énosis* with Greece failed because of European opposition. This caused general indignation in Greece, opening the way to a military coup and the premiership of the Cretan political leader Eleuthérios Venizélos. The Venizélos government introduced reforms, reorganized the army, and revised the constitution. Macedonia continued to be a magnet for the nationalist ambitions of the Serbs, Bulgars, and Greeks. The Young Turks banned political parties and national organizations in Macedonia in 1909, and, consequently, the armed bands of various nationalities reopened their guerrilla warfare. An opportunity for an effective cooperation against Turkey presented itself in September 1911, when war broke out between Turkey and Italy in North Africa.

The Balkan alliance against the Ottomans

War against the Ottomans required a Balkan alliance. Serbo-Bulgarian negotiations started in the fall of 1911 but were troubled by differences in regard to the future delimitation of Macedonia. Finally an agreement was reached under Russian auspices in March 1912, providing for the division of Macedonia. A Greek–Bulgarian agreement was reached in May 1912, without touching the delimitation problem. Montenegro then joined the alliance, which disposed of some 550,000 troops. The war began in October 1912. The Balkan allies were soon victorious: the Serbs defeated the Ottomans at Kumanovo, joined forces with the Montenegrins to enter Skopje, achieved another victory at Munushtir, and reached the Adriatic at Durrës. The Bulgarians defeated the main Ottoman forces at Kirklareli and Lüleburgaz, advancing to the Çatalca lines in front of Constantinople. The Greeks seized Thessaloníki and laid siege to Ioánnina. The Ottomans lost all their territories in Europe, except a small strip around Constantinople. On December 3 an armistice was concluded. Peace negotiations opened in London on December 16.

The victories of the Balkan allies affected many Austro-Hungarian interests. Vienna reacted vehemently, demanding the withdrawal of Serbian troops from the Albanian coast where an Albanian state had been proclaimed on November 28, 1912. The Austro-Serbian conflict automatically developed into an Austro-Russian one.

The crisis was settled at a conference of ambassadors in London in December 1912 that recognized the new Albanian state and obliged Serbia to withdraw its troops from the Adriatic. But at the end of January 1913, after a coup d'etat in Constantinople by the nationalistic Young Turks, the war with the Ottomans was resumed. The allies were again victorious: Ioánnina fell to the Greeks, and Adrianople to the Bulgarians. Another crisis arose when the Montenegrins refused to leave Shkodër, which the London ambassadors' conference had given to Albania. The Montenegrins were forced to yield under the threat of a European naval blockade of their coast. A peace treaty, signed in London on May 30, 1913, gave all the territory west of the Enez–Midye line to the Balkan allies. Crete was united with Greece.

Serbia and Greece against Bulgaria

The territorial settlement produced discords among the Balkan allies. Serbia refused to give up the parts of Macedonia assigned by the 1912 treaty to Bulgaria on the ground that it had already been forced to withdraw from the Adriatic. A bitter struggle then ensued between the

Greeks and the Bulgarians over Thessaloníki and Thrace. Romania, as a price for remaining neutral, demanded from the Bulgarians a part of the Dobruja. Both Serbia and Bulgaria were reluctant to accept Russian arbitration. Austro-Hungarian diplomacy sought to undermine the Balkan alliance. Serbia and Greece allied themselves against Bulgaria on June 1, 1913. King Ferdinand of Bulgaria, backed by army circles, ordered his troops to attack Serbia and Greece in Macedonia on June 30. But the Bulgarian armies were defeated by the Serbs and Greeks. At the same time the Romanians entered the Dobruja and the Ottomans recaptured Adrianople. An armistice was concluded on July 31 and a peace treaty signed in Bucharest on August 10, 1913.

Results of wars. As a result of the Balkan Wars, Greece obtained Thessaloníki, Kaválla, and a large coastal part of Macedonia; Serbia gained the northern and central part of Macedonia; Montenegro acquired a portion of the sanjak of Novi Pazar, establishing a common frontier with Serbia; Bulgaria retained a part of eastern Macedonia; and Romania procured its part of Dobruja. The long decline of Ottoman rule in the Balkans had ended.

The political consequences of the Balkan Wars were considerable. Apart from Turkey, the real loser was Austria-Hungary. The partitioning of the sanjak of Novi Pazar between Serbia and Montenegro made it impossible, in the subsequent crisis of June–July 1914, for Austria-Hungary to intervene in the Balkans by occupying the sanjak. The success of Serbia and Montenegro stimulated the Yugoslav movement for union in the Habsburg Empire. The wars similarly altered the structure of alliances in the Balkans. Dissatisfied, Bulgaria henceforth looked to Austria-Hungary for support, while Romania tended to move away from its allies and toward Russia.

The most alarming result was the growth of tension between Austria-Hungary and Serbia. Serbia had extensive claims upon Albanian territory. Having obtained an assurance of German support, Austria-Hungary delivered an ultimatum in October 1913 to compel Serbia to withdraw from the Albanian borderlands. This, however, did not solved the Southern Slav question for Austria-Hungary, and it emerged once again in an acute form with the assassination of the archduke Francis Ferdinand on June 28, 1914, in Sarajevo, Bosnia. This event was followed by Austria-Hungary's ultimatum and by its declaration of war on Serbia (July 28, 1914) and the outbreak of general war in Europe in August.

BALKANS AFTER 1914

World War I and peace settlements, 1914–23. *Role of Balkan states in war.* The World War of 1914–18 was triggered by Balkan revolutionary nationalism. Gavrilo Princip, who shot and killed Archduke Francis Ferdinand, heir apparent to the Habsburg throne, was one of many young Serbs who pinned so much faith upon the advantages of national unification as to risk their lives and flout existing political authorities, both in Serbia itself and in the adjacent lands of Bosnia, Hercegovina, Dalmatia, and southern Hungary, where Serbian populations lived under Habsburg rule.

Nationalist movements

The breakup of traditional peasant styles of life among the South Slav peoples—Slovenians, Croats, Serbs, and Macedonians—fuelled this revolutionary movement. Population growth made subdivision of peasant holdings necessary; but, when a father had to divide his land among several sons, the new families could not hope to live as their parents had. This pushed innumerable young men off the land and into revolutionary activities. The pattern was as follows: as life on the farm became impossible, ambitious persons tried to get enough formal education to qualify for a desk job in town. But even after several years of secondary schooling, desk jobs were hard to come by, and many young men who had gone that far by desperate effort were not willing to wait patiently until something turned up. Instead, they listened eagerly to those who preached extreme revolutionary action.

According to Serbian nationalist agitators, justice, freedom, and a decent regard for Serbian dignity required that all speakers of the South Slav tongue who were also of the Orthodox faith should belong to the same state. The fact that the end of Habsburg rule over Serbian populations would inevitably mean more government jobs for educated Serbs was an attractive additional advantage.

Some thought that Muslim and even Roman Catholic speakers of the South Slav language should join their Orthodox brethren in a new South Slav state. But this Yugoslav (*Yug,* "South") ideal had little appeal for most Serbs. It attracted support mainly in Dalmatia, where rural Serbs (Orthodox South Slavs) and Croats (Roman Catholic South Slavs) found it easy to cooperate against the Italians, who had long dominated town life along the Adriatic.

Despite Serbia's tiny size compared to the vastness of the Habsburg monarchy, many high Austrian officials concluded that intransigent Serbian nationalism constituted a serious threat to their state. The power of the nationalist ideal in the Balkans had been demonstrated in 1912 by the First Balkan War, which all but drove the Ottoman Empire from Europe and added substantial new territories to Serbia. This success fanned the Serbian nationalist ambition which was already at white heat, to complete the task of liberation by disrupting the Habsburg state.

What made such a program so frightening to the Austrians was that other nationalities within the Habsburg Empire shared in some degree the ambition to win greater control over their own affairs; a few even dreamed of achieving complete national independence. But in 1914 nationalist movements among the Czechs, Germans, Italians, Poles, Magyars, Slovenes, and Croats were less emotionally intense and, therefore, less immediately threatening to constituted authority than was the case among the Serbs.

Outbreak of war

Austrian officials, therefore, felt that a showdown was desirable. They decided to seize upon Archduke Francis Ferdinand's assassination to settle accounts with Serbia. Preliminary investigation failed to turn up definite evidence that the Serbian government had been connected with the assassination; but historians have since shown that the Serbian premier, Nikola Pašić knew what was going on and tried indirectly to warn Austrian authorities of the plot. Col. Dragutin Dimitrijević, chief of intelligence for the Serbian general staff and leader of the Black Hand—a secret society that planned the assassination and armed Princip (with several others)—was one of Pašić's political enemies and rivals. In hinting to the Austrians of what was afoot, Pašić did as much as he dared to thwart Dimitrijević's risky, revolutionary plans. But the Austrian authorities failed to take the hint. The Archduke was assassinated, official Europe was horrified, and on July 23, 1914, the Habsburg government delivered an ultimatum to the Serbs requiring suppression of patriotic societies and the establishment of a joint commission to investigate and punish those persons who were responsible for organizing the assassination.

The ultimatum was designed to be unacceptable. Despite a conciliatory reply, the Austrians declared war against Serbia on July 28, exactly a month after the assassination itself. Within a week Europe's alliance system swung creakily into action, pitting the Triple Entente—Russia, France, and Great Britain—on Serbia's side against the Central Powers—Germany and Austria-Hungary.

Russia's entry into the war upset Austrian plans for crushing Serbia. Austrian troops had to be diverted to the Russian front, and, when the Austrians were finally ready to attack the Serbs, on August 13, they were repulsed. A Serbian counteroffensive soon petered out, however, and by the end of 1914 the battle line stood very close to the prewar frontiers.

The outbreak of hostilities provoked intense diplomatic–military activity elsewhere in the Balkans. On August 11, 1914, two German cruisers that had been trapped in the Mediterranean Sea at the beginning of the war arrived in Constantinople. A fictitious sale transferred them to the Turks, and in October these vessels sailed into the Black Sea to bombard Russian coastal towns. The Allies (Entente) promptly declared war against Turkey (November 4–5, 1914).

Both the Entente and the Central Powers sought to rally support for their cause among the three remaining un-

committed Balkan states—Bulgaria, Romania, and Greece (Albania was in chaos and lacked a central government). Bulgaria wanted the parts of Thrace and Macedonia that had been annexed by the Serbs and Greeks after the Second Balkan War in 1913; Romania wanted the Habsburg territories of Transylvania and adjacent regions in Bukovina and the Banat; Greece had ambitions in Anatolia and, above all, desired to possess Constantinople (later Istanbul).

The Central Powers were able to promise the Bulgars most of what they desired, because Serbia would be the main loser. Similarly, the Entente was able to appease the Romanian appetite at the expense of the Habsburgs. Greece's ambitions were more difficult, however, because Russia, too, aspired to possess Constantinople, and so did the Bulgars.

Courtship of the Balkan states

The work of diplomats and intelligence agents in lining up allies in the Balkans for one side and the other came slowly to fruition in 1915–17. The Bulgars were the first to commit themselves, by allying with the Central Powers in September 1915. By then the strategic situation in the Balkans had altered greatly. The first important move was British. In February 1915 the Royal Navy bombarded Turkish forts in the Dardanelles, and a month later British warships tried unsuccessfully to force their way through the straits. Then, on April 25, 1915, British troops went ashore on the Aegean side of the Gallipoli Peninsula in order to take the Turkish defenses of the Dardanelles in the rear and open a way to Constantinople for the Royal Navy; but once again the Turks were able to stop the British advance before it could achieve strategic success.

The next major move came from Italy. Despite a defensive alliance with Germany and Austria-Hungary, the Italian government remained neutral in 1914, arguing that, because Austria had attacked Serbia, the terms of the alliance had not been fulfilled. Italian nationalists wished to add Dalmatia and other Austrian provinces to their country; despite Serbian objections, the Allies agreed to most of the Italian demands in the secret Treaty of London (signed in April 1915). Accordingly, in May the Italians declared war and opened a new front against Austria in the Alps. Italian troops also crossed the Adriatic to occupy Albania.

The intervention of Italy, plus Austrian commitments on the Russian front, forced the Austrians to postpone large-scale action against the Serbs until fall; but by the first week in October everything was ready for a major assault. The Bulgars saw in this their opportunity to take Macedonia from Serbia, and they prepared to join the attack.

In a last-minute effort to aid the Serbs, French and British troops landed at the Greek city of Thessaloníki on October 3. This touched off a major crisis inside Greece, pitting Prime Minister Eleuthérios Venizélos, champion of the Allies, against King Constantine, who favoured continued neutrality, at least until it was clearer which side would win the war. (In the end, by bombarding the royal palace in Athens the Allied powers were able to compel Constantine to abdicate in June 1917; and Venizélos, who took command of Greek affairs, promptly caused Greece to declare war against the Central Powers.)

A combined Austrian and German force attacked Serbia on October 6, 1915, with overwhelming strength. Allied troops in Salonika were too few to check the simultaneous Bulgar advance from the east. In November, the Serbian Army began a painful retreat through the mountain passes of Albania. A remnant 125,000 strong found refuge on the Greek island of Corfu, where the Serbian government, still being led by the aged and ailing King Peter I, with Nikola Pašić as prime minister, established a temporary headquarters (January 1916) in what had formerly been the German kaiser's holiday palace.

Meanwhile, the British withdrew their troops from Gallipoli, transferring most of them to the Thessaloníki front, which soon extended westward to link up with the Italians in Albania. Trench warfare then set in along a battle line extending all the way from the Adriatic coast to Kaválla on the Aegean. Neither side could break through the other's prepared defenses.

Stalemate of 1916

This stalemate was demonstrated in 1916, when the last Balkan neutral, Romania, entered the war on the Allied side on August 27. This move was planned to coincide both with a Russian offensive against Austria and with a major push against Bulgaria along the Thessaloníki front. Despite substantial reinforcement by rested and re-equipped Serbian troops transferred to Thessaloníki from Corfu, the offensive failed. The Romanian Army proved ineffective, and by January 1917 most of Romania was in the hands of the Central Powers.

The year 1917 saw no large-scale military action in the Balkans, but revolutions in Russia changed the realities of power profoundly. The Bolsheviks publicly renounced Russian claims on Constantinople; instead, Lenin appealed over the heads of all governments to the peoples of Europe to rise against their exploiters and inaugurate Socialism. Balkan response to Lenin's revolutionary summons was slight, partly because the Western Allies forestalled the Bolshevik appeal by endorsing a different revolutionary formula—national self-determination. The war thus became far more ideological than before, pitting nationalist revolutionary ideals against Socialist revolutionary ideals through the whole of eastern Europe.

The most complex nationality issue in the Balkans centred around Serbia's relationship to the other South Slav peoples of the Habsburg Empire. On July 20, 1917, the Serb prime minister Pašić signed a document declaring that Serbs, Croats, and Slovenes should form a single state after the war, under the Serbian Karageorgević dynasty but with appropriate local autonomies. Exiled Dalmatian politicians, claiming to represent the Croats and Slovenes, also signed this Pact of Corfu. In April 1918 a Congress of Oppressed Nationalities met in Rome and, with Italian blessing, reiterated the idea that Serbs, Croats, and Slovenes belonged together, despite the fact that the three nationalities distrusted one another profoundly and that most Croats remained loyal to the Habsburg cause.

End of the war

The long military stalemate in the Balkans ended on September 30, 1918, when the Bulgars sued for an armistice. From the Thessaloníki front, Allied troops under French command marched northward to the Danube. As the Allied forces approached, the Romanians, who had signed a peace with the Central Powers in May 1918, reentered the war on November 8, just in time to count as an Allied and victorious power at the peace conference.

The Ottoman government followed the example of the Bulgarians by suing for an armistice on October 30, 1918. The armistice terms allowed a British force to advance through the Dardanelles and to occupy Constantinople on November 13. Amid the crash of falling empires, the Habsburg monarch also signed an armistice on November 3; but events had stripped the Emperor of his power to influence affairs. The Romanians (already in possession of the former tsarist province of Bessarabia) hastened to take possession of as much of Transylvania, Banat, and Bukovina as possible; meanwhile, Serbian troops were moving into the former Habsburg territory from the south, while the victorious Italians also sought to get control of as much of the Adriatic coastlands as they could.

Under these circumstances the Slovenes and Croats had little room for manoeuvre. On October 29, 1918, a national council meeting in Zagreb proclaimed the independence of "Yugoslavia" (meaning the former Habsburg lands in which the South Slavs lived). Before a stable settlement with the Serbs could be achieved—a preliminary agreement reached at Geneva on November 9 was later repudiated—the Zagreb National Council broke apart.

Kingdom of Serbs, Croats, and Slovenes

A faction opted for immediate union with Serbia; and, accordingly, on December 1, 1918, the Serbian monarch formally proclaimed a new Kingdom of Serbs, Croats, and Slovenes from his capital, Belgrade. A political coup unseated the Prince of Montenegro, whose state was also merged with the new South Slav state. But whether the new state would be federal or unitary and the question of how Serbs and Croats would come to an understanding with one another remained completely unsettled.

Results of peace conferences. The Paris Peace Conference that began in January 1919 drew up separate treaties for each defeated enemy state. By the Treaty of St. Germain (signed September 10, 1919) Austria ceded Sloveni-

an and Dalmatian territory to the new Kingdom of Serbs, Croats, and Slovenes; by the Treaty of Neuilly (signed November 27, 1919) Bulgaria lost a strip of the Aegean coast (acquired in 1912) to Greece and surrendered small border territories to Serbia; by the Treaty of Trianon (signed June 4, 1920) Hungary transferred Transylvania and part of the Banat to Romania and surrendered Croatia, Slavonia, and the rest of the Banat to the new South Slav state; lastly, by the Treaty of Sèvres (signed August 10, 1920), Turkey assigned most of Thrace as well as the hinterland of Smyrna (Izmir) in Asia Minor, to Greece.

From L. Stavrianos, *The Balkans Since 1453*; Holt, Rinehart and Winston, Inc.

The Balkans after World War I.

These treaties settled many of the territorial questions that had long distracted Balkan politics and in a comparatively enduring way. But "national self-determination" proved a difficult formula to apply in lands where mixtures of nationalities were the rule rather than the exception. Some issues, such as the delineation of the Italian–Yugoslav boundary, were never resolved at the peace conference; instead, bilateral negotiation eventually (1924) defined a frontier that satisfied neither side.

Albania's borders were not fixed until 1926, when an international commission, established in 1912, finally concluded its labours. This settlement, which left large Albanian populations inside the new South Slav state, made little difference politically until after World War II, because Albanian national self-consciousness was weakened by traditional loyalties to rival kindred groupings, on the one hand, and by religious (Muslim, Orthodox, Roman Catholic) and linguistic (Gheg, Tosk) differences on the other.

Turkish and Tartar minorities along the Black Sea coast in Bulgaria and Romania shared the Albanians' prepolitical status; and Jews, important mainly in Romania and at Thessaloníki, offered no systematic resistance to the new masters of the Balkans. The case was far different, however, with other Balkan nationalities. Those who had formerly enjoyed a leading position in society and government found it all but impossible to accept willingly the loss of former privileges. The victors often retaliated by subjecting German, Magyar, Turkish, and (in Dalmatia) Italian minorities to flagrant administrative discrimination.

Hence, the territorial settlement of 1919–20 had the effect of transferring to Romania and the new Kingdom of Serbs, Croats, and Slovenes many of the nationality problems that had plagued the Habsburg and Ottoman empires before 1914. In Romania, Magyar, German, Jewish, Ukrainian, Bulgarian, and Turko-Tartar minorities amounted to at least 4,500,000 in a total population of about 18,000,000; but the Romanian majority did give a solid core to the new state. The situation in the Kingdom of Serbs, Croats, and Slovenes was less stable, for, although the Serbs constituted the largest single nationality, they were still a minority in the state considered as a whole.

Continuing nationality problems

German, Magyar, Albanian, and Romanian minorities totalled over 1,600,000; about 1,300,000 Muslims (mostly speaking Serbo-Croatian) constituted another distinct bloc; Slovenes (about 1,100,000) formed a self-conscious, distinct nationality, too; but the really critical matter was the relation between the Croats (about 3,500,000) and the Serbs (about 5,500,000). A new constitution went into effect on January 1, 1921, establishing a unitary state on democratic lines. Croats felt that the Corfu Declaration of 1917 had committed the Serbs to federalism, and they refused to accept the new arrangement. This was especially dangerous for the new state, because the Italian government was dissatisfied with the peace settlement in the Adriatic and set out actively to encourage disruptive forces. The death of King Peter in 1921 made small difference; his heir, King Alexander I (reigned 1921–34), had already exercised the royal powers for several years.

The southern Balkans were even more distracted in the first postwar years. A Turkish nationalist movement, headed by Kemal Atatürk, refused to accept the terms of the Treaty of Sèvres. The Greeks, seeking to make good their claim to even more extensive territories in Asia Minor, invaded the interior in hope of forcing the Turks to yield; in 1921 they met defeat, and the angry Turks forced all Greeks and other Christian inhabitants from the land. About 1,500,000 survivors fled across the Aegean in 1921–22.

A new peace, agreed to at Lausanne, Switzerland, in 1923, provided for the systematic exchange of populations between Greece and Turkey under League of Nations supervision. Greek and other Christian inhabitants of Constantinople were exempted from this exchange; in return, Greece promised to allow Turkish peasants in western Thrace to remain on their land. This treaty provided that the Greeks relinquish their claim to Asia Minor entirely and retroceded eastern Thrace to Turkey.

Exchange of population with Bulgaria was also arranged by a separate agreement. The result, by about 1927, when major transfers ceased, was the sorting out of the populations of Greece, Bulgaria, and the western parts of Turkey by nationality.

No politically important national minorities remained in the southern and eastern Balkans. This radical surgery allowed nationality frictions to subside slowly in later decades. In the northern Balkans, however, such frictions continued to constitute a major axis of politics during the interwar years.

Interwar developments, 1923–39. The upheavals of World War I did little to solve the underlying problems of Balkan society. It is not strange, therefore, that revolutionary discontent found new channels of expression after the war. Success for certain nationalities (Serbs, Romanians) automatically meant frustration for others (Bulgars, Magyars, Croats, Macedonians), so that in some regions of the peninsula old-fashioned nationalist conspiracy and agitation continued as before, but now directed against the new masters of the land.

But national self-determination lost much of its glamour as it became clear that old problems were not really relieved by the changes in political boundaries and shifts in dominating nationalities that had occurred in 1918–19. Two new revolutionary movements, therefore, surged to the fore: peasantism and Communism.

New revolutionary movements. The three main bearers

Peasantism

of the peasantist idea were the Peasant Party of Bulgaria, led by Aleksandŭr Stamboliyski; the Croatian Peasant Party, led by Stjepan Radić; and the Romanian Peasant Party, led by Iuliu Maniu. The latter, based mainly in Transylvania, opted for parliamentary and peaceable agitation and, even when Maniu briefly became prime minister (served 1928-30), accomplished little to reform rural conditions. The Croatian Peasant Party quickly became identified with Croat nationalism, thanks to Radić's unbending opposition to Serbian preponderance in the new Kingdom of Serbs, Croats, and Slovenes; by boycotting the parliament, Radić showed how shaky the new state really was, but his policy, too, accomplished no positive ends. Stamboliyski, on the other hand, came to power in 1919 on a wave of revolutionary feeling; but his efforts to end bureaucratic oppression and overthrow the parasitic classes that fattened on peasant labour only succeeded in putting crude former peasants and party men into administrative roles they were poorly equipped to handle; in 1923 a coup d'etat led to Stamboliyski's assassination and to the establishment of a shaky parliamentary regime, closely controlled from behind the scenes by royal, military, and semi-military manipulators.

The basic reason for the failure of peasant parties to achieve their ends lay in their programs. Men who wished to destroy the so-called social parasites (*i.e.,* everyone who did not work with his hands and raise his own food) could not take power without themselves becoming that which they wished to abolish: bureaucrats and paper shufflers.

Opposition to those who ruled was the only role such parties and movements could accept comfortably. Only in this way, in fact, could they hope to remain faithful to the perennial distrust their peasant constituencies felt toward government in any form and toward city people generally.

Rise of Communist parties

The other new revolutionary movement, Communism, was better equipped ideologically and organizationally. Communist parties had arisen in each Balkan state by 1921. In Bulgaria and Yugoslavia, the new parties met with rapid initial success but subsided into small, quarrelsome groups of hunted revolutionaries when the two governments officially outlawed Communist agitation, in 1921 (Yugoslavia) and 1923 (Bulgaria). In Romania, Greece, and Albania, Communist organizers met with only slight response in the 1920s, but they did succeed in creating revolutionary cadres ready and willing to operate outside the law.

The frustration of peasantist aspiration and the prevalance of nationalist revolutionary sentiment among such groups as the Macedonians seemed in 1924 to offer Communists a chance to unite all the disaffected elements of Balkan society into a grand alliance. The Comintern (Communist International, formed in 1919 to help in spreading Leninism around the world) approved the formula of Balkan federation as a solution for the peninsula's political and economic ills and instructed each national party to form "popular fronts" with any and all available groups. Radić flirted openly with Moscow; so did leaders of the Internal Macedonian Revolutionary Organization (IMRO).

But these incompatible bedfellows soon parted. IMRO leaders who cooperated with the Communists were killed by rivals within the organization. Radić became a cabinet minister for a brief period (1925–26), but in 1928, during a session of the parliament, he was shot and killed by a Montenegrin Serb. This assassination provoked a strong reaction among the Croats against any kind of cooperation with the Serbs. King Alexander, therefore, decided to scrap the constitution, which had done so little to heal the fissures within his kingdom; he proclaimed a dictatorship, dissolved the political parties, and officially renamed the state Yugoslavia.

Government reactions. By resorting to authoritarian government, Alexander openly admitted the breakdown of effective government by consent. The same thing had also happened in Bulgaria, Romania, and Albania; but in those countries the pretense of parliamentary elections and the rituals of party coalitions were preserved, and they sometimes registered real adjustments in public mood.

This was the case, for instance, when Maniu forged a coalition of peasant parties in Romania and emerged as premier in 1928. In Greece, too, the parliamentary elections that returned Venizélos to power in 1928 registered public feeling quite accurately; but Greek electoral politics were frequently punctuated by coups d'etat (1922, 1925, 1933, 1935), that were sometimes successful, sometimes not.

Official efforts to cope with the problems of Balkan society and to meet the new revolutionary thrusts directed against existing governments were not entirely fruitless. They took three forms: land reform, industrialization, and police repression.

Land reform

Widespread redistribution of land shifted ownership toward the peasant families who actually worked the soil. Such reforms went fastest and farthest when land could be taken from owners of a different nationality. Thus, Magyar estates in the north and Turkish estates in the south disappeared at once. Gradual reapportionment took place elsewhere, too, so that by 1939 large estates had almost disappeared from the Balkans, surviving only in those parts of Romania where the landlords were politically powerful Romanian nationals.

The new owners of small peasant plots were often unable to cultivate the soil as efficiently as had the large-scale operators. Redistribution of land was no solution to the ills of Balkan overpopulation and underdevelopment. Each of the Balkan states recognized this fact by attempting to forward industrialization. Romania, building upon an oil industry that had arisen in the 19th century, made by far the most substantial progress in this direction; Bulgaria made almost none. Tariff protection, subsidy, and state enterprise were the devices used to develop industry. But shortage of capital and a generally low level of skills made progress painfully slow.

Industrialization

The only important policy difference in the interwar period with respect to industrialization was about how to treat foreign capital. Romania tried to finance industrial development from internal sources and actively discouraged further foreign investment in the oil industry, fearing that control and the real benefits of such expansion would pass exclusively to the foreign capitalists. Albania, under Ahmed Zogu (president, 1925–28; king, 1928–39), on the other hand, depended wholly on Italian capital for whatever modernization was achieved. Greece and Yugoslavia gave an ambivalent welcome to foreign investment, but political instability in these countries kept the flow of foreign capital to modest proportions. Bulgaria was more xenophobic and attracted almost no foreign funds.

Repression

The third major official response to the problems of Balkan society was repression. High-handed police action was common; elections were often "made" to suit the interests of those in power by overt use of army and police personnel; and sharp legal restriction, if not outright prohibition, was generally imposed on revolutionary political organizations and propaganda. Such measures were generally successful, even when the revolutionaries received systematic encouragement from abroad.

The Soviet Union provided at least moral support for Communists throughout the period. Fascist Italy spun a web of intrigue aimed against Yugoslavia; by the late 1920s Mussolini's agents had entangled the Bulgaria-based IMRO, extreme Croat nationalists (Ustaše) based in Rome, and some elements of the Hungarian government in plots to dismember King Alexander's state.

In Romania, too, a Fascist movement, founded in 1927 (renamed the Iron Guard in 1928) by Corneliu Codreanu, rose quickly to prominence; it owed little to foreign patronage, however, because Codreanu based his appeal mainly upon harsh anti-Semitism, for which the ground was already well prepared.

Alliances

The Balkan governments took steps to counter the foreign threat. A diplomatic alliance of Czechoslovakia, Romania, and Yugoslavia—the so-called Little Entente—dated from 1921. In 1934 a new Balkan Pact allied Greece, Yugoslavia, Turkey, and Romania. Such treaties were aimed mainly against Hungarian (Little Entente) and Bulgarian (Balkan Pact) aspirations for frontier revision. In the background, France played the role of great-power patron vis-à-vis Romania and Yugoslavia, rivalling Italy, the patron of Bulgaria and Hungary; Britain, the patron

of Greece; and the Soviet Union, the pan-Balkan patron of Communists.

Balkans in 1930s. The economic depression that settled upon world trade in the early 1930s put the Balkan countries at a great disadvantage. Farm prices plummeted, making it all but impossible for high-cost Balkan peasant producers to compete on world markets. Hardship and a pervasive sense of failure and confusion in official quarters encouraged revolutionary sentiment, especially among the young. But the enhanced power of revolution, especially in Communist guise, provoked more ruthless repression. Democratic and parliamentary government seemed to have failed everywhere, especially after 1933, when the rising influence of Nazi Germany began to make itself felt in the Balkans.

The effects of the world depression

German trade policy, as a matter of fact, brought an effective solution to the economic crisis that had paralyzed the Balkan markets since 1930. The Nazis offered to buy agricultural products from the Balkans, at prices fixed through bilateral negotiation, and offered manufactured goods in exchange, again at prices fixed by interstate bargaining. Germany often drove a hard bargain in these trade negotiations, but only in Germany could high-cost Balkan farm products find any kind of sale. Hence, these exchanges—administered by state trading agencies and kept track of through blocked accounts managed by state banks—benefitted all parties. Romania and Bulgaria, in particular, began to market substantial surpluses in Germany.

By the late 1930s the resulting economic improvement allowed precarious political stabilization in both countries. Thus, for example, King Boris III of Bulgaria suppressed IMRO by condoning, if not instigating, a coup d'état in 1936, which brought to power a military group that dispersed IMRO's gunmen and drove its leaders from the country. Similarly, in 1938 King Carol II of Romania was able to have Codreanu killed and to repress the Iron Guard through unscrupulous and highhanded police methods; the king owed his success to the fact that, despite the strong appeal of its anti-Semitism, trade revival had taken the cutting edge from the Iron Guard's revolutionary agitation.

Greece followed a similar route. The early 1930s saw a rising political crisis, with abortive coups d'état in 1933 and 1935. A "managed" plebescite in 1936 led to the recall of King George II from exile; but new elections resulted in a parliamentary deadlock between royalists and republicans. A handful of Communist deputies held the balance of power, being in a position to make or break any parliamentary majority. King George reacted to this situation by entrusting the government to Gen. John Metaxas, who ruled without a parliament until his death in 1941.

In Albania, however, King Zog's regime collapsed in 1939, and Italians took over direct administration of the country. This allowed Mussolini to threaten both Yugoslavia and Greece across a new frontier. Such an advance of Italian power was profoundly disturbing to both Balkan governments. Ever since 1934, when King Alexander of Yugoslavia had been assassinated in Marseilles by an IMRO gunman (supported by Hungary and Italy), Yugoslavia's internal problems had offered the Italians a promising field of action. Prince Paul, brother of the assassinated Alexander, took over the reins of government as regent for the heir, King Peter II, who was still too young to rule. Paul, like other Balkan monarchs, experimented with authoritarian rule and worked diligently for diplomatic rapprochement with both Bulgaria and Italy.

Italian control of Albania

In the late 1930s Paul decided that the kingdom could survive only by coming to a basic understanding with the Croats. Prolonged negotiations led to an agreement, in August 1939, by which a generously defined Croatia would enjoy extensive autonomy; the Croatian Peasant Party accepted this arrangement, and only certain extremists (the Ustaša) remained irreconcilable. This drastically weakened the Italian leverage inside Yugoslavia; but it did not solve the state's problems, because most Serbs balked at the prospect of giving the Croats control over territory in which large numbers of Serbs lived. Yet nothing less would satisfy Croatian ambitions. As a result, the federal structure for Yugoslavia as promised in the 1939 agreement had not been fully implemented when the flood tide of World War II overwhelmed the Balkan Peninsula.

World War II, 1939–45. *Axis victories and occupation.* Stalin's cooperation with Hitler against Poland (September 1939) turned previously proferred Anglo-French guarantees of Polish and Romanian territorial integrity into worthless scraps of paper. The Romanian government had to yield Bessarabia and Bukovina to the Soviet Union (June 1940), part of Transylvania to Hungary (August 1940), and the southern Dobruja to Bulgaria (September 1940). King Carol, discredited by such losses, fled the country, and Gen. Ion Antonescu became dictator. Antonescu invited German troops to enter Romania in October 1940. The Romanian government remained a loyal and relatively enthusiastic ally of the Nazis in their struggle against the Soviet Union until 1944.

The Italian government, jealous of Germany's successes in Poland, Scandinavia, and France, decided to make Greece into a dependency. When the Greek dictator Metaxas refused to yield to Mussolini's ultimatum (October 1940), Italian troops crossed the Albanian frontier, expecting to meet only token opposition. To their surprise and discomfiture, the politically divided Greeks joined ranks against the Italians and drove the attacking forces back across the Albanian border. Fearing the provocation of German military intervention, the Greek government reacted coolly to the British offers of air and naval support; these fears assumed new plausibility when Nazi troops moved secretly into Bulgaria in March 1941.

German advance into Bulgaria

The German move attempted to forestall Soviet influence in Bulgaria and to compel Greece and Yugoslavia to repudiate ties with Great Britain and align themselves with the Nazi cause. As a diplomatic prelude to their planned attack on the Soviet Union, the Germans demanded that each Balkan state adhere to the Tripartite Pact (concluded initially by Germany, Italy, and Japan in September 1940). Hungary and Romania did so in November 1940; Bulgaria followed suit on March 1, 1941; and the Yugoslavs reluctantly did the same a few weeks later (March 25). News of this act led Serbian radicals, already bitterly opposed to the deal the government had concluded with the Croats, to seize power in Belgrade. This act of defiance outraged Hitler, then at the summit of his diplomatic success; to safeguard his southern flank for the thrust against the Soviet Union, he determined to crush the Yugoslavs and Greeks in a lightning campaign.

Accordingly, on April 6, 1941, German forces attacked and speedily overran Yugoslavia. A hastily assembled British expeditionary force scarcely reached Greece from North Africa when headlong retreat began. In May 1941 German parachutists invaded Crete, and by the end of the month they had won a costly victory there; German arms had thus chalked up yet another brilliant success, but it forced them to postpone by a few weeks the start of the campaign against the Soviet Union. Whether this delay actually helped the Soviets survive Hitler's assault can probably never be definitively decided; but Greeks and Yugoslavs easily convinced themselves that the defeat of their countries was an essential precondition for the later Soviet victory.

Greece and Yugoslavia remained under Axis occupation until 1944–45. Bulgarian, Italian, and German troops carved out separate zones of occupation—most of Macedonia was incorporated into Bulgaria; an independent Croatia, ruled by the Ustachi and under Italian patronage, was proclaimed. Romania, too, staked out its territorial claims in Bessarabia and adjacent regions of the Ukraine.

Resistance movements. The first people who actively opposed these arrangements were Serbs, who had everything to lose and whose national tradition of heroic outlawry against the Turks inspired guerrilla action. Bands of demobilized Serbian soldiers—"Chetniks"—formed under the leadership of Col. Draža Mihailović and engaged in acts of sabotage. When the Germans sent fresh troops into Serbia and retaliated brutally against communities suspected of harbouring guerrillas, the Chetniks abandoned active operations, husbanding their strength against a future day of liberation when Germany's defeat would per-

mit them to restore the Serbian nation to its accustomed and proper position in the Balkans.

After the Nazi attack on the Soviet Union (June 22, 1941), the Communist parties of the Balkans, which had previously cooperated with the Germans, made an abrupt about-face. Communist activity in Bulgaria remained marginal until 1944; in Romania the party was of trifling importance, being firmly identified with Jewish and other minority groups.

But in Yugoslavia, Albania, and Greece the Communists rapidly built up powerful resistance organizations. The Communist Party line was to cooperate with all anti-Fascist elements in the population; hence, popular fronts, uniting Socialists, peasants, nationalists, and anyone else willing to cooperate with Communists, sprang into existence. Communist policy systematically played down Marxism and disguised the extent of party control over the network of political and military resistance organizations they created.

The popular fronts

An essential strength of the Communists in this situation was the availability in each Balkan state of underground party cadres already accustomed to survival in face of police harassment. In addition, the Communists emphasized political organization in towns and countryside, thus providing the armed guerrilla bands responsive to their leadership with far firmer support than any rival organizations could offer. Finally, Communist policy aimed at helping the common cause of Socialist revolution by fighting Germans wherever they could be found; this simple policy had the effect of attracting the support of restless and active men throughout the western Balkans. Hence, by degrees the Communists were able to live down their traitorously antinational past and to far outdistance all rivals.

In Yugoslavia, when the Communist-led Partisans first took the field in the summer of 1941, they tried, in accord with popular front tactics, to cooperate with Mihailović's Chetniks. But violent quarrels soon broke out. Two points were at issue: whether to persist in active operations against the Germans and Italians, despite the cost to civilian populations, as Tito (Josip Broz), the Communist leader, desired (Mihailović opposed this); and whether to welcome all Yugoslavs into the resistance, as Tito assumed, or accept only Serbs, as Mihailović felt was necessary.

Behind these disagreements lay rival visions of the future: Mihailović desired above all to protect Serbdom against Croat, Bulgar, and other threats, whereas Tito envisioned a revolutionary brotherhood of all Balkan nationalities, as projected by the Comintern ever since the 1920s. In the long-drawn-out struggle that ensued, advantage lay overwhelmingly with Tito; his policy of conducting active operations against the occupiers of his country won the backing of the British, American, and Soviet allies (Tehrán Conference, November 1943). In addition, as the war continued to bite into their daily lives the peoples of Yugoslavia more and more rallied to the only active transnational Yugoslav organizations in sight: Tito's Partisans and the Anti-Fascist Peoples' National Council (AVNOJ), the political voice and arm of the movement.

In Greece, the Communist resistance also took the form of an armed guerrilla organization, known by the acronym ELAS, and of a political organization, called National Liberation Front (EAM). British policy, however, never abandoned support for the Greek government in exile, headed by King George II. In Greece itself, anti-Communist guerrilla groups that were supported by British agents and supplies continued to divide the ground with ELAS.

The situation in Albania was similarly confused; rival Albanian resistance groups achieved effective organization only after 1943, when the surrender of the Italian government to the Allies in September put large stocks of arms into Albanian hands. The Italian surrender also allowed the resistance movements of Yugoslavia and Greece to acquire large quantities of Italian weapons and briefly to take possession of territories formerly policed by Italian troops.

Acquisition of Italian weapons

The Germans were able to reoccupy major cities and lines of communication in the former Italian zones of occupation; but by 1944 the continuing retreat of German armies in the Soviet Union made clear the ultimate outcome of the war. On August 23, 1944, when the advancing Soviet forces were close to the Romanian border, King Michael kidnapped General Antonescu and adroitly changed from the Axis to the Allied side. As a result, Soviet troops were able to advance rapidly toward the Danube, and Romanian units, formerly Hitler's allies, switched allegiances, turning their arms against the Germans.

The Bulgarians followed suit on September 9, as the Soviet advance guard neared their border. The Soviets then turned westward, passing through a corner of Yugoslavia (Belgrade was liberated, October 20, 1944) on their way to Budapest.

This abrupt military reversal compelled the Germans to withdraw what forces they could from the western Balkans. Isolated German garrisons, such as that in Crete, were left behind; but the main forces moved northward in good order, and at the end of the war (May 1945) much of Croatia still remained under German occupation.

The last Germans left Greece in October 1944, whereupon the royal Greek government returned to Athens (October 18) with the protection of a handful of British troops; quarrels soon broke out, however, and, during six bitter weeks (December 1944 to January 1945), fighting flared in Athens between British forces and the resistance guerrilla army, ELAS.

World War II to present. *Postwar settlement, 1945–49.* The armed collision between British- and Communist-led forces in the streets of Athens showed how hard it was, as the prospect of final victory over Germany came closer, for the great Allied powers to keep on cooperating. In May 1944 the United States had reluctantly approved a division of the Balkans into British and Soviet spheres of influence; this was confirmed and adjusted in favour of the Soviet Union when the British prime minister, Winston Churchill, visited Moscow that September to settle details of armistice arrangements with Romania and Bulgaria and to clear the way for the British landing in Greece.

British and Soviet spheres of influence

The Soviets were not unhappy to see the British resort to high-handed means to enforce their will in Greece. They hoped for a similar free hand in Romania, where the absence of any strong native Communist party made it particularly difficult for them to establish a government they could depend on. The Bulgarian Communist Party, though, was relatively strong and, operating through a "Fatherland Front," gave the Russians no cause for concern.

In Yugoslavia, however, where Tito easily took power as the Germans withdrew, the Soviets found it hard to restrain the Partisans' revolutionary enthusiasm. In the first flush of victory, Tito's followers were eager to put the Communist recipe for Balkan federation into effect and saw no reason to compromise with the "effete capitalist imperialists" of Britain and the United States over such an issue as control of Trieste. When the Soviets, in conformity to their deal with Churchill to divide the Balkans into spheres of influence, advised Tito to make conciliatory gestures towards the Royal Yugoslav government (in exile since 1940), the Yugoslav Communists reluctantly complied by allowing King Peter's representative, Ivan Šubašić, briefly to join the Cabinet. But the Partisans had come to power by taking risks and despising compromise; accordingly, many of Tito's followers were appalled at the Soviet Union's unwillingness to act upon revolutionary principles in the immediate postwar period.

The British, American, and Soviet foreign ministers slowly negotiated peace treaties with the former enemy states of the Balkans (1945–47). As long as the Anglo-Americans had not recognized the postwar Communist-dominated regimes of Bulgaria, Romania, and Hungary, the Soviets had a powerful argument for moderation; Stalin accordingly supported collaboration with all anti-Fascists and opposed further revolutionary adventures in the Balkans.

In Romania and Hungary there were strong practical reasons why out-and-out Communist Party dictatorships could not come to power—national feeling was distinctly anti-Soviet Union and, therefore, anti-Communist, and pre-existing Communist Party structures were extremely weak. But even where there were strong Communist parties, as in Bulgaria and Yugoslavia, until 1947 Soviet policy continued to support anti-Fascist popular fronts in

which Communist preponderance was at least partially camouflaged.

Changes in Soviet policy toward the Balkans

In 1947 two events altered Soviet policy toward the Balkans. First, the United States and Great Britain signed peace treaties with Bulgaria, Romania, and Hungary in February. These treaties did not much alter interwar boundaries, although Romania did lose Bessarabia and Bukovina to the Soviet Union once again and ceded a small strip of Dobruja to Bulgaria; Greece acquired the Dodecanese Islands in the Aegean from Italy; and Yugoslavia annexed a strip of territory in the Istrian peninsula. The treaties did, however, disband the Allied armistice commissions, which had exercised some control over local affairs in both Bulgaria and Romania following 1944.

The cancellation of British and American legal claims to authority in these countries freed local Communists from what had been a real, if modest, hindrance. At the same time, because the treaties authorized the Soviets to maintain their forces in Romania as "lines of communication" troops to forward garrisons in Austria, the Communists retained what was still an essential guarantee of their hold over Romania.

The second event that altered Soviet policy occurred in March 1947, just a month after the peace treaties came into effect, when Pres. Harry S. Truman asked the United States Congress to authorize military and economic aid to Greece and Turkey, both of which were under Communist pressure. After prolonged debate, Congress voted to approve Truman's request and thereby endorsed the "Truman Doctrine," according to which the United States undertook to defend the rule of law internationally by coming to the aid of any government threatened with Communist subversion.

The U.S. decision to back the Greek government against a renewed Communist guerrilla movement signalized a sharp shift of American policy vis-à-vis the Soviet Union. Quarrels over the peace treaties, over Poland, over the occupation regimes in Germany and Japan, as well as over the rising tide of Communist power in China and several other parts of Asia, all contributed to the change of American public attitudes; but events in the Balkans were also important.

Attempts to form a Balkan confederation

In 1945 and 1946, through a series of diplomatic notes, the Soviets tried to convince the Turks to give them military bases on the straits between the Black Sea and the Aegean. In addition, Tito and other Balkan Communists, most notably Georgi Dimitrov of Bulgaria, set about actively implementing their ideal of Balkan confederation. A first step was to federalize Yugoslavia itself. A new constitution, closely modelled on that of the U.S.S.R., was accordingly promulgated in January 1946; it established six federal republics (Serbia, Slovenia, Croatia, Montenegro, Macedonia, Bosnia) and several autonomous regions. King Peter lost his throne, and Communist Party control came fully into the open.

A second step was to bring a reliable Communist regime to power in Albania. The Yugoslavs sent troops and technical advisers to help Albanian revolutionaries seize firm control (January 1946). Soon the entire country began to behave much like another constitutive republic of Tito's emerging Balkan superstate.

The next item on the Communists' agenda was never realized: the creation of a united Macedonia that would combine the portions of that land belonging to Greece, Bulgaria, and Yugoslavia into a single whole. Bulgaria did in fact briefly cede Pirin Province to the new Macedonia, but the Greeks refused to cooperate. Accordingly, Tito sent Greek veterans of the wartime guerrilla force (who had retreated into Yugoslavia at the end of the war) back to Greece, where they formed the core around which fresh bands of guerrillas quickly formed in 1946 and 1947.

The Greek government's efforts to repress this renewal of guerrilla activity were ineffective; British resources were too straitened at home to permit fresh involvement in Greece. Hence, for a few months—until the United States committed itself fully to stopping the Communist advance—Tito's revolutionary policy seemed on the verge of paying off.

Such heady prospects encouraged the Yugoslavs to be aggressive along their frontier with Italy, demanding further territory to unite all Slovenes in the new Slovene republic. They also entered into negotiations with the Bulgarians (and perhaps also with Romanian Communists) for merging their countries into the proposed Balkan federal state.

Tito's activity antagonized the United States and was a potent factor in persuading the U.S. Congress to support the embattled Greek government in 1947. Tito's effect on Soviet policy remains a matter for speculation; Stalin probably backed the idea of abandoning the popular-front tactic and the placing of out-and-out Communist regimes in power. Soviet diplomatic agents played the key role in driving King Michael from the Romanian throne (December 1947), thus instituting Communist Party dictatorship in that country. Bulgarian Communists needed no outside help to achieve the same result by the end of 1947.

Tito's break with the Soviet Union

Eventually, Tito's efforts to overthrow the royal government in Greece and to press ahead with Balkan federation alienated the Soviets. Perhaps Stalin feared Tito's independence or attributed the United States' involvement in Greece and Turkey to what he saw as Tito's recklessly revolutionary policies.

At any rate, in 1948 the Soviet dictator decided to call Tito to heel. With characteristic guile, Stalin set out to overthrow Tito by stirring up an intrigue within the ranks of the Yugoslav Communist Party. It did not work; Tito's prestige inside his own country was too great for an outsider—even Stalin—to succeed in unseating him.

When the quarrel between the Soviet Union and Tito came out into the open (June 1948), the entire strategic situation in the Balkans altered abruptly. Albanian Communists, warmly backed by the Soviet Union, broke away from Tito and unceremoniously evicted all the Yugoslav experts and advisers who had until then been running the country. Bulgaria and Romania disclaimed all sympathy for Tito and hurried to participate in Stalin's economic blockade and propaganda war against the stubborn Yugoslavs (all the more energetically because of their previous associations with the new heretic).

In Greece, the Tito–Stalin split meant, first of all, the cessation of Yugoslav aid to the Greek guerrillas. This crippled the guerrilla cause. Then, in an effort to get the Macedonians to imitate the Albanians and secede from Tito's dominion, the Cominform (Communist Information Bureau, established in 1947) announced its program of a united Macedonia. Radio broadcasts failed to stir the Yugoslav Macedonians to action; but the news did create consternation in the ranks of the Greek guerrillas, who were unwilling to fight for a cause that, it now appeared, would lead, if successful, to the surrender of Greek territory to a Slav people. Greek Communist morale therefore collapsed, so that Greek government troops—equipped, advised, and assisted by a large American military mission—found it easy to win a decisive victory in the summer of 1949.

Changes caused by the war. By August 1949, therefore, active military operations in the Balkans ceased; nearly a decade of war thus came to a conclusion. By that date Communist Party dictatorships were firmly established in all the Balkan countries except Greece and Turkey.

Yet, in spite of this fact, the changes World War II brought to the Balkans were distinctly less drastic than those that came during the 20th century's earlier decade of Balkan fighting, 1912–23. Boundaries shifted only slightly after 1945; and war or postwar population movements wiped out or greatly reduced the numbers of some national minorities—Germans and Jews in particular. The effect was to confirm and enhance the sorting out of Balkan populations into territorially defined national states, according to the patterns of 1918–19. From a political and social point of view the one-party regimes of the northern Balkans, set up by Communists, proved a little more ruthless and persistent in pursuit of the same goals that interwar Balkan governments had pursued: economic and political mobilization of the peasant mass—by police hectoring and controlled elections if need be—to hasten the development of industries and cities.

Confirmation of national states

All in all, the major crisis of transition from a traditional peasant and premodern style of life apparently took place

in the Balkans before and after World War I, whereas after 1949 somewhat more stable patterns of modernization and mobilization established themselves in Greece as well as in Communist lands. The waning force of revolutionary movements of every kind, a marked feature of the post-World War II Balkan scene, is an index of this basic transformation.

1950s and after. Though Balkan politics after 1949 were less tumultuous and also less bloody than was the case earlier, confusion and upheavals were not lacking. Among the Communist states, fluctuating relations with the Soviet Union defined major shifts of government policies.

Political changes

From 1948 to 1953 all of Stalin's satellites in eastern Europe purged real or imagined "Titoists"—*i.e.,* Communist leaders suspected of putting national interests ahead of subservience to the Soviet Union. The countries formerly closest to Tito were, not surprisingly, the most energetic in carrying out such purges.

Albania broke away from Yugoslavia and became for a while the Soviet Union's most enthusiastic satellite. The Bulgarian government staged a show trial against Titoists and used the occasion to implicate personnel of the United States embassy, with the result that official U.S.–Bulgarian relations were broken off in 1950, not to be resumed until 1966. Yet, in spite of a trade blockade and various kinds of subversive activity aimed against the Yugoslav regime, Tito's power remained unshaken. By cautiously accepting proffered American aid, the Yugoslavs managed to survive even Stalin's wrath.

After Stalin's death in 1953, the Soviet government tried to mend its fences with Tito. As a result, the Yugoslav government was able to balance itself between the Soviet Union and the United States—playing one off against the other and even getting economic and military aid from both great powers at once. The advantages of such an independent policy were obvious to other Balkan Communist states. But not until after 1961, when a quarrel between Chinese and Soviet Communists came into the open, did first the Albanians and then the Romanians venture to defy the Soviet Union.

Albanian and Romanian policies

Albania's policy was governed mainly by fear of a lasting Yugoslav–Soviet rapprochement; when that seemed likely in 1961, the Albanians threw out their Soviet advisers, as they had earlier ejected Yugoslavs from similar roles, and allowed the distant Chinese to become their new patrons. The Chinese sent substantial aid to Albania in the ensuing years, but after Mao Tse-tung's death in 1976, the Albanians quarrelled with Mao's successors. In 1978 the Chinese accordingly cut off all aid, leaving Albania without a foreign protector for the first time since 1912.

A far more serious break in the Communist ranks occurred in 1964, when Romania declined to accept the role assigned to it by the Soviet Union in the Comecon (Council for Mutual Economic Assistance) plan for economic development of eastern Europe. Instead of concentrating on agriculture for export, the Romanian government wished to continue to emphasize industry, even if this meant duplicating Czech or East German factories. Romanian national feeling, always strongly anti-Soviet, surged to the surface in support of the government's stand. In the following 15 years, until Polish trade unionists began to challenge Communist practices, Romania remained the Soviet Union's most vocal eastern European critic and gadfly. In late 1979, however, President Nicolae Ceaușescu found it necessary to import Soviet, in lieu of Iranian, oil. It was thought that this new link might diminish friction between the two countries, or at least muffle its public expression.

Post-war policy in Greece

In Greece, U.S. policy played a dominating role after 1947. Until 1956 U.S. funds continued to provide the Greek government with substantial aid for economic rehabilitation; the United States thus was able to control a number of important aspects of government policy.

After 1956, aid tapered off, and U.S. diplomats deliberately tried to pull out of Greek politics. Such aloofness was all the more attractive to the United States because Greece seemed to have attained a relatively stable parliamentary regime under Marshal Alexandros Papagos—hero of the Albanian war of 1940 and of the guerrilla war of 1947–49—and, after his death (1955), Konstantinos Karamanlis, who survived three elections to remain prime minister for an unprecedentedly long period (1955–63).

Yet the fact that Greece had become a member of the North Atlantic Treaty Organization (NATO) in 1952 meant that U.S. influence upon the Greek armed forces remained strong even after other forms of aid had stopped. And, because the political attitudes of the army mattered in Greek politics, U.S. efforts to leave the Greek politicians alone were never very successful. Thus, in April 1967, when a clique of army officers seized power by coup d'état, U.S. agents were generally suspected of being responsible for what was probably planned in secret by a narrow and purely Greek circle. The policy of the new Greek government lent some colour to the charges, however, because the officers who emerged as rulers of the country combined an enthusiastic anti-Communism with an earnest courtship of private foreign (principally U.S.) investment, which they needed to balance their international accounts.

Military government in Greece

The authoritarian military dictatorship, headed by Col. Georgios Papadopoulos, lasted until 1974, when intrigues aimed at bringing Cyprus into union with Greece miscarried and the military rulers of the country were discredited. Karamanlis was recalled from his self-imposed exile in Paris and organized new elections, thus restoring the legal forms of parliamentary democracy. In a national referendum in December 1974 the Greeks rejected the monarchy and became a republic. Relations with Turkey, which had nearly come to war over Cyprus, were not easily healed; and indignation at the failure of NATO commanders to support the Greek cause against Turkey led Karamanlis to cancel most of the agreements that had bound the Greek armed forces to NATO. Subsequently, long drawn-out negotiations restored some links with NATO, but the Greek government retained fuller control over NATO and U.S. bases on Greek soil than before. Efforts to normalize relations with Turkey met with more limited success. Far more important was the fact that on January 1, 1981, Greece became a member of the European Economic Community (EEC). Important changes in the Greek economy were likely to flow from this move, which also symbolized a psychological and cultural commitment on the part of the Greeks to the Western style of life.

Establishment of the Greek republic

Economic changes

The political upheavals and often noisy public debate that characterized Greece stood in sharp contrast to the strict controls on public discussion that Communist regimes enforced in other Balkan countries. This difference, however, should not disguise some important resemblances in the pattern of economic development pursued by all Balkan governments in the post-World War II era. Everywhere officials preferred industrial to agricultural investment and subjected most economic activities to elaborate, often cumbersome, bureaucratic control. Everywhere, too, cities grew rapidly, offering scope for peasant sons and daughters to pursue new careers more attractive than those their parents had known. This permitted a general relaxation of political and economic dissatisfactions, despite the numerous unsolved problems that persisted within all the Balkan nations.

The only important difference in economic policies was that Greece continued to import private foreign capital and linked internal prices to world markets, whereas Communist countries maintained a command price system at home and regarded all private investment as detestable capitalist exploitation. When importing foreign capital, the Communist countries were willing only to borrow from other governments—a policy that seemed unlikely to make borrowers any less dependent on lenders.

Tangible increases of industrial output occurred in every Balkan state. This did not mean, however, that problems of distribution and assortment of products to suit the consumers had been solved. Quite to the contrary, in the Communist lands shoddy goods and insufficient supplies of some commodities were still the rule; and many of the new factories, built as a result of political decisions, were distressingly inefficient when it came to costs. In Greece, unsolved problems were primarily those of income distribution among the different social classes, although inefficient and high-cost factories that sheltered behind tariff and quota protection were not absent.

Decentralization in Yugoslavia

Recognition of the difficulty of adjusting a command economy to consumer needs led the Yugoslavs to experiment with freer market prices on the one hand and with worker–management partnership in factory administration on the other. A new constitution, effective in 1963, gave enhanced power in economic matters to the federal republics in the hope that this, too, would bring planning and management closer to the people. Yugoslavia met some success in this effort at decentralization and bureaucratic simplification. But divisive tendencies among the various nationalities of the state were perhaps reinforced by allowing greater popular participation in management decisions. Nevertheless, on June 30, 1971, the federal government instituted amendments that further enhanced the powers of the republics and municipalities, granting the right, for example, to initiate investment projects. The federal government reserved for itself sole power in the areas of defense, foreign policy, and general economic policies. A new constitution promulgated in 1974 went even further toward institutionalizing "workers' " management, but frictions among the separate nationalities of Yugoslavia were not completely damped down by the policy of decentralization; and Marshal Tito's death in May 1980 brought the regime a new test of its stability. Tito was succeeded by a collective presidency representing each of the six republics and two autonomous provinces into which Yugoslavia was juridically divided. Internal diversity was thus proclaimed symbolically, but a far more centralized Communist party structure continued to counterbalance fissiparous tendencies.

In the 1970s, all of the Balkan countries faced new difficulties in economic management. Sharp increases in the international price of oil on the one hand and rising expectations at home on the other made planned investment in heavy industry difficult to achieve and, in fact, planned expansion was not realized. Deficit accounts in international trade and domestic inflation at rates considerably higher than those experienced by the more highly industrialized nations of Europe registered the gap between current productivity and the demand for goods and services.

Despite these unsolved difficulties and the repressive police regimes that supported the Communist monopoly of political power, Balkan history since 1949 must be considered an overall success, at least when compared to the earlier decades of the 20th century. Peace prevailed as seldom before, coups d'etat were far fewer, and urbanization increased by leaps and bounds. Most significant of all, age-old routines of peasant life altered profoundly. Family patterns changed so that lower birth rates prevailed in every country except Albania. This reduced population pressure and made rising standards of living easier to attain. Even in poor villages, new, powerful farm machinery lightened the labour of cultivation and increased production. The Balkan peasantries also accepted new ideas about the world and its possibilities, largely through daily exposure to radio and television broadcasts.

The Balkan nations, in short, struggled to transform themselves into provincial variants of the world-girdling Western style of civilization. Their success provoked new dissatisfaction to be sure, but nothing to compare with the fierceness of older revolutionary aspirations that had kept the Balkans in turmoil from 1850 to 1950. (For additional information on contemporary affairs in the Balkans, see ALBANIA; GREECE; ROMANIA; BULGARIA; and YUGOSLAVIA.)

BIBLIOGRAPHY

Physical and human geography. The physical geography of the Balkans is summarized in the AUSTRIAN EAST AND SOUTHEAST EUROPE INSTITUTE'S *Atlas of the Danubian Countries*, issued in fascicles (1971–). Long-term relations between the landscape and its human occupants are examined in FRANCIS W. CARTER (ed.), *An Historical Geography of the Balkans* (1977). The economic history of the region is provided by JOHN R. LAMPE and MARVIN R. JACKSON, *Balkan Economic History, 1550–1950: From Imperial Borderlands to Developing Nations* (1982); NICHOLAS V. GIANARIS, *The Economies of the Balkan Countries: Albania, Bulgaria, Greece, Romania, Turkey, and Yugoslavia* (1982). Detailed studies of the region prior to World War II include M.I. NEWBIGIN, *Southern Europe*, 3rd ed. (1949); C.S. COON, *The Races of Europe* (1939); M.E. DURHAM, *Some Tribal Origins, Laws and Customs of the Balkans* (1929); M.S. EVANS, *A Short History of Bulgaria* (1960), includes an outline of the early historical and cultural setting for the state; JOSEPH WIESNER, *Die Thraker* (1963), a detailed account of the Thracians to AD 600; MARIJA GIMBUTAS, "The Neolithic Cultures of the Balkan Peninsula," in *Aspects of the Balkans* (1972), a concise account of the Neolithic and Chalcolithic civilizations, 6500–3500 BC; *The Bronze Age Cultures in Central and Eastern Europe* (1965), a monograph that includes the Danubian region and Urnfield migrations; *The Slavs* (1971), an account of the early history of the Slavic peoples and their migrations to the Balkan peninsula; and the *Symposium* of the Centre d'Études Balkaniques, Sarajevo (1964), a collective work dedicated to the distribution and chronology of the prehistoric Illyrians. (*The Balkans in the Middle Ages*): Two books are quite reliable and up to date: GEORG STADTMULLER, *Geschichte Südosteuropas* (1950); and DIMITRY OBOLENSKY, *The Byzantine Commonwealth: Eastern Europe, 500–1453* (1971). The Byzantine context of the Balkan peninsula in the medieval period is well treated in the relevant chapters of *The Cambridge Medieval History*, 2nd ed., vol. 4 (1966); and on a more modest scale in GEORGE OSTROGORSKY, *Geschichte des byzantinischen Staates* (1965; Eng. trans., *History of the Byzantine State*, 2nd ed., 1968). On the Slavic states in the Balkans, see the two studies of FRANCIS DVORNIK, *The Slavs: Their Early History and Civilization* (1956) and *The Slavs in European History and Civilization* (1962). All these books have substantial bibliographies. (*The Ottoman era*): The best general discussion is to be found in L.S. STAVRIANOS, *The Balkans Since 1453*, ch. 3–12 (1958). The Ottoman conquest of the Balkans and its effects are ably described in PAUL COLES, *The Ottoman Impact on Europe* (1968); STEVEN RUNCIMAN, *The Fall of Constantinople, 1453* (1965); and THOMAS M. BARKER, *Double Eagle and Crescent: Vienna's Second Turkish Siege and Its Historical Setting* (1967). STEVEN RUNCIMAN, *The Great Church in Captivity* (1968), covers the patriarchate in Constantinople from the Turkish conquest until the 1820s. DIMITRIJE DJORDJEVIC and STEPHEN FISCHER-GALATI, *The Balkan Revolutionary Tradition* (1981), examines the nationalist revolutions in several Balkan states from the 16th to the 20th century.

The Balkans from 1815 to 1914: The period from the early 19th century until the 1950s is treated in RENE RISTELHUEBER, *Histoire des peuples balkaniques* (1950; Eng. trans., *A History of the Balkan Peoples*, 1971). A short review of the Balkans in the 19th century may be found in L.S. STAVRIANOS, *The Balkans, 1815–1914* (1963); and in CHARLES and BARBARA JELAVICH, *The Balkans* (1965). See also the relevant sections in Stavrianos' excellent general history, *The Balkans Since 1453*. The comparative method is applied in L.S. STAVRIANOS, *Balkan Federation* (1944); TRAIAN STOIANOVICH, *A Study in Balkan Civilization* (1967); CHARLES and BARBARA JELAVICH (eds.), *The Balkans in Transition* (1963), *The Establishment of the Balkan National States, 1804–1920* (1977); DIMITRIJE DJORDJEVIC, *Révolutions nationales des peuples balkaniques, 1804–1914* (French trans. 1965); DOREEN WARRINER (ed.), *Contrasts in Emerging Societies: Readings in the Social and Economic History of Southeastern Europe in the Nineteenth Century* (1965).

The Balkans after 1914: (*General works*): HUGH SETON-WATSON, *Eastern Europe Between the Wars, 1918–1941*, 3rd rev. ed. (1967); and *The East European Revolution*, 3rd ed. (1956); ROBERT L. WOLFF, *The Balkans in Our Time* (1956); R.V. BURKS, *The Dynamics of Communism in Eastern Europe* (1961); GHITA IONESCU, *The Politics of the European Communist States* (1967); YORICK BLUMENFELD, *Seesaw: Cultural Life in Eastern Europe* (1968); C.A. MACARTNEY and A.W. PALMER, *Independent Eastern Europe* (1962); A.W. PALMER, *The Lands Between: A History of East-Central Europe Since the Congress of Vienna* (1970); CHARLES JELAVICH (ed.), *The Balkans in Transition* (1963); STEPHEN A. FISCHER-GALATI (ed.), *Eastern Europe in the Sixties* (1963); NORMAN J.G. POUNDS, *Eastern Europe* (1969); J.F. BROWN, *The New Eastern Europe: The Khrushchev Era and After* (1966). (*On more specialized pan-Balkan topics*): W.E. MOORE, *Economic Demography of Eastern and Southern Europe* (1945); IRWIN T. SANDERS (ed.), *Collectivization of Agriculture in Eastern Europe* (1958); ALFRED BOHMANN, *Menschen und Grenzen*, vol. 2, *Bevölkerung und Nationalitäten in Südosteuropa* (1969).

Bangkok

Bangkok is the capital and chief port of Thailand. It is the only cosmopolitan city in a country of small towns and villages and is Thailand's cultural and commercial centre.

Bangkok is located on the delta of the Chao Phraya River, about 25 miles (40 kilometres) from the Gulf of Thailand. It was formerly divided into two municipalities—Krung Thep on the east bank and Thon Buri on the west—connected by several bridges. In 1971 the two were united as a city-province with a single municipal government. In 1972 the city and the two surrounding provinces were merged into one province, called Krung Thep Maha Nakhon (Bangkok Metropolis). Bangkok Metropolis has a total area of 604 square miles (1,565 square kilometres). It is a bustling, crowded city, with temples, factories, shops, and homes juxtaposed along its roads and canals.

The name Bangkok, used commonly by foreigners, is, according to one interpretation, derived from a name that dates to the time before the city was built—the village or district (*bang*) of wild plums (*makok*). The Thai call their capital Krung Thep, which is the first part of its mellifluous and lengthy official name meaning "the City of Gods, the Great City, the Residence of the Emerald Buddha, the Impregnable City (of Ayutthaya) of God Indra, the Grand Capital of the World Endowed with Nine Precious Gems, the Happy City Abounding in Enormous Royal Palaces Which Resemble the Heavenly Abode Wherein Dwell the Reincarnated Gods, a City Given by Indra and Built by Vishnukarm." The abbreviated name Krung Thep is often translated "City of Angels."

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

Climate. The climate of Bangkok is hot throughout the year, ranging from 77° F (25° C) in the "cold" season in December to 86° F (30° C) at the height of the hot season in April. The mean annual rainfall totals 60 inches (1,500 millimetres), four-fifths of which falls in brief torrential downpours during the late afternoons of the rainy season, which lasts from mid-May through September; the dry season lasts from December to February. Mean monthly relative humidity varies from a low of 60 percent in the cold season to more than 80 percent during the rainy season.

The city layout. Modern Bangkok has undergone explosive growth, which the authorities have only recently attempted to direct by means of a series of master plans. The city centre, formerly enclosed by a wall, has long been densely developed, while later expansion has sprawled outward well beyond the administrative boundaries into the surrounding agricultural areas. Some districts have evolved into functional units as the inner city has become more institutional and commercial and the outer city more residential and industrial. Throughout the city, walled Buddhist temples and monasteries called wats, often sumptuously ornamented, serve as focal points for religious, cultural, and even commercial life.

Traditional areas. The governmental and commercial districts of the city occupy traditional sites. Government offices were originally housed in the walled compound of the 18th-century Grand Palace, but by the late 19th century they occupied surrounding palaces and mansions. The bureaucracy then spread outward into nearby colonial-style or Thai-style office buildings and homes along Ratchadamnoen Road. Multistoried buildings have been erected to meet the ever-increasing demand for space, and the traditional government compounds have become overbuilt. A number of large camps around and north of the National Assembly Hall constitute the military area.

Principal districts of the city

When Bangkok became the national capital in the 18th century and its citadel was moved to the east bank of the Chao Phraya River, Chinese merchants and tradesmen occupying the site moved a short distance southward to the area now known as Sam Peng. Business was at first carried on in one-story wood and thatch houses. By the early 1900s a number of streets had been lined with two-story masonry shop-houses. This ever-expanding district now contains rows of shop-houses that are sometimes five or more stories high. Warehouses line both banks of the river just south of Sam Peng, while industry is concentrated at Sam Rong, south of the port. Nightlife flourishes on Pat Pong Road. The financial district straddles Silom Road.

In the Floating Market a variety of foods and merchandise are sold daily from boats on the canals near Wat Sai. Formerly several such markets and innumerable door-to-door floating vendors served the daily needs of the city's residents.

Housing. Homes generally consist of small, detached one- or two-story wooden houses or row houses. Most of these are overcrowded because there are far too few of them to house the expanding population. Government programs alone are insufficient to meet the housing shortage, and funds from the World Bank have been used to build low-income housing, such as the Din Daeng and Hua Mak developments.

Housing shortage

The government allows squatters to occupy unused public land. The number of squatters is small, and most of them are concentrated in the Khlong Toei area near the port. Private real-estate developers provide homes for middle-income groups, and many government agencies provide homes for their employees. Homes may be crowded onto small lots with rudimentary sanitation facilities. These developments have spread out haphazardly on the periphery of the city.

Luxury housing, mostly for the wealthy foreign community, usually takes the form of large, modern, two-story masonry structures set in private compounds and equipped with separate servants' quarters and kitchens. Bang Kapi is perhaps the most affluent neighbourhood. High-rise offices, hotels, and condominiums are increasingly common.

THE PEOPLE

The population's outstanding demographic characteristics—its youth and the low proportion of non-Thais—are explained by the high rate of natural increase and by the restrictive foreign immigration quotas adopted after World War II. Two-fifths of the residents are under 20 years of age; another one-fifth is under 30. The birth rate has declined since the introduction of a birth-control program. At the same time, the net in-migration of young

adults, particularly females, has increased greatly, so that more than a quarter of the resident population of the city is made up of migrant Thais from all parts of the country.

Less than 3 percent of the population is non-Thai. The Chinese are by far the largest minority, but there are sizable communities of other Asians, North Americans, and Europeans. Despite their small size, the foreign communities tend to live in certain areas. The Chinese concentrate in the commercial area of Sam Peng, Indians gather around mosques in the Wang Burapha section, and the Western and Japanese communities reside in the affluent, modern eastern section of the city.

Of the foreign groups, the Chinese enter the most intimately into city life. They appear to assimilate readily, and intermarriage is frequent. Their offspring are Thai citizens, and many Chinese families take Thai surnames and are naturalized.

Population density is highest in the Chinese district of Sam Peng, where it reaches about 390,000 persons per square mile (150,000 per square kilometre).

THE ECONOMY

Industry. There are many factories in the metropolitan area, but most operate on a small scale. Larger plants are located in the vicinity of the port, near the warehouses that store imported materials. Manufacturing is chiefly confined to food processing, textiles, the assembly of electronic equipment, and the production of building materials. After 1976, however, no new factories were permitted to be built in Bangkok, and the government has given high priority to locating industry in industrial parks on the outer fringes of Bangkok. Tourism has increased greatly and is now a major source of revenue in Bangkok.

Finance. Bangkok houses about one-third of the country's banking units, holding three-fourths of all deposits. The Industrial Finance Corporation of Thailand, the Board of Investment, and the Securities Exchange of Thailand are also located in the city.

Transportation. Bangkok's transportation system was originally based on water travel. The city's maze of canals connected with the river earned it the name Venice of the East. The advent of the automobile, however, brought drastic changes. The number of vehicles in the city (including three-wheeled taxis, private cars, and buses—colour coded according to the region of service) has increased, and a shortage of road space has developed. The problem was met first by filling in most of the smaller and a number of the larger canals. This proved to be more than an aesthetic loss, however, because the waterway system had served to drain the waterlogged delta; flooding of the lower-lying parts of the city thus became increasingly frequent. Furthermore, the measure did not solve the problem of lack of space; traffic became so congested that movement was increasingly difficult. To help ameliorate these problems, an authority was established in the 1970s to oversee bus transportation in the city.

Lines of communication radiate outward from the city. Roads run north to Laos and Chiengmai, east to Kampuchea, and south to Malaysia; railways run to the borders of Laos and Malaysia, to Chiengmai in the north, and to Ubon Ratchathani and the Kampuchean border in the east. Don Muang airport, one of the busiest in Southeast Asia, is served by international airlines.

The port of Bangkok, located on the Chao Phraya, at Khlong Toei, is connected to the sea by a channel dug through the sandbar at the river mouth some 17 twisting miles downstream. The port handles nearly all of the nation's imports and exports.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The government of Bangkok Metropolis is administered by a governor and deputies. Developmental responsibilities rest with a large number of governmental agencies. Bangkok houses the headquarters of the United Nations Economic and Social Commission for Asia and the Pacific (ESCAP). In addition, the city houses various other UN agencies, including branch offices of the World Health Organization (WHO), the International Labour Organisation (ILO), the United Nations Children's Fund (UNICEF), and the International Bank for Reconstruction and Development (World Bank).

Public utilities. Most of the city's water supply comes from purification plants; it is drawn from the Chao Phraya and from deep wells. The pumping of water from wells has caused subsidence in parts of the city, which has increased flooding.

Sanitation facilities consist partly of sewage storm drains and the canals; large buildings are often equipped with septic tanks. Bangkok consumes more than half of the country's electric power.

Health. Bangkok has most of the country's hospitals and clinics. Special services are offered for patients with tuberculosis and venereal disease, and there are government homes for the indigent, handicapped, and aged. The Pasteur Institute and WHO supply vaccines. Family-planning clinics have proliferated in recent years.

Education. Because of its high proportion of school-age citizens, Bangkok's educational facilities are overburdened. There are too few schools, and the standard of instruction varies. Literacy is extremely high, however.

Many of the government-built preprimary and primary schools are located on monastery grounds. Private primary and secondary schools run by foreign religious missions train the children of the elite. There are many private Chinese primary schools and night schools. The city has several universities.

CULTURAL LIFE

The most important cultural feature of Bangkok is the wat. There are more than 300 such temples, representing classic examples of Thai architecture. Most are enclosed

Buddhist monk at the Wat Arun in Bangkok.

by walls. Many wats have leased a portion of their grounds for residential or commercial use.

The National Museum houses prehistoric and Bronze Age art relics, as well as royal objects dating to the 6th century AD. The city also houses the National Library and the Thai National Documentation Department. Jim Thompson's Thai House, named for a U.S. entrepreneur and devotee of Thai culture, is composed of several traditional Thai mansions; it contains the country's largest collection of 17th-century Thai religious paintings. There are also collections of Dvaravati and Khmer sculpture, in addition to examples of Thai and Chinese pottery and porcelain.

All of the country's daily newspapers and most of its weeklies and monthlies are published in Bangkok. Newspapers are printed in Thai, English, and Chinese.

Radio and television are controlled by government agencies and by the military. Most of the nation's radio stations and all of its television stations are located in or near Bangkok. Most programs are in Thai, but some special programs are in English and Chinese.

Motion pictures are extremely popular. There is a thriving Thai cinema industry, but films are also imported. Fairs, festivals, and "kite-fighting" contests are held in the parks; the Ratchadamnoen and Lumphini stadiums present exhibitions of Thai boxing. Silapakorn National Theatre presents dancing, drama, and music.

History

Bangkok became the capital of Siam (as Thailand was previously known) in 1782, when General Chao Phraya Chakkri, the founder of the ruling Chakkri dynasty, assumed the throne as Rama I and moved the court from the west to the east bank of the Chao Phraya River. The move appears to have been dictated by strategic considerations: the wide westward bend in the river constituted a wide moat guarding the northern, western, and southern perimeters of the new site. To the east stretched a vast, swampy delta called the Sea of Mud, which could be traversed only with extreme difficulty. Rama I modeled the new city on the former capital, Ayutthaya, 40 miles to the north. By the end of his reign the city was established. The walled Grand Palace complex and Bangkok's oldest temple, Wat Po, were completed. A new city wall, perhaps the most imposing structure, skirted the river and Khlong Ong Ang to the east; it was four and a half miles long, 10 feet thick, and 13 feet high, and it had 63 gates and 15 forts. The area enclosed amounted to one and a half square miles.

Strategic location of the city

More wats were built during the reigns of Rama II (1809–24) and Rama III (1824–51). They served as schools, libraries, hospitals, and recreation areas, as well as religious centres. During these years Wat Arun, noted for its tall spire, Wat Yan Nawa, and Wat Bowon Niwet were completed, Wat Po was further enlarged, and Wat Sutat was begun. There were, however, few other substantial buildings and fewer paved streets; the river and the network of interconnected canals served as roadways.

Rama IV (1851–68) developed the city while continuing, at a reduced rate, the traditional building of wats. The Grand Palace was improved, a number of substantial dwellings were constructed for members of the royal family, several new streets were laid down, and a reduction was made in the large number of floating houses anchored along the river front. A new route, Charoen Krung (New Road), leading southward was constructed, and a new city moat, Khlong Phadung Krung Kasem, parallel to the city's first canal, was dug and fortified; a long canal led from it to the present port area (Khlong Toei), thus allowing small boats to bypass the large bend in the river immediately south of the city. A pony path, now Phra Ram Thi 4 Road, was laid atop the mud heaped up beside this waterway.

The transformation of the city under Rama V

During the long reign of Rama V, King Chulalongkorn (1868–1910), the city was transformed through a program of public works. The great triple-spired Chakkri Building in the Grand Palace was completed by 1880; the Dusit Palace and an ancillary garden city were later built beyond the wall, being connected to the Grand Palace by the European-inspired Ratchadamnoen Nok Road. A road- and bridge-building program was embarked on in earnest, because King Chulalongkorn, an early automobile enthusiast, foresaw the effect that the motor vehicle would have on city development. Most of the now obsolete city wall was pulled down to build the roads, but two forts, a large gate, and a section of the wall were preserved. The centenary of the city, in 1882, was marked by the inauguration of many social reforms, manifested in the public buildings used for their administration, as well as by the completion of the great royal temple, Wat Phra Kaeo, which housed the Emerald Buddha. A post and telegraph service was organized in the 1880s, an electric tram service was instituted on Charoen Krung in 1892, and the first line of the State Railway, running from Bangkok to Phra Nakhon Si Ayutthaya, opened in 1900. Nor were aesthetic considerations forgotten, for other new buildings included the marble temple of Wat Benchamabopit (1900), elegant bridges in the French style, and the Italian-inspired National Assembly Hall (Throne Hall).

Rama VI (1910–25) continued the program of public works. He established Chulalongkorn University in 1916, built a system of locks to control the level of waterways throughout the city, and gave the public its first and largest recreational area—Lumphini Park. During Rama VII's reign (1925–35) municipal areas were delimited as part of a general administrative reorganization aimed at decentralization. In 1937 Bangkok was formally divided into the municipalities of Krung Thep and Thon Buri. At the time of their establishment, the two municipalities, approximately equal in area, together covered about 37 square miles; about four-fifths of the city's population lived in Krung Thep.

Since World War II Bangkok has grown with unprecedented rapidity. As a result of this growth, problems with transportation, communication, housing, water supply, drainage, and pollution have become acute. That those responsible for modernizing the metropolis are coping with these problems suggests the appropriateness of its official emblem: the God Indra seated atop a sacred white elephant, the four tusks of which denote its celestial status and its ability to accomplish the impossible. The city's uniquely Thai character, while perhaps diminishing, provides a vibrant backdrop for Bangkok's increasingly cosmopolitan image.

BIBLIOGRAPHY. WILLIAM WARREN and MARC RIBOUD, *Bangkok* (1972), gives a panorama of life in the city through imaginative text and evocative photographs. ERIK SEIDENFADEN, *Guide to Bangkok, with Notes on Siam,* 2nd ed. (1928, reprinted 1985), is a beautifully illustrated guide with a wealth of historical data. Three useful works are LARRY STERNSTEIN, *Planning the Developing Primate City: Bangkok 2000* (1971), a translation and critique of three Thai plans, *Thailand: The Environment of Modernisation* (1976), a profusely illustrated study that includes a long section on Bangkok, and *Portrait of Bangkok* (1982), a series of 11 essays, with rare pictures and maps, on historical and contemporary affairs, published on the occasion of the bicentenary of the city.

(La.S.)

Bangladesh

Bangladesh (in full People's Republic of Bangladesh; Bengali: Gana Prajātantrī Bangladesh) is an independent Asian state located in the delta of the Ganges and Brahmaputra rivers in the northeastern part of the Indian subcontinent. As the eastern portion of the historic region of Bengal, it formed, with the Indian state of West Bengal, the province of Bengal in British India. From the partition of 1947 until 1971 it was, as East Pakistan, one of five provinces of Pakistan, separated from the other four by 1,100 miles (1,800 kilometres) of Indian territory.

Bangladesh has an area of 55,598 square miles (143,998 square kilometres) and is one of the most densely populated areas in the world. It is bounded by the Indian states of West Bengal to the west and north, Assam to the north, Meghālaya to the north and northeast, and Tripura and Mizorām to the east, by Burma to the southeast, and by the Bay of Bengal to the south. The capital is Dhākā (formerly spelled Dacca).

This article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Bangladesh constitutes the eastern two-thirds of the Ganges-Brahmaputra deltaic plain, which stretches northward from the Bay of Bengal. Except for small higher areas of jungle-covered old alluvium (rising to about 100 feet [30 metres]) in the northwest and north-centre—called, respectively, the Bārind and Madhupur tracts—the plain is a flat surface of recent alluvium, having a gentle slope and generally with an elevation of less than 30 feet above sea level. In the northeast and southeast the alluvial plains—called, respectively, the Sylhet and Chittagong hills—give place to ridges running mainly north–south, which form part of the mountain divide with Burma and India. Bangladesh is fringed on the south by the Sundarbans, a huge expanse of marshy deltaic forest.

In northwestern Bangladesh the Bārind Tract comprises a triangular wedge of land between the floodplains of the Ganges and Brahmaputra rivers. The soil of this region is hard, reddish clay, and the region is comparatively elevated. A depression called the Bhar Basin extends southeast of the Bārind Tract for about 100 miles between the floodplains of the Ganges and Brahmaputra rivers to their confluence. This area is inundated during the summer monsoon season. The drainage of the western part of the basin is centred in the vast marshy area called the Chalan wetlands, also known as Chalan Lake. The floodplains of the Brahmaputra (Jamuna), which lie north of the Bhar Basin and east of the Bārind Tract, stretch from the border with India (Assam) in the north to the confluence of the Ganges and Brahmaputra in the south. The Brahmaputra frequently overflows its banks in devastating floods. South of the Bhar Basin is the floodplain of the Ganges.

In north-central Bangladesh, east of the Brahmaputra floodplains, is the Madhupur Tract. It consists of an elevated plateau, with hillocks varying in height from 30 to 60 feet, and cultivated valleys. The Madhupur Tract contains *sal* trees, whose hardwood is comparable in value and utility to teak. East of the Madhupur Tract, in northeastern Bangladesh, is a region called the Northeastern Lowland. It encompasses the southern and southwestern parts of the Sylhet area (including the valley plain of the Surma River) and the northern part of the Mymensingh area and has a large number of lakes. The Sylhet Hills in the far northeast of the region consist of a number of hillocks and hills ranging from 100 feet to more than 1,100 feet in height.

In east-central Bangladesh the Brahmaputra River in its old course built up the Meghna Flood Basin, which includes the low and fertile Meghna-Lakhya Doāb (the land area between those rivers). This area is enriched by the Titās distributary, as well as the land areas formed and changed by the deposition of silt and sand in the riverbeds of the Meghna River, especially between Bhairab Bazar and Daudkandi. Dhākā is located in this region.

In southern Bangladesh the Central Delta Basins include the extensive lakes in the central part of the Bengal Delta, to the south of the Ganges (Padma). The basin's total area is about 1,200 square miles. The belt of land in southwestern Bangladesh bordering the Bay of Bengal constitutes the Immature Delta. The belt—a lowland of some 3,000 square miles—contains, in addition to the vast mangrove forest known as the Sundarbans, the reclaimed and cultivated lands to the north of it. The area nearest the Bay of Bengal is crisscrossed by a network of streams that flow around roughly oblong islands. The Active Delta, located north of the Central Delta Basins and east of the Immature Delta, includes the Dhaleswari-Padma Doāb and the estuarine islands of varying sizes that are found from the Pusur River in the southwest to the island of Sandwīp near Chittagong in the southeast.

Lying to the south of the Feni River in southeastern Bangladesh, the Chittagong region has many hills, hillocks, valleys, and forests and is quite different in aspect from other parts of the country. The coastal plain is partly sandy and partly composed of saline clay; it extends southward from the Feni River to the town of Cox's Bāzār and varies in width from one to 10 miles. The region has a number of offshore islands and one coral reef, St. Martin's, off the coast of Burma. The hilly area known as the Chittagong Hill Tracts in the far southeast consists of low hills of soft rocks, mainly clay and shale. The north–south ranges are generally below 2,000 feet in height.

Drainage. The rivers of Bangladesh have molded not only its physiography but also the way of life of the people. They may be divided into five systems—(1) The Ganges, or Padma, as the united streams of the Ganges and Brahmaputra are known, and their deltaic streams; (2) the Meghna and the Surma river system; (3) the Brahmaputra and its adjoining channels; (4) the North Bengal rivers;

and (5) the rivers of the Chittagong Hill Tracts and the adjoining plains.

The Ganges is the pivot of the deltaic river system of Bengal. The river and its tributaries enclose a large area of southwestern Bangladesh. The Ganges Delta itself covers about 20,000 square miles. The Ganges enters Bangladesh from the west and forms, for about 90 miles, the boundary between Bangladesh and West Bengal (India). It flows southeast to join the Brahmaputra and forms numerous distributaries and spill channels. Except at places where it is confined by high banks, the main channel of the river changes its course every two or three years; consequently no description of Bangladesh's topography retains its absolute accuracy for long. The river carries an immense volume of water mixed with silt, which gives it a muddy look. Silt deposits build temporary islands that reduce navigability but are so highly fertile that they have been for decades a source of feuds among peasants.

The Meghna is formed by the union of the Sylhet-Surma and Kusiyāra rivers. These two rivers are branches of the Barāk River, which rises in the Nagar-Manipur watershed in India. The main branch of the Barāk, the Surma, is joined near Azmiriganj in northeastern Bangladesh by the Kālni and farther down by the Kusiyāra branch. The Dhaleswari, a distributary of the Jamuna River, joins the Meghna a few miles above the junction of the Ganges and the Meghna. As it meanders south, the Meghna grows larger after receiving the waters of a number of rivers, including the Buriganga and the Sitallakhya.

The Brahmaputra and its adjoining channels cover a large area from north-central Bangladesh to the Meghna River in the southeast. The Brahmaputra receives waters from a number of rivers, especially on its right bank. The river, with its notoriously shifting channels, not only prevents permanent settlement along its banks but also inhibits communication between the northern area of Bangladesh and the eastern part, where Dhākā is situated.

The Tista is the most important water carrier of northwestern Bangladesh. Rising in the Himalayas near Darjeeling (India), it flows southward. After the floods of 1787, however, the Tista changed its course, moving southeastward to join the Brahmaputra. A number of small and medium-sized rivers in the southwest are silting up, adversely affecting the economic life of that region.

Four main rivers constitute the river system of the Chittagong Hills and the adjoining plains—the Feni, the Karnaphuli, the Sangu, and the Mātāmuhari. Flowing generally west and southwest across the coastal plain, they empty into the Bay of Bengal. Of these rivers the longest is the Karnaphuli. It is dammed at Kaptai, about 30 miles upstream from its mouth near the city of Chittagong.

None of the major rivers of Bangladesh originates within the country's territory. The headwaters of the Surma are in India; the Ganges rises in Nepal and the Brahmaputra in China (Tibet), but they, too, reach Bangladesh across Indian territory. Thus, Bangladesh lacks full control over the flow of any of the streams that irrigate it. The construction of a barrage upstream at Farakka in West Bengal has led to the diversion of a considerable volume of water from the Ganges, and the flow to western Bangladesh is insufficient in the dry season from November to April. The equitable distribution of the river's waters has been since the 1970s a source of friction between India and Bangladesh.

Each year between June and October the rivers overflow their banks, rising most heavily in September or October and receding quickly in November. The inundations are both a blessing and a curse. Without them, the fertile silt deposits would not be replenished. But severe floods regularly damage crops and ruin hamlets and sometimes take a heavy toll on human and animal populations.

Three main types of soils

Soils. There are three main categories of soils: the old alluvial soils, the recent alluvial soils, and the hill soils, which have a base of sandstone and shale. The fertile recent alluvial soils, found mainly in flooded areas, are usually pale brown, sandy, micaceous, and chalky clays and loams. They are deficient in phosphoric acid, nitrogen, and humus but not in potash and lime. The old alluvial soils in the Bārind and Madhupur jungles are dark-brown clays and loams. They are sticky during the rainy season and hard during the dry. The hill soils are permeable and can support dense forest growth.

Climate. Bangladesh has a typical monsoon climate characterized by rain-bearing winds, moderately warm temperatures, and high humidity. In general, maximum temperatures in the summer months, from April to September, range between 91° and 96° F (33° and 36° C). April is the warmest month in most parts. January is the coolest month in the winter season, which lasts from about November to March.

The conditions of lowest atmospheric pressure occur in Bangladesh in June and July, the storm season. Winds are mostly from the north and northeast in winter, blowing at a rate of one to two miles per hour in northern and central areas and two to four miles per hour near the coast. During the period of the northwesters (March to May), wind speeds may rise to 30 or 40 miles per hour.

Rainfall

Bangladesh receives heavy rainfall; except for some parts in the west, it generally exceeds 60 inches (1,500 millimetres) annually. Large areas of the south, southeast, north, and northeast receive from 80 to 100 inches, and the northern and northwestern parts of the Sylhet area receive from 150 to 200 inches. The maximum rainfall occurs during the monsoon period, from June to September or early October.

In the early summer (April and May) and late in the monsoon season (September to November), storms of very high intensity often occur; they may create winds with speeds of more than 100 miles per hour, piling up the waters of the Bay of Bengal to crests as high as 20 feet that crash with tremendous force onto the coastal areas and the offshore islands, inundating them and causing heavy losses of life and property. Since the early 18th century, when records were first kept, more than 1,000,000 people have been killed in such storms, 815,000 of them in three storms occurring in 1737, 1876, and 1970. Another severe storm occurred in May 1985.

Plant and animal life. Bangladesh in general possesses a luxuriant vegetation, with villages appearing to be virtually buried in groves of mango, jackfruit, bamboo, betel nut, coconut, and date palm. About 15 percent of the country's land surface is covered with forests.

Bangladesh has four different areas of vegetation. The eastern zone, consisting of parts of the Sylhet and Chittagong areas, has many low hills covered with jungles of bamboo and rattan. The central zone, covering parts of the country extending north of Dhākā, contains a large number of lakes and swampy vegetation, as well as the Madhupur jungles. The area lying to the northwest of the Brahmaputra and to the southwest of the Padma forms a flat plain, the vegetation of which consists mostly of cultivated plants and orchards. Babul (*Acacia arabica*) is the most conspicuous plant. The southern zone along the Bay of Bengal contains the Sundarbans, with their distinctive mangrove vegetation. Many commercially valuable trees, such as the sundri, for which the Sundarbans are named (*Heritiera fomes* or *minor*); *gewa,* or *gengwa* (*Excoecaria agallocha*), a softwood tree used for making newsprint; and goran (*Ceriops roxburghiana*), a type of mangrove, grow in this vast forest.

Elephants

Elephants are found in the Chittagong Hill Tracts and northeastern Sylhet. The domesticated, or water, buffalo are used for plowing and pulling carts. The barking deer, the *barosinga* (or 12-horned deer), and the sambar deer, with its maned neck, are well-known. Of the carnivores, the royal Bengal tiger is the best known. The clouded leopard, dark gray and with spots that are oval or oblong in form, is smaller than the leopard. The ferocious leopard cat is about the size of the domestic cat but with longer legs.

There are three types of bear: the sloth bear, the Himalayan black bear, and the Malayan sun bear. The sloth bear is the most numerous. The jackal is a common animal, as is the mongoose. The Bengal, or rhesus, monkey is the most common primate.

The common house crow is seen everywhere. The bulbul, the magpie robin, and a wide variety of warblers are also found; some are migrants that appear only in winter.

Other species include the common game birds, parakeets, cuckoos, hawks, owls, kingfishers, hornbills, woodpeckers, and vultures. Among the eagles, the crested serpent eagle and the ring-tailed fishing eagle are the most common. There are also hoopoes, herons, storks, ducks, and wild geese.

Settlement patterns. The extremely high population density of Bangladesh, averaging 1,900 persons per square mile, varies widely according to the distribution of flat land. The highest density, over 2,800 persons per square mile, occurs in and around the capital, which is also the centre of the most fertile zone; the lowest, at just over 100 persons per square mile, occurs in the hills of Chittagong.

Population density

Rural settlement. The rural area throughout Bangladesh is very densely settled. The inundation of most of the fields during the rainy season makes it necessary to build houses on higher ground. Continuous strings of settlements along roads are common in areas south of the Ganges and in the floodplains of the Mahānanda, Tista, Jamuna, Ganges, and Meghna rivers. Similar settlements are also found in the hilly regions of southern Sylhet and in the Chittagong region. In central and western Sylhet and in the Chittagong Hill Tracts, settlements occur in a nucleated, or clustered, pattern. The traditional character of rural villages has changed with the addition of prefabricated one- or two-storied structures scattered among the thatched bamboo huts.

Urban settlement. Although industrial development has prompted migration to the cities, Bangladesh is one of the least urbanized areas in South Asia. Eighty percent of the population lives in villages. There are only three major cities: Dhākā, Chittagong, and Khulna. Dhākā, the capital, is the largest. Chittagong, the country's major port, is second in importance. A number of industrial areas, such as Kalurghat, Sholāshahar, and Faujdār Hāt, have developed around Chittagong. Khulna, in the southwest, has become a commercial and industrial centre; the opening of the port of Chālna nearby and the growth of the Daulatpur industrial area has increased its population.

THE PEOPLE

Ethnic composition and distribution. The proto-Australoids, sometimes called Veddas, were one of the earliest groups to enter the area. According to some ethnologists, they were followed by Mediterranean Caucasoids (whites), also known as Aryans. Armenoids (of Indo-European stock) are believed to have entered as well. With the coming of the Muslims in the 8th century AD, new elements were introduced. Persons of Arab, Persian, and Turkish origin moved in large numbers to the subcontinent. By the end of the 12th century they had entered what is now Bangladesh. A substantial proportion of the population is descended from these Muslim immigrants.

Most of the tribal peoples of Bangladesh inhabit the Chittagong Hill Tracts in the southeast. They are predominantly Buddhist, and some of the tribes are related to the peoples of Burma. Of the approximately 12 ethnolinguistic groups of the Chittagong Hill Tracts, the four largest are the Chakmā, the Marma, the Tripura (Tipra), and the Mro. Tribal peoples in other parts of Bangladesh include the Santāls, of the proto-Australoid group, the Khāsis, the Gāro, and the Hajang. The Santāls live in the northwestern part of Bangladesh, the Khāsis in Sylhet in the Khāsi Hills near the border with Assam, and the Gāro and Hajang in the northeastern part of the country.

The Bengalis

Apart from these tribes, the rest of the people are Bengalis—an ethnic as well as a linguistic group. The Bengalis, however, are not homogeneous in origin. In general, the people of the coastal areas with whom the Muslim merchants of the Middle East were in close touch show physical features that seem to be the result of the admixture of local people with those of Turkish and Semitic origin.

Linguistic composition. Bengali, the language spoken in Bangladesh, belongs to the Indo-Aryan group of languages and is related to Sanskrit, not directly but by way of Gaudiya Prākrit, the language from which it is derived. Bengali is the mother tongue of about 98 percent of the people. Tribal peoples have their own distinct dialects, some of which are related to the Tibeto-Burman group of languages. English is spoken in urban centres and among educated groups.

Bengali has two distinct styles: *sādhu bhāṣā,* the literary language, contains many words derived from Sanskrit, and *calit bhāṣā,* the colloquial language. Until the 1930s *sādhu bhāṣā* was the standard medium of formal writing, but *calit bhāṣā* is now the basic form. There are a number of dialects. Bengali contains a large number of loanwords from Portuguese, English, Arabic, Persian, and Hindi.

Religions. More than 85 percent of the population follows the religion of Islām. Most Muslims belong to the Sunnī sect, but there are a small number of Shī'ite Muslims, mostly descendants of immigrants from Iran. Hindus, who constitute about 10 percent of the population, are divided into scheduled (low) and nonscheduled castes. Buddhists form less than 1% percent of the population. Of the tribes in the Chittagong Hill Tracts, the Chakmā,

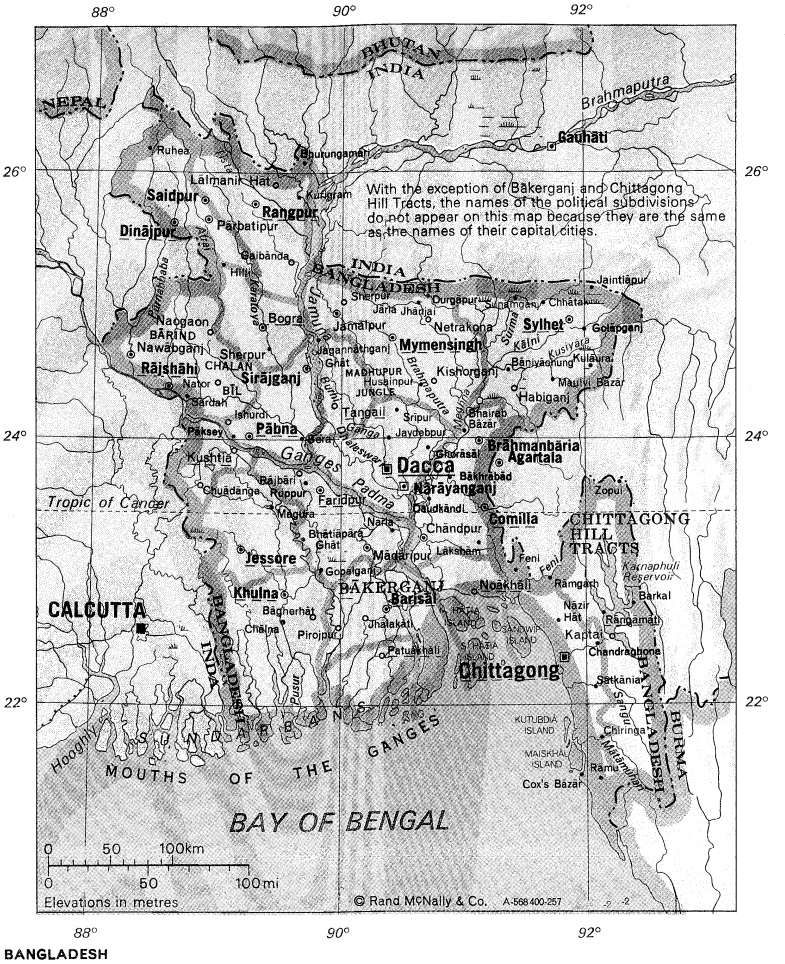
MAP INDEX

Political subdivisions

The name of a political subdivision if not shown on the map is the same as that of its capital city.

Cities and towns

Physical features and points of interest



BANGLADESH

Marma, and Mro are mostly Buddhists. The Kuki, Khomoi (Kumi), and some of the Mro are animists. While most of the Lushai are Christians, the Tripura are Hindus.

Demographic trends. Almost half of Bangladesh's population is under 15 years of age; the birth rate is high, and average life expectancy is about 50 years. The rate of infant mortality remains high. There has been almost no immigration since the 1970s. A relatively small number of Bangladeshis work in Britain and in Middle Eastern countries, and there has been a steady emigration of farm labourers into neighbouring Assam.

THE ECONOMY

Agriculture. Bangladesh is overwhelmingly agricultural, with some three-fifths of the population engaged in farming. Jute and tea, which are principal sources of foreign exchange, follow rice as the most important agricultural products. The country produces about one-fifth of the world's supply of raw jute. Other important agricultural products are wheat, pulses (leguminous plants, such as peas, beans, and lentils), sweet potatoes, oilseeds of various kinds, sugarcane, tobacco, and fruits such as bananas, mangoes, and pineapples.

Jute and rice production

Agriculture has in the past been wholly dependent upon the vagaries of the monsoon. A poor monsoon has always meant poor harvests or none and the threat of famine. Among the remedial measures adopted has been the construction of a number of irrigation projects designed to control floods and to conserve rainwater for use in the dry months. The most important are the Karnaphuli Multipurpose Project in the southeast, the Tista Barrage Project in the north, and the Ganges-Kabadak Project, to serve the southwestern part of the country. Economic planning has encouraged double and triple cropping, intercropping, and the increased use of fertilizers.

Irrigation and flood control

Fisheries. The rivers of Bangladesh are suitable for the breeding and raising of fish. Its rivers and seacoast offer opportunities for the operation of the usual types of fisheries, mostly in the estuaries of the Bay of Bengal. Among the varieties of fish caught are the marine *rupchanda,* or pomfret, and the freshwater hilsa, a relative of the shad.

Industry. The excessive—until recently almost exclusive—dependence upon agriculture leads to seasonal unemployment among peasants, as well as to a low standard of living. To counteract this imbalance, a policy of industrialization was adopted after 1947 and was pursued through five-year plans. The main obstacle to its fulfillment has been the comparative lack of mineral resources.

Power resources. Oil in marketable quantities has not been struck anywhere in Bangladesh. The country's first oil well, near Sylhet, was discovered in 1986. Natural gas is used mainly in the manufacture of fertilizer and for thermal power. More than half the proven gas reserves are in the Comilla area, and nearly all the rest in Sylhet.

Some deposits of coal have been found in northwestern Bangladesh in the Rājshāhi area. The thickest seams are located at relatively inaccessible depths of 3,000 to 3,500 feet. Smaller deposits of coal exist in northwestern Sylhet. The Chittagong Hill Tracts contain some brown coal and lignite. Peat deposits exist in several places, but some of the beds remain under water for half the year, making extraction difficult. Limestone is found in the Sylhet and Chittagong areas. Radioactive minerals have been detected in sand deposits along the beaches south of Cox's Bāzār.

Bangladesh's electricity is produced by thermal and hydroelectric processes. The main source of hydroelectricity is the Kaptai Dam in the Chittagong Hill Tracts.

Industrial development. Industrial policy between 1947 and 1971 was to give priority to industries based on indigenous raw materials such as jute, cotton, hides, and skins. The principle of free enterprise in the private sector was accepted, subject to certain conditions, which included the national ownership of public utilities. The policy also aimed to develop as quickly as possible consumer-goods

industries with a view to avoiding dependence on imports.

Autonomous corporations

Under Pakistani administration, new types of autonomous corporations were established to deal with industrial development, electricity, water and sewerage management, the development of forest industries, and road transportation. The Bangladesh government in 1972 nationalized these corporations and then established several new corporations to manage the nationalized enterprises. But hasty change, coupled with the inexperience of those placed in charge of the corporations, produced widespread disruptions, and industrial production came almost to a halt. The policy of nationalization was gradually revised and was replaced by a 19-point program announced in 1979. This program emphasized greater productivity and efficiency. In an attempt to encourage private investment, the government also returned many state-owned enterprises to the private sector.

Manufacturing and other industries. Because the export of raw jute is not highly remunerative, efforts were made between 1947 and 1971 to establish mills to produce and export jute products and thus earn foreign exchange. About 45 percent of the jute produced during that period was processed in the territory; the balance was exported raw. Next to jute, Bangladesh's main exports are tea and hides and skins. Among the minor exports are newsprint, ready-to-wear garments, shrimp, and frogs' legs.

The bamboo in the Chittagong Hill Tracts and the various softwood trees growing in the Sundarbans provide excellent raw material for papermaking. There are paper mills at Chandraghona, Chhātak, and at Pāksey, as well as a paper and board mill at Khulna.

Bangladesh has fertilizer factories, textile mills, sugar factories, glass works, and aluminum works. Its two cement factories, located at Chhātak, in the Sylhet area, are unable to meet the growing demand for cement. A shipyard has been opened at Khulna for repairing and reconstructing ships, and a steel mill is located at Chittagong.

Cottage industries

By far the most important cottage industry centres on the production of yarn and textile fabrics—mostly coarse and medium-quality fabrics. Carpets, ceramics, and cane furniture are also products of cottage industries.

Transportation. Central to the country's transportation system are its networks of waterways, roads, and railways, the latter mostly built during British rule. Inland waterways are of major importance, providing low-cost transport and access to areas where land transport cannot be economically developed. They carry most of the domestic and foreign cargo. The chief seaports are Chittagong and Chalna, and there are international airports at Dhākā and Chittagong.

The forms of transport used on Bangladesh's roads range from automobiles and buses to the bullock cart. Two-wheeled horse-drawn jigs and buffalo carts are still used in the north in Rājshāhi. Town- and city-dwellers both rely largely on the cycle rickshaw and two types of motorized transport, known locally as auto and tempo, both of which are three-wheeled.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The constitution of 1972 specified a parliamentary form of government under a prime minister and a president elected by a national assembly. In 1975, however, a military coup led to a regime of martial law. The form of government that obtained thereafter was a mixture of presidential and parliamentary systems, effective power remaining with the army. Following another coup in 1982, the constitution was suspended and the country placed under martial law. In 1986 martial law was lifted and parliamentary elections were held, but in 1987, following a series of strikes and riots, the government dissolved the parliament. A new parliament was elected in 1988.

A large-scale administrative reorganization was carried out in the 1980s. While the revenue divisions remained the same—namely, Dhākā, Chittagong, Rājshāhi, and Khulna—the older districts were subdivided and each subdivision raised to the status of a district. A new administrative unit, called *upazilla,* or subdivision, was created to facilitate decentralization of power. The *upazillas* are headed by an executive officer who has administrative and judicial functions.

Bangladesh has continued with substantially the same judicial system as had been in operation when the territory was a province of Pakistan, and which owed its origins to the system in operation under the British raj.

The 1972 constitution divided the Supreme Court of Bangladesh into Appellate and High Court divisions and mandated a complete separation of the judiciary and executive branches. During the subsequent authoritarian regime, however, the power of the Supreme Court was greatly reduced. In 1977 a Supreme Judicial Council was established to draw up a code of conduct for Supreme Court and High Court judges, who may be removed from office by the president upon the council's recommendation. The fragmentation of the High Court into five divisions located in different parts of the country—which had been decreed by the military in the 1970s—was rescinded in 1986. Provision was made, however, for the judges to go on circuit for part of the year to hear cases in other parts of the country.

Education. The foundation of the educational system in Bangladesh was laid down during the period of British rule; the system has three levels—primary, secondary, and higher education. Primary education, which is free but not compulsory, is for children up to about 10 years old. Only about half of all children attend primary school. Secondary education is divided into three levels—junior secondary, high school, and higher secondary (intermediate college)—with public examinations being held at the conclusion of each level of schooling. Schools in cities and towns are generally better staffed and financed than those in rural areas.

Higher education

There are more than 600 colleges, most of them affiliated with the University of Dhākā, the University of Rājshāhi, or the University of Chittagong. Other institutions include Jahangirnagar University on the outskirts of the capital, the Bangladesh Agricultural University at Mymensingh, the Bangladesh University of Engineering and Technology at Dhākā, and the Islāmic University at Tongi. Medical education is provided by several medical colleges and an institute of postgraduate medicine at Dhākā.

For vocational training Bangladesh relies on several engineering colleges and a network of polytechnics and law colleges. In addition, there exist a college of arts and crafts, an agricultural college, a college of home economics for women, and an institute of social welfare and research.

The demand for higher education has continued to rise. One of the problems that has continued to impede educational progress is student unrest.

Health and welfare. Malaria, cholera, and tuberculosis are the most serious threats to health. An effective approach to the treatment of cholera and tuberculosis has been developed by research laboratories and hospitals in Dhākā and Comilla. The incidence of malaria has been reduced by a malaria eradication program in which swamps and marshes are regularly sprayed with insecticides. A family planning program has also been introduced.

Social services are provided by private agencies and government departments. These services include community development projects, schools for handicapped children, youth centres, orphanages, and training institutes for social workers.

CULTURAL LIFE

The Bengali language, Islāmic religion, and rural character of Bangladesh all serve to unify the country's culture, although variations occur among ethnic, religious, and social minorities and in the urban centres.

Daily life. The typical household in Bangladesh, particularly in the villages, includes several generations of extended family. Most marriages are arranged by parents or other relatives, but educated men and women have tended increasingly to choose their own partners. Divorce is permissible among Muslims. Hindu marriage is sacramental, but a Hindu can obtain a separation by application to a court of law. Muslim law permits limited polygamy.

Religious festivals

The main festivals in Bangladesh are religious. The two most important are ʿId al-Fiṭr, which comes at the end

of Ramaḍān, the Muslim month of fasting, and ʿId al-Aḍḥā, or the festival of sacrifice, which follows two and a half months later. On both occasions families and friends exchange visits.

While rice, pulses, and fish continue to constitute the staple diet of Bangladeshis, shortages of rice since World War II have forced the acceptance of wheat and wheat products as alternatives. Meat, including goat and beef, is also eaten, especially in the towns.

The arts. There are four main types of music in Bangladesh—classical, light-classical, devotional, and popular. Classical music has many forms, of which *dhrupad*—Hindustani devotional songs—and *khayal*—a blending of the Perso-Arab and Indian musical systems—are the best known. Devotional music also is represented by *qawwāli* and *kīrtan,* forms that are part of the common musical heritage of the subcontinent. It is, however, in the field of popular music that Bangladesh can best claim originality. The forms known as *bhatiali, bhawaiya, jari, sari, marfati,* and *baul* have no exact equivalents outside the country. While they may lack the sophistication and artistry of the classical forms, they are characterized by a spontaneity and vigour missing in classical music.

Apart from such classical dances as kathakali and bharata natya—forms that are popular throughout the subcontinent—Bangladesh has evolved highly original indigenous dances. The best known are the *dhāli, baul,* Manipuri, and snake dances. Each form expresses a particular aspect of tribal or communal life and is danced on specific occasions. The best known among the academies devoted to music and dancing are the Bulbul Academy and the Nazrul Academy.

Painting in Bangladesh is a recently introduced art form. The main figure behind the art movement was Zainul Abedin, whose sketches of the Bengal famine of 1943 first attracted attention. He was able, after 1947, to gather around him a school of artists who experimented with various forms, both orthodox and original.

Traditional architecture in Bangladesh is represented by the many mosques, mausoleums, forts, and gateways that have survived from the Mughal period. These, like Muslim architecture elsewhere in the subcontinent, are characterized by the pointed arch, the dome, and the minaret. Although in style and conception traditional architecture belongs to the same school as medieval buildings in northern India, Bangladesh's distinctive contribution lay in the translation into brick and mortar of the sloping, four-sided, thatched roof found in the countryside.

Recreation. Association football (soccer) has in the course of the 20th century supplanted practically all traditional sports. Field hockey, cricket, tennis, badminton, and wrestling are also practiced. The best known of the indigenous games is *ha-do-do.* The rules require each team in turn to send out a player to raid the other's territory. The raider must, while chanting, touch as many opposing players as he can without taking a breath. Kite-flying is another traditional pastime enjoyed by young and old alike. The making of elaborate kites from cloth or paper is a distinctive visual folk art as well.

The game of *ha-do-do*

All towns and most villages have cinema houses. Plays are occasionally staged by amateur groups and drama societies in educational institutions and are broadcast regularly on radio and television. Musical concerts, though not as popular as the cinema, are well-attended. Especially popular in the countryside is *jatra,* a rudimentary form of opera that draws on local legends.

Press and broadcasting. Programs are broadcast on radio and television in English and Bengali; news on radio is also broadcast in Urdu, Hindi, Burmese, and Arabic. The Bengali newspapers have relatively small circulations, a fact that reflects the low level of literacy in the country. But for each reader there are commonly five or six listeners, sometimes more, so that the influence of the press on opinion is greater than the sales suggest. Although the circulation of the English dailies is even less, because their patrons are the educated classes they exercise a disproportionate influence. Both radio and television are controlled by the government. The majority of newspapers are privately owned, and the press is relatively free. (S.S.H.)

For statistical data on the land and people of Bangladesh, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

History

Bangladesh ("Land of Bengal," or "of the Bengalis") has existed as an independent state only since 1971, yet its national character dates to the ancient past (see also the history sections of the articles INDIA and PAKISTAN). This identity consists in three distinctive attributes—a land, a language, and a religion.

The land is shaped by the two great rivers Ganges and Brahmaputra, which join in central Bangladesh to become the Padma. They are the greatest of a series of rivers winding down to the Bay of Bengal. This region has always been isolated from the north Indian plain. In early times eastern Bengal was called Vaṅga, while western Bengal was known as Gauḍa.

The Bengali language began to assume a distinct form in the 7th century AD and by the 11th century had acquired its own literature. The "Bengali Renaissance" of the 19th century was centred in Calcutta, and its greatest figure was the poet Rabindranath Tagore. Almost all of the movement's literary and artistic celebrities were Hindus.

The Buddhism that under the Mauryan emperor Aśoka's patronage spread across the whole subcontinent in the 3rd century BC was driven out after the decline of Maurya power, as Brahmanical Hinduism reestablished its hold. However, in remote eastern Bengal Buddhism lingered on under the Pāla kings (8th–12th century) until their overthrow by the Vaishnavite Hindu Senas. The Senas encouraged the settlement of high-caste Hindus as lords of the land, but this did not greatly affect the general populace. Then, in about AD 1200, Muslim invaders from the northwest overthrew the Senas. Islām found a mass following among the Vaṅga people. In the eastern part of the country—Noakhali, Chittagong, and Sylhet—Arab traders also spread Islāmic teaching. Whereas in northern India the strength of caste Hinduism was enough to withstand centuries of Muslim dominance, culminating in the Mughal dynasty (16th–18th century), in eastern Bengal, Islām became the religion of the majority.

Introduction of Islām

As Mughal authority declined, the Suba, or Dominion, of Bengal—including Bihār and Orissa—became semi-independent. The threat to the Muslim rulers of the Suba came first from the east—from Arakanese pirates and Portuguese raiders. The capital was moved to Dhākā in 1608. When further invasion threatened from central India, from the rising power of the Marāṭhā kingdom, the capital was shifted to Murshidābād in 1704. It was during this period that the English East India Company established its base at Calcutta. From 1757 the British were the dominant political power in Bengal.

Reluctant to become involved in Indian administration, the British confirmed the landed magnates, or zamindars, in their charge of vast estates. Some were Muslims (such as the Nawab of Dhākā), but most were Hindu rajas, even in eastern Bengal. They were required to collect revenue from the land, and they appointed agents to ensure regular collection. These agents formed the new middle class of Bengal, the *bhadralok* ("respectable people"). Mainly upper-caste Hindus, they collected the revenue from peasants, who were mainly Muslims. The *bhadralok* resided in Calcutta and the larger towns; in time they became the most active advocates of Indian self-government.

The province of Bengal was almost impossible to administer, even though Assam was made a separate province in 1874. In 1905, largely at the initiative of the viceroy, Lord Curzon, two new provinces were created: Western Bengal, with Bihār and Orissa, and Eastern Bengal and Assam. The division followed one of the branch rivers of the Ganges from Rājmahāl in the north to the sea. The division was on a geopolitical rather than an avowedly communal basis. It gave Eastern Bengal, with its capital at Dhākā, a population of 31,000,000, all but 6,000,000 being Bengalis. Behind Curzon's move, besides greater efficiency, was the intention of encouraging the Bengali Muslims as a counterweight to the "seditious" Bengali Hindus.

The partition of Bengal

The partition elicited vociferous protest in Western Bengal, especially in Calcutta. A prominent part was played by Tagore, whose family had vast holdings along the Padma. The campaign included a boycott of British manufactures under the slogan "swadeshī" ("of our own country," or "India-made goods"). The Muslim notables, still loyal to the British, decided that they also needed to organize. Their principal leaders were in northern India, but in December 1906 they gathered at Dhākā under the patronage of Nawab Salimullah and set up the All-India Muslim League. Their efforts secured separate electorates and separate constituencies for the Muslims under the 1909 Reforms, but the campaign against the partition of Bengal went on, and in 1912 the province was reunited (Bihār and Orissa being separated and Assam reverting to separate status).

All-India Muslim League

Despite the separate electorates, the Muslim League had no majority in any province. In reunited Bengal, where Muslims formed a majority of the population (33,000,000 in a total of 60,000,000), they received 117 seats in the Bengal Legislative Council numbering 250. It was necessary to adopt coalition tactics. The politician most adept at this was Fazl ul-Haq, chief minister of Bengal from 1937 to 1943. He set up his own Peasants and Tenants Party, but he was also active in the Muslim League from its inception. When in 1940 the Muslim League held its annual gathering at Lahore, Fazl ul-Haq proposed a resolution calling for "independent states" for the Muslims. The press labeled this the "Pakistan Resolution," but for Fazl ul-Haq and many others it implied a plurality of states. Distrusted by the influential Indian Muslim politician Mohammed Ali Jinnah (the first governor general of Pakistan [1947–48]), Fazl ul-Haq was expelled from the league. In his place Khwaja Nazimuddin became chief minister. Nazimuddin, a relative of the Nawab of Dhākā, was loyal to Jinnah but lacked political finesse. He was displaced in 1945 by the more sophisticated Hussein Shaheed Suhrawardy. Suhrawardy was the main architect of the Muslim League's success in Bengal in the 1946 election. He became chief minister of Bengal in 1946.

After protracted negotiations it became clear that the Congress Party (Indian National Congress) could not expect to preserve a united India. A major factor was the intense intercommunal conflict in August 1946 known as the "Great Calcutta Killing." On his arrival as the new viceroy the following year, Admiral Lord Mountbatten of Burma drafted a plan to partition the subcontinent. Suhrawardy met with Sarat Chandra Bose, the acknowledged Hindu political leader in Bengal, and the two agreed that they should claim a separate, independent united Bengal. Jinnah was prepared to agree, as was Mountbatten, but Mahatma Gandhi and the Congress Party refused. Hence, when partition came it was decided by religion rather than language.

The boundaries of East Pakistan, as the region became, were determined by Sir Cyril Radcliffe, chairman of the Boundary Commission, there being total disagreement among his Hindu and Muslim colleagues. The boundary he defined did not follow any clear natural feature, as in the 1905 partition, nor was it wholly based on communal proportions. Excluded wholly or partly from East Pakistan were Murshidābād, Nadia, Jessore, and Dināj pur, each approximately 60 percent Muslim. Included were Khulna (49 percent Muslim) and the Chittagong Hill Tracts, where Muslims formed only 3 percent of the population. In addition, following a plebiscite, the Sylhet area (61 percent Muslim), formerly a part of Assam province, and a small area of Cachar (38 percent) were included.

he new oundary

On both sides of the new boundary, those who believed themselves a threatened minority moved into what they perceived as a place of refuge. Along with Muslim Bengalis arriving from Hindu majority districts, there were many Muslims who came from Bihār. One district, Purnea, had an actual Muslim majority and had been claimed by Jinnah. About 1,000,000 Bihāris settled in the new state.

At independence, Suhrawardy lingered in Calcutta, and Nazimuddin became chief minister of East Pakistan. From the beginning, the link between the two parts of Pakistan was tenuous; indeed, their only common interest was fear of Indian domination. Jinnah and his advisers believed that unification might be achieved through a common language, Urdu, which was used in the army and administration. The Bengalis perceived this as a threat. Their other major grievance was that their export products, jute and tea, provided most of Pakistan's foreign exchange; yet the central government mainly stimulated development in the West.

he two akistans

The Bengalis began to feel that they had no real power in Pakistan. When Jinnah died, Nazimuddin became governor general; but when Liaquat Ali Khan, the prime minister, was shot in October 1951, Nazimuddin took over, installing a Punjabi, Ghulam Mohammad, as governor general. Although Nazimuddin had a majority in the legislature, Ghulam Mohammad dismissed him in April 1953. The East Bengal electorate demonstrated its dissatisfaction when an election was held in March 1954. A "United Front" was formed, including the extreme right (religious fundamentalist) and left (quasi-Marxist). Its main leaders were the aged Fazl ul-Haq and his revamped Workers and Peasants Party and Suhrawardy, who made his comeback with a new party, the Awami League. The Front won 300 seats, while the Muslim League retained only 10. The Front ministers were dismissed after two months. Ghulam Mohammad appointed Major General Iskander Mirza governor of East Bengal. He announced a tough regime, and his task was simplified by the quarrels among the different elements of the United Front. The deputy speaker was killed in an assembly brawl.

In 1956 Pakistan at last obtained a proper constitution in which both wings were equally represented. Thus far, prime ministers had come and gone; Suhrawardy, who took office in September 1956 with a motley group of supporters, lasted only one year. In 1958, government by politicians was superseded by a military regime.

Military rule

Under the military the elite civil servants assumed great importance, which adversely affected the East wing. In 1947 there had been only one Bengali Muslim in the Indian Civil Service (ICS), whereas the West wing had produced about 40. Although recruitment policy was designed to diminish the difference, by 1960 only about one-third of the personnel in the Civil Service of Pakistan (successor to the ICS) were Bengalis, with none in senior positions.

Bengali discontent festered, finding a spokesman in Mujibur Rahman (known as Sheikh Mujib). Like previous leaders, Mujib belonged to a landed family. Mujib was one of the founders of the Awami League in 1949 and, after Suhrawardy's death, became its leading figure. Jailed repeatedly by the military, he acquired an aura of martyrdom, but he was an orator, not a statesman. He announced a six-point demand for autonomy. When in December 1970 President Yahya Khan ordered elections, the Awami League won 167 of the 169 seats allotted to East Pakistan, or Bangladesh as it was now popularly called, in the National Assembly. This gave the League an overall majority in a chamber of 313 members. In West Pakistan, however, the Pakistan People's Party, led by Zulfikar Ali Bhutto, won 81 of 144 seats; Bhutto saw himself as Mujib's rival.

Throughout March 1971 President Yahya Khan negotiated at length in Dhākā with Mujib while government troops poured in from West Pakistan. Then, on March 25, the army launched a massive attack in which there were heavy casualties, including many students. Mujib was arrested and flown to West Pakistan. Most of the Awami League leaders fled and set up a government-in-exile in Calcutta, declaring Bangladesh an independent state. Internal resistance was mobilized by some Bengali units of the regular army, notably by Major Zia ur-Rahman, who held out for some days in Chittagong before the town's recapture by the Pakistan army. He then retreated to the border and began to organize bands of guerrillas. A different resistance was started by student militants, among whom Abdul Kader Siddiqi with his followers, known as Kader Bahini, acquired a reputation for ferocity. Some 10,000,000 Bengalis, mainly Hindus, fled over the frontier into India. The Indian government watched the struggle with alarm. The Awami League, which they supported, was a moderate middle-class body like the Congress Party; but many guerrillas were leftist. The United States and

China, for different reasons, were committed to a united Pakistan; India and the Soviet Union wanted a Bangladesh dependent on India. Eventually, on Dec. 3, 1971, the Indian army invaded the territory of its neighbour. The Pakistani defenses surrendered on December 16. Mujib was released from jail and returned to a hero's welcome, assuming leadership of the new Bangladesh government in January 1972.

Invasion by India

Revenge was brought against those who had collaborated. Local paramilitary forces, known as Razakars, had been raised. The Bengali force was called Al-Badr, while another, Al-Shams, was recruited from Urdu speakers—still called Bihāris, though most had been born locally. A terrible retribution ensued, with Kader Siddiqi as public executioner. The Bihāris had to flee into enclaves where their numbers gave some security; many were killed. Their pleas to be allowed to go to (West) Pakistan were ignored by Bhutto. Ten years later, most remained in refugee camps.

Mujib preached a secular state: the new national anthem was a poem by Tagore. In 1973 an election gave Mujib a landslide majority, but the euphoria soon turned sour. Prices escalated, and in 1974 a great famine claimed 50,000 lives. Faced with crisis, Mujib became a virtual dictator; corruption and nepotism reached new depths. On Aug. 15, 1975, Mujib was assassinated along with most of his family.

Assassination of Mujib

Right-wing, pro-Pakistan army officers were behind the killing; there have been allegations of U.S. support. The reconstructed army split into rival factions. Some of those who had fought in the resistance were politicized, especially the soldiers. The 1,000 officers and 28,000 soldiers who had been serving in the West since 1970 were not repatriated until 1973–74; they were allegedly pro-Pakistan and jealous of the fighters whom Mujib had favoured. A third military group comprised those who had worked with the Pakistanis in their brutal repression. A second coup in November 1975 brought Major General Zia ur-Rahman into power. Despite his own resistance record he turned against India and favoured those considered pro-Pakistan. A referendum held in May 1977 gave him an enormous vote of confidence. This did not prevent several military coup attempts, and on May 30, 1981, he was assassinated by radical officers. The prompt action of the chief of staff, Lieutenant General Hossain Mohammad Ershad, foiled their plans, and the conspirators were hanged.

The civilian vice-president, Abdus Sattar, was confirmed as president by a nationwide election in 1981; but he was ill, and real power was exercised by Ershad and a National Security Council. On March 24, 1982, Ershad ejected Sattar and took over as chief martial-law administrator. In December 1983 he assumed the office of president. To legitimize his authority he called elections for a National Assembly. He formed his own National Party. The election of May 1986 was contested by many parties. The National Party won 210 of the 330 seats in the legislature, just short of the two-thirds majority required to pass a fundamental law to legalize the martial-law regulations and revert to constitutional practice.

Ershad retired from the military command the following August, demonstrating his confidence that the army was now under control. He called a presidential election for October. The main opposition remained the Awami League, now led by Mujib's daughter, Sheikh Hasina Wajad. One of Mujib's murderers, Lieutenant Colonel Farooq Rahman, who had been in exile, was also a candidate. Ershad received 84 percent of the total.

The political turmoil had little relevance to the country's basic problems. At the 1951 census the East Pakistan population numbered 42,000,000 (about 12,000,000 being Hindus); by the late 1980s there were more than 100,000,000, despite massive emigration to neighbouring Assam and Tripura in India and a smaller exodus over the Arakan border with Burma. Agriculture was still the occupation of more than half the labour force, and what economic development there had been was confined to the environs of Dhākā and Chittagong. (H.R.T.)

Banks and Banking

The principal types of banking in the modern industrial world are commercial banking and central banking. A commercial banker is a dealer in money and in substitutes for money, such as checks or bills of exchange. The banker also provides a variety of financial services. The basis of the banking business is borrowing from individuals, firms, and occasionally governments—*i.e.*, receiving "deposits" from them. With these resources and also with the bank's own capital, the banker makes loans or extends credit and also invests in securities. The banker makes profit by borrowing at one rate of interest and lending at a higher rate and by charging commissions for services rendered.

A bank must always have cash balances on hand in order to pay its depositors upon demand or when the amounts credited to them become due. It must also keep a proportion of its assets in forms that can readily be converted into cash. Only in this way can confidence in the banking system be maintained. Provided it honours its promises (*e.g.*, to provide cash in exchange for deposit balances), a bank can create credit for use by its customers by issuing additional notes or by making new loans, which in their turn become new deposits. The amount of credit it extends may considerably exceed the sums available to it in cash. But a bank is able to do this only as long as the public believes the bank can and will honour its obligations, which are then accepted at face value and circulate as money. So long as they remain outstanding, these promises or obligations constitute claims against that bank and can be transferred by means of checks or other negotiable instruments from one party to another. These are the essentials of deposit banking as practiced throughout the world today, with the partial exception of Soviet-type institutions.

Another type of banking is carried on by central banks, which are bankers to governments and "lenders of last resort" to commercial banks and/or other financial institutions. They are often responsible for formulating and implementing their country's monetary and credit policies, usually in cooperation with the government. In some cases—*e.g.*, the U.S. Federal Reserve System—they have been established specifically to lead or regulate the banking system; in other cases—*e.g.*, the Bank of England—they have come to perform these functions through a process of evolution.

Some institutions often called banks, such as finance companies, savings banks, investment banks, trust companies, and home-loan banks, do not perform the banking functions described above and are best classified as financial intermediaries. Their economic function is that of channelling savings from private individuals into the hands of those who will use them, in the form of loans for building purposes or for the purchase of capital assets. These financial intermediaries cannot, however, create money (*i.e.*, credit) as the commercial banks do; they can lend no more than savers place with them.

This article describes the historical development of various banking functions and institutions, the basic principles of modern banking practice, and the structure of a number of important national banking systems. Certain concepts not addressed here that are nonetheless fundamental to banking are treated in the articles ACCOUNTING and MONEY.

The article is divided into the following sections:

The development of banking systems

Banking is of ancient origin, though little is known about it prior to the 13th century. Many of the early "banks" dealt primarily in coin and bullion, much of their business being money changing and the supplying of foreign and domestic coin of the correct weight and fineness. Another important early group of banking institutions was the merchant bankers, who dealt both in goods and in bills of exchange, providing for the remittance of money and payment of accounts at a distance but without shipping actual coin. Their business arose from the fact that many of these merchants traded internationally and held assets at different points along trade routes. For a certain consideration, a merchant stood prepared to accept instructions to pay money to a named party through one of his agents elsewhere; the amount of the bill of exchange would be debited by his agent to the account of the merchant banker, who would also hope to make an additional profit from exchanging one currency against another. Because there was a possibility of loss, any profit or gain was not subject to the medieval ban on usury. There were, moreover, techniques for concealing a loan by making foreign exchange available at a distance but deferring payment for it so that the interest charge could be camouflaged as a fluctuation in the exchange rate.

ankers

Another form of early banking activity was the acceptance of deposits. These might derive from the deposit of money or valuables for safekeeping or for purposes of transfer to another party; or, more straightforwardly, they might represent the deposit of money in a current account. A balance in a current account could also represent the proceeds of a loan that had been granted by the banker, perhaps based on an oral agreement between the parties (recorded in the banker's journal) whereby the customer would be allowed to overdraw his account.

English bankers in particular had by the 17th century begun to develop a deposit banking business, and the techniques they evolved were to prove influential elsewhere. The London goldsmiths kept money and valuables in safe custody for their customers. In addition, they dealt in bullion and foreign exchange, acquiring and sorting coin for profit. As a means of attracting coin for sorting, they were prepared to pay a rate of interest, and it was largely

in this way that they began to supplant as deposit bankers their great rivals, the "money scriveners." The latter were notaries who had come to specialize in bringing together borrowers and lenders; they also accepted deposits.

It was found that when money was deposited by a number of people with a goldsmith or a scrivener a fund of deposits came to be maintained at a fairly steady level; over a period of time, deposits and withdrawals tended to balance. In any event, customers preferred to leave their surplus money with the goldsmith, keeping only enough for their everyday needs. The result was a fund of idle cash that could be lent out at interest to other parties.

Origin of the check

About the same time, a practice grew up whereby a customer could arrange for the transfer of part of his credit balance to another party by addressing an order to the banker. This was the origin of the modern check. It was only a short step from making a loan in specie or coin to allowing customers to borrow by check: the amount borrowed would be debited to a loan account and credited to a current account against which checks could be drawn; or the customer would be allowed to overdraw his account up to a specified limit. In the first case, interest was charged on the full amount of the debit, and in the second the customer paid interest only on the amount actually borrowed. A check was a claim against the bank, which had a corresponding claim against its customer.

Another way in which a bank could create claims against itself was by issuing bank notes. The amount actually issued depended on the banker's judgment of the possible demand for specie, and this depended in large part on public confidence in the bank itself. In London, goldsmith bankers were probably developing the use of the bank note about the same time as that of the check. (The first bank notes issued in Europe were by the Bank of Stockholm in 1661.) Some commercial banks are still permitted to issue their own notes, but in most countries this has become a prerogative of the central bank.

In Britain the check soon proved to be such a convenient means of payment that the public began to use checks for the larger part of their monetary transactions, reserving coin (and, later, notes) for small payments. As a result, banks began to grant their borrowers the right to draw checks much in excess of the amounts of cash actually held, in this way "creating money"—*i.e.,* claims that were generally accepted as means of payment. Such money came to be known as "bank money" or "credit." Excluding bank notes, this money consisted of no more than figures in bank ledgers; it was acceptable because of the public's confidence in the ability of the bank to honour its liabilities when called upon to do so.

Bank money or credit

When a check is drawn and passes into the hands of another party in payment for goods or services, it is usually paid into another bank account. Assuming that the overdraft technique is employed, if the check has been drawn by a borrower, the mere act of drawing and passing the check will create a loan as soon as the check is paid by the borrower's banker. Since every loan so made tends to return to the banking system as a deposit, deposits will tend to increase for the system as a whole to about the same extent as loans. On the other hand, if the money lent has been debited to a loan account and the amount of the loan has been credited to the customer's current account, a deposit will have been created immediately.

One of the most important factors in the development of banking in England was the early legal recognition of the negotiability of credit instruments or bills of exchange. The check was expressly defined as a bill of exchange. In continental Europe, on the other hand, limitations on the negotiability of an order of payment prevented the extension of deposit banking based on the check. Continental countries developed their own system, known as giro payments, whereby transfers were effected on the basis of written instructions to debit the account of the payer and to credit that of the payee.

The business of banking

The business of banking consists of borrowing and lending. As in other businesses, operations must be based on capital, but banks employ comparatively little of their own capital in relation to the total volume of their transactions. The purpose of capital and reserve accounts is primarily to provide an ultimate cover against losses on loans and investments. In the United States capital accounts also have a legal significance, since the laws limit the proportion of its capital a bank may lend to a single borrower. Similar arrangements exist elsewhere.

FUNCTIONS OF COMMERCIAL BANKS

The balance sheet

The essential characteristics of the banking business may be described within the framework of a simplified balance sheet. A bank's main liabilities are its capital (including reserves and, often, subordinated debt) and deposits. The latter may be from domestic or foreign sources (corporations and firms, private individuals, other banks, and even governments). They may be repayable on demand (sight deposits or current accounts) or repayable only after the lapse of a period of time (time, term, or fixed deposits and, occasionally, savings deposits). A bank's assets include cash (which may be held in the form of credit balances with other banks, usually with a central bank but also, in varying degrees, with correspondent banks); liquid assets (money at call and short notice, day-to-day money, short-term government paper such as treasury bills and notes, and commercial bills of exchange, all of which can be converted readily into cash without risk of substantial loss); investments or securities (substantially medium-term and longer term government securities—sometimes including those of local authorities such as states, provinces, or municipalities—and, in certain countries, participations and shares in industrial concerns); loans and advances made to customers of all kinds, though primarily to trade and industry (in an increasing number of countries, these include term loans and also mortgage loans); and, finally, the bank's premises, furniture, and fittings (written down, as a rule, to quite nominal figures).

All bank balance sheets must include an item that relates to contingent liabilities (*e.g.,* bills of exchange "accepted" or endorsed by the bank), exactly balanced by an item on the other side of the balance sheet representing the customer's obligation to indemnify the bank (which may also be supported by a form of security taken by the bank over its customer's assets). Most banks of any size stand prepared to provide acceptance credits (also called bankers' acceptances); when a bank accepts a bill, it lends its name and reputation to the transaction in question and, in this way, ensures that the paper will be more readily discounted.

Deposits. The bulk of the resources employed by a modern bank consists of borrowed money (that is, deposits), which is lent out as profitably as is consistent with safety. Insofar as an increase in deposits provides a bank with additional cash (which is an asset), the increase in cash supplements its loanable resources and permits a more than proportionate increase in its loans.

The way in which deposits may be increased

An increase in deposits may arise in two ways. (1) When a bank makes a loan, it may transfer the sum to a current account, thus directly creating a new deposit; or it may arrange a line of credit for the borrower upon which he will be permitted to draw checks, which, when deposited by third parties, likewise create new deposits. (2) An enlargement of government expenditure financed by the central bank may occasion a growth in deposits, since claims on the government that are equivalent to cash will be paid into the commercial banks as deposits. In the first instance, with the increase in bank deposits goes a related increase in the potential liability to pay out cash; in the second case, the increase in deposits with the commercial banks is accompanied by a corresponding increase in commercial bank holdings of money claims that are equivalent to cash.

Taking one bank in isolation, an increase in its loans may result in a direct increase in deposits. This may occur either as a result of a transfer to a current account (as above) or a transfer to another customer of the same bank. Once again, there is an increase in the potential liability to pay out cash. On the other hand, if there has been an increase in loans by another bank (including an increase

in central bank loans to the government), this may give rise to increased deposits with the first bank, matched by a corresponding claim to cash (or its equivalent). For these reasons a bank can generally expect that, if there is an increase in deposits, there will also be some net acquisition of cash or of claims for receipt of cash. It is in this way that an increase in deposits usually provides the basis for further bank lending.

Except in countries where banks are small and insecure, banks as a whole can usually depend on their current account debits being largely offset by credits to current accounts, though from time to time an individual bank may experience marked fluctuations in its deposit totals, and all banks in a country may be subject to seasonal variations. Even when deposits are repayable on demand, there is usually a degree of inertia in the deposit structure that prevents sharp fluctuations; if money is accepted contractually for a fixed term or if notice must be given before its repayment, this inertia will be greater. On the other hand, if a significant proportion of total deposits derives from foreign sources, there is likely to be an element of volatility arising from international conditions.

In banking, confidence on the part of the depositors is the true basis of stability. Confidence is steadier if there exists a central bank to act as a "lender of last resort." Another means of maintaining confidence employed in some countries is deposit insurance, which protects the small depositor against loss in the event of a bank failure. Such protection was the declared purpose of the "nationalization" of bank deposits in Argentina between 1946 and 1957; banks receiving deposits acted merely as agents of the government-owned and government-controlled central bank, all deposits being guaranteed by the state.

Maintaining liquidity

Reserves. Since the banker undertakes to provide depositors with cash on demand or upon prior notice, it is necessary to hold a cash reserve and to maintain a "safe" ratio of cash to deposits. The safe ratio is determined largely through experience. It may be established by convention (as it was for many years in England) or by statute (as in the United States and elsewhere). If a minimum cash ratio is required by law, a portion of a bank's assets is in effect frozen and not available to meet sudden demands for cash from the bank's customers. In order to provide more flexibility, required ratios are frequently based on the average of cash holdings over a specified period, such as a week or a month. In addition to holding part of the bank's assets in cash, a banker will hold a proportion of the remainder in assets that can quickly be converted into cash without significant loss. No banker can safely ignore the necessity of maintaining adequate reserves of liquid assets; some prefer to limit the sum of loans and investments to a certain percentage of deposits, not allowing their loan–deposit ratio to run for any length of time at too high a level.

Unless a bank held cash covering 100 percent of its demand deposits, it could not meet the claims of depositors if they were all to exercise in full and at the same time their rights to demand cash. If that were a common phenomenon, deposit banking could not long survive. For the most part, the public is prepared to leave its surplus funds on deposit with the banks, confident that they will be repaid if needed. But there may be times when unexpected demands for cash exceed what might reasonably have been anticipated; therefore, a bank must not only hold part of its assets in cash but also must keep a proportion of the remainder in assets that can be quickly converted into cash without significant loss. Indeed, in theory, even its less liquid assets should be self-liquidating within a reasonable time.

A bank may mobilize its assets in several ways. It may demand repayment of loans, immediately or at short notice; it may sell securities; or it may borrow from the central bank, using paper representing investments or loans as security. Banks do not precipitately call in loans or sell marketable assets, because this would disrupt the delicate debtor–creditor relationships and increase any loss of confidence, probably resulting in a run on the banks. Ready cash may be obtainable in this way only at a very high price. Banks must either maintain their cash reserves and other liquid assets at a high level or have access to a "lender of last resort," such as a central bank, able and willing to provide cash against the security of eligible assets. In a number of countries the commercial banks have at times been required to maintain a minimum liquid assets ratio. But central banks impose such requirements less as a means of maintaining appropriate levels of commercial bank liquidity than as a technique for influencing directly the lending potential of the banks (see below).

Kinds of assets of commercial banks

Among the assets of commercial banks, investments are less liquid than money-market assets such as call money and treasury bills. By maintaining an appropriate spread of maturities, however, it is possible to ensure that a proportion of a bank's investments is regularly approaching redemption, thereby producing a steady flow of liquidity and in that way constituting a secondary liquid assets reserve. Some banks, particularly in the United States and Canada, have at times favoured the "dumbbell" distribution of maturities, a significant proportion of the total portfolio being held in long-dated maturities with a high yield, a small proportion in the middle ranges, and another significant proportion in short-dated maturities. Following redemption the banks usually reinvest all or most of the proceeds in longer term maturities that in due course become increasingly short-term. Interest-rate expectations frequently modify the shape of a maturity distribution, and, in times of great uncertainty with regard to interest rates, banks will tend to hold the bulk of their securities at short term, and something like a T-distribution may then be preferred (mainly shorts, supported by small amounts of medium to longer dated paper). Investments and money-market assets merge into each other. The dividing line is arbitrary, but there is an essential difference: the liquidity of investments depends primarily on marketability (though sometimes it also depends on the readiness of the government or its agent to exchange its own securities for cash); the liquidity of money-market assets, on the other hand, depends partly on marketability but mainly on the willingness of the central bank to purchase them or accept them as collateral for a loan. This is why money-market assets are more liquid than investments.

INDUSTRIAL FINANCE

Long-term and medium-term lending. Banks that do a great deal of long-term lending to industry must ensure their liquidity by maintaining relatively large capital funds and a relatively high proportion of long-term borrowings (*e.g.*, time deposits, or issues of bonds or debentures), as well as valuing their investments very conservatively. Such banks, notably the French *banques d'affaires* and the West German commercial banks, have developed special means of reducing their degree of risk. Every investment is preceded by a thorough technical and financial investigation. The initial advance may be an interim credit, later converted into a participation. Only when market conditions are favourable is the original investment converted into marketable securities, and an issue of shares to the public is arranged. One function of these banks is to nurse an investment along until the venture is well established. Even assuming its ultimate success, a bank may be obliged to hold such shares for long periods before being able to liquidate them. In addition, they often retain an interest in a firm as an ordinary investment as well as to ensure a degree of continuing control over it.

The long-term provision of industrial finance in Britain and the Commonwealth countries is usually handled by specialist institutions, with the commercial banks providing only part of the necessary capital. In Japan, the long-term financial needs of industry are met partly by special industrial banks (which also issue debentures as well as accepting deposits) and partly by the ordinary commercial banks. In West Germany the commercial banks customarily handle long-term finance.

Term loans

Since World War II the commercial banks in the United States have developed the so-called term loan, especially for financing industrial capital requirements. The attempt to popularize the term loan began in the economic depression of the 1930s, when the banks tried to expand their business by offering finance for a period of years. Most

term loans have an effective maturity of little more than five years, though some run for 10 years or more. They are usually arranged between the customer and a group of lending banks, sometimes in cooperation with other institutions such as insurance companies, and are normally subject to a formal term loan agreement. Banks in Britain, western Europe, the Commonwealth, and Japan began during the 1960s to give term loans both to industry and to agriculture.

Short-term lending. Short-term loans are the core of the banking business even in countries where commercial banks make long-term loans to industry. Much short-term lending consists in the provision of working capital, but the banks also provide temporary finance for fixed capital development, aiding a customer until long-term finance can be found elsewhere.

Overdrafts

Much of this short-term lending is done by overdraft, particularly in the United Kingdom and a number of the Commonwealth countries, or by way of "current account lending" in many western European countries. The overdraft permits a depositor to overdraw an account up to an agreed limit. In theory, overdrafts are repayable on demand or after reasonable notice has been given, but often they are allowed to run on indefinitely, subject to a periodic review. An advance is reduced or repaid whenever the account is credited with deposits and recreated when new checks are drawn upon it, interest being paid only on the amount outstanding.

An alternative method of short-term lending is to debit a loan account with the amount borrowed, crediting the proceeds to a current account; interest is usually payable on the whole amount of the loan, which normally is for a fixed period of time. (In Britain arrangements are sometimes more flexible, and the term of the loan may be set by oral agreement.)

Discountable paper

In a number of countries, including the United States, the United Kingdom, France, West Germany, and Japan, short-term finance is often made available on the basis of discountable paper—commercial bills or promissory notes. Some of this paper is usually rediscountable at the central bank, thus becoming virtually a liquid asset, unlike a bank advance or loan.

Credit may be offered with or without formal security, depending on the reputation and financial strength of the borrower. In many countries a customer may use a number of banks, and these institutions usually freely exchange information about joint credit risks. In Britain and The Netherlands, however, most concerns tend to use a single banking institution for most of their needs.

Liability management

Traditionally bankers took the view that the liabilities of a bank (in particular, its deposits) were more or less stable and concerned themselves primarily with the investment of these funds. Since the late 1950s and 1960s, especially in North America and latterly in the United Kingdom, there has been a change in emphasis. Banks began to find it more difficult to obtain deposits. Interest rates rose to high levels, and banks were obliged to compete with each other and with other institutions for funds. At the same time, there was little point in paying a high rate of interest for money unless it could be employed profitably. Bankers began to relate the cost of borrowed money directly to the return on loans and investments. Previously the main limitation on a bank's expansion had been its ability to find profitable new business, but now the determining factor became the availability of funds to lend out. The essence of assets and liabilities management, as it came to be called, was deciding what kinds of new money to buy and what to pay for it. In the United States the liabilities side of bank balance sheets now included, *inter alia,* in much larger proportion than during the 1960s, repurchase agreements (under which securities are sold subject to an agreement to repurchase at a stated date), federal funds purchases (on the assets side, federal funds sales), excess balances of commercial banks and other depository institutions (regularly traded throughout the United States), negotiable certificates of deposit (which can be traded on a secondary market), and, for the larger banks, Eurocurrency borrowings, mostly Eurodollars (dollar balances held abroad). In the United Kingdom, "bought" money consisted of wholesale (*i.e.,* large) deposits (on which money market rates were paid), negotiable certificates of deposit, interbank borrowings, and Eurocurrency purchases. This bought money could then be used to finance the loan demand, including term loans, long favoured in the United States but a more recent innovation in the United Kingdom and elsewhere, where they were developed considerably in the 1970s. Although much of the lending financed by bought money was by way of term loans, these could be "rolled over," with an interest rate adjustment, every three or six months, and there could therefore be a measure of interest-rate matching and also sometimes a matching of maturities. In less sophisticated environments than North America and the United Kingdom, there was again an increasing emphasis on bought money to meet any expansion in loan demands (much of which was now term lending), with an adjustment at the margin when more funds were needed—*e.g.,* wholesale deposits, certificates of deposit, interbank borrowings, and purchases of Eurocurrencies.

The principles of central banking

The need for a central bank

The principles of central banking grew up in response to the recurrent British financial crises of the 19th century and were later adopted in other countries. Modern market economies are subject to frequent fluctuations in output and employment. Although the causes of these fluctuations are various, there is general agreement that the ability of banks to create new money may exacerbate them. Although an individual bank may be cautious enough in maintaining its own liquidity position, the expansion or contraction of the money supply to which it contributes may be excessive. This raises the need for a disinterested outside authority able to view economic and financial developments objectively and to exert some measure of control over the activities of the banks. A central bank should also be capable of acting to offset forces originating outside the economy, although this is much more difficult.

RESPONSIBILITIES OF CENTRAL BANKS

The first concern of a central bank is the maintenance of a soundly based commercial banking structure. While this concern has grown to comprehend the operations of all financial institutions, including the several groups of nonbank financial intermediaries, the commercial banks remain the core of the banking system. A central bank must also cooperate closely with the national government. Indeed, most governments and central banks have become intimately associated in the formulation of policy.

Relationships with commercial banks. One source of economic instability is the supply of money. Even in relatively well-controlled banking systems, banks have sometimes expanded credit to such an extent that inflationary pressures developed. Such an overexpansion in bank lending would be followed almost inevitably by a period of undue caution in the making of loans. Frequently the turning point was associated with a financial crisis, and bank failures were not uncommon. Even today, failures occur from time to time. Such crises in the past often threatened the existence of financial institutions that were essentially sound, and the authorities sometimes intervened to prevent complete collapse.

The willingness of a central bank to offer support to the commercial banks and other financial institutions in time of crisis was greatly encouraged by the gradual disappearance of weaker institutions and a general improvement in bank management. The dangers of excessive lending came to be more fully appreciated, and the banks also became more experienced in the evaluation of risks. In some cases, the central bank itself has gone out of its way to educate commercial banks in the canons of sound finance. In the United States the Federal Reserve System examines the books of the commercial banks and carries on a range of frankly educational activities. In developing countries such as India and Pakistan, central banks have also set up departments to maintain a regular scrutiny of commercial bank operations.

The most obvious danger to the banks is a sudden and

overwhelming run on their cash resources in consequence of their liability to depositors to pay on demand. In the ordinary course of business, the demand for cash is fairly constant or subject to seasonal fluctuations that can be foreseen. It has become the responsibility of the central bank to protect banks that have been honestly and competently managed from the consequences of a sudden and unexpected demand for cash. In other words, the central bank came to act as the "lender of last resort." To do this effectively, it was necessary that the central bank be permitted either to buy the assets of commercial banks or to make advances against them. It was also necessary that the central bank have the power to issue money acceptable to bank depositors. But if a central bank was to play this role with respect to commercial banks, it was only reasonable that it or some related authority be allowed to exercise a degree of control over the way in which the banks conducted their business.

The central bank as lender of last resort"

Role of central banks in the banking system

Most central banks now take a continuing day-to-day part in the operations of the banking system. The Bank of England, for example, has been increasingly in the market to ensure that the banks have a steady supply of cash, even during periods of credit restriction. It also lends regularly to the discount houses, supplementing their resources whenever the commercial banks feel the need to call back money they have on loan to them. In the United States the Federal Reserve System has operated in a similar way by buying and selling securities on the open market and by lending to dealers in government securities on the basis of repurchase agreements. The Federal Reserve may also discount paper submitted by the commercial banks through the Federal Reserve banks. The various techniques of credit control in use are discussed in greater detail below.

The evolution of those working relations among banks implies a community of outlook that in some countries is relatively recent. The whole concept of a central bank as responsible for the stability of the banking system presupposes mutual confidence and cooperation. For this reason, contact between the central bank and the commercial banks must be close and continuous. The latter must be encouraged to feel that the central bank will give careful consideration to their views on matters of common concern. Once the central bank has formulated its policy after a full consideration of the facts and of the views expressed, however, the commercial banks must be prepared to accept its leadership. Otherwise, the whole basis of central banking would be undermined.

The central bank and the national economy. *Relationships with other countries.* Since no modern economy is self-contained, central banks must give considerable attention to trading and financial relationships with other countries. If goods are bought abroad, there is a demand for foreign currency to pay for them. Alternatively, if goods are sold abroad, foreign currency is acquired that the seller ordinarily wishes to convert into the home currency. These two sets of transactions usually pass through the banking system, but there is no necessary reason why, over the short period, they should balance. Sometimes there is a surplus of purchases and sometimes a surplus of sales. Short-period disequilibrium is not likely to matter very much, but it is rather important that there be a tendency to balance over a longer period, since it is difficult for a country to continue indefinitely as a permanent borrower or to continue building up a command over goods and services that it does not exercise.

Maintaining the balance of foreign payments

Short-period disequilibrium can be met very simply by diminishing or building up balances of foreign exchange. If a country has no balances to diminish, it may borrow, but normally it at least carries working balances. If the commercial banks find it unprofitable to hold such balances, the central bank is available to carry them; indeed, it may insist on concentrating the bulk of the country's foreign-exchange resources in its hands or in those of an associated agency.

Long-period equilibrium is more difficult to achieve. It may be approached in three different ways: price movements, exchange revaluation (appreciation or depreciation of the currency), or exchange controls.

Price levels may be influenced by expansion or contraction in the supply of bank credit. If the monetary authorities wish to stimulate imports, for example, they can induce a relative rise in home prices by encouraging an expansion of credit. If additional exports are necessary in order to achieve a more balanced position, the authorities can attempt to force down costs at home by operating to restrict credit.

The objective may be achieved more directly by revaluing a country's exchange rate. Depending on the circumstances, the rate may be appreciated or depreciated, or it may be allowed to "float." Appreciation means that the home currency becomes more valuable in terms of the currencies of other countries and that exports consequently become more expensive for foreigners to buy. Depreciation involves a cheapening of the home currency, thus lowering the prices of export goods in the world's markets. In both cases, however, the effects are likely to be only temporary, and for this reason the authorities often prefer relative stability in exchange rates even at the cost of some fluctuation in internal prices.

Quite often governments have resorted to exchange controls (sometimes combined with import licensing) to allocate foreign exchange more or less directly in payment for specific imports. At times, a considerable apparatus has been assembled for this purpose, and, despite "leakages" of various kinds, the system has proved reasonably efficient in achieving balance on external payments account. Its chief disadvantage is that it interferes with normal market processes, thereby encouraging rigidities in the economy, reinforcing vested interests, and restricting the growth of world trade.

Whatever method is chosen, the process of adjustment is generally supervised by some central authority—the central bank or some institution closely associated with it—that can assemble the information necessary to ensure that the proper responses are made to changing conditions.

Moderating booms and slumps

Economic fluctuations. As noted above, monetary influences may be an important contributory factor in economic fluctuations. An expansion in bank credit makes possible, if it does not cause, the relative overexpansion of investment activity characteristic of a boom. Insofar as monetary policy can assist in mitigating the worst excesses of the boom, it is the responsibility of the central bank to regulate the amount of lending by banks and perhaps by other financial institutions as well. The central bank may even wish to influence in some degree the direction of lending as well as the amount.

An even greater responsibility of the central bank is that of taking measures to prevent or overcome a slump. Recessions, when they occur, are often in the nature of adjustments to eliminate the effects of previous overexpansion. Such adjustments are necessary to restore economic health, but at times they have tended to go too far; depressive factors have been reinforced by a general lack of confidence, and, once this has happened, it has proved extremely difficult to stimulate recovery. In these circumstances, prevention is likely to be far easier than cure. It has therefore become a recognized function of the central bank to take steps to preclude, if possible, any such general deterioration in economic activity.

For the central bank to be effective in regulating the volume and distribution of credit so that economic fluctuations may be damped, if not eliminated, it must at least be able to regulate commercial bank liquidity (the supply of cash and "near cash"), because this is the basis of bank lending. Monetary authorities in a number of countries have begun to resort increasingly to the management of monetary aggregates as a basic policy. This does not mean an uncritical acceptance of monetarist philosophy but rather what the U.S. economist and banker Paul A. Volcker has called "practical monetarism." In addition to the Federal Reserve in the United States, a growing number of western European countries have adopted the practice of setting growth targets for the money supply and sometimes other monetary targets as well (like domestic credit expansion), usually setting some range of allowable variation. Japan has had reservations and has preferred to indicate monetary projections or forecasts, partly because

of the difficulty of changing a set target should it become necessary. Nor is there any great degree of consensus as to which target or aggregate to employ. In general terms, choice of a particular aggregate as a basis for reference would be linked to the theories—more or less explicit—on which the actions of a particular central bank are based and also on the state of the country's economy and its financial environment. Where there are publicly declared targets, these can have an important effect by the very fact of being announced.

There is now little dispute about the broad objectives, though the techniques of control are various and depend to some extent on environmental factors. It would be incorrect to suppose, however, that the actions of the central bank can, unaided, achieve a high degree of stability. It can by wise guidance contribute to that end, but monetary action is in no sense a panacea; at all times, the degree to which it is likely to be effective depends on the provision of an appropriate fiscal environment (see GOVERNMENT FINANCE).

Developing the banking system

Banking services. Another responsibility of the central bank is to ensure that banking services are adequately supplied to all members of the community that need them. Some areas of a country may be "under-banked" (*e.g.*, the rural areas of India and the northern and more remote parts of Norway), and central banks have attempted, directly or indirectly, to meet such needs. In France, this need underlay the early extension of branches of the Bank of France to the *départements*. In India the authorities encouraged the opening of "pioneer" branches by the former Imperial Bank of India and its successor, the State Bank of India, latterly by all the nationalized banks, and particularly their extension to rural and semirural areas. In Pakistan, officials of the State Bank of Pakistan played an active part in the foundation of the semipublic National Bank of Pakistan with a similar objective in view.

A different sort of problem arises when the business methods of existing banks are unsatisfactory. In such circumstances, a system of bank inspection and audit organized by the central banking authorities (as in India and Pakistan) or of bank "examinations" (as in the United States) may be the appropriate answer. Alternatively, the supervision of bank operations may be handed over to a separate authority, such as France's Banking Control Commission or South Africa's Registrar of Banks.

In developing countries, central banks may encourage the establishment and growth of specialist institutions such as savings institutions and agricultural credit or industrial finance corporations. These serve to improve the mechanism for tapping existing liquid resources and to supplement the flow of funds for investment in specific fields.

The central bank as a public institution

Responsibilities to the government. Central banks have over the years acquired a number of well-defined responsibilities to their respective national governments. Some, notably the Bank of England, developed into central banks after being, in origin, bankers to the government. More recently it has become a matter of course for a new central bank to accept responsibility for the financial affairs of its government. The reasons are self-evident. Government transactions have become of increasing importance in influencing the workings of the economy, and the institution that holds the government's account is in a strategic position to cushion the commercial banks against the impact of large movements of cash originating in this way. As banker to the government, furthermore, the central bank has an obvious responsibility to provide routine banking services, such as arranging loan flotations and supervising their service, renewal, and redemption. The central bank also usually issues the currency.

Equally important are its responsibilities as an adviser on the probable monetary consequences of any proposed action. In this role the central bank should scrutinize the government's proposals with a certain amount of objectivity and state its point of view with vigour. One may cite a now-famous dictum of Montagu Norman as governor of the Bank of England:

> I think it is of the utmost importance that the policy of the Bank and the policy of the Government should at all times be in harmony—in as complete harmony as possible. I look upon the Bank as having the unique right to offer advice and to press such advice even to the point of "nagging"; but always of course subject to the supreme authority of the Government.

Many central banks are now nationalized, reflecting the increasingly general recognition of the significance of the central bank's role as a servant, if not a creature, of the government. This development is also, in a way, a final recognition of the central bank as a responsible public institution whose major function is to serve the community as a whole, untrammelled by narrow dictates of profit and loss. Most central banks, nevertheless, make very handsome profits.

TECHNIQUES OF CREDIT CONTROL

Central banks have developed a variety of techniques for influencing, regulating, and controlling the activities of commercial banks. These may be divided into (1) the so-called classical, or indirect, techniques and (2) various direct controls. The classical techniques make use of open-market purchases or sales by the central bank of certain types of assets that are invariably associated with fluctuations in interest rates. Direct, or quantitative, credit controls are employed to influence the cash and liquidity bases of commercial bank lending by means of freezing or unfreezing their liquid resources; sometimes ceilings are imposed on bank loans.

Purchases and sales of securities by the central bank

Open-market operations. The way in which open-market operations influence the cash reserves and, through them, the general liquidity of the commercial banks is essentially simple. If the central bank buys securities in the open market, the cash it offers in exchange adds to the reserves of the banks; if the central bank sells securities in the open market, the cash necessary to pay for them is either withdrawn from the banks' reserves or obtained by diminishing holdings of other assets (with the possibility of capital losses in consequence of these sales). It does not matter whether this buying and selling takes place between the central bank and the commercial banks directly or between the central bank and other financial sectors, including the public at large, since these are the customers of the commercial banks.

Open-market operations are invariably associated with related changes in one or more "strategic" rates of interest, the most influential of these rates being the minimum rate at which the central bank does business (the bank rate, or the discount rate), since other rates tend to move in sympathy with it. The central bank seeks to achieve an appropriate and consistent structure of interest rates. If a particular rate structure is desired (*e.g.*, prior to a new issue of government securities or in order to change the emphasis of institutional investment between, say, long-term and short-term securities), it may be necessary to precondition the market by means of open-market operations. To achieve its purposes the central bank must possess (if it is selling) or be willing to absorb (if it is buying) the appropriate types of securities.

In London the specialist banks known as discount houses effectively put to work the revolving fund of cash that circulates through the British banking system. If temporarily there is an inadequate supply of cash, the Bank of England either lends on a short-term basis or buys some of the assets held by the discount market. (From 1980 there was a shift in emphasis from lending to open-market operations, especially by dealing in bankers' acceptances.) Alternatively, the Bank of England may buy assets from the clearing banks (the large joint-stock banks), which then make the relevant moneys available to the market. On the other hand, if the discount market is oversupplied with funds, the Bank of England sells treasury bills, in this way mopping up the excess of cash. These transactions are known as smoothing-out operations. In addition, the Bank of England is also responsible for managing the national debt, and, whether the object is to influence the flows of money or not, such transactions in fact have monetary effects.

In the United States the Federal Reserve System regulates the money supply. Within the Federal Reserve System, the Federal Open Market Committee is the most important single policy-making body. It is presided over by the chair-

The Open Market Committee of the Federal Reserve

man of the Board of Governors, with the president of the Federal Reserve Bank of New York as its permanent vice chairman. The main responsibility of the Open Market Committee is to decide upon the timing and amount of open-market purchases or sales of government securities. Since open-market operations must obviously be consistent with other aspects of monetary and credit policy, it is in the committee that broad agreement is reached on matters such as changes in discount rates or reserve requirements.

One of the big differences between London and New York is that the central banking authorities in New York maintain direct relationships more or less continuously with the nonbank government securities dealers as well as with the commercial banks. The Federal Reserve Bank of New York may make temporary accommodation available to some 35 primary dealers (including certain banks) under a repurchase agreement, whereby securities are sold to the bank under an agreement that they be repurchased after a stipulated time. These agreements are made only for the purpose of supplying reserves to the banking system, but from the dealer's standpoint they are helpful in financing portfolios. Such repos, as they are called, may also be done with foreign official accounts. Since early 1966 the bank has also been prepared to mop up money by undertaking reverse repurchase agreements, in which the dealers act as intermediaries for large commercial banks with temporarily surplus money that they are prepared to place against bills, subject to the bank's repurchasing them a few days later; the commercial bank concerned lends the dealer the money to finance the holding of the bill. Similar arrangements are also made by the Federal Reserve directly with bank dealers.

All member banks of the Federal Reserve System, and now also other depository institutions, have direct access to the discount service of their Federal Reserve Bank, of which there is one in each of 12 districts. This is a privilege, however, and not a right. In the early years of the system the banks would sell discountable paper to the Federal Reserve, but now they usually borrow against a pledge of government securities held in safe custody with the Federal Reserve Bank in question. The Federal Reserve lends for a number of purposes but always at a time of general stress. It is assumed that, as the pressure abates, borrowing banks will repay their indebtedness as quickly as possible. Under ordinary conditions, the continuous use of Federal Reserve credit by a member bank over a considerable period is not regarded as appropriate.

Direct controls. The so-called classical techniques of credit control—open-market operations and discount policy—can only be employed where there is a sufficiently developed complex of markets in which to buy and sell assets of the type that commercial banks ordinarily hold. Direct credit controls have a wider range of application. They may be used either as a substitute for the classical techniques or as a supplement to them. Direct controls are more likely to be resorted to when the money market is undeveloped, because then a central bank can only impose its authority by means of direct action. This is often the situation facing a newly established central bank. Rather than wait for the slow evolution of a money market, the authorities may provide the central bank from the start (as in Pakistan, the Philippines, Sri Lanka, and Malaysia) with very full powers to control the banking system.

The aim in imposing a direct, quantitative regulation of credit is to curb inflationary pressures that may result from an expansion of commercial bank lending. This can be done in four main ways: (1) the commercial banks may be required to maintain stated minimum reserve ratios of cash to deposits, a stated liquid assets ratio, or some combination of both; (2) part of the cash resources of the commercial banks may be immobilized at the discretion of the central bank; (3) ceilings may be imposed on the amount of accommodation to be made available to the commercial banks at the central bank (sometimes referred to as "discount quotas"); and (4) a ceiling may be prescribed for commercial bank lending itself.

Variations in reserves

Minimum reserve requirements. The variation of minimum cash reserve requirements as a direct means of quantitative credit control has become increasingly general in recent years. The practice has largely derived from experience in the United States. In its origin the U.S. insistence on stated minimum reserve requirements for commercial banks was simply a means of prescribing minimum standards of sound behaviour. Only later did such ratios come to be seen as a useful supplementary quantitative credit control.

The power granted by the Banking Act of 1935 to the Federal Reserve System to determine the cash reserves of the commercial banks in the United States was employed for the first time during the boom of 1936–37, and periodic variation of minimum reserve requirements subsequently came to be recognized as an appropriate technique for controlling the money supply. The Federal Reserve Board's decisions were sometimes subject to considerable criticism, but, as it became more experienced in the use of this technique, variation in reserve requirements combined with other measures came to be regarded as a useful means of cushioning the economy against a recession. The variation of reserve requirements did not prove as effective in preventing inflation, largely because of the government's insistence that the Federal Reserve simultaneously support the prices of government bonds through open-market operations. This insistence was abandoned by the Treasury in March 1951. Since then, much greater emphasis has been placed on the use of open-market operations, which had become more effective, and the importance of varying minimum reserve requirements as a means of controlling the credit base has diminished in the United States. The technique is still widely used, however, in many countries.

In some countries the authorities require the maintenance of minimum liquid assets ratios. This is often combined with minimum requirements for cash reserves, as in India, Pakistan, and West Germany, though not always (in France, for example, until 1967 there were no minimum cash reserve requirements). Where prescribed minima relate to liquid assets and not to cash as such, reserves are held in the form of earning assets—an important distinction from the point of view of the commercial banks.

An important step toward a uniform and explicit minimum liquidity ratio for the London clearing banks was taken in 1951, when the governor of the Bank of England indicated to the banks that a liquidity ratio of from 32 to 28 percent would be regarded as normal and that it would be undesirable for the ratio to be allowed to fall below 25 percent. By 1957 a fairly rigid 30 percent minimum was in place (it was reduced to 28 percent in 1963). After 1946 the London clearing banks (but not the Scottish banks) also observed a more or less fixed cash ratio of 8 percent. A new element was introduced in 1960, when the Bank of England launched its system of "special deposits" as a means of reinforcing other methods of credit control. Calls were made from time to time on the London clearing banks to deposit with the Bank of England by a specified date some specified percentage of their gross deposits; similar arrangements applied to the Scottish banks, but the calls were smaller. This system lasted until 1971, when a new 12.5 percent minimum reserve ratio (excluding till cash) was introduced. This ratio related to "eligible liabilities" (primarily sterling deposits of up to two years maturity, including sterling certificates of deposit). The banks could also be required to place special deposits with the Bank of England. These arrangements were replaced in August 1981 by a voluntary holding of operational funds with the Bank of England by the London clearing banks ("for clearing purposes") and a uniform requirement of 0.5 percent of an institution's eligible liabilities that would be applied to all banks and licensed deposit-takers with eligible liabilities averaging more than £10,000,000. All banks that were eligible acceptors were also normally required to hold an average equivalent to 6 percent of their eligible liabilities either as secured money with discount houses or as secured call money with money brokers and gilt-edged jobbers, but the amount held in the form of secured money with a discount house was not normally to fall below 4 percent of eligible liabilities. This money became known as "club money."

The use of variable minimum reserve requirements as a means of credit control can, if carried far enough, produce results, especially when the requirements include the holding of cash balances. It is more useful as an anti-inflationary weapon than as a means of countering recession, since it cannot overcome a possible unwillingness of the banks to lend or of their customers to borrow. It is a somewhat clumsy technique, however, and cannot make adequate allowance for the special needs of different institutions.

Immobilization of cash resources. A second group of direct quantitative credit controls involves keeping a portion of the cash resources of commercial banks immobilized at the discretion of the central bank. Two leading examples of this technique were the use of the Treasury Deposit Receipt (TDR) in the United Kingdom during and after World War II and the "special account procedure" adopted in Australia in 1941. Both were means of immobilizing the increased liquidity deriving from wartime government expenditure.

The direct issue of Treasury Deposit Receipts at a nominal rate of interest to banks in the United Kingdom began in July 1940. They were not negotiable in the market nor transferrable between banks, but they could be tendered in payment for government bonds (and tax certificates); hence, during the war years they had a limited degree of liquidity. The Bank of England communicated to the banks collectively the amount of the weekly call, which was divided among them in proportion to their deposits. After the war, TDR's were replaced by treasury bills; in order to reduce the consequent high liquidity of the banks, there was a "forced funding" of £1,000,000,000 of treasury bills in November 1951, which were required to be invested in Serial Funding Stocks.

Special accounts in Australia

The special account procedure introduced in Australia in 1941 had a similar objective. The surplus investable funds of the Australian trading banks, defined as the amount by which each bank's total assets in Australia at any time exceeded the average of its total assets in Australia in August 1939, were required to be placed in special deposit accounts with the Commonwealth Bank (then the central bank) at a nominal rate of interest. A bank was not to withdraw any sum from its special account except with the consent of the Commonwealth Bank; during the war years, the bank generally directed the trading banks to lodge in their special accounts each month an amount equal to the increase in their total assets in Australia during the preceding month, although as a rule a lodgment was not required if it was known that a rise in assets would be followed by an early fall. Legislation in 1945 adopted the special account procedures as a means of general credit control (*e.g.,* to curb inflation), but the provisions were made more flexible. In 1953 a more complicated formula was introduced, and in 1960 the system was abandoned in favour of minimum reserve ratios.

Accommodation ceilings. Some countries have tried placing a limit on the amount of accommodation that the central bank may make available to the commercial banks. The difficulty in this type of quantitative credit control is to make it effective while at the same time allowing for changes in the economy; its most obvious use is as a means of checking inflation, but if the upward pressures on prices are strong, there is a temptation to increase the ceilings so that the restraint then becomes little more than a temporary check.

Usually, it is only when a control begins to be felt and to affect bank profits that the banks become really sensitive to changes in credit policy and the implementation of the control becomes truly effective. The postwar experience

The French *plafonds*

of France is a case in point. *Plafonds,* or "ceilings," were first introduced in France in 1948. Rediscount ceilings (or discount quotas) were fixed for each bank, though some categories of paper were excluded. Ceilings could be increased or (after 1957) reduced.

From the authorities' point of view, the chief difficulty in operating this control was the persistent building up of pressure against the ceilings. This was met partly by upward revisions in the ceilings themselves and partly by instituting a number of safety valves. The degree of elasticity required constituted the chief weakness of the ceiling technique. The central bank was constantly under pressure to adjust the ceilings upward. Some upward revisions were unavoidable, but the problem was to decide which claims were legitimate and which not. Much bilateral bargaining took place between the Bank of France and individual commercial banks, but the banks continued to complain that the strictness of the control was excessive and that the technique was lacking in flexibility.

The inadequacies of the *plafonds* technique in its original form became apparent when prices began to rise rapidly during the Korean War boom, and even the built-in safety valves failed fully to accommodate the pressures on bank liquidity. The need to strengthen the mechanism was obvious, and this was attempted in 1951. Previously, rediscounts had frequently exceeded the ceilings during the month and were only brought within the *plafonds* by special action (*e.g.,* through open-market purchases). The situation was brought under control by introducing a secondary ceiling to which a penalty rate of interest was applied. This was extended in 1958 to permit rediscounts even beyond the secondary ceiling, provided a further penalty was paid; each application, however, was scrutinized by the Bank of France. The system lasted until about the spring of 1964, though it did not finally disappear until 1968, when it was largely replaced by Bank of France operations in the open market. After early 1967 banks also were subject to minimum reserve requirements.

Plafonds, or discount quotas, have also been employed in West Germany, being introduced in 1952 and strengthened in 1955. Quotas may be reduced periodically (after 1964 they were also used to discourage institutions from borrowing abroad). Again there were safety valves (although less generous than in France) and the possibility of extra accommodation (Lombard credits) at a higher rate. In some circumstances, supplementary quotas might be approved for up to six months. A bank might also raise funds through the money market, though likely at higher cost. Discount quotas are still an important tool of credit control in West Germany.

Other countries have employed this technique, including Sweden, where for a time the central bank imposed formal or informal ceilings on banks and sometimes on finance companies. If the banks failed to observe the ceiling, a penalty was applied based on the amount of the excess borrowing and its duration. In Finland, commercial banks have at times been able to borrow limited amounts from the Bank of Finland by way of traditional credit quotas. Beyond these quotas, funds could formerly be obtained as supra-quota credit at a higher rate, but banks now are forced into the official call money market. Denmark, too, has permitted borrowing from the central bank in tranches, with higher (penalty) rates applying after the first tranche of the loan quota has been resorted to, a practice that can be expensive.

General ceilings on credit. Attempts have been made to prescribe a general ceiling within which the quantity of commercial bank lending must be held. This is even more difficult to achieve. One example of such an attempt was the adoption of a "rising ceiling" by Chile in 1953. All banks were required not to expand the volume of their loans to businesses and individuals by more than 1.5 percent a month, using as their basis the average of a bank's advances on selected dates in 1953. Certain types of loans were forbidden, and bank resources were to be directed to productive and distributive activities that really contributed to the expansion of the national economy. Banks were also required to provide information on the destination of their loans. In succeeding years adjustments were made on several occasions in the maximum permitted credit increase, expressed either as a percentage of advances or sometimes as a total for the banking system as a whole. In 1959 all quantitative credit restrictions were removed, and banks were permitted to advance funds up to their financial capacity, provided that they operated within the general banking law. There was no evidence the controls had been effective, but the major problem in Chile was budgetary rather than monetary. A temporary ceiling on loans was imposed by agreement in Canada (in 1951–52), The Netherlands (1957–58), and France (1958–59).

Ceilings on bank advances in the United Kingdom

The United Kingdom had considerable experience with this type of ceiling, introducing it as a temporary measure in 1955, when the banks were asked to bring their advances down by an average of 10 percent. Later an attempt was made to impose a true ceiling, requiring that bank advances not exceed the average of the period October 1956 to September 1957. This was continued until July 1958. Again, in 1961, the authorities indicated the banks must aim at checking the rate of rise in bank advances; this came to be interpreted as a request that the level of advances at the end of 1961 be no higher than in the previous June. The banks also were not to encourage an increase in the volume of commercial bills. The request was modified in May 1962 and largely withdrawn in October; but it was made again in May 1965, when the clearing banks were requested not to increase their advances to the private sector, at an annual rate of more than about 5 percent, in the 12 months to mid-March 1966 (likewise with commercial bills). Other financial institutions were requested to observe a comparable degree of restraint. For 12 months after March 1966, advances and discounts, allowing for seasonal factors, were not permitted to rise above levels set for March 1966. This represented an intensification of the credit squeeze because prices were rising. The credit restriction led to a falling off in business confidence, and, consequently, toward the end of 1966 bank lending was well below the official ceiling. In April 1967 authorities announced a change in techniques, with an emphasis on making calls to special deposits, but the ceilings returned again in November 1967. There was to be no increase in bank advances to the private sector (excluding exports and shipbuilding) except for seasonal reasons. In May 1968 a new ceiling was instituted for all such lending (including that for exports and shipbuilding); the clearing banks were asked to restrict the total of this lending, after seasonal adjustment, to 104 percent of the November 1967 figure, with priority to be given to finance for exports and for activities directly related to improving the balance of payments. The restrictions also extended to other types of credit. Credit became even tighter (in March 1969) when the ceiling was reduced to 98 percent of the November 1967 level. The banks had considerable difficulty in meeting this requirement and agreed merely to "do their best." Advances increased above the ceiling, and, as a penalty, the interest paid by the Bank of England on special deposits was halved. Not until late 1969 did it become clear that the authorities were prepared to abandon their long campaign to get bank loans down to the target figure. The ceiling was subsequently replaced by minimum reserve requirements. The system of quantitative credit control requires, for its successful implementation, the full cooperation of the banking community. In the United Kingdom, where banks base much of their lending on the overdraft technique, the system was very unpopular.

In France, however, the *encadrement du crédit,* as it is called, temporarily imposed in 1958–59, was revived during the first half of 1973. Subject to certain exclusions (*e.g.,* certain investment credits, agricultural credits, export credits, the financing of energy savings and innovation, leasing transactions, and special medium-term construction loans), the mechanism chosen was to permit a certain percentage rate of growth in bank credits in relation to a particular month in the previous year, these limits being fixed quarterly and subject to variation from time to time. Subsequently, in early 1975, reference was made to a fixed base defined as equal to an index of 100, in relation to which the index might be increased (or decreased) and credit expanded (or contracted). The system was further refined to vary the rate of change of credits within different financial sectors, and over the years it has been subject in the interests of flexibility to many amendments. In effect, there has been a combination of quantitative and qualitative credit controls.

Selective controls on credit

In addition to regulating the quantity of credit, central banks have sometimes attempted to influence the directions in which the commercial banks lend. A loose system of control prevailed in the United Kingdom during World War II and afterward, based initially on directives from the Bank of England. A highly formalized technique was employed in Australia during the war and earlier postwar years; detailed and specific instructions were given to the trading banks, marginal cases being referred to the central bank. The system of Voluntary Credit Restraint in the United States in 1951 was similar. The more formal controls seemed to be no more effective than the looser system employed in the United Kingdom.

Selective controls have been imposed on consumer installment finance in the United States and elsewhere (*e.g.,* by stipulating the percentage of deposit that is required and the length of the term over which repayments may be made). Even when these are not varied in order to serve as a control over credit, there is a case for insisting on such requirements for prudential reasons. In the United States, under the Securities Exchange Act of 1934, the Federal Reserve can vary the margins that purchasers of securities must pay in cash, thereby limiting the credit available for this purpose.

The structure of modern banking systems

The banking systems of the world have many similarities, but they also differ, sometimes in quite material respects. The principal differences are in the details of organization and technique. The differences are gradually becoming less pronounced because of the growing efficiency of international communication and the tendency in each country to emulate practices that have been successful elsewhere.

Unit banking and branch banking

Banking systems may be classified in terms of their structure as unit banking, branch banking, or hybrids of the two. For example, unit banking prevails in large areas of the United States. In other countries it is more usual to find a small number of large commercial banks, each operating a highly developed network of branches. This is the system used in England and Wales, among others. Examples of hybrid systems include those of France, West Germany, and India, where banks that are national in scope are supplemented by regional or local banks. Some of these hybrid systems are slowly changing their character, the banks becoming fewer in number and individually larger, with a larger number of branches.

UNIT BANKING: THE UNITED STATES

Bank organization in the United States during the years after World War II was still passing through a phase of structural development that many other countries had completed some decades earlier. Development in the United States has been subject to constraints not found elsewhere. The federal Constitution permits both the national and state governments to regulate banking. Some states prohibit branch banking, largely because of the political influence of small local bankers, thus encouraging the establishment and retention of a large number of unit banks.

Even in its early years the United States had an unusually large number of banks. As the frontiers of settlement were pushed rapidly westward, banks sprang up across the country. One reason for this was the demand for capital in the expanding frontier economy. There was also an obvious need for a large number of banks to serve the diverse and rapidly expanding demands of a growing and constantly migrating population. It must be remembered, too, that at this time communications between the frontiers of settlement and the established centres of commerce and finance were still inadequately developed.

The U.S. concern for competition

As long as communications remained imperfect, the existence of large numbers of competing institutions is not difficult to explain. The subsequent failure of bank mergers or amalgamations to produce a concentration of financial resources in the hands of large banking units can be attributed in part to the character of the federal Constitution as noted above. Among the people, moreover, there was a widespread distrust of monopoly and a deep-rooted fear that a "money trust" might develop. This went hand in hand with a political philosophy that emphasized the virtues of individualism and free competition; restrictions on branching, merging, and on the formation of holding companies were a feature of both the state and the federal

banking laws. Where permitted, however, bank branches are numerous in the United States (especially in California and in New York); in states in which branching is prohibited, one often finds local bank monopolies in small towns. Interstate banking is prohibited by federal law, but large banking organizations have provided financial services (*e.g.*, through loan offices and offices of nonbank subsidiaries) for many years across state lines. A number of states have passed limited interstate or reciprocal banking laws, so that banks in other states with similar laws can acquire or merge with local banks. The banking system of the United States would not work without a network of correspondent bank relationships, which are more highly developed there than in any other country.

From the 1970s there was an acceleration in the evolution of U.S. banking patterns. Unregulated financial institutions (and some nonfinancial institutions) moved into traditional banking activities; at the same time, depository institutions began offering a fuller range of financial services. Money-market mutual funds, for example, secured access to open-market interest rates for investors with relatively small amounts of money. Securities firms and insurance companies moved aggressively into providing a range of liquid financial instruments. Likewise, large manufacturing and retail firms moved into the commercial and retail lending businesses—*e.g.*, by acquiring a savings and loan association, a securities brokerage house, an industrial loan company, a consumer banking business, or even a commercial bank. Meanwhile, depository institutions developed a number of new services, most notably the Negotiable Order of Withdrawal (NOW) account, an interest-bearing savings account with a near-substitute for checks. These appeared first in 1972 in New England and after 1980 spread to the whole nation; they were offered both by commercial banks and by thrift institutions. Share drafts at credit unions also became a means of payment, and after 1978 the automatic transfer services of commercial banks permitted savings-account funds to be transferred automatically to cover overdrafts in checking accounts. So-called Super-NOW accounts (with no interest rate ceilings and unlimited checking facilities with a minimum balance) were subsequently introduced, along with money-market deposit accounts, free of interest rate restrictions but with limited checking.

Rapid changes in financial structure and the supply of financial services posed a host of questions for regulators, and, after much discussion, the Depository Institutions Deregulation and Monetary Control Act was passed in 1980. The object was to change some of the rules—many of them obsolete—under which U.S. financial institutions had operated for nearly half a century. The principal objectives were to improve monetary control and equalize more nearly its cost among depository institutions; to remove impediments to competition for funds by depository institutions, while allowing the small saver a market rate of return; and to expand the availability of financial services to the public and reduce competitive inequalities among financial institutions offering them. The major changes were: (1) Uniform Federal Reserve requirements were phased in on transaction accounts (demand deposits, NOW accounts, telephone transfers, automatic transfers, and share drafts) at all depository institutions—commercial banks (whether Federal Reserve members or not), savings and loan associations, mutual savings banks, and credit unions. (2) The Federal Reserve Board was authorized to collect all data necessary for the monitoring and control of money and credit aggregates. (3) Access to the discount window at Federal Reserve banks was widened to include any depository institution issuing transaction accounts or nonpersonal time deposits. (4) The Federal Reserve was to price its services, to which all depository institutions would now have access. (5) Regulation Q, which had long set interest-rate ceilings on deposits, was to be phased out over a six-year period. (6) An attempt was made to grasp the nettle of the state usury laws. (7) NOW accounts were authorized on a nationwide basis and could be offered by all depository institutions. Other services were extended. (8) The permissible activities of thrift institutions were broadened considerably. (9) Deposit insurance at commercial banks, savings banks, savings and loan associations, and credit unions was raised from $40,000 to $100,000. (10) The "truth in lending" disclosure and financial regulations were simplified to make it easier for creditors to comply.

BRANCH BANKING: THE UNITED KINGDOM

If the United States banks can be taken as representative of a unit banking system, the British system is the prototype of branch banking. Its development was linked to the growth of transportation and communications, for otherwise banks cannot clear checks drawn on other banks and effect remittances speedily and efficiently. The Scots favoured branch banking from the very beginning (the Bank of Scotland was founded in 1695), but at first they were not very successful—largely because of poor communications and the difficulty of supplying branches with adequate amounts of coin. Not until after the Napoleonic Wars, when the road system of Scotland had been greatly improved, did branch banking begin to develop vigorously there. As the Industrial Revolution progressed and as the size of businesses increased, the structure of English banking underwent a corresponding change. Greater resources were required for lending, and banks also needed more extensive interconnections in order to provide an increasing range of services. Where banks remained small, they were frequently unable to take the strain of the larger demand; they tended to become overextended and often failed.

The growth in size of banks was also greatly encouraged by legislation that encouraged joint-stock ownership, beginning in 1826. Joint-stock ownership, which reduced the risk to any individual, must be distinguished from limited liability, which did not become widely accepted until the failure of the City of Glasgow Bank in 1878 demonstrated the need for a legal device to protect the stockholder. The early joint-stock banks tended to remain localized in their business interests; it was only gradually (with the spread of limited liability and disclosure of accounts) that amalgamations began to convert the banking system in England and Wales into its highly concentrated modern form. The main movement was completed before World War I, though there was to be a further degree of concentration in the years after World War II. By these means, British banks were able to attract deposits from all parts of the country and to spread the banking risk over a wide range of industries and areas.

HYBRID SYSTEMS

A third group of banking systems differs from the unit banking system of the United States and also from the branch banking systems of countries that have followed the British model (such as Australia, Canada, New Zealand, and South Africa). This group is characterized by the existence of a small number of banks with branches throughout the country, holding a significant part of total deposits, along with a relatively large number of smaller banks that are regional or local in emphasis. Such systems exist in France, West Germany, and India. Japan has a small number of large city banks with branch networks but a larger number of local banks.

France. Banking institutions in France were classified after World War II into three main groups: deposit banks, *banques d'affaires* (or investment banks), and institutions that were either specialized or operated mainly outside France. New banking legislation in 1966 greatly reduced the importance of the distinction between deposit banks and *banques d'affaires*. There was also (1) a further concentration of banking resources, as a result of several large mergers and also of greater financial integration through share-exchange agreements and interlocking directorates, and (2) the conversion of a number of *banques d'affaires* into deposit banks, which hived off their investment interests into separate investment or holding companies.

Integration in France

Further legislation in 1982 nationalized the remaining large and medium-sized banks (36 in all, plus two financial holding companies—those of Indosuez and Paribas); the largest deposit banks had already been nationalized after World War II. Another new law in 1984 abolished the old divisions between the several categories of banks, which

were now defined simply as *établissements de crédit,* able to receive deposits from the public, undertake credit operations (including loans), and provide means of payment. The intention was to move cautiously toward a system of "universal banking." The new law was extended to cover the Caisse Nationale de Crédit Agricole, the *banques populaires,* the *crédit mutuel,* the central organizations of the cooperatives and the savings banks (and thereby institutions affiliated with them), and semipublic institutions like the Crédit Foncier and the Crédit National, but not the Caisse des Dépôts et Consignations nor the central banking institutions.

All of the regional banks and some local banks have branches. The balanced character of the regional economies often provides these banks with a good portfolio of risks; they serve not only a prosperous agriculture but also a number of local industries. Some of the local banks are also very sound institutions, despite their small size.

The survival of a hybrid system in France, despite the long-run trend toward centralization, reflects certain characteristics of French society. These included, until recently, a strong emphasis on small business, together with a preference for individual and personal service. Particularism in some parts of France manifests itself in support for local institutions, and the local banker also often has the advantage of special knowledge of local industries and people, which makes possible the acceptance of risks that the big banks decline.

West Germany. An even more direct conflict between the forces favouring concentration and those working against it may be seen in Germany, where banking grew in the latter part of the 19th century along with industry. The banks were inclined to rely mainly on their own capital resources and did not at first try to attract deposits from the public. Not until 1874 did the Deutsche Bank A.G. begin to seek deposits through offices specially opened for the purpose. This was done to provide cheap finance for traders, the deposits being invested in mercantile bills that were regarded as both safe and liquid. In pursuit of deposits, the banks built up a widespread network of branch offices, which were also used to establish and maintain industrial contacts throughout the country. The unification of Germany in 1871 removed the political obstacles to a more integrated banking system, and the selection of Berlin as the capital made that city the country's financial centre. Four of the largest banks were already established there; the new Reichsbank was set up in 1876. In addition, the larger and more enterprising of the provincial banks were attracted to the capital. The Berlin stock exchange rapidly displaced that of Frankfurt am Main as the country's leading securities market.

The Berlin banks

The Berlin banks extended their influence by developing correspondent relationships and subsequently by acquiring a financial interest in the provincial banks and being represented on their boards. Each of the big Berlin banks came to be associated with a group of provincial banks more or less under its control. At the same time, all of the banks, Berlin and provincial alike, expanded their business by opening branches.

During World War I the degree of centralization increased; by 1918 the big Berlin banks held more than 65 percent of total deposits. In the early 1920s there were amalgamations, and branch systems became much larger. Bank failures and the financial crisis of 1931 resulted in further consolidation until the German banking system was dominated by three giants. But there were countervailing forces. Probably the most important of these was the establishment of publicly owned banking institutions, such as the communal savings banks and their central institutions, the *Girozentralen,* which became of increasing importance after World War II.

West German savings banks, which were permitted to have checks drawn on them from 1909 and which had giro clearing from the 1920s, now offer a wide range of services, especially to lower income groups and smaller businesses. The large commercial banks have concerned themselves more with big business and with wealthy individuals. The savings banks now compete in wholesale banking as well. A number of them, together with their *Girozentralen,* are to all intents and purposes "universal banks," like the Big Three and the larger regional banks. The Big Three (the Deutsche Bank, the Dresdner Bank, and the Commerzbank) remain unchallenged only in stock exchange and foreign banking business.

Of the private bankers, only about a half-dozen are of any size. The bigger private banks are important in the fields of investment and wholesale banking, while the smaller ones flourish in the leading stock-exchange cities, such as Düsseldorf and Frankfurt am Main. Many of these private bankers, however, are not bankers in the true sense; they subsist mainly on stock-exchange transactions, investment services, portfolio management, and insurance and mortgage brokerage. There are also consumer finance institutions, mortgage and other specialist banks, and a large number of cooperatives.

Regional and private banks are often within the sphere of influence of the Big Three. In some cases the latter have a financial interest in these banks, and in some cases they own them. The Big Three also have shares in certain of the private mortgage banks. There are also "cooperation agreements," and a number of mergers have taken place. In these several ways, much more integration exists than appears on the surface. While banking in West Germany remains a hybrid system, a trend toward greater concentration is evident.

India. Until the 1950s, banking in India was carried on by a large number of banks, many of them quite small. India is still primarily an agricultural country, with an economic and social structure based largely on the village. The integration of banking has been impeded by poor communications, by illiteracy, and by the barriers of language and caste. Banking and credit have remained largely in the hands of the so-called indigenous banker and the village moneylender. Although their influence has been greatly reduced in recent years, they still remain important in many an up-country area. The indigenous banker, who is also a merchant, offers genuine banking services: accepting deposits and remitting funds; making loans quickly and with a minimum of formality; and, by means of the *hundi* (a credit instrument in the form of a bill of exchange), financing a still significant, if declining, portion of India's internal trade and commerce.

Problems in the integration of banking in India

Efforts were made to eliminate the moneylender by developing a network of rural credit cooperatives. When progress proved to be slow, a more successful alternative was found in requiring banks to open "pioneer" branches in rural areas. The first branches were those of the semipublic Imperial Bank of India and its nationalized successor, the State Bank of India (and its subsidiaries). Many smaller banks began to disappear, sometimes by merger and sometimes as a result of failure. Between 1952 and 1967 the number of "reporting" banks fell from 517 to 90. Nationalized banks, including the State Bank of India and its seven subsidiaries, the 14 large commercial banks taken over in 1969, and the six additional banks nationalized in 1980, accounted for more than 90 percent of aggregate deposits in commercial banks. Banking services are also provided by chit funds, which accept and pay interest on monthly deposits against which it is possible to draw only by way of loan, and by Nidhis, mutual loan societies that have developed into semibanking institutions but deal only with their member shareholders.

The main path of banking development in India is the expansion of bank branches into the under-banked areas. The authorities have sought to expand the number of branches but to avoid their concentration in the larger towns and cities and, in particular, to provide the rural areas with adequate facilities. The ultimate objective is to encourage the mobilization of deposits on a massive scale throughout the country, a formidable challenge in a country of 575,000 villages, and a stepping up of lending to weak sectors of the economy.

Japan. Banking business in Japan is largely concentrated in the hands of the big banks (some of which are specialized), though a number of small banks still survive. The principal classes of banks are city banks and regional banks, but it should be noted that the distinction has no legal basis, though they are separately supervised.

Both belong to the Federation of Bankers' Associations of Japan. The city banks service mainly manufacturing industry and commerce, particularly the big firms, while the regional banks are based on a prefecture, though some extend their operations into neighbouring prefectures, collecting deposits and lending to local business and smaller firms. The regional banks have city bank correspondents, not only to hold surplus balances but also for assistance in investing their funds, especially in the call-money market. In addition, a city bank may introduce certain of its large customers to a regional bank (*e.g.*, a big company having a local factory). City correspondents in Japan do not, however, provide the wide range of ancillary services common in the United States.

Decline of city banks

Since World War II there has been much stability in Japanese banking, but the city banks have suffered a relative decline in the importance of their business in competition with other institutions, especially the agricultural cooperatives, which attract the larger part of the Treasury's payments on account of government purchases of the rice crop. There has also been a relative increase in the importance of the life insurance companies and the trust funds, which have attracted sizable funds from the general public.

BANKING IN PLANNED ECONOMIES

The Soviet Union. The present-day Soviet banking system was established by the credit reforms of the early 1930s, which centralized practically all short-term credit in the hands of the Gosbank (State Bank, established in 1921). There was much restructuring of banking during succeeding years, mainly to ensure that the system became an effective instrument for carrying out the national economic plan. The Gosbank's control over payments flows was also tightened in order to maintain stability of prices. The activities of the Gosbank are by no means limited to purely financial operations, and it actively controls the implementation of production and financial plans and the spending of wages funds. In addition, it has a monopoly of the note issue and is responsible for putting money into circulation.

Functions of the Gosbank

The Gosbank was originally concerned with the provision of short-term credit; a number of other banks were created to finance capital investment in the socialized economy. Even in the 1930s there was a tendency to consolidate these banking units, and this continued into the postwar period. In 1959 there were further mergers and a reallocation of activity, as a result of which the Stroybank emerged as the credit and financial institution responsible for canalizing state budgetary appropriations and also short- and long-term credits into capital investment in various sectors of the economy. The savings bank system, with 79,000 branches, became part of the Gosbank in 1963. The only other banking institution is the Vneshtorgbank (Bank for Foreign Trade), whose operations were considerably expanded in 1961. Originally concerned mainly with the provision of currency for tourists and diplomatic missions and with remittances from abroad, the Vneshtorgbank came to handle all foreign-exchange transactions, including those relating to trade.

Since the functions of the Stroybank are essentially administrative (supervising the disbursement of funds), the Gosbank is the only domestic bank servicing the cash, credit, and payment needs of a population exceeding 273,000,000. The organization of the Gosbank is as follows:

Organizational structure of the Gosbank

it has a policymaking head office and principal offices in the various Soviet republics. There are also regional offices and a network of 4,500 local branches; the latter are the bank's main points of contact with a variety of economic enterprises, collective farms, and lower level government units. The Gosbank serves the needs of the urban population through its network of branches, which collect rent, taxes, and other compulsory payments and contributions. It maintains a small number of special cash service agencies in large industrial establishments and at construction projects. Seasonal agencies are operated at remote places where large purchases of farm products are made.

In the industrial area, the Gosbank services hundreds of thousands of state enterprises that operate on the basis of cost accounting. Each of these enterprises has its own working capital and prepares a balance sheet and a statement of income; it may borrow regularly or occasionally, depending on its needs. The Gosbank has hundreds of thousands of other customers comprising collective farms, party, trade union, cultural and other organizations, and individuals. The aggregate balances maintained by Gosbank customers are small in comparison with the cash balances held by business and government accounts in the United States.

Transactions of individuals. Although consumer loans are extended by stores rather than by banks, there has also been a rapid increase in the transactions of individuals. This has resulted from rising incomes, an increase in savings, and the provision of facilities for crediting wages to savings accounts and making periodic payments from them. Housing loans and tourism have also been growing in importance. As savings bank offices handle virtually all the accounts and transactions of individuals, the considerable increase in the volume of these transactions was probably the main reason for absorbing the savings bank system into the Gosbank in 1963.

Transactions of collective farms. An even greater problem has been created by the rise in transactions involving the collective farms. Before 1953 the collectives paid in kind for the services performed by the state-owned tractor and farm-machinery stations. Since 1953 these transactions have gradually shifted to payment in cash. As a first step, the tractor and machinery stations were closed down and their equipment sold to the collectives. The farms now had to pay in cash for all machinery and fuel, as well as for building materials, fertilizers, and other supplies. Subsequently, they were enabled to sell their output to the state for money.

Farm labour likewise has come to be remunerated in cash rather than in kind. In 1953 only one-third of the "compensation" for work contributed by members of the collectives was in cash; by 1963 the proportion was nearly three-quarters. In 1965 the flow of money income to the farm population was increased further by the introduction of state pensions for collective farmers. In 1966 it was decided to make minimum monthly payments to the members of collective farms, and this resulted in an even greater use of money in the farm sector.

The growth of money flows and of bank lending in rural areas, as well as the need to service a growing clientele in the villages, greatly added to the complexity of Gosbank operations, which had been geared primarily to the needs of industry and government. The Gosbank attempted to resolve its problems by simplifying payments procedures, through its efforts to work out a system of offsetting mutual claims were not initially very successful.

Interest rates in the U.S.S.R.

After the credit reforms of 1930–32, a uniform system of interest rates was applied to all short-term credits, irrespective of the purpose of the loan or the financial condition of the borrower. Higher rates were charged as a penalty on overdue loans. In the 1960s there was a move to differentiate rates, it being accepted as a matter of principle that bank funds should be more expensive than an enterprise's own working capital and that borrowings made necessary by shortcomings of management (*e.g.*, excessive inventories or the erosion of working capital) should carry higher rates than loans to finance normal needs. Penalty rates for overdue loans and for late payments were also increased, and collection was more vigorously enforced. Today, interest rates in the Soviet economy are seen as an integral part of the relationship between the bank and the enterprises that it both services and regulates.

Yugoslavia. Yugoslavia's banking system is very different from those of non-Communist countries and also from that of the Soviet Union. It derives from basic principles incorporated in the federal constitution. For example, the monetary and credit system is based on "self-management by workers in associated labour working with social resources," and it provides for uniform currency and monetary and foreign-exchange systems.

Until 1971 the central bank, or bank of issue, was the National Bank of Yugoslavia, with its head office in Belgrade and six offices in the main cities of the federal

republics. Following constitutional amendments in 1971, separate National Banks for the republics and the two autonomous provinces were established, and in 1972 a new central system was set up consisting of the National Bank of Yugoslavia and the National Banks for the republics and the autonomous provinces. Under the federal constitution of 1974 and federal laws of 1976, the National Banks have responsibility for regulating the quantity of money, for ensuring the stability of the currency and the general liquidity of payments at home and abroad, for implementing joint monetary and foreign-exchange policy, and for providing the bases of credit policy.

The nine National Banks operate as a uniform central banking system. Integration of the system is carried out though the Council of Governors of the National Bank of Yugoslavia. The Yugoslav concept of central banking thus reflects the federal structure of the nation, accommodating the principle of a single Yugoslav market, within which, however, the republics and the autonomous provinces are responsible for their own development.

Below the level of National Banks, the banking system consists of two types of organizations—the banks proper, and savings–credit organizations. The banks are classified as internal banks, basic banks, and associated banks. The savings–credit organizations include chiefly savings banks. There is also provision for banking consortia and associations.

An internal bank provides a financial nexus between its members such that funds can be transferred from sectors that are in surplus to other sectors which have need of funds. It also attracts savings deposits from workers employed by its members and from the general public; the latter deposits may be earmarked for special purposes. In addition, it may grant consumer credits. An internal bank cannot receive sight deposits. It is managed by its members.

A basic bank may be founded by organizations of associated labour, internal banks, self-managing communities of interest, and other social–legal entities; it is managed by those parties that have entered into a self-management agreement. Basic banks are the only banking organizations that can carry out all credit and banking operations, including the acceptance of sight deposits. Subject to special conditions, these banks can carry out payments and credit operations abroad. In order to maintain adequate liquidity, every such bank must hold a reserve fund with a National Bank; an additional reserve must be held in a separate account with a National Bank. Banks may pool surpluses of liquid resources as well as part of their reserve fund, and they may obtain short-term credits from the pool in order to maintain current liquidity.

The associated banks are the third form of legally constituted banking organization in Yugoslavia. Only basic banks may be members of such a bank. The associated bank carries out operations of common interest to the members of two or more basic banks—*e.g.*, credit operations and payments abroad, and operations of exceptional significance for the development of large economic complexes. The associated bank cannot accept sight deposits in home currency nor carry out operations with the general public. If the associated bank effects payments abroad, it may keep part of the resources of its reserve fund in foreign exchange, thereby ensuring its liquidity abroad.

The Yugoslav Bank of International Economic Cooperation is a specialized banking organization set up under a federal law in 1978. The basic task of the bank is to stimulate expansion of production over the long term and financial cooperation between domestic social–legal entities and foreign parties and joint action in third markets.

Savings banks may be established by organizations of associated labour and other social–legal entities to attract savings deposits and deposits in current and giro accounts from the public, to effect payments, and to grant business, consumer, or house construction or purchase credits to the public. There is also a Post Office Savings Bank, established jointly with the associations of organized labour, that conducts the whole range of savings bank business throughout Yugoslavia. It may grant credits through basic and associated banks and the National Bank of Yugoslavia or directly on the basis of their guarantees. Other savings–credit organizations are savings–credit cooperatives (founded by citizens) and savings–credit services provided by agricultural, artisan, and other cooperatives.

Barcelona

On his visit to the city in 1862, Hans Christian Andersen remarked that Barcelona was the "Paris of Spain." The city is, indeed, a major cultural centre with a remarkable history. The capital of the autonomous region of Catalonia, it abounds with archives, libraries, museums, and buildings of interest, and it contains superb examples of modernist and Art Nouveau decor and architecture. Since the late 1970s, with the official recognition of the Catalan language and the granting of significant levels of self-government, cultural life has been revitalized, bringing a new awareness of the depth and variety of Catalan culture. This vitality combines with the striking physical setting of Barcelona, between scenic mountains and the Mediterranean Sea, its benign climate fostering street life, and its significance as an economic power and a major port, to create a city of infinite variety.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Barcelona, facing the Mediterranean to the southeast, is located on a plain generally confined by the Río Besós and Río Llobregat, the rocky outcrop of Montjuich (630 feet, or 192 metres), and the semicircle of mountains, of which Tibidabo (1,745 feet) is the highest point. Throughout its past Barcelona has had to contend with the consequences of its strategic location and political significance. The city was heavily fortified until relatively recent times and did not spread much beyond its medieval confines until the 19th century, a factor that contributed to the emergence of industrial satellite suburbs and towns around the city proper. This combination of a concentrated core with a highly developed industrial belt has made Barcelona one of the most congested cities in the world.

Climate. Although Barcelona is sometimes windy, its protective semicircle of mountains shields it from the harsh, cold winds that blow out of the north and west. The average annual temperature is 61° F (16° C); January is the coldest month, averaging 49° F (9° C), and August is the hottest, at 76° F (24° C). Precipitation amounts to about 23 inches (600 millimetres) per year.

The Barrio Gótico

The city layout. At the core of the city lies the Barrio Gótico; located between the Ramblas, a series of connected boulevards, and the Via Layetana, it is a close-packed maze of narrow streets, punctuated by magnificent medieval buildings. The cathedral, episcopal palace, and churches bear witness to Barcelona's importance as a religious centre. The government buildings, such as the Palau de la Generalitat, the Casa de la Ciudad (a 14th- and 15th-century building with Baroque and Neoclassical facades), and the Palacio Real Mayor, attest to the city's importance as an administrative capital. The Roman walls survive in places largely because stretches of them were incorporated into the medieval city, and the wall built in the 13th century along the Ramblas effectively hemmed it in. The defenses that played such a large part in the battle for Barcelona during the War of the Spanish Succession (1701–14) were augmented by the construction of a citadel after the city was taken.

City fortifications

By the mid-19th century the need for elaborate defenses had passed, and the city was bursting at the seams. Accordingly, plans were devised to extend the city. The final plans were based on geometric blocks, allowing for open spaces, greenery, and social areas. The area into which the town expanded, now called the Ensanche ("extension"), was open land left originally to give a clear field of fire from the city walls. Unfortunately, the city plan was not carried out completely, and within 30 years the open areas were being exploited, causing the density of buildings to triple. Urban sprawl and uncontrolled speculative development during the Francisco Franco era added to the congestion.

The Ramblas

For the visitor, the main attraction still tends to be in the city centre, particularly around the Ramblas. The famous promenade is separated from the Ensanche by the monumental Plaza de Cataluña, and it leads down to the port and the Plaza Puerta de la Paz, where the Columbus monument stands in commemoration of the discovery of America and the explorer's announcement of it in Barcelona. The Ramblas form one of the most delightful aspects of the city, their broad treelined centre strips given over to a series of stalls and kiosks selling items such as flowers, pets, and books and newspapers.

The skyline of the modern city inevitably reflects the style of the present age, but Barcelona has always attracted distinguished and original architects. Some people find the more modern buildings along the Diagonal quite striking, but little of it can compare with the work of the Catalan sculptor and architect Antonio Gaudí, whose huge and elaborate Templo Expiatorio de la Sagrada Familia has become a symbol of the city itself. He made a number of other notable contributions, including the multistory apartment buildings Casa Batlló and Casa Milá. Other architects, such as Luis Doménechy Montaner, produced remarkable structures in the modernist style, such as the Palacio de la Música.

THE PEOPLE

Immigration has played a key part in the economic growth of the region. Up to 30 percent of the population of modern Barcelona was born outside Catalonia, a condition that has caused some social strain, given the Catalans' firm sense of national identity and their aloof attitude, which is often displayed toward the rest of Spain as a whole. In many respects, however, the city is outward-looking, conscious of cultural trends in the rest of Europe and of its historical links with other Mediterranean countries.

The Catalonian temperament

THE ECONOMY

Industry and trade. Barcelona's industry is relatively up-to-date, and the city has long-established external markets to give it stability. Almost a quarter of Spanish exports come from Catalonia, and three-quarters of Catalan industry is concentrated in the Barcelona area, which provides some 20 percent of Spain's industrial output. The textile

industry, set up in the second half of the 18th century, was the driving force behind the development of other major industries, such as metals and machinery, which overtook textiles in economic importance. The textile industry, however, received some impetus to modernize as a result of the agreement in 1985 for Spain to join the European Communities. Other industrial products include chemicals, pharmaceuticals, cosmetics, and leather goods.

A thriving business community

Commerce and finance. The Catalans are renowned for their business acumen. Emphasis commercially is on small firms, and among the companies registered in Catalonia few have more than 200 people on their payrolls. Nonetheless it has become policy to attract major international investors to the region. The city has a free economic zone near the port, the *zona franca,* where distribution centres are concentrated. Barcelona is a major site for conferences, exhibitions, and trade fairs. The main event, the Feria de Barcelona, has been held annually since 1929 at the Palacio de las Naciones, the exhibition centre on Montjuich. Barcelona's stock exchange is one of the most active in Spain.

Transportation. Public transportation is provided by buses, subways, and surface railways. There are also cable cars. Freeways link Barcelona to the Catalonia highway network, which joins the service up to the Cadí mountain tunnel in the Pyrenees, providing access to the French highway network. The metropolitan subway, opened in 1924, connects with the urban railway and provides regular service to the international airport at Prat de Llobregat, about eight miles southwest of the city. Connections can be made there to major world cities. The port of Barcelona accommodates ships from all parts of the world, as well as providing ferry service to the Balearic Islands and to Genoa in Italy.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Barcelona, the traditional centre of Catalan movements for independence, is the capital of both the province of Barcelona and the autonomous region of Catalonia. The city is governed as a municipality of Spain, and its elections are held every four years. The councillors elect the mayor, who selects three deputies from their number to assist in the duties of the mayor's office.

Services and education. Under the present government services have been decentralized and made more accountable to the public. Electricity is supplied from sources in France as well as elsewhere in Spain, and some hydroelectric power comes from the Pyrenees. Nuclear power plants at Vandellós, in the province of Tarragona, are of particular importance to the city. A receiving terminal for natural gas has been installed in the port to supply a regional distribution network, but most private houses rely on bottled butane gas. With the rapid growth of the population after World War II water supply has become a problem. Local rivers cannot supply both industrial and domestic needs. Some drinking water is drawn off upstream from the Llobregat, but more is provided by the Río Ter in the province of Gerona.

Water shortage

The tradition for higher education in Barcelona goes back to 1430, the year that its major school, the Universidad de Barcelona, was founded. It is one of the country's 22 state universities and one of three universities in the city. The other two are the Universidad Autónoma de Barcelona (1968) and the Universidad Politécnica de Cataluña (1971). Courses in most of the municipality's schools are taught in Spanish and Catalan.

CULTURAL LIFE

Barcelona has long been a major cultural centre. The city abounds in archives and libraries, including dozens of specialized collections, many of which are in private hands. Barcelona is, in fact, one of the major publishing centres for the Spanish-speaking world, and the Fiesta del Libro, held on April 23, is a major event for the book trade. It is also the day of Catalonia's patron saint, St. George.

Publishing centre

The more classical forms of culture are well represented. The Gran Teatro del Liceo, founded in 1847, presents opera and ballet performances; the Teatro Romea has been a focal point of Catalan-language drama since the last century. Classical music is amply provided for by the Palacio de la Música and the city's symphony orchestra. Museums range from the monumental maritime museum, which houses a full-size replica of a galley from the Battle of Lepanto in 1571, to the waxworks museum. Art of past ages is housed in the Museo de Arte de Cataluña (Romanesque and Gothic paintings) and the Federico Marés museum (12th- to 18th-century sculpture), while the Museo de Arte Moderno displays works by contemporary Catalan artists. There are also collections dedicated to famous artists connected with Barcelona, most notably the painters Joan Miró and Pablo Picasso. The Casa de Cervantes commemorates Barcelona's association with the writings of Miguel de Cervantes. Perhaps the most striking feature of culture in Barcelona is its easy availability at many levels—from major art exhibitions at the Palacio de Pedralbes to the pavement artists in the Ramblas. There are amusement parks on Tibidabo and Montjuich and a zoo in the Parque de la Ciudadela.

Museums and art galleries

History

FOUNDATION AND MEDIEVAL GROWTH

According to tradition Barcelona was founded by either the Phoenicians or the Carthaginians, who had trading posts along the Catalonian coast. It is no longer thought, however, that the city owes its name to the family of the Carthaginian leader Hamilcar Barca. In Roman times the Colonia Faventia Julia Augusta Pia Barcino did not become a centre of any real importance until the 3rd century AD. During the three centuries of Visigothic occupation the city was known as Barcinona. It became an important religious centre before the arrival of the Islāmic Moors in AD 717. Barjelūnah, as the Moors called the city, was seen as a prime objective by the Carolingian Franks, who gained control of Barcelona in 801 and, under an appointed count, established the Río Ebro on the edge of

Historical origins

Catalonia as the southerly limit of their power. In 985 the city was sacked by the forces of al-Manṣūr, chief minister of the Umayyad caliphate of Córdoba. The counts of Barcelona consolidated their influence over Catalonia in the 10th and 11th centuries, and after the union of Catalonia and Aragon in 1137 Barcelona grew into a major trading city.

Barcelona, weakened by outbreaks of plague in the 14th century, began to decline when Naples became the capital of the Catalan-Aragonese kingdom in 1442. The advent of the Habsburg monarchy, the rise of Turkish power in the Mediterranean, and the discovery of America all furthered this decline. Relations with the court in Madrid worsened in the 17th century. After 1705, when the Catalans permitted the archduke Charles III of Austria to establish his court in Barcelona, honouring his claim to the Spanish throne during the War of the Spanish Succession, Philip V of Spain besieged Barcelona. After the city fell in 1714, Philip dismantled all forms of local self-government. Ironically, this led to a period of prosperity spurred largely by the development of the cotton industry.

Philip V's capture of the city

THE MODERN CITY

Barcelona found itself occupied again, this time by Napoleon's troops, from 1808 to 1813. The war with the French left the province ravaged, but the postwar period saw the start of modern industrialization. The growth of textiles was to have a twofold effect: it led to the development of a modern industrial sector and to the emergence of Catalonia as Spain's wealthiest region. It also led to rapid population growth through immigration, largely from outside the province, and the development of class conflict between the bourgeoisie and industrial workers. Anarchist movements flourished, and the period up to the Spanish Civil War was punctuated by unrest. Notable incidents included the uprising of 1835 in which a number of convents were burned; the riots in the mid-1850s over the introduction of automated machinery; and the Setmana Tràgica (Catalan: "Tragic Week") in 1909, which led to more church burning.

On a positive note, the exhibition of 1888 attracted 400,000 visitors, and by 1900 nearly half of Spain's imports came via Catalonia. Economic strength led to the reemergence of calls for self-rule, culminating in a period of semiautonomy from 1913 to 1923. In 1931 a Catalan republic was declared in Barcelona. The following year the region attained a significant level of self-government, and it was the main centre of Republican strength when the Civil War broke out in 1936. Its fall in January 1939 led to the final surrender of the republic. Defeat brought the loss of many rights and privileges, and even the Catalan language was prohibited for a time. Only in 1977 was the Generalitat, an autonomous Catalan government, restored. Agreements with the national government, signed in 1979, outlined new areas for self-government and encouraged a wide range of developments in Barcelona.

Autonomy restored

BIBLIOGRAPHY. Among volumes on Barcelona in the series *Enciclopèdia catalana Aedos,* written in Catalan, are AUGUSTÍN DURÁN Y SANPERE *et al., Història de Barcelona* (1975); and PAU VILA DINARÉS and LLUÍS CASSASAS SIMÓ, *Barcelona i la seva rodalia al llargo dels temps* (1974). AUGUSTÍN DURÁN Y SANPERE, *Barcelona i la seva historia,* 3 vol. (1972–75), covers the history, culture, and economic aspects of the city. Later works in English and Spanish tend to include Barcelona within the scope of Catalonia overall, or as part of a broader canvas. A good starting point for geographical research is provided in MONTSERRAT GALERA MONEGAL, *Bibliografía geografica de la ciudad de Barcelona* (1973–), a multivolume work. An informative and well-illustrated article on the city is PASQUAL MARAGALL, "Barcelona," in *Gran enciclopèdia catalana,* vol. 3, pp. 188–225 (1971). ROBERT FERRAS, *Barcelone: Croissance d'une métropole* (1977), is lavishly supplied with charts, maps, and statistical data. Serviceable guidebooks include *All Barcelona,* 4th ed. (1982). For the more informed visitor there are JOSÉ PAMIAS RUIZ (ed.), *Guía urbana de Barcelona,* 2 vol., 22nd ed. (1981–82); BERTRAM STRAUSS and FRANCES STRAUSS, *Barcelona Step by Step* (1974); JAUME FABRE and JOSEP M. HUERTAS, *Tots els barris de Barcelona,* 7 vol. (1976–77). See also ALEXANDRE CIRICI, *Barcelona, City of Art* (1975; originally published in Catalan, 1973).

(T.J.Co.)

Beethoven

A universal genius widely regarded as the greatest composer who ever lived, Ludwig van Beethoven dominates a period of musical history as no one else before or since. Rooted in the Classical traditions of Haydn and Mozart, his art reaches out to encompass the new spirit of humanism expressed in the works of Goethe and Schiller, his elder contemporaries in the world of literature, and above all in the ideals of the French Revolution, with its passionate concern for the freedom and dignity of the individual. He revealed more vividly than any of his predecessors the power of music to convey a philosophy of life without the aid of a spoken text; and in certain of his compositions is to be found the strongest assertion of the human will in all music, if not in all art. Though not himself a Romantic, he became the fountainhead of much that characterized the work of the Romantics who followed him, especially in his ideal of program or illustrative music, which he defined in connection with his *Sixth* (*Pastoral*) *Symphony* as "more an expression of emotion than painting." In musical form he was a considerable innovator, widening the scope of sonata, symphony, concerto, and quartet; while in the *Ninth Symphony* he combined the worlds of vocal and instrumental music in a manner never before attempted. His personal life was marked by a heroic struggle against encroaching deafness, and some of his most important works were composed during the last 10 years of his life when he was quite unable to hear. In an age that saw the decline of court and church patronage, he not only maintained himself from the sale and publication of his works; he was also the first musician to receive a salary with no other duties than to compose how and when he felt inclined.

LIFE AND WORK

The early years. Baptized on December 17, 1770, in Bonn, northwest Germany, Beethoven was the eldest surviving child of Johann and Maria Magdalena van Beethoven. The family was Flemish in origin and can be traced back to Malines. It was Beethoven's grandfather who had first settled in Bonn when he became a singer in the choir of the Archbishop-Elector of Cologne. He eventually rose to become Kappellmeister. His son Johann was also a singer in the electoral choir; thus, like most 18th-century musicians, Beethoven was born into the profession. Though at first quite prosperous, with the death of his grandfather in 1773 and the decline of his father into alcoholism, the Beethoven family became steadily poorer. By the age of 11 Beethoven had to leave school; at 18 he was the breadwinner of the family.

Having observed in him signs of a talent for the piano, Johann had tried to make of his son a child prodigy like Mozart but without success. It was not until his adolescence that Beethoven began to attract mild attention.

When, in 1780, Joseph II became sole ruler of the Holy Roman Empire, he appointed his brother Maximilian Francis as adjutant and successor-designate to the archbishop-elector of Cologne. Under Maximilian's rule, Bonn was transformed from a minor provincial town into a thriving and cultured capital city. A liberal Roman

Beethoven, oil painting by Ferdinand Schimon, 1819. In the Beethoven-Haus, Bonn.

Catholic, he endowed Bonn with a university; limited the power of his own clergy; and opened the city to the full tide of the German literary renaissance, associated with Lessing, Klopstock, and the young Goethe and Schiller. A sign of the times was the nomination as court organist of Christian Gottlob Neefe, a Protestant from Saxony, who became Beethoven's teacher. Although somewhat limited as a musician, Neefe was nonetheless a man of high ideals and wide culture, a man of letters as well as a composer of songs and light theatrical pieces; and it was to be through Neefe that Beethoven in 1783 would have his first extant composition (*Variations on March by Dressler*) published at Mannheim. By June 1782 Beethoven had become Neefe's assistant as court organist.

In 1783 he had also been appointed continuo player to the Bonn opera. By 1787 he had made such progress that Maximilian Francis, archbishop-elector since 1784, was persuaded to send him to Vienna to study with Mozart. The visit was cut short when, after only two months, Beethoven received the news of his mother's death. According to tradition, Mozart was highly impressed with Beethoven's powers of improvisation and told some friends that "this young man will make a great name for himself in the world." For the next five years Beethoven remained at Bonn. To his other court duties was added that of playing viola in the theatre orchestra; and, although the archbishop for the time being showed him no further mark of special favour, he was beginning to make valuable acquaintances. Sometime previously he had come to know the widow of the chancellor, Joseph von Breuning, and she engaged him as music teacher to two of her four children. From then on the Breunings' house became for him a second home, far more congenial than his own. Through Mme von Breuning, Beethoven acquired a number of wealthy pupils. His most useful social contact came in 1788 with the arrival in Bonn of Count Ferdinand von Waldstein, a member of the highest Viennese aristocracy and a music lover. Waldstein became a member of the Breuning circle, where he heard Beethoven play and at once became his devoted admirer. At a fancy dress ball given in 1790, the ballet music, according to the *Almanach de Gotha* (a journal chronicling the social activities of the aristocracy), had been composed by Count Waldstein; but it was generally known that Beethoven had written it for him. The same year saw the death of the emperor Joseph II. Through Waldstein again, Beethoven was invited to compose a funeral ode for soloists, chorus, and orchestra; but the scheduled performance was cancelled because the wind players found certain passages too difficult. He then added to it a complementary piece celebrating the accession of Joseph's brother Leopold II; but there is no record that either was ever performed until the end of the 19th century, when the manuscripts were rediscovered in Vienna and pronounced authentic by Johannes Brahms. But in 1790 another great composer had seen and admired them: that year Haydn, passing through Bonn on his way to London, was feted by the elector and his musical establishment; when shown Beethoven's score, he was sufficiently impressed by it to offer to take Beethoven as a pupil when he returned from London. Beethoven accepted Haydn's offer and in the autumn of 1792, while the armies of the French Revolution were storming into the Rhineland provinces, Beethoven left Bonn, never to return. The album that he took with him (preserved in the Beethoven-Haus in Bonn) indicates the wide circle of his acquaintances and friends in Bonn. The most prophetic of the entries, written shortly after Mozart's death, runs:

> The spirit of Mozart is mourning and weeping over the death of her beloved. With the inexhaustible Haydn she found repose but no occupation. With the help of unremitting labour you shall receive Mozart's spirit from Haydn's hands. (Count Waldstein.)

The compositions belonging to the years at Bonn—excluding those probably begun at Bonn but revised and completed in Vienna—are of more interest to the Beethoven student than to the ordinary music lover. They show the influences in which his art was rooted as well as the natural difficulties that he had to overcome and that his early training was inadequate to remedy. Three piano sonatas written in 1783 demonstrate that, musically, Bonn was an outpost of Mannheim, the cradle of the modern orchestra in Germany, and the nursery of a musical style that was to make a vital contribution to the classical symphony. But at the time of Beethoven's childhood, the Mannheim school was already in decline. The once famous orchestra was, in effect, dissolved after the war of 1778 between Austria and Prussia. The Mannheim style had degenerated into mannerism, which took the form of trivial and often inappropriate experimenting with dynamic contrasts as reflected even in Mozart's *Piano Sonata in C major,* K. 309. The preoccupation with extremes of piano (soft) and forte (loud), often in contradiction to the musical phrasing, is found in Beethoven's early sonatas and in much else written by him at that time—which is not surprising since the symphonies of later Mannheim composers formed the staple fare of the Bonn court orchestra. But what was for Mozart only a deviation from his normal style was to remain a fundamental element in that of Beethoven. The sudden pianos, the unexpected outbursts, the wide leaping arpeggio figures (chord notes played rapidly up or down over several octaves) known as "Mannheim rockets"—all these are central to Beethoven's musical personality and were to help him toward the liberation of instrumental music from its dependence on vocal style. Beethoven may, indeed, be described as the last and finest flower on the Mannheim tree.

Early influences. Like other composers of his generation, Beethoven was subject to the influence of popular music and of folk music, influences particularly strong in the Waldstein ballet music of 1790 and in several of his early songs and unison choruses. Heavy Rhineland dance rhythms can be found in many of his mature compositions; but he could assimilate other local idioms as well—Italian, French, Slavic, and even Celtic. Although never a nationalist or folk composer in the 20th-century sense, he often allowed the unusual contours of folk melody to lead him away from traditional harmonic procedure.

French music impinged on him from two main directions: from Mannheim, whose artistic links with Paris had always been strong; and from the Bonn Nationaltheater, which relied mainly for its repertory on comic operas translated from the French. In fashionable Bonn society, sympathy with the French Revolution was very strong, and the flavour of the French Revolutionary march is present in many of Beethoven's symphonic allegros. The jigging rhythms to be found in several of his scherzos are also clearly of French provenance.

Like all pianists of the late 18th century, Beethoven was raised on the sonatas of Carl Philipp Emanuel Bach, the chief exponent of "expressive" music at a time when music was regarded as the art of pleasing sounds. These sonatas, with their quirks of rhythms and harmony and their occasional wordless recitative, were equally familiar to Haydn and Mozart; but in Beethoven they evoked a much readier

Influence of C.P.E. Bach

response, not only for reasons of temperament, but also because of the intellectual climate in which he himself was reared. The favourite literary fare of the Breunings and their friends was associated with the *Sturm und Drang,* a reaction against the rationalism of the early 18th century, an exaltation of feeling and instinct over reason. Its gospel was enshrined in Goethe's early novel *Die Leiden des jungen Werthers* (*The Sorrows of Werther*), the language of which finds an echo in certain of Beethoven's letters and especially in the "Heiligenstadt Testament" (see below).

In such a movement music took on a new importance as an art of feeling. The sharp conflicts of mood that characterize the sonatas of C.P.E. Bach appear much more powerfully again in Beethoven; to Beethoven "feeling" was as important in practice as it was in theory to his master Neefe, who proclaimed it the only condition of artistic value. All of this does not make Beethoven a Romantic, although Romantics attempted to claim him as one of themselves. His literary world—he read widely and voraciously despite a formal education that in arithmetic had not carried him as far as the multiplication table—was rooted in the German classics, above all Goethe and Schiller. Like them he was to achieve in music a balance of form and emotion that can only be called classical.

The Bonn compositions of most enduring interest date, as might be expected, from the last years: a *Rondino* and an *Octet,* for wind instruments, composed in 1792, probably for the elector's *harmonie* (wind band); a *Trio in G Major for Flute, Bassoon, and Piano* (1791); and the two cantatas. The songs, which were doubtless written under Neefe's inspiration, show no great feeling for the solo voice. This is strange in one whose father and grandfather both had been singers, but it remained a limitation that pursued Beethoven throughout his career. Of particular interest are 24 variations on a theme by Vincenzo Righini, an Italian composer, which, like the *String Trio in E Flat Major,* Opus 3, Beethoven revised and then published at a much later date. These variations, representing a compendium of Beethoven's piano technique, for a long time were to serve as the mainstay of his repertory in the salons of Vienna.

Beethoven as pianist

Vienna. Before Beethoven left Bonn he had acquired a very considerable reputation in northwest Germany as a piano virtuoso, with a particular talent for extemporization. Mozart had been one of the finest improvisers of his age; by all accounts Beethoven surpassed him. In the age of sensibility he could move an audience to tears more easily than any other pianist of the time. For this reason especially he was taken up by the Viennese aristocracy almost from the moment he set foot in Vienna. Count Waldstein had, of course, prepared the way with his talk of a successor to Mozart; and it is significant that Beethoven's earliest patrons in Vienna were Baron van Swieten and Prince Karl Lichnowsky, who alone among the aristocracy had remained Mozart's supporters until his death. In the Vienna of the 1790s, music had become more and more the favourite pastime of a cultured aristocracy, for whom politics under the reactionary emperor Francis II were now discreditable and dangerous and who had, moreover, never shown a like appreciation of any of the other fine arts. Many played instruments themselves well enough to be able to take their place beside professionals. Probably at no other time and in no other city was there such a high standard of amateur and semiprofessional music making as in the Vienna of Beethoven's day.

As a composer, however, Beethoven still had many technical problems to overcome, and it soon became clear that Haydn was not the best person to help him. Outwardly their relations remained cordial; but Beethoven soon began taking extra lessons in secret. One of his teachers was the organist of St. Stephen's Cathedral, Johann Georg Albrechtsberger, a learned contrapuntist of the old school who equipped him with the comprehensive technique that he needed. He also studied vocal composition with Antonio Salieri, the imperial Kappellmeister. By 1794, when Haydn had left for his second visit to London, there was no longer any question of Beethoven's returning to Bonn, which was then in French hands. The elector himself had left, and consequently Beethoven's subsidy came to an end. But he had no need to worry for, apart from what he was able to earn by teaching and playing, he received free board and lodgings from Prince Lichnowsky. The year 1795 marked Beethoven's first public appearance as a pianist in Vienna. He played a concerto (No. 2, Opus 19) of his own and one by Mozart and also took part in a benefit concert for Haydn. More important still, his *Three Trios for Piano, Violin and Cello,* Opus 1, were published with a long list of aristocratic subscribers. In the next three years he undertook concert tours in Berlin and Prague and might have travelled more widely still had the international situation permitted. In 1800 he launched a public concert on the grand scale, in which one of his own piano concerti, the *Septet* (Opus 20), and *First Symphony* were given, together with works by Haydn and Mozart. The event did much to spread Beethoven's fame abroad.

The turn of the century concluded what is generally referred to as Beethoven's first period, a period during which his art stayed within the bounds of 18th-century technique and ideas. Most of his published works during that time are for the piano, alone or with other instruments, important exceptions being the *String Trio in E Flat Major,* Opus 3; the *Three String Trios,* Opus 9; the *Six String Quartets,* Opus 18; and the *First Symphony.* Beethoven extended his range slowly and methodically, but he was still a piano composer par excellence.

The "Heiligenstadt Testament"

Approaching deafness. The change in direction occurred with Beethoven's gradual realization that he was becoming deaf. The first symptoms had appeared even before 1800, yet for a few years his life continued unchanged: he still played in the houses of the nobility, in rivalry with other pianists, and performed in public with such visiting virtuosos as violinist George Bridgetower (to whom the *Kreutzer Sonata* was originally dedicated). But by 1802 he could no longer be in doubt that his malady was both permanent and progressive. During a summer spent at the (then) country village of Heiligenstadt he wrote the "Heiligenstadt Testament." Ostensibly intended for his two brothers, the document begins:

> O ye men who think or say that I am malevolent, stubborn or misanthropic, how greatly do you wrong me. You do not know the cause of my seeming so. From childhood my heart and mind was disposed to the gentle feeling of good will. I was ever eager to accomplish great deeds, but reflect now that for six years I have been in a hopeless case, made worse by ignorant doctors, yearly betrayed in the hope of getting better, finally forced to face the prospect of a permanent malady whose cure will take years or even prove impossible.

He was tempted to take his own life, "But only Art held back; for, ah, it seemed unthinkable for me to leave the world forever before I had produced all that I felt called upon to produce. . . ." There is a Werther-like postscript:

> As the leaves of autumn wither and fall, so has my own life become barren: almost as I came, so I go hence. Even that high courage that inspired me in the fair days of summer has now vanished.

More significant, perhaps, are his words in a letter to his friend Franz Wegeler: "I will seize fate by the throat. . . ." Elsewhere he remarks, "If only I were rid of my affliction I would embrace the whole world." He was to do both, though the condition he hoped for was not fulfilled.

From then on his days as a virtuoso were numbered. Although it was not until about 1819 that his deafness became total, making necessary the use of those conversation books in which friends wrote down their questions while he replied orally, his playing degenerated as he became able to hear less and less. He continued to appear in public from time to time, but most of his energies were absorbed in composing. He would spend the months from May to October in one or another of the little villages near Vienna. Many of his musical ideas came to him on long country walks and were noted in a sketchbook.

Beethoven's sketchbooks

These sketchbooks, many of which have been preserved, reveal much about Beethoven's methods of work. The man who could improvise the most intricate fantasies on the spur of the moment took infinite pains in the shaping of a considered composition. In the sketchbooks such famous melodies as the adagio of the *Emperor Concerto* or the andante of the *Kreutzer Sonata* can be seen emerging

from a trivial and characterless beginning into their final form. It seems, too, that Beethoven worked on more than one composition at a time and that he was rarely in a hurry to finish anything that he had on hand. Early sketches for the *Fifth Symphony,* for instance, date originally from 1804, although the finished work did not appear until 1808. Sometimes the sketches are accompanied by verbal comments as a kind of *aide-mémoire.* Sometimes, as in the sketching of the *Third* (*Eroica*) *Symphony,* he would leave several bars blank, making it clear that the rhythmic scheme had preceded the melodic in his mind. Many of the sketches consist merely of a melody line and a bass—enough, in fact, to establish a continuity. But in many works, especially the later ones, the sketching process is very elaborate indeed, with revisions and alterations continuing up to the date of publication. If, in general, it is only the primitive sketches and jottings that have survived, this is because Beethoven kept them beside him as potential sources of material for later compositions. The working out of a musical composition in all its detail ceased to interest him once the piece had been completed.

Beethoven and the theatre. The next few years were those of Beethoven's short-lived connection with the theatre. In 1801 he had provided the score for the ballet *Die Geschöpfe des Prometheus* (*The Creatures of Prometheus*). Two years later he was offered a contract for an opera on a classical subject with a libretto by Emanuel Schikaneder, who had achieved fame and wealth as the librettist of Mozart's *Magic Flute* and who was then impresario of the Theater an der Wien. Two or three completed numbers show that Beethoven had already begun work on it before Schikaneder himself was ousted from the management and the contract annulled—somewhat to Beethoven's relief, as he had found Schikaneder's verses "such as could only have proceeded from the mouths of our Viennese applewomen." When the new management re-engaged Beethoven the following year, it was largely on the strength of his now almost forgotten oratorio, *Christus am Ölberg* (*Christ on the Mount of Olives*), which had been given in an all-Beethoven benefit concert, together with the first two symphonies and the *Third Piano Concerto.* The year 1804 was to see the completion of the *Third Symphony,* regarded by most biographers as a landmark in Beethoven's development. It is the answer to the "Heiligenstadt Testament": a symphony on an unprecedented scale and at the same time a prodigious assertion of the human will. The work was to have been dedicated to Napoleon, one of Beethoven's heroes, but Beethoven struck out the dedication on hearing that Napoleon had taken the title of emperor. Outraged in his republican principles, he later substituted the words "for the memory of a great man." From then on the masterworks followed hard on one another's heels: the *Piano Sonata in F Minor,* Opus 57, known as the *Appassionata;* the *Piano Concerto No. 4 in G Major,* Opus 58; the three *Razumovsky Quartets,* Opus 59; the *Fourth Symphony,* Opus 60; the *Violin Concerto,* Opus 61. To this period also belongs his one opera, *Fidelio,* commissioned for the winter season of 1805. The play concerns a wife who disguises herself as a boy in order to rescue her imprisoned husband, and, in setting this to music, Beethoven was influenced by Paer and by Luigi Cherubini, composer of similar "rescue" operas and a musician whom he greatly admired. *Fidelio* enjoyed no great success at first, partly because the presence of French troops, who had occupied Vienna after the Battle of Austerlitz, kept most of the Viennese away. With great difficulty Beethoven was persuaded to make certain changes for a revival in the following spring, with modified libretto. This time the opera survived two performances and would have run longer, but for a quarrel between Beethoven and the management, after which the composer in a fury withdrew his score. It was not until eight years later that *Fidelio,* heavily revised by Beethoven himself and a new librettist, returned to the Vienna stage, to become one of the classics of the German theatre. Beethoven later turned over many other operatic projects in his mind but without bringing any to fruition.

Mature masterpieces

The established composer. During all this time, Beethoven, like Mozart, had maintained himself without the benefit of an official position—but with far greater success insofar as he had no family to support. His reputation as a composer was steadily soaring both in Austria and abroad. The critics of the Leipzig *Allgemeine musikalische Zeitung,* the most authoritative music journal in Europe, had long since passed from carping impertinence to unqualified praise, so that, although there were as yet no copyright laws to ensure a system of royalties, Beethoven was able to drive far more favourable bargains with the publishing firms than Haydn and Mozart before him or Schubert after him. Despite the restrictions on Viennese musical life imposed by the war with France, Beethoven had no difficulty in getting his most ambitious works performed, largely because of the generosity of such patrons as Prince Lichnowsky, who at one point made him a regular allowance of 600 florins a year. Others would pay handsomely for a dedication; *e.g.,* Count Oppersdorf, for the *Fourth Symphony.* Also, Beethoven's pupils included the archduke Rudolf, youngest brother of the emperor. Consequently, poverty was never a serious threat. But, doubtless because of increasing deafness combined with a habitual readiness to take offense, Beethoven's relations with the Viennese musicians, on whose cooperation he depended, became steadily worse; and in 1808, at a benefit concert where the *Fifth* and *Sixth* symphonies were first performed, together with the *Choral Fantasia,* Opus 80, there occurred a quarrel so serious that Beethoven thought of leaving Vienna altogether. But the threat of his departure was sufficient to stir his patrons into action. The archduke Rudolf, Prince Lobkowitz, and Prince Kinsky banded together to provide him with an annuity of 4,000 florins, requiring only that he should remain in Vienna and compose. The agreement remained in force until Beethoven's death, though it was to be affected by circumstances, one of which was the devaluation of 1811; although the Archduke increased his contribution accordingly, it was some time before his partners could do the same. Nevertheless, from 1809 onward Beethoven remained adequately provided for, although his habits of life often gave visitors the impression that he was miserably poor. Inevitably, his public appearances became less frequent.

Beethoven and his patrons

Beethoven and women. In this period, too, he considered more seriously than before the idea of marriage. As early as 1801, letters to his friend Wegeler refer to "a dear sweet girl who loves me and whom I love." This is thought to have been the Countess Giulietta Guicciardi, a piano pupil and the cousin of two other pupils, Therese and Josephine, daughters of Count von Brunsvik. It was to the Countess Giulietta that he dedicated the *Piano Sonata in C Sharp Minor,* Opus 27, No. 2, known as the *Moonlight Sonata.* But Giulietta married Count Gallenberg in 1803, and in later years Beethoven seems to have remembered her only with mild contempt. It seems clear, however, that he did propose marriage to her cousin Josephine, whose elderly husband, Count von Deym, died in 1804; and the understanding appears to have continued for about three years, until it was brought to an end partly by Beethoven's own indecisiveness and partly by pressure from Josephine's family. The prospective bride of 1810 is thought to have been Therese Malfatti, daughter of one of Beethoven's doctors, but, like the other marriage projects, this, too, lapsed, and Beethoven remained a bachelor. A curious item, however, was found among his effects, locked away in a drawer, at the time of his death: three letters, written but never sent, to the "Immortal Beloved." The content, which varies from high-flown poetic sentiments to banal complaints about his health and discomfort, makes it clear that this is no literary exercise but was intended for a real person. The month and day of the week are given, but not the year. The periods 1801–02, 1806–07, and 1811–12 have been proposed, but the last is the most probable. The identity of the person addressed is uncertain.

Wider recognition. In 1810 E.T.A. Hoffmann in Berlin produced an appreciation of the *Fifth Symphony,* which undoubtedly did much to launch that work on its triumphant career throughout the world and, above all, to interest the Romantics in its composer. The same year, Beethoven made the acquaintance of the writer Bettina

Brentano, the sister of the German poet and novelist Clemens Brentano and, later, wife of Achim von Arnim, the two compilers of the famous collection of German folk poetry, *Des Knaben Wunderhorn.* Of the letters that Bettina gave out as having been written to her by Beethoven, only one can be accepted as genuine; at least one of the others, in which the composer is made to philosophize on music in the most uncharacteristically romantic terms, must be dismissed as spurious. Bettina also performed the questionable service of bringing together Beethoven and Goethe at Teplitz in 1812. The admiration had been all on Beethoven's side; to Goethe, Beethoven was little more than a famous name. The meeting was not a success. "Goethe is too fond of the atmosphere of the courts," Beethoven wrote to Breitkopf and Härtel, the music publishers, "more so than is becoming to a poet. . . ." Goethe considered Beethoven to be "an utterly untamed personality, who is not altogether in the wrong in holding the world to be detestable, but surely does not make it any the more enjoyable either for himself or for others by his attitude." He showed a certain interest in the incidental music written in 1810 for *Egmont* "out of pure love for the subject."

Meeting with Goethe

The chief compositions of 1811–12 were the *Seventh* and *Eighth* symphonies, the first of which had its premiere in 1813. Another novelty at the same concert was the so-called *Battle Symphony,* written to celebrate Arthur Wellesley's (later duke of Wellington) decisive victory over Joseph Bonaparte at Vitoria. Composed originally for a mechanical musical instrument, the Panharmonicon, invented by J.N. Maelzel, Beethoven later scored the work for orchestra. He frankly admitted it was program music of the worst kind, so different from the ideals of "mehr Ausdruck der Empfindung als Malerei" ("more as an expression of feeling than painting") expressed in his own *Pastoral Symphony;* but in view of its success he was ready enough to score it for orchestra and even to send a copy of the score to the English prince regent, who, much to Beethoven's annoyance, made no acknowledgment. The concert, profitable as it was for the composer, led to a bitter quarrel with Maelzel, from which Beethoven emerged with little credit.

Despite the difficulties over the annuity caused by the devaluation of 1811, the years 1813–14 were profitable ones for Beethoven. The first performance of the *Seventh Symphony* was a huge success, and the audience insisted on the allegretto being repeated. When the Congress of Vienna assembled in 1814, Beethoven's music was universally known, and he himself was courted by the crowned heads of Europe. *Fidelio* was revived with tumultuous success, and Beethoven celebrated the fall of France with a grand patriotic cantata, *Der glorreiche Augenblick* (*The Glorious Moment*). In 1814, after years of war, Vienna was to enjoy a brief hour of glory before the Austrian economy collapsed and the city sank into a state of dowdy provincialism that lasted for nearly 40 years.

The last years. With the start of Metternich's long reign and the so-called Biedermeier period, marked by simplicity and homeliness in art and design, Beethoven's creative life entered its third and final phase. Because of his deafness he became more of a recluse than ever. His rate of composition, too, began to decrease. The works written between 1815 and 1827 comprise a mere fraction of his output after 1792; but they have a density of musical thought far surpassing anything that he had composed before. Though he now went less into society, he concerned himself more and more with business matters, not always with happy results.

At about this time he was brought in touch with the Philharmonic Society of London. Earlier, in 1803, he had been approached by the Edinburgh publisher George Thomson with a proposal that he should write sonatas based on Scottish folk tunes. Although nothing came of this, Thomson somewhat later succeeded in contracting him to arrange national folk melodies for voice, violin, cello, and piano, each with an introduction and coda. These remained an easy and profitable source of income to Beethoven for many years. It was in 1815, however, when Beethoven's pupil Ferdinand Ries settled in London and became one of the founder-members of the Philharmonic Society, that English music lovers began to take an active interest in the promotion of Beethoven's works. Another society member, Charles Neate, visited Beethoven in Vienna and later brought about the commission of three new overtures to be performed by the society. The overtures *König Stephan, Namensfeier,* and *Die Ruinen von Athen* were, however, late in arriving, and the discovery that they were not new, after all, caused considerable bad feeling; for a time, relations became strained on both sides. Ries did much to effect a reconciliation, but a visit to London, planned as early as 1813, never materialized, though Beethoven continued to hope that it would. The Philharmonic Society never ceased to interest itself in Beethoven's music and it undoubtedly played an important part in the genesis of the *Ninth Symphony,* which in a sense it commissioned. The society's archives contain an autograph of the first movement with a dedication by the composer. The first performance of the work was not, however, given in London but in Vienna, and the printed edition was dedicated to Frederick William III, king of Prussia. Beethoven, on his deathbed, received from the society a gift of £100, which moved him profoundly.

Commissions from England

In 1815 all prospects of foreign travel were cut short for Beethoven by the death of his brother Caspar Anton Carl, who left a widow, Johanna, and a son, Karl, aged nine. The will, which appointed Beethoven and the widow as joint guardians, was contested by Beethoven on the grounds of the widow's immorality; and after three years of litigation he won his case. But, for all the affection that he lavished on young Karl, Beethoven was far from being an ideal guardian. Quarrels between uncle and nephew were frequent and bitter and came to a head in 1826 when, just before sitting for his university examination, Karl attempted suicide. He recovered in a hospital, and Beethoven, on the advice of friends, agreed reluctantly that the boy should be launched on an army career. Once away from his uncle, Karl seems to have led a successful, law-abiding life. But the events of 1826 upset Beethoven profoundly and almost certainly hastened his death.

The important compositions of the final period begin with the *Two Sonatas for Piano and Cello,* Opus 102, the *Piano Sonata in A Major,* Opus 101, and the *Piano Sonata in B Flat Major,* Opus 106, the latter known as the *Hammerklavier.* Beethoven then reverted to sketches he had begun for the *Ninth Symphony.* This was broken off when the news came that the archduke Rudolf was to be appointed archbishop of Olmütz, and Beethoven decided to write a large-scale solemn mass for the installation ceremony. Work on this progressed slowly, and, like the early cantata for Joseph II, it was not completed in time for the intended occasion. Not until 1823, three years after the enthronement, was Beethoven able to send to the new archbishop the completed manuscript of the *Missa Solemnis.*

Late masterworks

In the meantime, Beethoven had written the three final piano sonatas (1820–22) and had worked desultorily on the symphonic sketches. The mass was followed by his last important piano work (completed 1823), variations on a theme that the publisher and composer Anton Diabelli had sent to a number of composers, Beethoven among them. Most of them, including Schubert and the archduke Rudolf himself, obliged; Beethoven at first declined, then changed his mind and decided to write a complete set of 33 variations himself.

The *Ninth Symphony* had begun to take shape; by the following year (1824) it was finished and was performed, together with movements from the *Missa Solemnis* and the overture from Opus 124, with great success at the Kärntnertor Theatre. The composer, who conducted the symphony's premiere, remained unaware of the applause until one of the soloists made him turn to face the audience. The *Ninth Symphony* was Beethoven's last work for large-scale forces. His final commission came in 1823 from Prince Nikolas Galitzin, who offered 50 ducats each for three string quartets. Beethoven accepted with alacrity, though only in 1825 was the first of the three, the *String Quartet in E Flat Major,* Opus 127, completed. Not two but four more followed, including an extra movement,

which was substituted for the original fugal finale (*Grosse Fuge*) of the *String Quartet in B Flat Major,* Opus 130. The last quartet was finished in 1826, about the time of Karl's attempted suicide. Beethoven spent that summer on the estate belonging to his surviving brother, Nikolaus Johann. On his return to Vienna he contracted pneumonia, from which he never fully recovered. He remained bedridden and died from cirrhosis of the liver in Vienna on March 26, 1827. The funeral three days later was attended by 20,000 people. Pallbearers included the famous pianist Hummel; Schubert was among the torchbearers; Franz Grillparzer, Austria's greatest living dramatist, wrote the funeral oration.

Death

REPUTATION AND INFLUENCE

Beethoven's achievement. Beethoven's greatest achievement was to raise instrumental music, hitherto considered inferior to vocal, to the highest plane of art. During the 18th century, music, being nonimitative, was ranked below literature and painting. Its highest manifestations were held to be those in which it had the aid of a text—that is, cantata, opera, and oratorio—the sonata and the suite being relegated to a lower sphere. A number of factors combined to bring about a gradual change of outlook: the instrumental prowess of the Mannheim Orchestra, which made possible the development of the symphony; the reaction on the part of writers against pure rationalism in favour of feeling; and the works of Haydn and Mozart. But, above all, it was the example of Beethoven that made possible the late-Romantic dictum of the English essayist and critic Walter Pater: "All arts aspire to the condition of music."

After Beethoven it was no longer possible to speak of music merely as "the art of pleasing sounds." His instrumental works combine a forceful intensity of feeling with a hitherto unimagined perfection of design. He carried to a further point of development than his predecessors all the inherited forms of music (with the exception of opera and song), but particularly the symphony and the quartet. In this he was the heir of Haydn rather than of Mozart, whose most striking achievements lie more in opera and concerto.

Three periods of work. It was his biographer Wilhelm von Lenz who first divided Beethoven's output into three periods, omitting the years of his apprenticeship in Bonn. The first period begins with the completion of the *Three Trios for Piano, Violin and Cello,* Opus 1, in 1794, and ends about 1800, the year of the first public performance of the *First Symphony* and the *Septet.* The second period extends from 1801 to 1814, from the *Piano Sonata in C Sharp Minor* (*Moonlight*) to the *Piano Sonata in E Minor,* Opus 90. The last period runs from 1814 to 1827, the year of his death. Though the division is a useful one, it cannot be applied rigidly. A composition begun in one period may often have been completed in another, hence the existence of such transitional works as the *Third Piano Concerto* and the *Second Symphony,* which belong partly to the first period and partly to the second. Again, the tide of Beethoven's maturity advanced at a rate that varied according to his familiarity with the medium in which he happened to be writing. The piano was his home ground; therefore, it is in the piano sonatas that the middle-period characteristics first make their appearance, even before 1800. The mass, on the other hand, was unfamiliar territory, so that the *Mass in C Major,* written during the same period as the *Fourth Piano Concerto* and the Razumovsky string quartets, sounds in many ways like an early work.

First period. Apart from the *First Symphony* and first two piano concerti, the works of the first period consist entirely of chamber music, most of it based on Beethoven's own instrument, the piano. All show a preoccupation with craftsmanship in the 18th-century manner. The material, for the most part, has a family likeness to that of Haydn and Mozart but, in keeping with the contemporary style, is slightly coarser and more blunt. Beethoven's treatment of the forms in current use is usually expansive. The expositions are long and polythematic; the developments are relatively short. Slow movements are long and lyrical with copious decoration. The third movement, though sometimes called a scherzo, remains true to its minuet origins, though its surface is often disturbed by unminuet-like accents. Finales are at once high-spirited and elegant. Two characteristics, however, mark Beethoven out strongly from other composers of the time: one is an individual use of contrasted dynamics and especially the device of crescendo leading to a sudden piano; the other, most noticeable in the piano sonatas, is the gradual infiltration of techniques derived from improvisation—unexpected accents, rhythmic ambiguities designed to keep the audience guessing, and especially the use of apparently trivial, almost senseless material from which to generate a cogent musical argument.

Use of dynamics and improvisation

Second period. The second period may be said to begin in the piano music with two sonatas "quasi una fantasia," Opus 27, of 1801, but in the symphony and concerto it is not fully apparent before the *Eroica* (1804) and the *Fourth Piano Concerto* (1806). Here the use of improvisatory material is more and more marked; but, whereas in the earlier period Beethoven was more concerned to show how it could fit naturally into a traditional 18th-century framework, here he explores in greater detail the logical implication of every departure from the norm. His harmony remains basically simple—much simpler, for instance, than much of Mozart's; what is new is the way it is used in relation to the basic pulse. From this Beethoven creates in his main themes an infinite variety of stress and accent, out of which the form of each movement is generated. The result is that, of all composers, Beethoven is the least inclined to repeat himself; all his works, but especially those of the middle and late period, inhabit their own individual formal world. Other characteristics of the middle period include shorter expositions and longer developments and codas; slow movements, too, become much shorter, sometimes vanishing altogether. The third movement is now always a scherzo, not a minuet, with frequent use of unexpected accents and syncopation. Finales tend to take on much more weight than before and in certain cases become the principal movement. Decoration begins to disappear as each note becomes more functional, melodically and harmonically. Another feature of these works is their immediacy. Here Beethoven's power is most evident; and the majority of the repertory works belong to this period.

Third period. The third period is marked by a growing concentration of musical thought combined with an increasingly wider range of harmony and texture. Beethoven's enthusiasm for Handel began to bear fruit in a much more thoroughgoing use of counterpoint. But he never lost touch with the simplicity of his earliest manner, so that the range of expression and mood in these last works is something that has never been surpassed. A form to which he gave more and more attention at this time was that of the variation. As an improviser he had always found it congenial, and, though some of the sets he had published in earlier years are merely decorative, he had created such outstanding examples of the genre as the finale of the *Eroica* and the *Prometheus* variations, both on the same theme. It is this type of variation that Beethoven began to pursue in his final period. A unique feature of the sets that occur in his last string quartets and sonatas is the sense of cumulative growth, not merely from variation to variation but within each variation itself. In the quartets, everything in the composer's musical equipment is deployed—fugue; variation; dance; sonata movement; march; even modal and pentatonic, or five-tone, melody.

Use of variations

Structural innovations. Beethoven remains the supreme exponent of what may be called the architectonic use of tonality. In his greatest sonata movements, such as the first allegro of the *Eroica,* the listener's subconscious mind remains oriented to E-flat major even in the most distant keys, so that when, long before the recapitulation, the music touches on the dominant (B flat), this is immediately recognizable as being the dominant. Of his innovations in the symphony and quartet, the most notable is the replacement of the minuet by the more dynamic scherzo; he enriched both the orchestra and the quartet with a new range of sonority and variety of texture.

The same is true of the concerto, in which, strictly

speaking, he introduced no formal innovations, the entry of solo instrument before an orchestral ritornello in the *Fourth* and *Fifth* piano concerti having been already anticipated by Mozart. Although, in the finale of the *Ninth Symphony* and the *Missa Solemnis,* Beethoven shows himself a master of choral effects, the solo human voice gave him difficulty to the end. His many songs form, perhaps, the least important part of his output. His one opera, *Fidelio,* owes its pre-eminence to the excellence of the music, rather than to any real understanding of the operatic medium. But even this lack of vocal sense could be made to bear fruit, in that it set his mind free in other directions. A composer such as Mozart or Haydn, whose conception of melody remained rooted in what could be sung, could never have written anything like the opening of the *Eroica,* in which the melody takes shape from three instrumental strands each giving way to the other. Wagner was not far wrong when he hailed Beethoven as the discoverer of instrumental melody.

Influence on piano music

Beethoven holds an important place in the history of the piano. In his day, the piano sonata was the most intimate form of chamber music that existed—far more so than the string quartet, which was often performed in public. For Beethoven, the piano sonata was the vehicle for his most bold and inward thoughts. He did not anticipate the technical devices of such later composers as Chopin and Liszt, which were designed to counteract the percussiveness of the piano, partly because he himself had a pianistic ability that could make the most simply laid-out melody sing; partly, too, because the piano itself was still in a fairly early stage of development; and partly because he himself valued its percussive quality and could turn it to good account. Piano tone, caused by a hammer's striking a string, cannot move forward, as can the sustained, bowed tone of the violin, although careful phrasing on the player's part can make it seem to do so. Beethoven, however, is almost alone in writing melodies that accept this limitation, melodies of utter stillness in which each chord is like a stone dropped into a calm pool. Beethoven was less successful in combining the piano with one other instrument, and his duo sonatas remain on a slightly lower level. But it is above all in the piano sonata that the most striking use of improvisatory techniques as an element of construction is found. Among later composers it was chiefly Liszt who extended Beethoven's principle of transferring structural weight from the first movement to the finale, making it the basis of his symphonic poems as well as of his two concertos. The two works of Beethoven that undoubtedly had most influence over succeeding generations were the *Fifth* and *Ninth* symphonies, with their progression from storm and stress to triumph. Brahms' *Symphony No. 1 in C Minor,* Tchaikovsky's *Symphony No. 5 in E Minor,* César Franck's *Symphony in D Minor,* and Mahler's *Symphony No. 2 in C Minor* are all examples of Beethoven's spiritual progeny, though few will grant that they equal, let alone surpass, their models.

MAJOR WORKS

Orchestral music

SYMPHONIES: *No. 1 in C Major,* op. 21 (1800); *No. 2 in D Major,* op. 36 (1802); *No. 3 in E Flat Major,* op. 55 (*Eroica;* 1804); *No. 4 in B Flat Major,* op. 60 (1806); *No. 5 in C Minor,* op. 67 (1808); *No. 6 in F Major,* op. 68 (*Pastoral;* 1808); *No. 7 in A Major,* op. 92 (1812); *No. 8 in F Major,* op. 93 (1812); *No. 9 in D Minor,* op. 125 (*Choral;* 1824). *Wellington's Victory,* op. 91 (also known as *The Battle of Vitoria* and the *Battle Symphony;* 1813).

CONCERTI: (PIANO): *"No. 1" in C Major,* op. 15 (1798), *"No. 2" in B Flat Major,* op. 19 (in fact composed first 1795, revised 1798); *No. 3 in C Minor,* op. 37 (1800); *No. 4 in G Major,* op. 58 (1806); *No. 5 in E Flat Major,* op. 73 (*Emperor;* 1809). (VIOLIN): *Violin Concerto in D Major,* op. 61 (1806); *Triple concerto in C Major,* op. 56 (violin, cello, piano; 1804).

OTHER ORCHESTRAL COMPOSITIONS: 2 romances for violin and orchestra; various overtures, including *Coriolan,* op. 62 (1807); *Leonore No. 1,* op. 138, *2,* op. 72A and *3,* op. 72B.

Chamber music

STRING QUARTETS: No. 1–6, op. 18 (1798–1800); No. 1-3, op. 59 (*Razumovsky;* 1806); op. 74 (*Harp* 1809); op. 95 (1810); and the late quartets (1824–26); op. 127, 130, 131, 132, 133 (*Grosse Fuge,* originally the finale to 130) and op. 135.

OTHER CHAMBER WORKS: *Octet,* op. 103 (winds; 1792); *Septet* (strings and wind; 1800); *Sextet for Horns and String Quartet,* op. 81B (1795); *Quintet for Piano and Winds,* op. 16 (1796); *String Quintet in C Major,* op. 29 (1801); 7 piano trios; 5 string trios; 10 sonatas for violin and piano, including *Sonata in A Major (Kreutzer;* 1803); 5 sonatas for cello and piano; sonata for horn and piano.

Piano music

32 sonatas, including *Sonata in C Sharp Minor,* op. 27, no. 2 (*Moonlight;* 1801); and *Sonata in F Minor,* op. 57 (*Appassionata;* 1804); 3 sets of Bagatelles; 20 sets of variations; 4 rondos.

Vocal music

Missa Solemnis (mass in D major; 1823); *Mass in C Major,* op. 86 (1807); *Christus am Ölberg* (oratorio 1803); various smaller works for chorus and orchestra including *Choral Fantasia,* op. 80 for piano, chorus, and orchestra (1808); songs, including the cycle *An die ferne Geliebte,* op. 98 (1816), and Goethe and Gellert settings; Scottish, Irish, and Welsh folk-song settings.

Theatre music

One opera, *Fidelio* (1805; revised versions, 1806, 1814—the final version is the one usually heard today); one ballet, *Die Geschöpfe des Prometheus* (1801); incidental music to four plays; *Egmont,* op. 84 (1810), *Die Ruinen von Athen,* op. 113 (1811), *König Stephan,* op. 117 (1811), *Die Weihe des Hauses,* op. 124 (1822). (J.M.Bu.)

BIBLIOGRAPHY

Works: A multivolume complete edition has been begun by the Beethoven Archives in Bonn: LUDWIG VAN BEETHOVEN, *Werke,* ed. by JOSEPH SCHMIDT-GÖRG (1961–). The important works for the most part have opus numbers allocated by Beethoven himself. Lists of those of Beethoven's works without opus numbers (*Werke ohne Opuszahl*) may be found in the catalogs of Kinsky and Hess: GEORG KINSKY, *Das Werk Beethovens: Thematisch-bibliographisches Verzeichnis seiner sämtlichen vollendeten Kompositionen,* ed. by HANS HALM (1955), supplemented by KURT DORFMÜLLER (ed.), *Beiträge zur Beethoven-Bibliographie: Studien und Materialen zum Werkverzeichnis von Kinsky-Halm* (1979); and WILLY HESS, *Verzeichnis der nicht in der Gesamtausgabe veröffentlichten Werke Ludwig van Beethovens* (1957). None of the above is complete in its information. ALAN TYSON, *The Authentic English Editions of Beethoven* (1963), is a bibliographic study with facsimiles and musical illustrations; KURT E. SCHÜRMANN (ed.), *Ludwig van Beethoven: Alle vertonten und musikalisch bearbeiteten Texte* (1980), is a compilation of texts of Beethoven's vocal works; a discography, with reviews, is *The Recordings of Beethoven as Viewed by the Critics from High Fidelity* (1971, reprinted 1978); a collection of facsimiles and transcriptions in modern musical notation is presented in LUDWIG VAN BEETHOVEN, *Autograph Miscellany from Circa 1786 to 1789,* ed. by JOSEPH KERMAN (1970).

Letters and conversation books: *The Letters of Beethoven,* 3 vol., collected, trans., and ed. by EMILY ANDERSON (1961), is the standard edition of Beethoven's letters; a selection from these has been issued, with additional notes by ALAN TYSON, in *Selected Letters of Beethoven* (1967). *New Beethoven Letters,* trans. and annotated by DONALD W. MACARDLE and LUDWIG MISCH (1957); and *Beethoven Letters in America,* ed. by OSCAR G. SONNECK (1927), are other selections. Also see GEORG SCHUNEMANN, *Ludwig van Beethovens Konversationshefte,* rev. and enl. ed. by KARL-HEINZ KOHLER and GRITA HERRE, 8 vol. (1968–81). The Conversation Books represent Beethoven's only way of keeping contact with his friends after the onset of complete deafness; they represent mostly his friends' side of the conversation. A compendium is LUDWIG VAN BEETHOVEN, *Letters, Journals, and Conversations,* ed. by MICHAEL HAMBURGER (1966, reprinted 1977).

Life: ALEXANDER W. THAYER, *The Life of Ludwig van Beethoven,* 2 vol., ed. by ELLIOT FORBES (1964, reissued in 1 vol., 1973), is the standard biography, representing the third completed edition, revised and brought up-to-date, of Thayer's original work. It is, however, considerably condensed; and students are recommended to consult in addition the earlier American edition, *The Life of Ludwig van Beethoven,* ed. and trans. by HENRY E. KREHBIEL, 3 vol. (1921); and the German *Ludwig van Beethovens Leben,* 5 vol., ed. by HERMANN DEITERS and HUGO RIEMANN (1907–11, reissued 1917–23). ANTON F. SCHINDLER, *Biographie von Ludwig van Beethoven,* 3rd rev. ed. (1860; trans. into English by CONSTANCE S. JOLLY as *Beethoven As I Knew Him,* ed. by DONALD W. MACARDLE, 1966, reprinted 1972), has the value of a detailed life written by someone who knew the composer intimately, and its errors and distortions of fact are corrected in some excellent annotations. *Beethoven: Impressions of Contemporaries,* ed. by OSCAR G. SONNEK (1926, reissued 1967), is a useful anthology of opinions and accounts given by those with whom Beethoven came into contact. GEORGE R. MAREK, *Beethoven: Biography of a Genius* (1969, reissued 1972), gives a balanced, readable, and convincing ac-

count of the composer's life without going into as much detail as Thayer. EDITHA and RICHARD STERBA, *Beethoven and His Nephew: A Psychological Study of Their Relationship*, trans. by WILLARD R. TRASK (1954, reissued 1971), is a controversial exercise in posthumous psychoanalysis. H.C. ROBBINS LANDON (comp.), *Beethoven: A Documentary Study* (1970; abridged ed. 1975; originally published in German, 1970), is a commemorative scholarly study, with documents and colour illustrations; THOMAS K. SCHERMAN and LOUIS BIANCOLLI (eds.), *The Beethoven Companion* (1972), is an anthology combining biography, analysis, reminiscences, and letters; MARTIN COOPER, *Beethoven: The Last Decade 1817–1827* (1970), includes an account of his medical history; PETER PÖTSCHNER, *Das Schwarzspanierhaus: Beethovens letzte Wohnstätte* (1970), is a description, with illustrations, of the composer's last home in Vienna; JOSEPH SCHMIDT-GÖRG, *Beethoven: Die Geschichte seiner Familie* (1964); and JOSEPH SCHMIDT-GÖRG and HANS SCHMIDT (eds.), *Ludwig van Beethoven* (1974), is a commemorative pictorial biography; FRITZ ZOBELEY, *Portrait of Beethoven* (1972), is an illustrated biography based on contemporary research; MAYNARD SOLOMON, *Beethoven* (1977), is a psychoanalytical approach to Beethoven's life and music; MUNDANEUM, *Beethoven: Biographies* (1972), is one in a series of scholarly bibliographies prepared at the National Bibliographic Centre of Belgium.

Studies of the music: DONALD F. TOVEY, *Beethoven*, ed. by HUBERT J. FOSS (1944, reprinted 1975), is a series of penetrating essays on various aspects of Beethoven's work; it was intended to form the basis of a full study, which the author never lived to complete. Equally valuable is his *Companion to Beethoven's Pianoforte Sonatas* (1931, reprinted 1976), which provides a close structural analysis of all 32 works. ERIC BLOM, *Beethoven's Pianoforte Sonatas Discussed* (1938, reissued 1968), is compiled from a set of notes written for the famous recordings made by Artur Schnabel. CARL CZERNY, *On the Proper Performance of All Beethoven's Works for the Piano* (1970), is a work by a great pianist and teacher, edited by another great pianist, PAUL BADURA-SKODA; KENNETH DRAKE, *The Sonatas of Beethoven As He Played and Taught Them* (1972, reprinted 1981), is an interpretative analysis of the sonatas; WILFRID MELLERS, *Beethoven and the Voice of God* (1983), is also devoted to the piano sonatas. See also WILLIAM NEWMAN, *Performance Practices in Beethoven's Piano Sonatas* (1971); and RUDOLPH R. RETI, *Thematic Patterns in Sonatas of Beethoven* (1967). JOSEPH KERMAN, *The Beethoven Quartets* (1967, reprinted 1982), offers a comprehensive and stimulating treatment of the music.

PHILIP RADCLIFFE, *Beethoven's String Quartets*, 2nd ed. (1978), is a shorter study but very concentrated; ROBERT WINTER, *Compositional Origins of Beethoven's Opus 131* (1982), is another study of the string quartets. In the symphonic field GEORGE GROVE, *Beethoven and His Nine Symphonies*, 3rd ed. (1898, reprinted 1962), is an established classic; ANTONY HOPKINS, *The Nine Symphonies of Beethoven* (1981), is a later study that provides structural and harmonic analysis of every movement, with illustrations; LIONEL PIKE, *Beethoven, Sibelius, and the "Profound Logic"* (1978), is a comparative study. For a great musician's opinion, see HECTOR BERLIOZ, *A Critical Study of Beethoven's Nine Symphonies, with a Few Words on His Trios and Sonatas, a Criticism of Fidelio, and an Introductory Essay on Music* (1913, reprinted 1976), a translated selection from the author's *A Travers Chants* (1898). The only Beethoven opera is discussed in the English National Opera guide *Fidelio* (1980), which includes the libretto in the original German, an English translation, a critical essay, and a bibliography and discography. IRVING SINGER, *Mozart and Beethoven: The Concept of Love in Their Operas* (1977), explores moral, aesthetic, and erotic concepts in the music of the Romantic composer. ROBERT WINTER and BRUCE CARR (eds.), *Beethoven, Performers, and Critics* (1980), is the material of the International Beethoven Congress of 1977. ALAN TYSON (ed.), *Beethoven Studies* (1973), *Beethoven Studies 2* (1977), and *Beethoven Studies 3* (1982), are collections of scholarly essays on the composer's music and life. IRVING KOLODIN, *The Interior Beethoven: A Biography of the Music* (1975), explores the development of Beethoven's musical ideas and their influence on others. DAVID B. GREEN, *Temporal Processes in Beethoven's Music* (1981), examines musical form and aesthetics. DENIS ARNOLD and NIGEL FORTUNE (eds.), *The Beethoven Reader* (1971), is a collection of essays. CHARLES ROSEN, *The Classical Style*, rev. ed. (1976), is a blend of musical, literary, and art criticism; GERALD ABRAHAM (ed.), *The Age of Beethoven: 1790–1830* (1982), is a history of the music of the period. PAUL NETTL, *Beethoven Encyclopedia* (1956, reprinted 1975 as *Beethoven Handbook*), is a reference source. DONALD W. MACARDLE, *Beethoven Abstracts* (1973), provides an index to and summarizes the Beethoven literature.

Animal Behaviour

Animal behaviour includes any activity of an intact organism. A living animal behaves constantly in order to survive, and all animals must solve the same basic problems. They must, for instance, periodically replace their energy source (consume food), avoid dehydration (drink), avoid becoming another animal's energy source (avoid being eaten), maintain their body surfaces (clean and groom), and reproduce. This article discusses these and other basic behavioral activities of animals ranging from protozoans to higher vertebrates. It not only treats the behavioral patterns of individuals but also considers those of animals in groups. Coverage of the latter includes reciprocal altruism, communication, and various other factors involved in social interaction. Although references are made to human behaviour, the reader should consult the articles BEHAVIOUR, THE DEVELOPMENT OF HUMAN and BEHAVIOUR, INNATE FACTORS IN HUMAN for specific information. Likewise treated in passing are certain behavioral tendencies of plants that resemble or parallel simple unlearned behavioral responses and adaptive mechanisms of animals (see also GROWTH AND DEVELOPMENT: *Plant development*).

This article is divided into the following sections:

NATURE AND PATTERNS OF ANIMAL BEHAVIOUR

Diversity of behavioral activity

Any animal may be regarded as an agglomeration of interacting and interdependent structures and behaviours that are responses to environmental conditions. The behavioral features of modern animals are the accumulated results of millennia of selective pressures acting on small variations inherent in individuals. This selection is relentless because environments are constantly changing.

An understanding of comparative behaviour is helpful in understanding human behaviour, just as an understanding of comparative anatomy is helpful in understanding human anatomy. The reason for this is that both behaviour and anatomy have a genetic basis. All vertebrates, for example, share certain anatomical features that distinguish them as vertebrates; and smaller groupings such as fish, amphibians, reptiles, birds, and mammals may be distinguished from one another on the same basis. This type of distinction holds true between species and even between individuals within a species. Consequently, an understanding of the anatomy or behaviour of any species is helpful in understanding other species, including man himself. In general, the closer the relationship between any two species, the more similar are the structures and behaviours of the two species. The converse is also true. Exceptions, however, do exist. Human beings and chimpanzees, for instance, are closely related genetically, but, because of historic differences in environment, the behaviour of humans is, in many ways, more like that of wolves, which experience many problems similar to those of ancient man. Such convergences and divergences are commonplace in biological evolution. Convergence occurs when unrelated animals independently evolve similar responses to similar environmental conditions—*e.g.,* the similar body shapes of porpoises and sharks; the similar social behaviour of wolves and humans (see below *Behaviour of animals in groups*). Divergence occurs when closely related species are adapted to different conditions, with a resultant difference in behaviour and structure. This is the usual type of response; sometimes, however, divergence is extreme enough to obscure a close relationship. The males of many species of closely related hummingbirds, birds of paradise, pheasants, and ducks, for example, are superficially so different from one another that many of these species were formerly assigned to different genera.

Behaviour as a taxonomic aid

The study of behaviour has provided valuable information about relationships among animals. The Greek philosopher Aristotle was one of the first to use behaviour as a taxonomic aid, but only in recent times have behavioral features been important in animal taxonomy. Aristotle regarded pigeons and doves as closely related to the sand grouse, basing his view partly on their similar way of drinking. Pigeons, doves, and sand grouse, unlike most other birds, keep the bill in the water and drink with a pumping action.

Behaviour may be quite simple, as in taxis (movement toward or away from a stimulus) and kinesis (undirected response proportional to the intensity of a stimulus). These two types of behaviour—most often descriptive of invertebrates—may be further subdivided. Orthokinesis, for example, is a response that involves change in the speed of movement of the body as a whole. Klinokinesis involves changes in the rate of turning from side to side. Klinotaxis is a type of orientation to stimuli in which, in alternate body movements, external stimuli are received with equal intensity. In tropotaxis the orientation of the animal is similar to that in klinotaxis, but it depends upon stimuli acting simulaneously upon two receptors or upon two parts of one receptor. These are stimulated unequally if the animal is not oriented directly toward or away from the source of stimulation. In telotaxis the animal orients to one or the other of conflicting stimuli affecting the same sensory mechanism. In menotaxis, or light compass response, animals (*e.g.,* honeybees, ants) do not orient either directly away from or toward a source of stimulation but assume a constant angle to the direction of the stimulus. Complex behaviours such as nest building, courting, and fighting do not lend themselves to the simple labelling of taxes or kineses and are classified according to other systems, which are dealt with below.

Classification of behaviour

TYPES

An animal's behaviour may be described according to the nature of the muscular contractions involved or in terms of the consequences of the behaviour. Because the muscle contractions involved in specific behaviours are often complex, a kind of shorthand is commonly used to describe them. Terms such as tail flick, head bob, and threat posture are of this nature. In describing behaviour in terms of its consequences, terms such as avoidance, courtship, nest building, and burrowing are often employed. Sometimes a behaviour must be described both in terms of the type of muscle contraction and in terms of the consequences of the behaviour.

Types of classification

Three types of behavioral classification are used most commonly: (1) on the basis of immediate causation, (2) on the similarity of evolutionary history, and (3) on the similarity of function.

Immediate causation. Classification based on immediate causation requires that the causal factors first be identified. All behaviours triggered by similar causal factors are then grouped together. Whether or not behaviours share the same causal factor can be determined by either of two methods. One method is to administer the causal factor and see if all of the behaviours are elicited and affected similarly. The other method, used when the causal factor is not known, is to examine the chronological correlations between the activities in question. Two activities that consistently occur together are likely to be causally related. This method is often used in studies of agonistic (attack–escape) courtship, feeding, egg laying, and similar complex behaviours.

Evolutionary history. Types of behavioral evolution are often classified according to similarities in biological evolution. Similarities between patterns of muscular contractions are compared among species believed to be related. The degree of difference between presumably homologous behaviours provides a criterion for measuring the degree of evolutionary affinity and for determining the direction of evolutionary changes. Data useful in classification may sometimes also be obtained by observing the appearance or disappearance of behaviours during ontogeny, or individual development.

Function. Classification based on similarity of function depends on the identification of behaviours with similar evolutionarily adaptive values. Such behaviours may or may not be homologous. The flying behaviour of a bird, for example, is not homologous with that of a butterfly, but both have similar functional and adaptive significance and may be classified together on this basis. A functional classification often closely agrees with a causal classification; this is because evolutionarily functional and causal mechanisms are commonly associated. The more distantly animals are related, the less likely it is that their functional and causal classifications will overlap; the converse also tends to be true: the more closely animals are related, the more likely it is that the two classifications will overlap.

In the case of behaviour in juveniles and adults of the same species, causal and functional categories may sometimes not overlap; an example is penis erection in juvenile mammals, in which reproduction is not a causal factor, compared with that in adults, in which it is.

THE INFLUENCE OF GENETICS AND EXPERIENCE

nnate versus learned ehaviour

Behaviour is sometimes classified according to the nature of the changes occurring during evolution or ontogeny. From these bases groupings such as learned, innate (*i.e.,* unlearned, or instinctive), and ritualized behaviour are derived. This classification scheme is useful in studies such as those dealing with the acquisition of communication behaviour.

Every aspect of an animal—behavioral as well as structural—is influenced to some degree by heredity as well as by experience. Although a muscle can become larger, harder, and more vascularized (*i.e.,* supplied with blood vessels) or smaller, softer, and less vascularized depending upon the nature of the experience to which it is subjected, the possibility of such modification is not infinite because of genetic limitations. Some behaviours are inherited in the same sense that an organ is inherited, and they exhibit little or no capacity to be modified by experience. Other types of behaviour achieve definitive form and employment only with experience.

Various intermediate conditions exist. If the environment is predictable relative to the appropriateness of a given behaviour in an animal, it is biologically advantageous for this behaviour to be innate, because presumably there is no need for a variety of response. Variability would, in fact, be disadvantageous, because an inappropriate response could threaten the animal's chance of survival. On the other hand, if the environment is unpredictable in certain respects, it is biologically advantageous to have some degree of inherent variability based upon response to experience. In this case, however, it is likely that the animal would sometimes respond with the wrong behaviour, resulting in a lowered survival value. In behaviours that may be modified by experience, the nature and extent of the modification are not limitless. The nature, intensity, timing, and duration of experience that may influence a given behaviour vary with the type of behaviour involved. The kind of response to these aspects of experience is determined genetically and has evolved to the extent that the maximum possible survival value is achieved.

Some behaviours are innate in the same sense that an organ of the body is innate. Their functions are relatively fixed and predictable. Other behaviours have an inherent resiliency and may respond radically to changes in the environment. Genetically determined limits, however, are always imposed upon even the most variable behaviours. An animal would otherwise be capable of limitless modifications of its behaviour, within its structural limitations, and be able to associate arbitrarily any environmental stimulus with any behaviour.

A general evolutionary trend exists for more and more behaviours to be modified by environmental stimuli as the phylogenetic scale ascends (*i.e.,* as the animal becomes more complex and "advanced"). This tendency has reached its extreme expression in vertebrates, particularly mammals, and especially in humans.

Components of behaviour

FIXED ACTION PATTERNS

A behaviour that is independent of environmental stimuli for its form is known as a fixed action pattern (FAP). An environmental stimulus may, however, be responsible for the elicitation and proper orientation of the FAP and may have an influence on the completeness of the response. Common examples of FAP's include displays (visible and audible signals), nest-building movements, various food-gathering and food-preparation movements, thermoregulatory movements, and attack and escape movements.

Species specificity of FAP's

Because FAP's are often specific for particular species, they are frequently useful in taxonomic and evolutionary studies. The homologous relationship among FAP's of related species is often easily determined, and their qualitative and quantitative differences can be evaluated.

FAP's are ordinarily quite constant in form, but this stereotypy is not a defining characteristic. Some vary considerably in the degree of completeness, even though the proportions of the components of the response may remain quite constant, relative to one another. Some FAP's share a single environmental stimulus. Sight of a rival male, for example, may elicit flight, attack, or any of a variety of agonistic (attack–escape) displays.

It is sometimes difficult to distinguish an FAP from its orienting movements. In such cases the eliciting stimulus can be manipulated, and the subsequent effects on the behaviour can be observed. The graylag goose (*Anser anser*), for example, retrieves eggs displaced from the nest by means of a highly stereotyped behaviour. While sitting on the nest, the goose extends its head beyond the egg so that the undersurface of the bill is against it. The head is then pulled toward the body until the egg is again safely in the nest. While the head is being pulled toward the body, it makes balancing adjustments that compensate for the tendency of the egg to roll to either side. If the egg is removed during retrieval, the head continues its movement toward the nest, but compensatory movements to counter the erratic roll cease. The FAP is elicited by the egg-out-of-nest stimulus and, once triggered, goes to completion whether or not the egg is still balanced against the underside of the bill. The balancing movements, however, depend upon continuing stimulation by the egg itself and are not part of the head-withdrawing FAP. The balancing movements also cease if a smoothly rolling cylinder is substituted for the egg.

This egg-retrieving FAP illustrates other features of FAP's in general. Every species can perform a finite number of FAP's and have a limited capacity, or none at all, for developing new ones. The limitations may be determined by physical structure: a woodchuck cannot fly, nor can a pelican burrow. Yet neural organization may provide restrictions as ubiquitous and rigid as anatomical ones. The egg-retrieving graylag goose is physically capable of retrieving an egg with its broadly webbed feet or with

a wing used as a kind of broom. This never happens, however, because the goose's neural organization permits egg retrieving only in the manner described. Alternative behaviours can sometimes be employed. Parrots of the genus *Agapornis,* for instance, always scratch the head by bringing a foot forward over the wing on the same side; however, when a foot is brought forward for cleaning the bill, it always passes below the wing on the same side. The bird has the physical structure as well as the neural organization necessary for both movements, but each method is specific for its particular stimulus.

KEY STIMULI

An animal reacts to relatively few of the stimuli present in its environment. This is a basic characteristic of behaviour. It is seldom known whether an animal actually perceives but does not react to the various available stimuli or whether it fails to perceive stimuli of no significance to it—at least of no significance within a given context. Both situations are probably true, at least for some species, under given circumstances. The human eye, for instance, focusses on the retina a detailed picture of all that the eye is directed toward. The human observer, however, is unaware of much within his field of vision. The same is true of other sensory modalities. At some point, insignificant stimulation is filtered out. An animal could not function if it had to respond to all of the stimuli its sensory organs are capable of receiving at any moment. Each species has, therefore, evolved responses only to those stimuli significant to itself and at such times that responses to such stimuli are relevant. This simpler world that actually falls within the animal's perception at any particular moment is termed its *Umwelt.*

Umwelt

The tick's response to its relatively simple *Umwelt* graphically illustrates how an animal selectively responds to only those stimuli pertinent to its immediate requirements. The mature female tick responds to light falling on her photosensitive body surface by moving to the tip of a twig or some suitable substitute, where she waits for a mammal to approach. The tick is capable of waiting for years until that occurs. When a mammal passes close by, she releases her grip on the twig and, if successful, falls onto the body of the mammal. The key stimulus causing her to release her grip is the scent of butyric acid, which naturally issues from the body of any mammal. When the female tick is on the host's body, she reacts to its body heat by inserting her proboscis (feeding organ) into the mammal's skin and sucking herself full of blood. This behavioral sequence depends on three stimuli: light, the odour of butyric acid, and warmth. The tick will relinquish its perch for anything with the scent of butyric acid, sink its proboscis into any warm surface—even a balloon filled with warm water—and fill herself with whatever fluid is within. The taste of blood and mammalian characteristics are not meaningful to the tick.

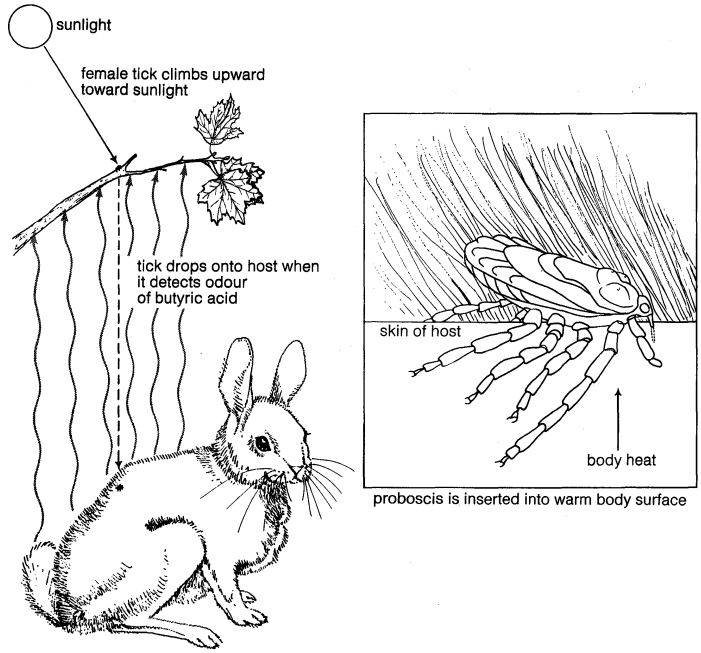

Figure 1: Response of the tick to environmental stimuli. Before obtaining a blood meal from the proper host, it must successively react to the stimuli of light, butyric acid, and body warmth.

Aggressive behaviour in the male stickleback fish (*Gasterosteus aculeatus*) occurs when the fish sees the red belly of other males. Crude dummies are attacked as long as they have red bellies; realistic models or actual fish without red bellies are not attacked.

Various species of predacious animals utilize lures that simulate the natural foods of prey species. The alligator snapping turtle (*Macrochelys temmincki*) has two slender, reddish structures projecting from the tip of its tongue that move like small worms. The turtle, with its mouth open, rests on a river bottom. A fish attracted by the false worm is snapped up by the turtle. Several species of deep-sea anglerfish have a long slender projection from the forepart of the dorsal fin. This "fishing rod" terminates in a wriggling wormlike structure that is dangled close to the anglerfish's mouth. When another fish investigates the lure, it is easily snapped up by the anglerfish. Different species of anglerfish possess different lures that are specific for different prey species.

The male swordtail characin fish attracts female mates by means of an organ resembling a daphnia, a favourite prey. The gill covers of the male are modified into a long, slender projection terminating in this "daphnia," which is moved within view of the female. When she has been lured close enough, the male copulates with her.

Female fireflies of the genus *Photurus* lure males of other genera by imitating their flashing codes, then seize and eat them. A certain petal in various species of fly orchids is modified to resemble the females of various wasp species, and the odour of these female wasps is also imitated. When a male wasp is attracted to a model female of the same species and attempts to copulate with it, the pollen of the flower adheres to the male and is, in turn, carried to the next flower that attracts the wasp.

Fertilization behaviour in cichlid fish

Males of certain African cichlid fish (genus *Haplochromis*) deceive females by means of a body pattern that resembles cichlid eggs. The females, which are mouth breeders, take into their mouths the eggs they have laid before the male fertilizes them. Visual models of these eggs are part of the pattern of the ventral fins of the male. After the female has placed the eggs in her mouth, the male spreads his ventral fin before her. The male emits sperm as the female snaps at the false eggs, thus permitting the real eggs in her mouth to be fertilized.

Another mouth-breeder fish, *Tilapia macrochir,* ensures fertilization by means of a different deception stimulus. The male produces sperm in filament-like packets (spermatophores), which are shed into the water. Later, they are picked up by the female. She may not always find them, however, and the male has evolved long filament-like spermatophore models that project from his genital region. For some reason, these models exert a stronger stimulus than the real spermatophores. The female takes them into her mouth and at the same time receives real spermatophores that have been placed among the models.

Visual behaviour in the frog

The eyes of the meadow frog, *Rana pipiens,* have five types of cells, each of which responds to a different kind of stimulus. One type responds briefly when a light is turned on or off; it also responds to the passing of the leading and trailing edges of an image moving across the retina. It does not respond to a stationary image, however. A second type of cell responds to the passing of straight or curved edges. A third type does not respond to changes in light intensity but to the passage of the image of a small object, in contrast to its backround, across the retina. The fourth type of cell measures a decrease in illumination, and the fifth type measures light intensity.

The frog is capable, therefore, of receiving information about the size, shape, movement, and illumination of objects and is particularly well equipped to perceive small

moving objects—its normal food. Much of the stimulus filtering in the frog's vision takes place peripherally at the retinal level. Studies of other subjects such as cats, rabbits, and moths reveal that the processing and integrating of sensory data occurs at various levels in the central nervous system (brain and spinal cord).

Releasing mechanisms. Hundreds of types of responses to a few key stimuli have been identified in various animals. These responses are mediated in the central nervous system by a so-called releasing mechanism (RM) and are responsible for triggering the specific motor response appropriate to the stimulus. If the releasing mechanism is innate, it is termed an IRM. If it is acquired through individual experience, it is termed an ARM. Some innate releasing mechanisms may be modified as a result of individual experience; such a mechanism is termed an IRME.

A given stimulus does not always prompt the same response in the same individual. Such differences are due to internal factors. Some changes are seasonal and are brought about by internal conditions that may, for example, be related to reproduction and associated aggressive behaviour. In the spring, a male wood thrush (*Hylocichla mustelina*) responds to a female with courtship behaviour and to another male with aggression. In the winter the same thrush fails to respond in this way. Relatively short-term changes in responsiveness also occur. An animal that has just fed, for example, shows no further interest for a time in food. In such an instance a short-term internal change has taken place.

The strength of a stimulus necessary to evoke a response of standard intensity also varies with time. The longer an animal is deprived of food, for example, the more unappetizing the food can be and still be accepted. The converse is also true. The more recently an animal has eaten, the more appetizing the food must be to be accepted.

The intensity of a noxious stimulus or the degree of difficulty of an obstacle that an animal will attempt to surmount varies with time. The longer an animal has been without food (short of physical debilitation), the more difficult an obstacle can be and still be surmounted by the hungry animal. Again, the converse is true.

DRIVE AND MOTIVATION

Internal changes that initiate behavioral changes are commonly termed drive or motivation. These terms are usually applied to short-term reversible changes in response to a constant stimulus. They are not applied to long-term changes that are the result of learning or to short-term changes that result from muscular fatigue, sensory accommodation, and sensory adaptation.

Searching behaviour

When internal conditions are intense enough to initiate a particular drive, an animal commonly behaves as if it were searching for the correct environmental stimulus necessary to trigger the appropriate response. Such searching, or appetitive, behaviour is often highly variable. The true nature of a particular appetitive behaviour can, as a rule, be ascertained only as the act progresses. The drive that motivates a robin to search a lawn, for example, cannot be determined until the search nears culmination. If the robin seizes an earthworm, it is evident that hunger was the activating drive. If it picks up mud or grass, the appetitive phases of nest-material gathering are apparent. Appetitive behaviour tends to become less and les variable as the appropriate terminating situation becomes more and more likely to occur. A hunting falcon flies a search pattern until a potential prey is sighted. The bird dives upon it, after which the exact flight path is determined by whatever evasive action the prey may take. If the falcon is successful, the prey is struck and killed, carried to a perch, and systematically pulled apart and eaten. When the hunger is satisfied, the drive state no longer exists, and some other activity follows. The closer the appetitive sequence is to termination, the more stereotyped the falcon's behaviour becomes. The consummatory act is the most stereotyped behaviour of all.

Courtship behaviour culminating in successful copulation provides many examples of characteristic appetitive–consummatory chains of behaviour. In such cases copulation itself is the terminal appetitive behaviour and is highly stereotyped. Ejaculation, or discharge of sperm by the male, in certain species is completely stereotyped and is followed by temporary cessation of the sex drive.

Learned behaviour is important in appetitive sequences in many animals. A jay, for instance, quickly discovers the best places to find particular foods, and it learns to begin its search in such places rather than search at random until a suitable forage area is found.

"SUPERNORMAL" STIMULI

A major subject of investigation in animal behaviour has been the determination of key stimuli necessary to trigger particular behaviours. In order to determine those characteristics of an egg by which an incubating bird identifies it as such, a selection of model eggs can be presented to the bird, each model differing in one respect from a normal egg. The reactions to variations in colour, pattern, shape, size, and texture vary according to the species. Generally, differences in shape do not seem important to an incubating bird; but models with more rounded contours appear to be favoured. Differences in colour, pattern, and size are important, but differences in texture do not seem to be.

A model in which the key stimulus has been exaggerated to an extreme degree may be chosen in preference to a normal model. The oystercatcher, for example, prefers a "supernormal" egg, several times the usual size. It also prefers an abnormal clutch of five eggs to the normal clutch of three.

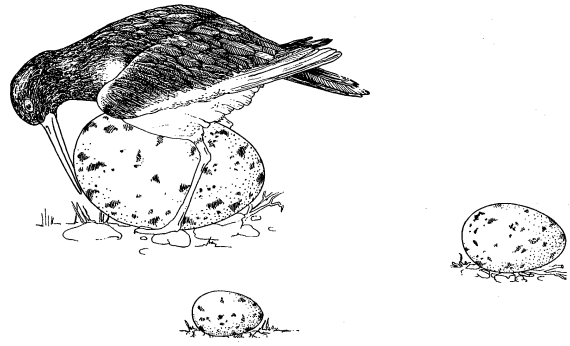

Figure 2: Oystercatcher (*Haematopus ostralegus*) reacting to giant egg in preference to normal egg (foreground) and herring gull's egg (right).

Feeding behaviour of herring gull chicks

Chicks of the herring gull (*Larus argentatus*) are stimulated by a red spot on the lower bill of the adult. When the chick pecks at this spot, the adult regurgitates food for it. By presenting the chick with various models of beaks, it has been found that differences in the colour of the head and bill are not significant; but the red spot, narrowness of the bill, movement, low position of the head, and a downward pointing of the bill are all important in eliciting a response. A thin rod with a red band near the tip moved in a low position provides a supernormal set of stimuli, which elicit a positive response.

When more than one stimulus elicits a given response, the stimuli may supplement one another. If two or more stimuli are required to evoke a response, a weakness of one stimulus may be counterbalanced by the strength of another. Such a compensatory effect is termed the law of heterogenous summation. In higher animals, learned behaviour may play an important role in this phenomenon. A response may originally depend upon one or a few key stimuli, but, as a result of experience, an animal may come to regard previously irrelevant conditions as among those stimuli necessary for the response, resulting in a kind of gestalt response, in which several stimuli are perceived as an integrated whole. Animals lower on the phylogenetic scale may be more apt to respond to heterogeneous summation, and those higher on the scale may be more apt to respond to a gestalt, however acquired.

The supernormal stimuli discussed above have been observed experimentally. The tendency of an animal to respond more vigorously to enhanced stimulation may be of evolutionary significance, because animals with a geneti-

cally based tendency to prefer more advantageous variants of a stimulus would tend to have a higher probability of survival. In social situations in which the relevant stimuli are part of an animal's body, those structures offering a favourable departure from the normal would enhance the probability of survival in the offspring.

MOVEMENT

Form. The form of movement of a response is not determined by either the eliciting stimulus or by the properties of the musculature involved. It is possible, however, that the form of movement may be determined by either of two other factors. First, the sequence in which muscles contract to produce a movement may be determined solely by the properties of central nervous system mechanisms responsible for the movement. In this case the movement, once initiated, is independent of further sensory stimulation.

Second, the muscle contractions near the completion of a movement may also be influenced through a feedback mechanism provided by the earlier contractions. The form of the movement would thus be continuously monitored by sensory control. Fixed action patterns, although independent of further stimulation once elicited, may depend upon such internal feedback mechanisms.

Distinction between external and internal movement. The way by which animals are able to distinguish between movements of the environment and movements of the sense organs is not fully understood. When the human eye views a moving object, the object appears to move. If the eye is moved while looking at a stationary object, the object appears stationary, though in both cases the image moves across the retina. But if a stationary object is viewed while the eye is displaced slightly by pushing with a fingertip, the object appears to move.

Equilibration in fishes

If a resting fish is tilted to one side, the statolith (organ of equilibrium) on that side shifts position, thereby activating sensory endings; these set in motion muscular action that restores the fish to an upright position. A fish often deliberately tilts sideways, however, and, in this case, the automatic reflex does not pull the fish upright. It was formerly believed that the righting reflex is blocked during spontaneous movement. Studies have shown, however, that such blocking does not occur. If a fish is whirled in a centrifuge, the deliberate tilting movements made by the free-swimming fish are of lower intensity. The tilting movements become less because the statoliths are made heavier. The righting reflex is not blocked during deliberate tilts, therefore, but is dependent upon the feedback caused by the tilts.

During spontaneous movement, the stimuli that otherwise release postural reflexes are not inactivated but must be neutralized in another way. The principle of reafference has been hypothesized to account for this. By this hypothesis the functional system is visualized as a feedback loop, whereby afferent nerves carry impulses toward the central nervous system and efferent ones carry impulses away from the central nervous system to the motor areas. Afferences can be divided into receptor excitations caused by internal changes in the musculature (reafference) and those produced passively by external stimulation (exafference). Reafference and exafference are integrated in some manner in the higher centres of the nervous system. The reafference hypothesis postulates that, with each voluntary movement, a copy of the efferent motor impulse is stored in a subordinate nervous centre. The efferent impulse continues to the effector, and movement results. The sense organs then report the result of this movement as a reafference—a feedback of information. This reafference is matched with the efferent copy and is cancelled. If the total afference is too much or too little, as the result of external stimulation, there remains a plus or minus value as compared to the efferent copy stored in the subordinate centre. The discrepancy is reported to the higher centre, which then strengthens or weakens the initial command.

BEHAVIORAL CHAINS

When an animal responds to a stimulus, the releasing situation is often altered because the animal has progressed to a new position, in which other stimuli are effective. For example, when a female three-spined stickleback enters the territory of a male, he performs a zigzag dance. She responds to this with a signal of her own, which, in turn, releases a behaviour in the male that causes her to follow him. The male shows her the nest opening, which she enters. The male trembles with his snout against her tail, stimulating her to spawn, after which she leaves the nest. The male then fertilizes the eggs. Each of these behaviours depends upon the appropriate stimulus. If one is omitted, the chain terminates without a productive conclusion.

The behaviour of the bee-hunting wasp *Philanthus triangulum* illustrates another such chain. This wasp flies from flower to flower as it searches for bees. It responds initially to the visual stimulus afforded by any moving bee-size object; during this time it is indifferent to bee scent. After the wasp perceives the visual stimulus, it hovers about 10 to 15 centimetres (four to six inches) downwind of the bee and then is sensitive to bee scent; if the scent is appropriate, the wasp attacks the bee and seizes it. Following seizure, bee scent is no longer an effective stimulus. Moving models of the appropriate size attract the wasp, but they will not be seized unless they have bee scent. The behaviour depends upon a succession of stimuli that must occur in a precise sequence.

Scent and vision in wasps

Many such behavioral chains are known for vertebrates as well as invertebrates. They are not always precisely ordered, and variations may occur. Many such behavioral chains do not exhibit a succession of stimuli made available as a result of the responses. Single causal factors may stimulate several responses. Activities occurring near the end of a chain may require a higher intensity of stimulus than earlier ones. If a causal factor proves inadequate at

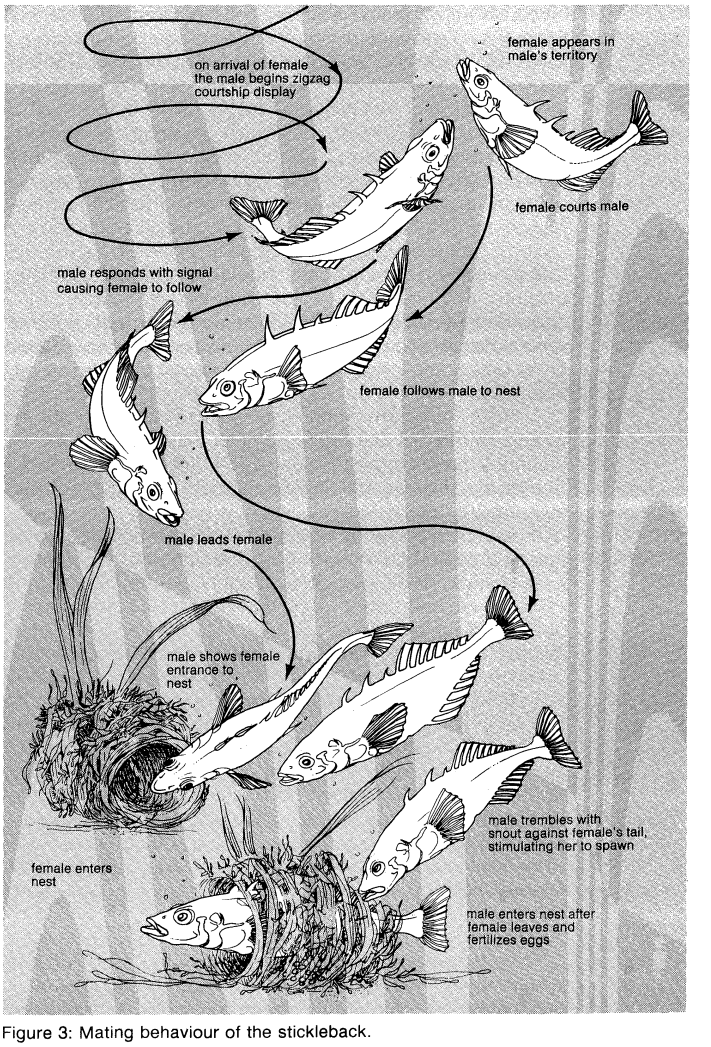

Figure 3: Mating behaviour of the stickleback.

some point, the behaviour reverts to an earlier stage in the sequence. This is probably true in the courtship of the three-spined stickleback in which all the activities of both sexes depend upon common endocrine factors (*i.e.*, hormones), on short-term states of heightened responsiveness, and on the nature of the external stimuli.

CONFLICT RESOLUTION

Simultaneous stimulation. Causal factors for many types of behaviour are usually present at any given moment. A male stickleback may be simultaneously confronted with several stimuli: a ripe female, food, a rival male, and a predator. Animals usually respond to one stimulus at a time and according to a certain priority of sequence. In the male stickleback, escape from a predator almost always takes priority over concurrent stimuli.

More than one drive is often activated simultaneously by the same situation. A conflict between the drives occurs, and the situation must be resolved. The resolution may occur in any one of several ways. Sometimes two drives may be expressed simultaneously. Pecking and head turning, when activated together, often occur simultaneously in chickens. Chickens that are in conflict between watching out with an elongated neck and making wide sweeping movements of the head as they peck, elongate the neck even further but reduce the extent of the head sweeping. Such conflicts can also be resolved by alternately performing the activities appropriate to the conflicting drives. The separate activities are often incomplete. A housewife, for example, may perform in this manner if the telephone begins ringing just as something begins to boil over on the stove.

Redirection and displacement. Sometimes an animal has a drive to perform a particular behaviour but is prevented from doing so and directs the behaviour to another object. If an animal is prompted to attack another but is prevented by fear of the opponent or by a reluctance to leave its territory, it might attack a harmless companion, the ground, vegetation, or even itself. Such behaviour is termed redirection. Displacement is the resolution of a conflict situation in which a seemingly irrelevant activity is performed. When an animal is obviously in conflict between, for example, sex and aggression or between aggression and fear, it will often perform an apparently irrelevant activity such as grooming, feeding, or scratching, or the animal may go to sleep. It is as if the two activated drives neutralize one another and the surplus energy is fed into another system. In disinhibition, two drives that appear to independently inhibit a third mutually inhibit each other in a conflict situation and lose their inhibiting effect on the third, which then becomes free to activate its own behaviour.

Disinhibition hypothesis

The probable reason that displacement activities are so often comfort behaviours (*e.g.*, preening) is that such behaviours have a typically low threshold of performance; ordinarily, they do not have a particularly high priority and are, therefore, easily elicited when more urgent demands are not being made upon the animal. This explanation is consistent with the fact that, though the frequent performance of these displacement activities is essential to survival, they are seldom associated with any condition of urgency.

The nature of the displacement activity may also depend upon the immediate environment or upon the effects of autonomic nervous activation on the animal; sometimes the activity depends on both factors. A wood thrush caught, while sitting in a horizontal position, by a strong attack–escape conflict will wipe its bill on its perch. The same bird caught by the same conflict, while sitting almost vertically, will make perfunctory preening movements directed at its upper breast. The relationship of the bird to its immediate environment makes it easier to perform a particular comfort activity. Autonomic responses—the result of fear or aggression in man, for example—may cause an expansion or constriction of blood vessels, a tingling sensation in the skin, a tendency to urinate or defecate, and so on. Scratching and temperature-adjustment behaviours may sometimes be prompted by such physiological changes.

Transitional activity. In transitional activity, another type of conflict resolution, the animal is stimulated to perform a particular behaviour, but the required environmental stimulus becomes unavailable during the course of the response. The animal discontinues its initial behaviour and substitutes another behaviour that it initially had not "intended" to perform.

The common grackle demonstrates a transitional activity in the form of a threat behaviour termed a spread–squeak; the bird ruffles its plumage, then utters a squeak as it compresses its feathers. If a rival approaches, prompting a spread–squeak, and turns away only at the plumage-ruffling stage, the bird will then, instead of squeaking, often shake its body—a normal comfort activity customarily preceded by plumage ruffling. When a man offers his hand to be shaken and it is not accepted, he often behaves as if he had really intended to gesture or perform a similar action. Transitional activities may be cases of displacement in which the nature of the behaviour is determined by the immediate environment. A grackle involved in the ruffling stage of a spread–squeak, after the rival leaves, may simply shake its body because, in the absence of further stimuli for fear and aggression, it is left with the stimulus for shaking, which may be ruffling. Conflict situations are of great interest from an evolutionary standpoint, because they are often the raw material from which signals have evolved.

Behavioral evolution and development

Behaviours are believed to evolve in the same way as structures. The recombination of genes afforded by sexual reproduction ensures that each individual differs in some degree from all others of its species. Even slight variations from the norm increase or decrease the probability of survival. Advantageous features tend to be conserved and disadvantageous ones eliminated. Marked changes are the result of the slow accumulation of small variations over long periods of time, representing many generations. A species never becomes totally adapted to its environment because the environment is constantly changing. As a result, selective pressures always exist, and the process of evolution continues.

SELECTION IN DOMESTIC ANIMALS

Animals can be selectively bred for specific behavioral changes. Many domestic animals differ markedly in behaviour from their wild progenitors. Domestic breeds such as fighting cocks and Siamese fighting fish are hyperaggressive, but most domestic animals tolerate greater crowding and are more docile than their wild ancestors. House mice have been selectively bred in the laboratory to produce unusually aggressive, as well as unusually timid, strains. Mating selection in domestic animals is usually less restrictive than in their wild counterparts. Reciprocal signalling systems between animals become less precise with domestication, and behavioral components may be omitted or lost altogether. Promiscuity may replace pairing in certain animals.

Courtship in pigeons

Marked differences in courtship displays occur between wild pigeons (*Columba livia*) and domestic breeds. Wild males loudly clap the wings over the back in flight and then glide with the wings held well above the horizontal position. In pouter pigeons (a breed of *C. livia*), the wings are clapped so frequently that two-thirds of the length of the primary wing feathers may thus be worn off, with the result that flying becomes very difficult. The elevation of the wings during the glide phase becomes so exaggerated that the wing tips touch, and the bird quickly loses altitude. In roller pigeons, another breed, the gliding flight has become a series of backward somersaults. On the ground the male wild pigeon, while cooing, twirls and makes a small hop when the female walks away. The German ringbeater breed elaborates on this behaviour by performing a wing-clapping flight around the female, who remains on the ground.

Domesticated zebra finches (*Poephila guttata*) show marked loss of specificity in their mating interactions and in care of the young, when compared with their wild counterparts. Wild chickens will kill their own chicks that

lack specific colour patterns. Domestic chickens, on the other hand, will care for almost any chick regardless of colour and pattern; yet, they retain specific reactions to the species-specific calls of chicks so that they do not ordinarily accept other young birds, such as ducklings. Highly domesticated chicken breeds, such as Plymouth Rocks and barred Plymouth Rocks, however, will rear even ducklings. The least domesticated breeds, such as certain game bantams, still show much of the specificity characteristic of wild birds. Wild graylag geese form pairs only after a very long courtship period and remain monogamous. Domestic derivatives, on the other hand, pair quickly with any member of the opposite sex and are not monogamous. All of these differences between wild animals and their domesticated derivatives have a genetic basis.

BEHAVIOUR IN HYBRIDS

Two closely related species of small African parrots, the peach-faced lovebird (*Agapornis roseicollis*) and Fischer's lovebird (*A. personata fischeri*), have completely different methods of carrying nesting material. The females of both species prepare nesting material by cutting long, narrow strips of bark, leaves, or paper. The peach-faced lovebird tucks each strip, after she cuts it, into the feathers of the lower back, or rump. When she has accumulated about six strips, she flies to the nest cavity, retrieves the strips, and places them in her nest. Fischer's lovebirds carry each strip in the bill, one at a time, to the nest cavity.

Female hybrids between these two species initially tuck nest material into their rump feathers, but the strips fall out before the birds reach the nest. The birds gradually develop, through learning, an increased tendency to carry each strip singly in the bill. About four months after the onset of the tucking behaviour, they are utilizing both behaviours about equally. Although the tendency to carry in the bill continues to increase after this point and the tendency to tuck continues to decrease, the rate of divergence between the two methods becomes much slower. By the end of the third year the hybrids carry all strips in the mouth, but they make small intention movements to tuck. These intention movements consist of little tic-like, side movements of the head just before the bird flies off to the nest.

The courtship behaviour of male hybrids, paired with female hybrids of this same cross, is intermediate between that of the two parental-species males. When the hybrid males are paired with parental-species females, their courtship behaviour, in most cases, is closer to that of the parental species of the female, although it sometimes remains intermediate. The species-typical behaviour of the females is thus seen to influence the pattern of male courtship. The courtship behaviours of some bird hybrids are not so greatly modified; for them, no permissible variability has been inherited.

Behaviour inheritance of crickets

Two cricket species, *Gryllus campestris* and *G. bimacularis,* are so similar morphologically that they can be distinguished from one another only with great difficulty. Their behaviours on the other hand, differ markedly. If the two species are crossed, however, the inheritance patterns may be traced by means of behaviour. Four behaviour patterns—antennal vibration in the post-courtship period, pendulum movements of the thorax, stridulation (rubbing one body part against another to produce sound), and fighting by young adults—have been investigated in particular detail. It has been found that antennal vibration and juvenile fighting in the hybrids have a monofactorial inheritance (*i.e.,* are caused by a single gene). The pendulum-like movement of the thorax during mating is found only in *G. campestris* and has a polygenic basis (*i.e.,* is caused by more than one gene). The stridulating sounds preceding courtship, performed only by *G. bimacularis,* are seemingly based on one pair of alleles (*i.e.,* different forms of a single gene).

Two races of honeybees are distinguished from one another by the presence or absence of hygienic behaviour. The race exhibiting hygienic behaviour opens comb cells containing dead pupae, which are removed. The nonhygienic race leaves dead pupae in their cells. The first generation (F_1) of hybrids contain only nonhygienic bees. One F_1 queen produces four kinds of drones, or males. When the F_1 is backcrossed with the hygienic form, a second generation (F_2) is obtained, which is made up of four different types of bees. One group is hygienic; one group opens the cells of dead pupae but does not remove the dead pupae; one group does not open the cells of dead pupae but removes the dead pupae if the cells are open; and the remaining group is nonhygienic.

THE INFLUENCE OF EXPERIENCE ON BEHAVIOUR

The adaptive change of behaviour as the result of experi-

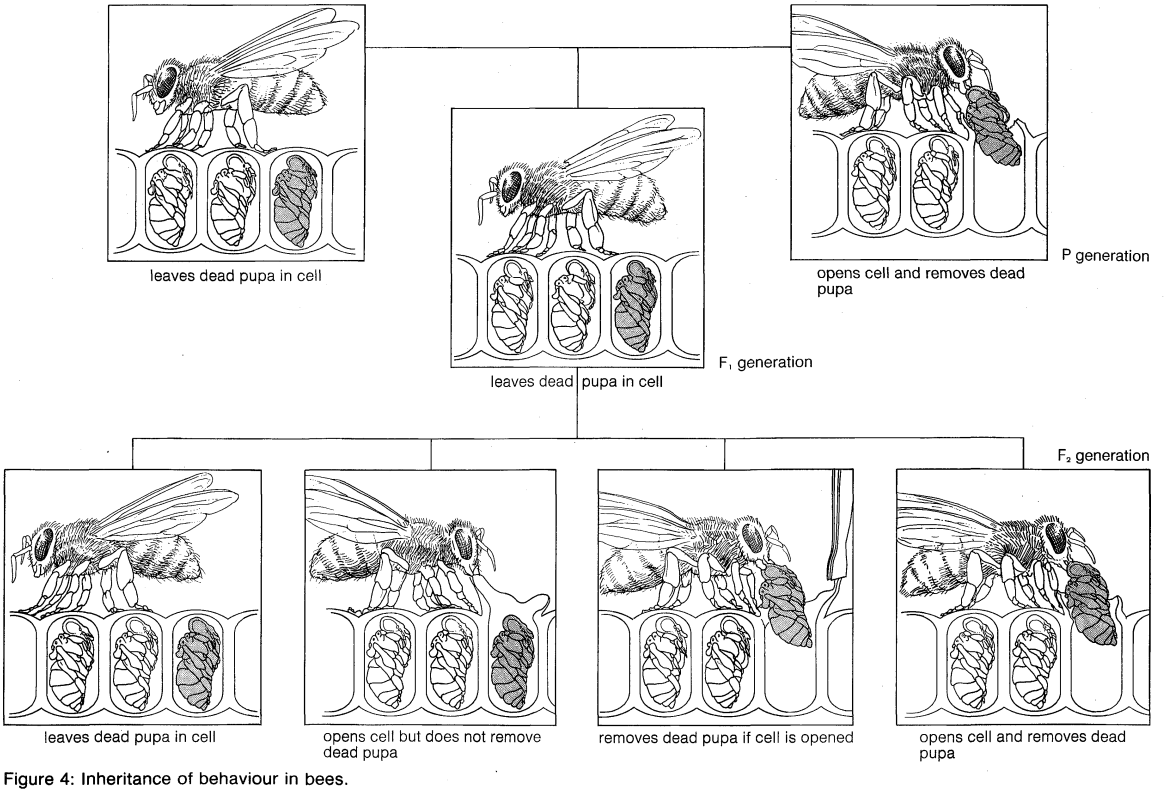

Figure 4: Inheritance of behaviour in bees.

ence—usually known as learned behaviour or experience-dependent behaviour—may be observed in all higher vertebrate forms. Several types of such learning in animals are recognized: habituation, classical conditioning (CR Type I), trial and error (CR Type II, instrumental conditioning, or operant conditioning), latent learning, insight learning, and imprinting.

Habituation. Habituation is learning to disregard stimuli that are without significance to the animal. In many respects it is the simplest form of learning, and it is sometimes regarded as a fundamental property of all living matter. Most animals inherit a response to be frightened by sudden and strong stimuli such as loud sounds, flashes of light, and the sudden intrusion of anything foreign into the animal's sensory field. Yet, if an animal reacts nonselectively to all phenomena such as rustling leaves, thunder, snapping twigs, and the sudden appearance of harmless animals, those phenomena that are significant to the animal's well-being will not receive the intensity of response that they often require. All animals, then, quickly habituate to such harmless stimuli, but the adaptation is highly specific. An animal that habituates to one type of sound does not, as a consequence of this habituation, become habituated to other sounds. Habituation is distinct from failing to respond to stimulation as a result of fatigue, sensory adaptation, or injury. The effects of habituation are generally long lasting. If an animal is repeatedly exposed to a potentially harmful stimulus (such as to a predator) without being harmed, habituation does not generally occur. Responses to dangerous stimuli often seem to have an inherited resistance to habituation—a mechanism of obvious survival value.

alivation xperi- nents of avlov

Classical conditioning. Classical conditioning was studied early in the 20th century by the Russian physiologist Ivan Pavlov, who observed that dogs salivate when food is placed in their mouths. He gave dogs food and, at the same time, provided another stimulus such as a flashing light or the sound of a bell. After a few such pairings of stimuli, a dog would salivate upon seeing the light or hearing the bell but without the presence of food. The dog had learned to associate the flashing light or the sound of a bell with food. A previously irrelevant stimulus that assumes significance as a result of association with a relevant stimulus is called a conditioned stimulus (CS). Salivation in response to such a stimulus is termed a conditioned response (CR). Prior to the learning experience, only the food (unconditioned stimulus) was effective in producing salivation (unconditioned response).

Such conditioned responses have been observed in a wide variety of animals, from lower invertebrates to man. Birds learn to avoid noxious insects in this manner; the distasteful monarch butterfly (*Danaus plexippus*) or a species of stinging wasp provide effective stimuli that quickly become associated with the appearance of such insects. This kind of association together with the conditioned response relevant to it is also the basis for Müllerian mimicry, in which palatable insects and other animals evolve to resemble noxious ones, thus enhancing their chances of survival.

Trial and error. In trial-and-error learning, an animal learns to behave in a particular way by associating something it does with a desired effect. If a dog's foot is lifted by the experimenter and food then given, the dog, after a few such trials, will spontaneously lift its foot in anticipation of food. Both classical conditioning (CR Type I) and trial-and-error learning (CR Type II) are termed associative learning, because in both cases an unconditioned response is associated with a conditioned stimulus. In natural situations an animal probably learns to associate certain spontaneous activity of its own with certain desired results, thus fixing the conditioned stimulus and response. Learning of this type often occurs when animals modify their behaviour during appetitive sequences such as those involving feeding and mating.

Latent learning. Latent learning is the association of indifferent stimuli or situations with one another without reward. The phenomenon is clearly exemplified in exploratory behaviour. Animals finding themselves in unfamiliar environments or among unfamiliar objects, but in familiar surroundings, show exploratory behaviour. The animal uses its sense organs on all that is novel, shows much ambivalence between approach and avoidance, and, finally, as the hesitancy to approach wanes, will test the novelty. A mammal may, at this point, sniff, nudge, or handle a strange object; a bird may peck at it. The first contact often results in abrupt avoidance, but, typically, the object or situation is, at last, thoroughly explored and finally abandoned if neutral. A mouse sniffs and pokes about most of a new environment. A bird, having sight and hearing, rather than smell and touch, as dominant sensory modalities does not have to occupy physically as much of a novel environment. Instead, it places itself successively at several vantage points and then carefully peers about and listens.

Subsequent behaviours of an animal can reveal that it has learned much about its environment during such an exploratory phase. It may learn, for example, the physical features of the environment and their spatial relationships to one another, the location of food and water, and the location of places safe from predators. Animals apparently learn all of these things early in their exposure to an environment, even though the information acquired may become significant only at some time in the future. The learning takes place without being associated with immediate reward (unlike that in conditioned response Types I and II) unless a need to know is postulated as a kind of immediate self-reward.

Insight learning. Insight learning is believed to be an advanced type of learning. Insight involves the spontaneous combination of a number of isolated experiences; the result is a new experience that is effective for gaining a desired result. Humans are able to exercise insight; it is extremely difficult, however, to identify such behaviour in most other animals. Animals are believed to use insight when they solve a problem too rapidly for normal trial and error to occur. It is possible that such an animal is carrying out trials in its brain; this implies reasoning ability. The higher primates are probably capable of insight learning at times, but further down the phylogenetic scale the evidence of such learning becomes progressively less conclusive.

Chimpanzees, to get food out of reach, will pile boxes to make a stand for themselves or will fit sticks together to knock the food down. These solutions may come quickly, an obvious result of prior experience (latent learning). Much trial-and-error learning is demonstrated, however, when they actually pile boxes or fit sticks together. In humans, insight is probably often aided by latent learning and trial and error.

Insight in chimpanzees

Imprinting. Imprinting, a learning process observed in young birds and mammals, is the identification of an animal with another animal. Normally, it is a relationship between members of the same species, but it can occur, for example, between a bird and a human. Imprinting can take place only during a particular period of the animal's development—a time span that is specific for each species.

In 1935 the Austrian ethologist Konrad Lorenz first observed the process in ducklings and goslings. After goslings hatch and become dry, they follow their parents. The adults provide warmth, safety, and shelter and bring the goslings food. The more uncomfortable a gosling becomes (*e.g.*, cold, frightened, hungry), the more intensely it follows. If goslings are reared by a human, they become imprinted to humans; thus, they ignore geese.

The development of this response occurs during a sensitive period, before and after which the response cannot be learned; if the response is not acquired during the sensitive period, it will never occur. Zebra finches that are isolated from their own species before they are 35 days old are never able to distinguish males and females of their own species. This is because their sensitive period for imprinting occurs before they are 35 days old.

The duration and time of onset of the sensitive period depend on the species and on the type of behaviour involved. Some animals imprinted to animals of another species will mate with members of their own species but, if given a choice, will prefer the animal to which they have been imprinted. Many species refuse social contact with any animal except the one to which they are imprinted.

Male golden pheasants (*Chrysolophus pictus*) imprinted to humans will court females of their own species but immediately transfer this behaviour to a human, should one appear. The same is true for budgerigars (*Melopsittacus undulatus*) and turkeys (*Meleagris gallopavo*). Mallard ducks imprinted to humans, on the other hand, will not associate with members of their own species (conspecifics) and will continue throughout their lives to treat humans as conspecifics. Imprinting is fixed for life, in contrast to other types of learning, in which forgetting is common. Imprinting of motor patterns, such as birdsong, also occurs. Exposure to a particular birdsong may be relatively brief and still be permanently fixed in the bird's memory. Chaffinches (*Fringilla coelebs*) learn their songs during the first 13 months of life, although they do not sing until nearly a year later. A 12-day-old nightingale (*Erithacus megarhynchos*) was kept in the same room with a singing black-capped warbler (*Sylvia atricapilla*) for about one week. The following spring the nightingale sang a typical black-capped warbler song.

Little is known about imprinting in mammals, but hoofed animals, such as sheep and horses, that are imprinted to man express this response by following him about. Dogs from four to six weeks old develop normal social responses to dogs or to another species such as man.

Imprinting in man

Imprinting apparently also occurs in humans. An infant deprived of its mother for a short period during its first year may develop serious mental retardation. A separation of several months—particularly during the seventh to the 12th month—will frequently result in irreparable damage; under such conditions, death may result.

PLAY BEHAVIOUR AND CURIOSITY BEHAVIOUR

Play and curiosity are exhibited by many mammals and by some birds and figure importantly in the learning of numerous activities. Play is especially characteristic of young animals, but the adults of many species also engage in it. Spontaneous curiosity, in which the animal actively seeks out novel situations for exploration, is exhibited by the young of mammals and some birds; indeed, they seem to be under the compulsion of some drive to do so. Carnivores and primates exhibit more curiosity than rodents, which gnaw novel objects and may hoard them. Monkeys inspect and manipulate such objects.

The curiosity drive implements the development of new motor skills and ensures the acquisition of new perceptual impressions, thereby resulting in new knowledge. The only reward, however, seems to be the performance of the activities themselves. Rhesus monkeys will learn a puzzle game without any reward except its successful solution. Among rats, it has been observed that the nerve cells in the lateral hypothalamus and preoptic regions of the brain are more active in those rats that explore. Electrical stimulation of these brain areas is rewarding to rats, and they will learn to press a lever that activates this stimulation.

Such curiosity behaviour seems linked to play behaviour. Play is difficult to define; it is usually easy, however, to distinguish a playing animal from one that is seriously occupied. An animal plays only when it is satiated and not preoccupied with other tasks. Play seems not to be dictated by immediate need but is extremely important in behavioral development. Only animals that spontaneously seek new situations on their own initiative play in the true sense. Invertebrates, fish, and amphibians do not seem to play. The taxonomic distribution of play among mammals and birds suggests that play is related to learning. Play involves interactions with the environment; this leads to the acquisition of knowledge about environmental features, including information about conspecifics and the animal's own possibilities of movement. Play behaviour occurs only at particular times; progression to a second play activity takes place only after a certain level of skill has been achieved in the first.

Mock fighting and fleeing

Much play appears to be fighting or fleeing behaviour, and usually it is easily identified as such. An animal that is play escaping or play attacking does not actually escape or attack. A rodent play fleeing into a hole, for example, quickly reappears. If a rodent's flight is truly an effort to escape, it reappears only after a much longer interval. Play-fleeing animals often reverse roles quickly, and the pursuer becomes the pursued. Threat behaviour that is associated with real attack is missing, and there is strong reluctance to bite. Play tends to be highly repetitive. A dog may retrieve a stick many times or play fight until it is exhausted or until a more interesting activity distracts it.

Bernhard Grzimek

Figure 5: Young chimpanzees exhibiting mock fighting behaviour.

Such play behaviour could mistakenly be postulated as the performance of immature instinctive activities. In many instances, however, this is known not to be the case. Much playful behaviour occurs at a time in an animal's life when it is fully capable of serious activity. Play also involves the use of species-typical patterns of behaviour in various sequences that do not occur in serious activity.

MODIFICATION OF INSTINCTIVE BEHAVIOUR BY EXPERIENCE

Behaviours based on both instinct and learning are commonly intercalated into functional wholes. In the peach-faced lovebird, for example, the cutting of nest-material strips is partly instinctive and partly the result of experience. The propensity for cutting is instinctive. This includes punching holes in the sheet of material from which the strips are fashioned and a "knowledge" of the proper width, length, and straightness of strips. The spacing of punch holes in such a manner as to form a strip is learned through experience. It is as if the animal has an instinctive picture in its central nervous system and persistently tries punching holes, in various relationships to one another, until the right pattern is made. The bird tends to repeat punching patterns that most closely approach the ideal and, thus, gradually, through progressively more satisfying feedbacks, approach the definitive functional technique of cutting strips. Idiosyncratic techniques develop—some birds stand on the sheet while cutting, and others stand off the sheet; some cut to the left, others to the right, and still others cut in various combinations of these directions. Birds developing their techniques try all of the directions and places of standing but gradually act with less and less variation. They do not need to observe experienced birds in order to develop a technique. The stimuli necessary for learning response are intrinsic to the birds' individual activities.

Song learning

If a meadowlark (*Sturnella magna*) is exposed to an alien song during its sensitive period for learning song, it will learn the alien song. Meadowlarks, then, learn their species-typical songs rather than inherit the capacity for particular melodies. But, if they are exposed during the sensitive period to alien songs along with meadowlark songs, they will learn only the normal species-typical song. Although the song must be learned, the bird instinctively learns the species-typical song if there is a choice. The bullfinch (*Pyrrhula pyrrhula*) instinctively learns the male parent's song rather than the species-typical song. Bullfinches raised by foster parents of another species will learn the song of the male foster parent, even though the

normal bullfinch song is also audible to it during the same period. In both types of song acquisition, learned and instinctive elements combine in the development of the species-typical song. Some species, however, do not learn their songs and do not need the experience of hearing others sing during their development. Different vocalizations in the same species are commonly acquired in more than one way. Some are purely instinctive; others are learned.

The behaviour of an individual animal is the result of a genotype that has developed over millions of years of evolution—a genotype that also permits a certain degree of variability through experience.

Hormonal and nervous control of behaviour

INTERACTION OF ENDOCRINE AND NERVOUS SYSTEMS

Physiological changes within an animal are largely the direct or indirect result of nervous and endocrine (hormonal) changes and their interactions. These changing states are also responsible for a changing responsiveness to internal and external environmental stimuli.

Neurosecretion

The endocrine system and the nervous system are probably of equal evolutionary age; the two systems may be evolutionarily linked. Certain nerve cells, or neurons, that are highly modified produce substances that pass through the axons (threadlike extensions of neurons) and into the bloodstream. These neurosecretory cells are sometimes clustered, forming glands that have connections with both the nervous system and the bloodstream. The endocrine glands are similarly distributed. Some may have evolved from clusters of neurosecretory cells. The vertebrate pituitary gland has evolved as a fusion between neural tissue and epithelial tissue (the lining, or covering, of organs) and is intimately associated with the hypothalamus, a ventral portion of the brain. The pituitary may be regarded as a master gland that regulates, with its secretions, all the other endocrine glands. The nervous system, in turn, has a regulatory effect upon the pituitary, which may also be influenced by feedback effects stemming from the secretions of other endocrine glands. This relationship permits the outside and inside environments to exert influences on the endocrine system. Seasonal changes in day length, for example, influence the nervous system by means of visual stimuli. The endocrine system is then activated through stimulation of the pituitary gland by the hypothalamus; the pituitary, in turn, secretes hormones appropriate to the most adaptive response. The ultimate effect of a seasonal change in day length may be migration or reproduction (see ENDOCRINE SYSTEMS).

The nervous system and the endocrine system interact with and complement each other. The nervous system sends information with great speed but of short duration along its pathways. Its messages can change rapidly. Hormones, secreted by the endocrine system into the bloodstream, travel much more slowly than nervous inpulses. The endocrine system can keep a message constantly available for many months if necessary. The nervous system generally affects only muscles and glands, but hormones can reach every cell in the body. Adrenaline is a hormone that acts with relative speed. It is secreted by the two adrenal glands, which are attached to the kidneys. The adrenals consist of two portions that differ from one another both in origin and in function. The inner portion is the adrenal medulla, and the outer portion is the adrenal cortex. During stress, such as occurs in fighting, mating, and fear, the adrenal medulla is stimulated by the autonomic nervous system to release adrenaline into the bloodstream. Some of the changes that occur throughout the body under the stimulus of adrenaline include hair erection, sweating, and acceleration of heartbeat and breathing; adrenaline also causes the blood to be diverted from the digestive tract to the muscles. All of these changes, and others, help prepare the animal for extreme effort. During brief stressful periods the bloodstream is quickly flushed with adrenaline, but the hormone is quickly dissipated. If the stress situation persists, other events take place—the adrenal cortex becomes involved, and its hormones are released. The cortex, unlike the medulla, is not under direct nervous control but is stimulated by another hormone, the adrenocorticotropic hormone, or ACTH, produced by the pituitary gland. Prolonged stress stimulates cells in the hypothalamus, which, in turn, stimulates the pituitary gland to produce ACTH. The cortical hormones in turn stimulate various responses to prolonged stress. Some of these responses are concerned with the metabolism of glucose, a sugar that may be associated with the utilization of food reserves. The effects of cortical hormones are, in any case, profound, and continuing stress will result in enlargement of the adrenal cortex, which leads to increased production of the cortical hormones. Chronic stress may cause severe illness and even death. It has been shown that rats confined to the territories of other rats will die as the result of overproduction of cortical hormones in response to the stressful situation. Stress as a result of overcrowding may also cause death in animals. Such stress may, in fact, be the cause of a decline in numbers of mice after they have reached a certain population level in a given area.

ACTH

SEX HORMONES

The pituitary hormones that have a direct effect upon reproductive behaviour are the follicle-stimulating hormone (FSH), the luteinizing hormone (LH), and prolactin (lactogenic hormone or luteotropic hormone). FSH and LH are called gonadotropins because they stimulate the gonads (ovaries and testes) to produce germ cells and gonadal tissue; gonadal tissue, in turn, secretes other hormones. Prolactin has a variety of effects. In different species of vertebrates, prolactin affects different target organs. In female mammals, for example, it stimulates growth of the mammary glands and the secretion of milk. It also stimulates the corpora lutea—glandular bodies of the ovary—causing them to produce another hormone, progesterone. In pigeons and doves, prolactin causes the characteristic modification of the crop (stomach) associated with the production of so-called pigeon's milk—a soft white substance that is passed from the mouth of the adult pigeon to that of the young. A slow change of colour in some fish is caused by the influence of prolactin on pigment cells. (Rapid colour changes are under nervous control.)

The gonads secrete hormones from special cells when stimulated by FSH and LH from the pituitary gland. Collectively, the female hormones are termed estrogens, and the male hormones are called androgens. Both androgens and estrogens belong to a chemical group known as steroids. All steroids have closely related chemical structures; the different vertebrate groups have slightly different steroid hormones that seem to be largely interchangeable in function. Removal of the testes or ovaries (castration) in vertebrates causes profound changes in behaviour and structure, especially if done early in life. Among many invertebrates castration has no such profound consequences. Apparently, therefore, only in the vertebrates are the gonads important endocrine organs.

Effect of castration

Androgens and estrogens control the development of the secondary sexual characteristics; they also effect the production of eggs and sperm from the gonads. Secondary sexual characteristics tend to be relatively permanent throughout life, but many are temporary, occurring only during the breeding season. Examples of temporary characteristics include the special breeding plumages and songs of many birds, the antlers of deer, colour changes in some fish, and all the behaviour associated with the formation of fertilized eggs (zygotes).

Progesterone, the production of which is stimulated by prolactin, is produced in mammals by the ovary. After an egg is shed, the empty follicle enlarges, forming the corpus luteum, a conspicuous yellowish structure, which secretes progesterone; progesterone, in turn, stimulates changes in the uterus preparatory to its receiving the fertilized egg. Progesterone also inhibits the contraction of uterine muscles. The females of other vertebrate groups produce structures similar to the corpora lutea of mammals. Birds, which have rather inconspicuous corpora lutea, also produce progesterone.

The amount of any hormone normally present in the bloodstream is minute. Artificially high levels often have marked effects; the introduction of massive doses of testosterone into females, for example, causes male sexual

behaviour. It will also cause female sexual behaviour in both sexes, in which case testosterone may be acting as a general stimulant.

Sometimes a massive dose of hormone has an effect opposite to the one expected. Female canaries (*Serinus canarius*) given overdoses of estrogen would be expected to show enhanced sensitivity of their brood patches (highly vascularized areas of skin in close contact with the eggs during incubation); instead, overdoses of estrogen may result in some desensitization of these areas.

It is tempting to conclude that the sex hormones have a direct effect on all the structures and behaviours concerned with the formation and nourishment of zygotes. Much is not known, however, about the hormonal control of behaviour. There may be feedback effects after the hormones have initiated a particular response; for instance, estrogen in conjunction with progesterone in some birds causes increased thickening and vascularization of the brood-patch area. The target tissues in this case (skin, blood vessels, and feather follicles) all have a nerve supply, and feedback through them to other parts of the nervous system could initiate further behavioral modifications. Physiological changes resulting from hormonal action may render an animal more or less responsive to its environment and thus modify its behaviour.

There is evidence that hormones directly affect behaviour by acting directly on neurons in the hypothalamus. If estrogen is injected into certain areas in the hypothalamus of castrated female cats, they develop strong estrous behaviour, even though the reproductive system remains underdeveloped.

Behavioral stimulation of hormone production

Behaviour may stimulate hormone production. Female cats, rabbits, and some other mammals are "induced ovulators." In other words, copulation stimulates the hypothalamus via the nervous system, and the pituitary gland is then stimulated to produce luteinizing hormones (LH), which in turn affects the ovaries. A few hours after copulation ovulation occurs at about the time the sperm have reached the upper levels of the reproductive tract; the germ cells meet, and fertilization takes place. In deer, sheep, and weasels, stimulation of the pituitary gland (resulting in the production of follicle-stimulating hormones [FSH]) is achieved when the animal senses a change in day length. The females of other mammal species (*e.g.*, the house mouse [*Mus musculus*]) seem to have an internally based clock that periodically triggers the release of FSH regardless of environmental changes. They may still be influenced, however, by the presence of a male.

Complex interactions between hormones and behaviour are known to occur in birds. The sight of a courting male stimulates the release of FSH and LH in a female dove (*Streptopelia risoria*). Physical contact between the birds is not necessary for this response to take place.

NERVOUS SYSTEM AND BEHAVIOUR

The nervous system receives information about the external environment through sensory receptors and about the internal environment through hormones, internal neural responses, and other physiological events. This information, regardless of the source, is processed in the brain or spinal cord, and appropriate responses are initiated by outgoing (efferent) nerve impulses leading to muscles or glands.

There is much evidence to support the view that the central nervous system (CNS) is hierarchically organized. Its organization is thought to consist of a system of centres, each with the function of collecting stimuli and appropriately redispatching them. Reproduction in the peach-faced lovebird depends first upon the activation in the proper sequence of a number of subordinate centres. These involve formation of a pair bond between a male and female; selection of a nest site; conduction of courtship; laying and incubating of eggs; and caring for the young. Nest building occurs throughout courtship, egg laying, incubation, and care of the young.

Subordinate events such as those mentioned above control, in turn, other neurally controlled events. Nest building, for example, consists of various subordinate activities that have already been described. Each of these subordinate activities also has subordinate activities. Tucking a strip of nesting material consists of several activities: simultaneously turning the head back over the rump, lowering the unfolded wing on the same side, and erecting the rump feathers; pushing the strip into the feathers, performing rapid hooking movements, which seem to function as an anchoring behaviour; releasing the strip; and, finally, simultaneously bringing the head, wing, and rump feathers back to the normal position.

It has been proposed that the smallest irreducible neuromuscular coordinations of an activity be thought of as acts. Each species is capable of performing a finite number of acts, and these are combined in various ways to produce all the behaviours of which an animal is capable. Each act is thought to have an act centre in the CNS. The act centres are subordinate to the behavioral centres, which coordinate them; behavioral centres are, in turn, subordinate to their initiating and coordinating centres and so on. The term centre in each case refers to a functional rather than to an anatomical locus. Portions of the CNS responsible for mediating a given response may be quite diffuse anatomically; typically, there may be much redundancy—a condition that frequently enables an animal to regain normal behaviour following damage to the CNS. Brain tissue, however, does not regenerate.

Act centres in central nervous system

Detailed implementation of various subordinate activities may depend upon the details of environmental feedback, as in the taxis components of many fixed action patterns (see above *Fixed action patterns*). Such detailed implementation may also depend upon long-term changes in behaviour that result from experience. Various releasing mechanisms may also be altered as a result of experience, as may the significance of various environmental stimuli. Experience may therefore exert modifying effects upon the input of information, its mediation in the CNS, and the details of its implementation through muscle coordination and glandular activity. These experiential effects may be of long or brief duration.

For many years the classical reflex was thought to explain adequately the mechanism of various behaviours. Such a reflex consists, in its simplest form, of an afferent neuron carrying information to the CNS, excitation then being carried to an effector (muscle or gland) via an efferent neuron. Intermediate neurons often occur between the afferent and efferent neurons. This entire mechanism is termed a reflex arc. In certain reflexes, the excitations activate the same muscles or glands from which the stimuli originate (monosynaptic reflexes). Most reflexes have intermediate neurons, and the stimulation of a single receptor may activate many effectors; similarly, the stimulation of many receptors may activate but a single effector. Chain reflexes occur as a result of one reflex triggering another. Additional reflex arcs may become established as a result of experience (conditioned reflexes), and some reflexes are thought to have facilitatory or inhibitory effects on others.

Reflex arc

It is now known that not all behaviours are the result of afferent impulses. Early in the 20th century it was found that cats' leg muscles with all afferent nerves removed still demonstrate rhythmic movement. Afferent impulses are not necessary for coordinated response; the swimming movements of eels and other fish, the crawling of earthworms, and the flying movements of grasshoppers are some examples. It is now known that spontaneously generated stimulation of the central nervous system initiates and controls much behaviour.

The evolutionarily older portions of the CNS, such as the spinal cord and the medulla and hypothalamus of the brain, seem to be concerned mainly with inborn behaviour such as heartbeat, breathing, and reflexes and with instinctive behaviour. The evolutionarily newer portions of the brain, such as the cerebrum of mammals, seem to be concerned either with new behaviours resulting from experience or with the modification of inborn behaviours. The conspicuous cerebrum of mammals often comprises a major portion of the brain. Although it is generally accepted that mammals, as a class of vertebrates, are the most intelligent of all animals, many birds seem to be capable of greater modification of behaviour through experience than are some mammals. Many other vertebrates, such

as certain reptiles and fish, are capable of learning new behaviours rather easily. It was long believed that, because birds and other nonmammalian vertebrates have little or no discernible cerebral tissue, their behaviours were instinctive. It is now known, however, that such animals are often capable of much behavioral modification as a result of experience and that some other portion of the brain must be involved. Different portions of the brain in different animal groups seem to have been selected for the development of learning ability. (W.C.Di.)

UNLEARNED BEHAVIORAL REACTIONS

Stereotyped response

A stereotyped response may be defined as an unlearned behavioral reaction of an organism to some environmental stimulus. It is an adaptive mechanism and may be expressed in a variety of ways. All living organisms exhibit one or more types of stereotyped response.

GENERAL CONSIDERATIONS

The capacity for unlearned behaviour is genetically determined in much the same sense as are the position, size, shape, and function of organs. Like structural features, stereotyped responses are the result of a continuing process of evolutionary modification and refinement. Those actions that most successfully aid the animal or plant in its basic drives (*e.g.*, reproduction, search for nourishment, escape from predators) are the ones most likely to be retained in succeeding generations. As environmental conditions change, inherently determined responses also become modified in order to ensure continuation of the species.

Problems of identification and analysis

The problems that arise in the study of stereotyped responses are many and varied. Particular responses in animals do not readily lend themselves to identification in highly evolved forms because learned behaviour patterns obscure the underlying unlearned behaviour; in addition, stereotyped responses provide the building blocks of instinctive behaviour, the complexity of which may obscure the integral parts (see below *Instinctive behaviour*). In lower animals, just as in plants, in which learned behaviour is absent or nil, the analysis of behavioral mechanisms is limited by the fact that many of the most fundamental cell processes are not well understood.

Animal behaviour, as a branch of psychology, represents a confluence between the disciplines of ethology and comparative psychology. Most of the pioneer work in stereotyped responses of animals was done by ethologists. During the first half of the 20th century, when much of the groundwork in experimental psychology was laid, ethologists (who were for the most part European) concerned themselves with behaviour in insects, fishes, and birds and were particularly interested in the evolution of instinct. The comparative psychologists during this formative period were mostly Americans. They studied primarily behaviour in common laboratory animals such as guinea pigs, mice, rats, and monkeys, and their interest tended to focus on environmental influences on behaviour as opposed to genetic influences. Since the 1950s, psychologists in general have recognized that both environmental and genetic factors play essential roles in any biological phenomenon. As a consequence of the separate development of ethology and comparative psychology, however, some difficulties have arisen in the use of terminology. The German-American biologist Jacques Loeb applied the term tropism to all oriented movements of organisms, and he proposed that all behaviour is composed of tropisms. Subsequently, to avoid confusion, the terms taxes (singular: taxis) and kineses were introduced by other investigators to refer to animal responses other than those of sedentary, plantlike forms. The terms also have been applied to certain plant movements. Although a variety of discrete stereotyped response movements occur in plants, particularly in higher forms such as flowering plants, these autonomous movements usually occur too slowly to permit detection by casual observation. That movements of plants or plant organs actually take place can be strikingly demonstrated by time-lapse photography, in which single photographs are taken at regular intervals as brief as seconds or as long as several days or more. The photographs are then compared or viewed in rapid sequence as a motion picture.

TYPES OF STEREOTYPED RESPONSES

Stereotyped response in animals may be separated into the following four categories: unorganized or poorly organized response, reflex movements of a particular part of an organism, reflex-like activity of an entire organism, and instinct.

Unorganized or poorly organized responses are given by early embryos or by animals (such as sponges) that lack nervous systems.

Reflex. Reflexes proper, or reflex-arc movements, include responses such as the immediate withdrawal of the hand on touching a hot surface. The basic components of the reflex arc are the receptor, or sensory-nerve cell, which senses the stimulus, and the affector, the nerve cell that directly activates the muscle. These are a theoretical minimum rather than an observed functional arrangement of cells in the body of an animal (see below *Varieties of instinctive behaviour*).

Reflex-like activities. Reflex-like activities of entire organisms may be unoriented or oriented. Unoriented responses include kineses—undirected speeding or slowing of the rate of locomotion or frequency of change from rest to movement (orthokinesis) or of frequency or amount of turning of the whole animal (klinokinesis), the speed of frequency depending on the intensity of stimulation. Examples of orthokinesis are seen in lampreys, which are

Orthokinesis and klinokinesis

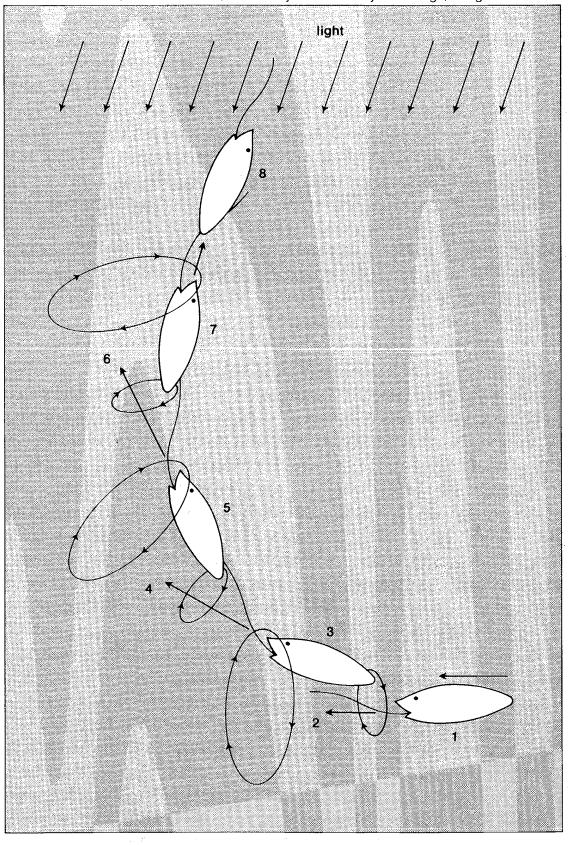

Figure 6: Klinotaxis in *Euglena*. As the animal swims in a spiral, the single eyespot at its front end swings in a circle. *Euglena* gradually orients itself so that the eyespot continues to receive even illumination.

more active in high intensities of light, and in cockroaches, which are more active in low intensities; flatworms and many fly larvae, among other invertebrates, show orthokinesis. Klinokinesis is well demonstrated by the movements of the wood louse (*Porcellio scaber*). When wood lice are placed in dry air, they crawl about actively but without direction until they become gradually dehydrated. When the lice are placed in humid air, they move at first, but any activity they exhibited soon ceases and they become quiet. Wood lice placed in a container with dry air at one end and humid air at the other gradually congregate at the humid end. This transfer is achieved through apparently random rather than directed movements.

Oriented reflex activities of entire organisms include tropisms, taxes, and orientations at an angle. Tropisms in animals are those directed growth-curvature movements of sessile (*i.e.*, sedentary) forms that lead to equal intensities of stimulation of symmetrically placed body parts. These movements are demonstrated by hydroid animals such as *Eudendrium.*

Taxes. Taxes may be described as oriented locomotory reactions of motile organisms. They exist in purest form as oriented, forced movements; that is, as reflex actions of entire organisms. When exposed to a single source of stimulation, the body is oriented in line with the source. Movement toward the source is said to be positive; that away from it is negative.

Klinotaxis is the achievement of orientation by alternate lateral movements of part or all of a body; there appears to occur a comparison of intensities of stimulation between one position and another and a "choice" between them. Klinotaxis is shown by animals with a single intensity receptor such as the protozoan *Euglena,* earthworms, and fly larvae. For several days before going into the pupal (or resting) state, the blow fly maggot tends to move away from a light source. As it crawls, it swings its head alternately left and right. Presumably a light receptor is located on the maggot's head, and differences in intensity between successive light stimuli as it moves its head determine the direction in which the maggot travels. This type of response is given more commonly to chemical stimuli than to light.

Blow fly maggot response to light

From N. Tinbergen, *The Study of Instinct;* The Clarendon Press, Oxford

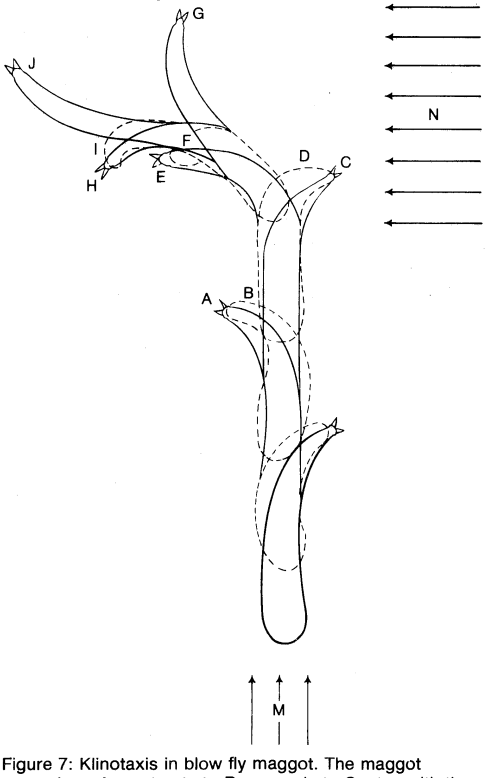

Figure 7: Klinotaxis in blow fly maggot. The maggot expands to A, contracts to B, expands to C, etc., with the light M on. At D, M is put out and N put on. The lateral movement to E is somewhat larger than A; the next one, G, increases the light falling on the receptors and is corrected by a swing over to H.

In tropotaxis, attainment of orientation is direct, resulting from turning toward the less stimulated (negative) or more stimulated (positive) side as simultaneous, automatic comparisons of intensities on two sides of the body are made. No deviations (trial movements) are required. Tropotaxis is shown by animals with paired intensity receptors. If exposed to stimulation from two sources, orientation is to some intermediate point and is determined by the relative intensity of the sources. If one receptor is effectively covered, the animal moves in spirals (circus movement). Tropotaxis is shown by many arthropods, especially insects.

In telotaxis, known only for responses to light, attainment of orientation is direct and without trial movements. When between lights from two sources, the animal orients to one light, rather than to some intermediate point. The animal switches orientation from one source to the other at unpredictable intervals and consequently follows a zigzag course. The response is given to the source as though it were a goal. Bilateral balance is not necessary, and circus movements, if they occur, demonstrate that the animal is reacting tropotactically rather than telotactically. Honeybees (*Apis*) and hermit crabs (*Eupagurus*), among others, show telotaxis.

Orientations at an angle (transverse orientations) may or may not be accompanied by locomotion. They include the light-compass reaction (menotaxis) and dorsal (or ventral) transverse reaction. Menotaxis is shown by foraging insects such as ants and bees that return to a fixed nest. It has been demonstrated experimentally by covering for 2½ hours an ant returning to its nest. After being uncovered, the ant proceeds not toward the nest but at the same angle to the Sun that it had been moving at the time it was hidden from the light.

In another demonstration of menotaxis, the sea slug *Elysia viridis* has been shown to move at angles of from 45° to 135° in relation to a steady source of light. No satisfactory explanation for this type of response in the sea slug is known.

Dorsal transverse action

Dorsal (or ventral) transverse reaction is demonstrated when the impact of the stimulus is kept at right angles to both longitudinal and transverse axes of the body. Locomotion need not occur. This reaction is given to light by various aquatic crustaceans—*Argulus,* the fish louse, and *Artemia,* the brine shrimp—and is given to gravity by crayfish. (Ed.)

Instinctive behaviour

The concept of instinct has come to refer to complex unlearned behaviour that is recognizable and predictable in at least one sex of a species.

CHARACTERISTICS OF INSTINCTIVE BEHAVIOUR

Heritability. Instinctive behaviour is largely heritable. Many of the activities of a species of animal are sufficiently constant and predictable to serve as specific characteristics in the same way, and often to the same degree, as do bodily structures. Examples of such heritable traits include the display movements of birds (*e.g.*, peacocks), the web-spinning movements of spiders, the burrowing habits of marine worms, the prey-catching techniques of weasels or wolves, the food-hoarding movements of squirrels, and the browsing methods of antelope.

The genetic or inherited nature of instinctive behaviour is particularly evident in aggressive and submissive sexual behaviour and in fighting of various kinds. Other instinctive activities of this kind serve nutrition, including methods of obtaining and eating food; care of the body surface, including cleaning, grooming, and scratching movements; escape from predators, including methods of concealment, freezing or "playing dead," and taking flight; social behaviour, including ways of responding to others both sexually and regardless of sex; and sleep, including the rhythms of rest and wakefulness and bodily positions assumed in sleep.

Many of these relatively fixed, species-characteristic types

of behaviour appear to be primarily inherited; at first sight, at least, they may seem little influenced by the particular experiences of the individual animal. But much instinctive behaviour as, for example, playing or exploring, is, nevertheless, modifiable, and the detailed form of the action taken may vary according to the circumstances of the moment and the individual experience previously encountered.

Complexity of pattern. Instinctive activity is not usually a limited response to a simple stimulus but rather is a sequence of behaviour that runs a predictable course; for example, nest-building behaviour that shows a patterned sequence of acts among many birds and some fishes. Many of these actions are far from being either simple or brief. Extraordinary elaboration may be found, and, although some instinctive behaviours may be complete in seconds, others may take minutes, hours, or days.

Adaptive function. Since instinctive behaviour is assumed to be genetically based and therefore shaped by the pressures of natural selection, it follows that most of the consequences of instinctive activity contribute to the preservation of an individual or to the continuity of the species; that is, instinctive activity tends to be adaptive, contributing to the animal's ability to reach maturity and to breed.

Stability under external change. Ideally, instinctive behaviour seems not to depend on learning or practice (see LEARNING, ANIMAL) but to emerge in full complexity without rehearsal when appropriate stimuli or circumstances are encountered. Often, such stimuli do not guide or mold the instinctive behaviour but seem simply to trigger or release it. This characteristic gives instinct the appearance of driving the animal endogenously (from within); the quality of instinctive activity thus appears to depend only secondarily on exogenous (external) stimulation.

Instinct and learning

Experiments in which an animal is raised in a very limited environment (perhaps in isolation, as when a songbird is kept alone in a soundproofed chamber from the moment of hatching) may indicate the extent to which behaviour is spontaneous (or endogenous) or is governed (or triggered) by external circumstances. Rather than seeking to distinguish sharply between instinct and learning, however, it may be more useful to assess the degree to which a given item of behaviour is environmentally stable or unstable (labile). Indeed, aspects of behaviour of a single species may differ greatly in this respect; thus, the nesting activity, calls of alarm, and courting behaviour of birds may be extraordinarily constant under varying conditions. On the other hand, food seeking and feeding may be extremely labile (or susceptible to learning), so that geographically disparate groups of individuals belonging to the same species may have very different feeding habits.

VARIETIES OF INSTINCTIVE BEHAVIOUR

No animal is ever completely isolated from some kind of environment; even in the egg or in the womb it is exposed to environmental variations just as it is after hatching or birth. There is, nevertheless, a sharp distinction between the egg or uterus phase and the free-living, active, sensing animal exposed to environmental stimuli of great diversity. In the case of the egg of an insect enclosed in a largely impervious shell or of a parasitic worm similarly isolated by an impermeable cyst wall, isolation from the environment may be so great that the animal undergoes little more than changes of temperature and oxygen supply. Thus, when such an animal emerges from its egg or cyst, the details of its structure and behaviour would seem maximally attributable to the genetic proteins in its cells; that is, its behaviour appears to be as much inherited as is its bodily structure. This sort of behaviour is environmentally so stable that it is naturally and quite reasonably given the label instinctive.

Reflex activity. A variety of what may be called simple instinctive behaviour has long been known as reflex action. When this term was introduced, it meant the simple and almost invariable response of a simple organ system (*e.g.*, a single muscle) to a simple stimulus, such as a touch or a flash of light. In its most elementary versions, this activity has been seen as the function of an idealized mechanism that has been called the reflex arc. The primary components of the reflex arc have been identified as the sensory-nerve cell (or receptor) that receives the stimulation, in turn connecting (hence the term arc) to another nerve cell that activates the muscle cell (or effector).

Although such a reflex arc might be the simplest imaginable mechanism for inflexibly automatic behaviour, it is, as noted above, a theoretical minimum rather than an actually observed functional arrangement of cells in the body of the animal; nevertheless, a mechanism but little more complicated than this helps to account for the locomotion of such animals as millipedes. In some insects, for example, the stepping movement of one limb or muscle provides stimuli that set off another limb or muscle on a similar course of movement, providing a kind of feedback system or chain of reflex arc activities. In most cases of this sort, however, the basic physiological mechanism is more complicated than the simple arc theory would suggest. Additional nerve cells capable of communicating with other parts of the body (beyond the receptor and effector) are invariably present in reflex circuits. Such connections are what make possible the conditioning of reflex responses.

Among higher animals, and perhaps many others (such as insects), what once were thought to be chain reflexes are not systems simply linked or chained together; they are systems under the precise control of coordinated complexes of nerve cells in particular parts of the nervous system, such as the spinal cord and brain. Even without evidence of a chain of feedback (or reafferent) stimuli, performance may be smoothly integrated. This is well illustrated by the complex movements of swallowing in mammals; in the dog, for example, 11 separate muscles or muscular systems are found to discharge one after the other, precisely timed to a matter of milliseconds, and all under the control of the central nervous system (CNS: brain and spinal cord). Such complexes of precisely controlled movement, known as fixed action patterns (FAP's), are thought to form the hard core of the inborn movement forms of instincts. When such sequences of uniform stereotyped responses seem to constitute an end point or goal-directed climax of some sort, they are known as consummatory acts.

Consummatory behaviour

Fixed action patterns. Some male spiders perform elaborate courtship actions that affect selectively females that are ready to respond sexually. The male, in testing for a receptive female, first stands out of reach and goes through elaborate precise gestures with limbs, pedipalps, and other body parts that are distinctively shaped or patterned in a manner characteristic of the species. Perhaps even more remarkable FAP's are found in the displays of male fiddler crabs of the genus *Uca*, about 40 species of which are distributed over the Earth's tropical ocean beaches. One of the two claws is enormously enlarged, seemingly having been evolved primarily for sexual and aggressive displays, and its ritualistic gestures are quite characteristic

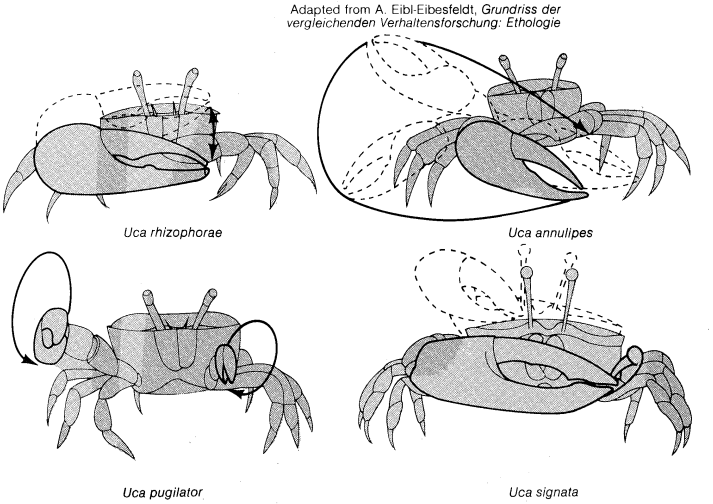

Figure 8: Species-specific instinctive movements of the claws in courtship behaviour movements of fiddler crabs (*Uca*).

of the species. The timing and form of movement are so invariable from one individual to another that an expert can distinguish by this alone the species of crab, whether it comes from the shores of Panama, Tahiti, or Bali.

There must be some very precise, built-in mechanism, presumably some integration of hormonal and nervous-system controls, which ensures that each individual in a species exhibits the distinctive FAP at the right speed, amplitude, and intensity. Beyond those noted for fiddler crabs and spiders, innumerable examples of such instinctive patterns are found among the elaborate display movements of many other animals, such as insects, fishes, and birds. Among the latter three groups, these movements also are part of the species communications mechanism, serving to permit members of a species to distinguish the signals of their fellows and prospective mates from all other visual stimuli. Thus, there is a system of instinctive perceptual abilities at least as complex as the inborn tendencies to exhibit patterns of motor behaviour. Likewise, the perceptual instincts are of primary importance for the survival of the species.

Modifiable action patterns. Some types of instinctive behaviour, while showing a rigid core of fixed action pattern, are still modifiable by conditioning and other learning processes (see above). A good example is provided by the nestbuilding behaviour of many birds: after the breeding female has chosen a nest site, she finds and deposits sticks or twigs or pieces of grass there. A jackdaw (*Corvus monedula*) or rook (*C. frugilegus*) standing on a potential nest locality with twigs held in its beak performs a downward and sideward sweeping movement that brings the material into contact with the ledge or the branches on which the nest is to be built. The moment the twig or branch carried by the bird meets resistance, the sideways movements become more vigorous and merge into a series of quick trembling thrusts (so-called tremble shoving). When the twig is in a position that offers even more resistance, the efforts become more intense until the twig wedges fast. After this consummatory achievement the bird apparently loses interest in his activities for the moment.

Tremble shoving

An inexperienced jackdaw at first will try any objects small enough to be handled, even pieces of ice and the metal ends of small electric bulbs. None of these ever becomes lodged firmly enough by the tremble shoving to result in a stimulus that is sufficiently consummatory to ensure successful nest building. Such failure quickly extinguishes the bird's tendency to fetch inadequate objects; equally rapid positive conditioning is effected, and the jackdaw learns to be a twig connoisseur, coming to use only those that are just right in shape and flexibility. Indeed, it has been observed that the nests of entire groups of such birds are predominantly constructed of twigs and other pieces that are taken from only one kind of tree, even though there are other building materials that are readily available.

In contrast to jackdaws, many small songbirds do apparently have an inborn tendency to select the kinds of materials that are appropriate for different phases of nest construction. This innate predilection for suitable building materials has been shown dramatically among canaries reared in man-made nests of felt. Even though female canaries thus reared have never encountered anything long and flexible before, when nest-building time comes, they can select materials appropriately. As soon as pieces of grass, bits of string, cotton, or any long flexible objects are placed in the cage, these female canaries display interest and, within seconds, carry the objects to the nest place and commence weaving movements. Once the proper state of construction has been reached, and not before, the birds display an innate tendency to line their nests with feathers, plucking out their own when no others are to be found.

A caged female canary long deprived of nesting material may take hold of one of its own feathers in its beak and, without detaching it, go through the motions of lining the nest with it again and again without, of course, actually lining the nest. Another striking example of complex nest building is found in the extraordinarily complicated movements and responses by which weaver birds build their elaborate hanging nests with such architectural features as roof, egg chamber, antechamber, and entrance tunnel. Research has identified an elaborate system of relations among external stimuli, internal hormonal conditions, neural function, and reproductive development in the behaviour of female canaries during the course of their breeding cycle. Evidence of an elaborate combination of innate physiological activity and individual experience also comes from studies concerning the development of songs and call notes among birds.

A young bird isolated from other members of its kind, or even more rigorously from all patterned auditory stimulation, produces an extremely limited, basic sound pattern. If the young bird is allowed to develop and sing along with other members of the species, however, the instinctive tendencies seem to be more fully realized through fine adjustments added by imitative learning.

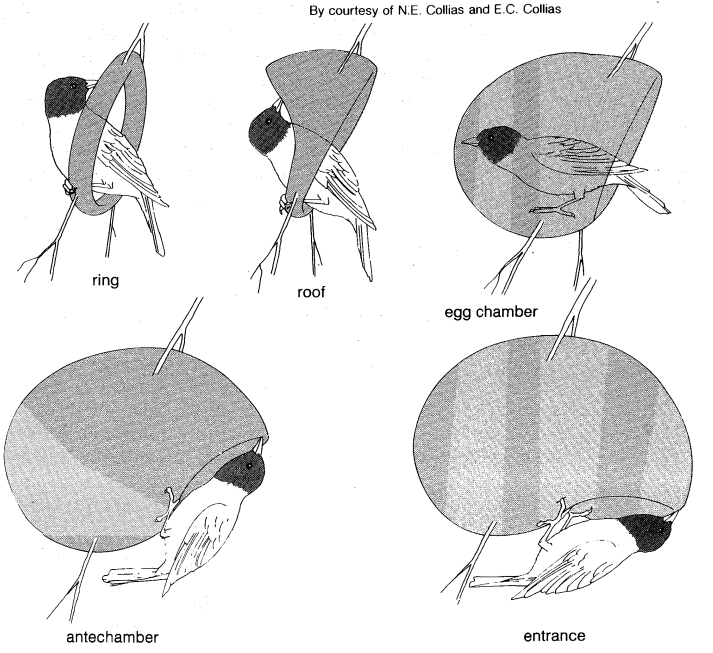

Figure 9: Five stages in the construction of a nest by the male village weaver (*Ploceus cucullatus*).

With more complexity in brain structure and function as is found in many mammals, behaviour is relatively flexible, and fixed action patterns tend to be overlaid by learned patterns and to that extent obscured; nevertheless, an inexperienced brown rat deprived of nest material tends to use its own tail instead, carrying it about in behaviour that is reminiscent of that shown by a feather-deprived canary. After gathering materials, brown rats typically heap them up in a more or less circular wall and then begin to tap down and smooth the inner surface of the nest cavity. When a very inexperienced rat is offered paper strips or other soft material for the first time, it goes into a random frenzy in which the sequence (gathering, heaping, and smoothing) is confused. Yet, each of the three phases is performed to perfection, not differing even on analysis by slow-motion films from those of an experienced rat. After having placed two or three paper strips together flat on the ground, however, the novice rat will perform heaping-up movements in the empty air above them, then apparently pat down a nest wall that is not yet in existence! Only later, after the animal has had more experience as a builder, does the rat seem to learn to inhibit the instinctive heaping and patting movements until the appropriate stages of construction have been reached.

Nesting rats

The catalog of instinctive behaviour among animals is much richer than the few examples offered here. Despite the clear differences observable in the detailed manifestations of instincts in comparing frog, goldfish, pigeon, cat, rabbit, and man, for example, all of these behaviours may be seen to hinge on genetically transmitted physiological structures and functions. Indeed, many animal instincts may profitably be compared with some of the built-in forms of behavioural tendency among plants. (W.H.T.)

Periodic biological phenomena

Continuous change characterizes both living organisms and their physical environment. Many of these changes occur irregularly and are termed aperiodic. Examples include the irregular variations in temperature, light, humidity, and other physical factors associated with the passage of weather systems; aperiodic, also, are the biological fluctuations in response to them. In contrast, are periodic fluctuations, relatively regular changes repeated at constant intervals of time. Clearly periodic, for example, are the natural fluctuations in daylight and in tides. Similarly periodic are the daily and tidal variations in both animals and plants as they respond and adjust to these periodic changes. Phenomena that recur with such regularity are termed rhythmic. Fluctuations of organisms in direct responses to long term environmental fluctuations are termed phenological. Examples of phenological phenomena include changes such as migratory movements and breeding periods.

The range of biological rhythms

Rhythmic variations in living systems are commonplace and span a very wide gamut of intervals. Among those possessing short periods and hence a high frequency of recurrence are wing beats of insects (20 to 2,000 cycles per second), brain waves (1 to 60 c/sec), walking and chewing rhythms (1 to 8 c/sec), heartbeats (20 to 1,000 c/min), and respiratory rhythms (4 to 250 c/min).

Other biological rhythms have only a few cycles per day. Examples are the variations in activity of very young infants, in depth of sleep of adults, in metabolism of chick embryos, in spiralling of growing plant tips, and in a number of bodily processes of the human during certain illnesses. Longer periods include the well-known several-day recurrences of fever in malaria and the few-day to several-month reproductive rhythms of mammals. Still lower frequency rhythms include the several- to many-year cycles of reproduction in the periodic cicadas, of abundance in animal populations, of prosperity in business, and of outbreaks of wars.

Fluctuations in living creatures occur at every level from the cell to activities of the organism as a whole and are evident in altered chemistry, physiology, and behaviour, including changing responsiveness to all factors of the environment.

Periodic biological phenomena fall into two more or less distinct different categories: those correlated with periodic changes of the planet (geophysical correlates) and those having no such correlates. Biological rhythms correlated with ocean tides, days, months, and years clearly relate the activities of organisms to the fluctuations of their physical environment as a consequence of the movements of the Earth. These rhythms possess properties that clearly set them apart from rhythms without external correlates, such as heartbeat and respiratory rate. The frequencies of these latter rhythms can be altered in response to changes in the immediate environment. Their frequencies also are altered readily by drugs and other chemicals and, as with metabolic rate itself, altered greatly as body-temperature changes. On the contrary, rhythmic variations with geophysical correlates have relatively fixed periods and are resistant to alteration in their frequency by either temperature or chemicals.

This extraordinary stability of the periods of the biological rhythms with geophysical correlates is not dependent upon direct responses to light and temperature rhythms. It was demonstrated more than two centuries ago that the capacity of plants to display their daily rhythm in sleep movements, the daytime raising and nighttime lowering of their leaves, persisted even when the plants were shielded from light changes and maintained in a relatively constant temperature. More recently, daily rhythms in a wide variety of living things, from single-celled forms to mammals and flowering plants, have been shown similarly to continue under constant conditions of light and temperature. Tidal rhythms in many shore organisms persist even after the organism is removed from the tidal environment. Comparably, semimonthly, monthly, and annual rhythmic variations continue even when organisms possessing them are deprived of every obvious periodic cue. Such organisms behave as if they possess the ability independently to time all Earth's major natural periods.

Adaptive significance of periodicity

A timing capacity, geared to the rhythmic variations of the natural environment, is indeed a most useful attribute. A time sense enables organisms to anticipate and exploit the most favourable portions of the day, tide, month, etc. It can be used by members of a species to synchronize their urge to breed. A time sense may serve, in conjunction with the Sun, Moon, and stars, as a means of geographic orientation for the migratory and homing activities of many organisms, just as a chronometer and a sextant enable a navigator to find his position or to plot a course.

BIOLOGICAL RHYTHMS AND NATURAL GEOPHYSICAL CYCLES

Living things are extraordinarily well adapted to their rhythmic environments and have become periodic in diverse aspects of their physiology and behaviour. The biological rhythms that have resulted are in part direct responses to the environment and in part indirect ones via the complex clock-timed organization.

Solar-day rhythms. Twenty-four-hour rhythms of organisms in nature are the rule; they are variously called solar day, circadian, diel, daily, diurnal, and nycthemeral. The evolution of life on Earth has proceeded in the direction of maximal utilization of every habitable niche, with species specialized to deal with virtually every kind of environmental site. This specialization is related not only to space but also to time. Some organisms have become specialized for the darker, cooler, more humid nighttime; others for the lighter, warmer, drier daytime; and still others for the transitional twilight periods. The environment is in use full-time, but for maximal efficiency organisms

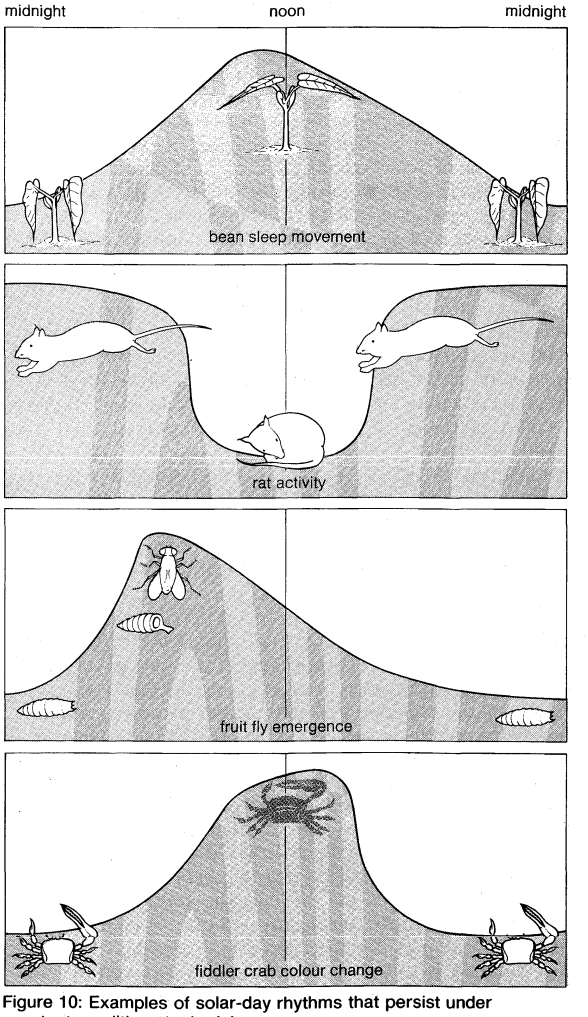

Figure 10: Examples of solar-day rhythms that persist under constant conditions in the laboratory.

are organized to work largely in "shifts." The night shift includes animals such as mice, cockroaches, scorpions, moths, owls, bats, skunks, opossums, and raccoon; the day shift includes songbirds, hawks, lizards, butterflies, and honeybees. Green plants alternate between the daytime use of sunlight in photosynthesis and the nighttime emphasis on growth and assimilation. Many plants undergo a daily sleep rhythm, their leaves drooping at night and rising by day. Some plants open their blossoms only at night, others only by day, with times commonly synchronized to the activity schedules of animals that pollinate them.

In each organism's daily pattern, a multiplicity of supporting chemical and physiological variations occur as the organism's whole being is thrown periodically into activity. In man, as an example, the daily alternation of sleep and wakefulness is accompanied by many changes, including activities of the nervous and endocrine systems and the liver and kidneys. Daily variations occur in body temperature, in heart and respiratory rates, and in pressure and composition of the blood. There are daily variations, also, in chemical syntheses and in cell divisions. Such rhythmically recurring phenomena are each set to the most efficient time of day for the organism and collectively contribute to the characteristic 24-hour phase map, or activity record, of that individual (Figure 10).

Daily variations in responsiveness

One of the very striking manners in which the presence of fundamental 24-hour variations is reflected in man and other animals is in changing responsiveness or susceptibility to physical and chemical insults. The following are a few examples. Doses of X-rays that at one time of day can kill every individual exposed will at another time kill only a few individuals or none. Doses of powerful poisons, fully lethal at one time of day, leave animals unharmed at another. Noise that can induce fatal convulsions in mice at one time of day fail to do so at another. The ability of histamines to induce inflammatory response, and the effectiveness of alcohol, insulin, and even aspirin vary systematically with time of day. In insects the degree of resistance to insecticides or to exposures to high temperatures also depends upon the time of day.

Lunar tidal rhythms. Another major environmental period is the lunar tidal rhythm, the regular ebb and flow of the ocean tides, a cycle that subjects seashore plants and animals to a rhythmic change with typically two high and two low tides occurring each lunar day of about 24 hours' 50 minutes' duration. Some intertidal organisms, such as barnacles, green crabs, snails, clams, and oysters, are most active when submerged by the rising tide. Others, such as shorebirds and fiddler crabs, are especially adapted to feed on beaches exposed at ebb tide. Some single-celled algae called diatoms move down into the sand and mud when the beaches are submerged and rise onto the surface to permit photosynthesis when the tide recedes. The diatoms and many of the shorebirds are active only when the beaches are exposed during daylight. Such organisms, therefore, display simultaneously 24-hour and tidal rhythms, which steadily undergo changing phase relations with respect to one another, coming into the same relationships exactly once each half-month. Indeed, all the organisms of the intertidal region must deal with both the daily light and temperature changes and the tidal ones. Fiddler crabs, for example, show concurrently a daily rhythm of skin colour change adaptively set to the times of day and night and a tidal rhythm of locomotor activity adjusted to the local tidal schedule.

Although the ocean tides are affected chiefly by the Moon, the gravitational attraction of the Sun also has an influence. The Sun and Moon "cooperate" at new and full moons to produce the greatest tidal ranges of each month, the so-called spring tides. At the Moon's quarters the Moon and Sun maximally oppose one another, resulting in the smallest tidal ranges. As a consequence, inhabitants of the seashore that occupy the highest and the lowest levels of the intertidal zone experience periodic tidal submergences or exposures only for brief intervals once each half-month. One species of marine snail that inhabits the upper level of the beaches has been reported to show a semimonthly activity rhythm.

Any living creature that possesses both tidal and daily variations will exhibit day-by-day patterns of variation that systematically change from one day to the next as the peaks and troughs in the tidal cycles, like the tides themselves, occur at progressively later times of day. The specific pattern of organismic variation through any given day will repeat itself exactly a half month later.

Animal navigation

An interesting expression of these rhythmicities is evident in the reported phenomenon of celestial navigation by animals. Such animals as birds, fishes, turtles, spiders, insects, and crustaceans have been variously described to navigate or to "home" by using the relative positions of the Sun or the Moon or, in the case of birds, even the constellations as geographic navigational guides. Such Sun-compass, Moon-compass, or star-compass navigation requires that the animals be able systematically to alter their orientational angle at rates to compensate exactly for the Earth's rotation relative to each of these celestial references.

Monthly rhythms. The synodic month, averaging 29.5 days, and the semimonth can be sensed by organisms, as noted earlier, through "beats" between their lunar tidal and circadian rhythms. Another kind of environmental monthly variation involves nighttime moonlight. Synodic monthly variations occur in such unlikely phenomena as rat and hamster running activity, light responsiveness of guppies, human colour vision, potato metabolic rate, and light responses of freshwater flatworms, even when shielded from all moonlight.

Among the biological activities linked to the synodic month are reproductive cycles of many different kinds of marine animals and plants. Best known and most studied of these are the monthly reproductive rhythms of palolo worms of the southwest Pacific, the fireworms of Bermuda, the grunions of the California coast, and the brown marine algae *Dictyota.* These rhythms are sufficiently precise in their relation to Moon phase and season of the year as to be predictable. The changing relations of the solar-day and lunar-day physical rhythms appear to time these breeding cycles, since the phase of Moon at which, for example, *Dictyota* breeds is related to the times of occurrence within the lunar day of the local high tides, which differ from place to place. The grunion's breeding is timed to within a few minutes of high tide on the local beach on the nights of its breeding, and the breeding times of palolo worms and fireworms are very accurately timed to within a few minutes in the day.

Precision timing of sea lily reproduction

The most spectacular precision in timing of a month- and year-related reproductive rhythm has been described for a deep-sea sea lily near Japan. This echinoderm liberates its sex cells once each year in October at about 3 PM on the day of one of the Moon's quarters. In succeeding years the time of sex cell release changes, among the Moon's two quarters, first-third-first, to progressively slightly earlier dates in October. The triplets are repeated until about the first of the month whereupon the following year it jumps abruptly to near the end of the month to start the advancing triplet progression again. The result is an 18-year cycle, which is essentially the period of regression of the Moon's orbital plane. There have been reports of monthly menstrual cycles in some primates with initiation of menstruation linked to the new moon. Reproductive swarming of mayflies has also been related to Moon phase.

Little is known about the timing of such cycles as the human menstrual cycle, the approximately semimonthly estrus cycles of sheep, the three-week cycles of cattle and pigs, and the six-month cycles of dogs. Three kinds of hypotheses have been offered for their timing: (1) they are timed by fully independent periodic oscillations within the organism; (2) they are dependent for their timing on periodic interference between 24-hour and lunar-day clocks, since most of them appear to be simple multiples of a quarter month; and (3) they depend for timing on monthly variations in moonlight (directed chiefly at the primate menstrual cycle). Some recent studies have given strong support for a long-held belief that the menstrual period is in some manner regulated by the Moon ("menses" means lunar month). In a study of a number of women with variable onset of menstrual periods, artificial illumination of the bedroom through the 14th to 17th nights following

the onset of menstruation resulted in a regularization of the period, with the period length coming very close to 29.5 days, the natural synodic month. That this period is a biologically significant one for the human species is further suggested by the fact that the average duration of pregnancy (from ovulation to birth) in the human is rather precisely nine 29.53-day synodic months.

Associated with the human menstrual cycle are related variations in almost every measurable bodily factor: temperature, blood chemistry, weight, heart rate, blood-cell counts, and pain thresholds are among the described variations. These factors pass through maxima and minima at different times but in such characteristic time relationships to one another that phase maps for the menstrual rhythm, comparable to those for the circadian, can be determined.

Annual rhythm. Another major rhythmic period for living things is the year. In most parts of the world substantial seasonal changes in light and temperature are correlated with rhythmic biological phenomena predominantly related to activity, reproduction, and growth. For example, in higher plants in the temperate zones, growth, flowering, and seed production typically occur over the course of the warmer months. In the oceans and fresh waters there are annual rhythms in plankton abundance. Annual reproductive rhythms in animals are typically set to the time of year that provides the optimum opportunity for birth and rearing of young. Annual rhythms include also hibernation to bridge the coldest period of the year and estivation to avoid hot-summer droughts.

The readily observable systematic annual variations in the activities of the plants and animals are accompanied by innumerable less obvious changes within their bodies, variations that pass through their peaks and depressions with such regularity that annual phase maps can be made.

Seasonal variations in human biology

Seasonal rhythms occur in humans and are evident in such phenomena as birthrate and weight and in growth rate of children. There are annual variations also in innumerable other factors, among them body temperature, heart rate, basal metabolic rate, blood-cell counts, and blood chemistry. Not surprising, also, are reports of annual variations for many systemic noninfectious diseases, and even for mortality. Many human infectious diseases are well known to exhibit peaks at characteristic times of year, while diseases without such evident annual fluctuations could perhaps be expected to display an annual variation in degrees of complications and mortality as a consequence of a probable annual variation in susceptibility related to the rhythmically changing biochemical and physiological states.

Too little investigated for man but difficult to treat because of the long period involved is the degree of phase shifting possible for the annual rhythms by manipulation of such physical factors as photoperiod and temperature.

Epochal rhythms. There are innumerable natural geophysical periods both shorter and longer than a year resulting from periodic activities in the Sun and from relative movements of the Earth, Sun, Moon, planets, and stars. Among the well-known shorter periods are the Sun-generated 10-cycles per second electromagnetic fields, suggestively similar to the 10-cycles per second alpha rhythm of the human brain. Variations in climate, rainfall, temperature, and light have been claimed to be correlated with many longer periods. Among the periods, and perhaps the best known, are the 11- and 22-year sunspot cycles, the 18.6-year period of lunar "wobble" (nutation), and the 26,000-year precession of the Earth's rotational axis. Beyond the solar system are the fluctuating galactic fields. Probably the longest physical period that has been suggested is the approximately 250,000,000-year period of rotation of the galaxy, which some believe to be correlated with terrestrial glacial periods. All these periods are accompanied by subtle alterations in the gravitational and electromagnetic fields of the terrestrial environment and so influence all living things.

Numerous several- to many-year biological periodicities involving a wide variety of phenomena have been described. Perhaps most familiar are the three–four-year cycles of lemming migrations and the eight–10-year cycles in abundance of the Canadian lynx, varying hare, and ruffed grouse. Still other biological periodicities described from tree rings, shell deposition in mollusks, fossil depositions, business, and wars have been claimed. Very commonly reported are cycles of about nine, 11, 18, and 22 years. Although it seems plausible that such geophysically correlated biological periodicities are real, their long-period durations, together with their cycle irregularities, tend to make difficult the critical establishment of their exact lengths or causal associations with environment periodicities.

THE BIOLOGICAL CLOCK

Natural time. Many organisms, man included, when removed from their natural surroundings and placed in a laboratory under constant conditions, can often repeat a rhythmic pattern that they had experienced before such isolation. It is concluded from such behaviour that the organism can time the length of the natural day and even determine the points and measure durations of relatively detailed periods within a single day. This timing capacity is essentially uninfluenced by temperature changes and all ordinary drugs and chemicals. Every living system studied behaves as if it contains a highly dependable clock. The specialized properties of this clock suggest that it involves some unique biological mechanism indissociable from life itself; however, the clock can be investigated only indirectly, through observing the more conventional biochemical, physiological, and behavioral processes timed by it.

Biological clocks that time the solar day, the period of the Earth's rotation relative to the Sun, have been the most extensively studied. Except possibly for the bacteria, the same kind of clock exists in members of every major group of living creatures. Single-celled animals and plants appear to possess just as accurate and effective clocks as do the most highly differentiated multicellular organisms.

A number of general properties of the clock-timed solar-day rhythms have been discovered. One such property is that under constant conditions in the laboratory the rhythms usually change slightly, becoming instead a little longer or shorter than 24 hours. This commonly observed deviation from the 24-hour period under these conditions led to the concept of circadian (about a day) rhythms. (The explanation for such variance is discussed below.) In day-active (diurnal) vertebrates circadian rhythms, in constant light and temperature, are typically shorter than 24 hours, while in night-active (nocturnal) ones they are typically longer. The periods of circadian rhythms under these conditions rarely exceed the range of 20 to 28 hours and usually are within an hour or so of 24 hours.

The basic circadian rhythm

When an organism is returned to its normal 24-hour light–dark environment, it soon resumes an accurate solar-day rhythm. The transitions from light to darkness and darkness to light appear to be the signals for readjusting the organism's daily physiological cycles. A nocturnal mammal, for example, adjusts its time of activity to the time of darkness, a diurnal songbird to the time of daylight. Such resetting or phase-adjusting factors for the rhythms are termed daily clues, phase setters, or synchronizers.

Involved in adjusting an organism's daily activity pattern to the appropriate time of day is a rhythmic variation in the influence of the light as a resetting factor. This variation has been termed a response curve. A light change near the time of the beginning of an organism's activity pattern advances slightly the phases of the cycle to an earlier time of day; a comparable light change near the end, on the other hand, extends it. At other times during the cycle comparable light changes have little or no phase-shifting influence. Although response curves appear to possess the same general form regardless of the kind of organism, each individual possesses its own detailed form of response curve, which adjusts its activity pattern to the light–dark cycles in its own characteristic manner.

Whereas light appears to be the dominant phase setter in adjusting clock-timed rhythms to natural 24-hour cycles, temperature is also effective. Many organisms are able to adjust their activity patterns to 24-hour rhythms in temperature in the absence of light variations. Still other phase setters have been reported, including sound, feeding time, and social interactions.

Free running rhythms

Modifiable clock-timed rhythms. The circadian rhythms that continue under experimental conditions of constant light and temperature are termed free-running; they reflect the underlying natural rhythms of an organism. The free-running period can usually be altered, but only very slightly, by changing the intensity of the illumination or the temperature. A 10° C (18° F) temperature increase seldom changes a circadian period more than 10 percent, and in most organisms the period is shortened. For fiddler crabs in constant darkness the free-running period, of exactly 24 hours, remains unchanged over a 20° C (36° F) range. In contrast to these relatively resistant rhythms, the rates for ordinary biochemical or physiological processes typically double or triple for each 10° C rise in temperature. Free-running rhythms sometimes cease spontaneously, only to resume at a later time as if the rhythms had been continuing undetected during the intervening time. In other words, a clock-timed phenomenon within the organism may become uncoupled from the underlying clock. Circadian rhythms sometimes fade out over the course of a few cycles under constant conditions; in other cases they appear to continue indefinitely, sometimes even with increasing amplitude and sharpness.

Although chemical inhibitors or stimulants of general metabolic processes can influence rhythmic processes, they appear not to affect the underlying clock in any way. Some powerful metabolic inhibitors such as cyanide will eliminate all overt rhythmic variation in an organism, but upon removal of the inhibitor, the rhythm returns as if it had been uninterrupted. On the other hand, exposure to near-freezing temperatures inhibits rhythmic changes in such organisms as fiddler crabs and cockroaches; but when the temperature is elevated again, the restored rhythms have been phase shifted by the approximate duration of the time of chilling.

There appears to be a genetic component to circadian organization. Organisms reared from eggs in constant light and temperature may display circadian rhythms spontaneously or may be induced to do so by a single abrupt light or temperature change, a signal that itself conveys no information as to period length. Furthermore, bean plants selected and interbred for longer and for shorter circadian periods under a given set of constant environmental conditions will beget offspring with, respectively, longer and shorter circadian periods under these same experimental conditions. The length of the free-running period is clearly genetically determined in part.

The influence of heavy water, which is D_2O, on circadian rhythms is of particular interest. Treatment of organisms as different as algae and mice results in a lengthening of the free-running periods. Under a 24-hour, light–dark regime, heavy water appears to alter the phase relations of the activity patterns of organisms to the light cycles.

Clock-timed circadian rhythms have been observed during rapid geographic translocations of organisms eastward or westward by airplane to other time belts. Investigations of this type, performed with fiddler crabs and honeybees, confirmed that the organisms carry circadian rhythms still adjusted to the light cycles of their former location (Figure 11). To reset them to the new local time requires several days of exposure to the local phase setters. This phenomenon is quite familiar to persons who have travelled long distances rapidly by jet airplane. The resultant rhythmic dislocation and the need for gradual adjustment over two to ten days at the end of such a trip is often referred to as the "jet syndrome."

Time dislocation: The "jet syndrome"

It is well known that, among the innumerable periodic changes that underlie and support the overt rhythms of behaviour of organisms, the peak values occur in a characteristic sequence over the day. A description of these comprises what is called a phase map. Such a sequence and spacing reflects the order and temporal relationships of cause–effect in the normal interactions of the various bodily processes. Phase maps may undergo transitory disruptions when an organism is compelled to make a rapid phase adjustment as, for example, after a rapid move to a new geographic longitude. Under such circumstances the various individual 24-hour components comprising the circadian phase map do not reset their phases to the new environmental times at the same rate. They may become somewhat displaced in their relations to one another. This dissociation of rhythmic components is probably the major cause of the fatigue and the lowered efficiency that characterizes the jet syndrome in human beings.

Another remarkable property of free-running rhythms is their capacity sometimes to maintain well beyond chance, and for extended periods, precise 24-hour periods and, in some cases, even to set their active period to their normal time of day without any obvious daily clues. The former has been described for fiddler crabs, gila monsters, mice, and kangaroo rats. The latter capacity has been observed in chicks and some lizards. These animals are apparently able to set their newly developed behavioral system to times of outside day and night by the use of subtle and as yet not fully identified signals.

The biological clock also times other natural environmental periods. Many plants and animals whose activities vary rhythmically with the tides have been found, when taken into the laboratory, to continue rather accurately their tidal rhythms. The period of these rhythms is about 12 hours 25 minutes, or 24 hours 50 minutes for the double-cycle, which is called a lunar day. The period of the tidal changes is correlated with the rotation of the Earth relative to the Moon. The tide, as does the Moon, rises on the average of 50 minutes later each day.

The properties of the tidal, clock-timed rhythms differ in

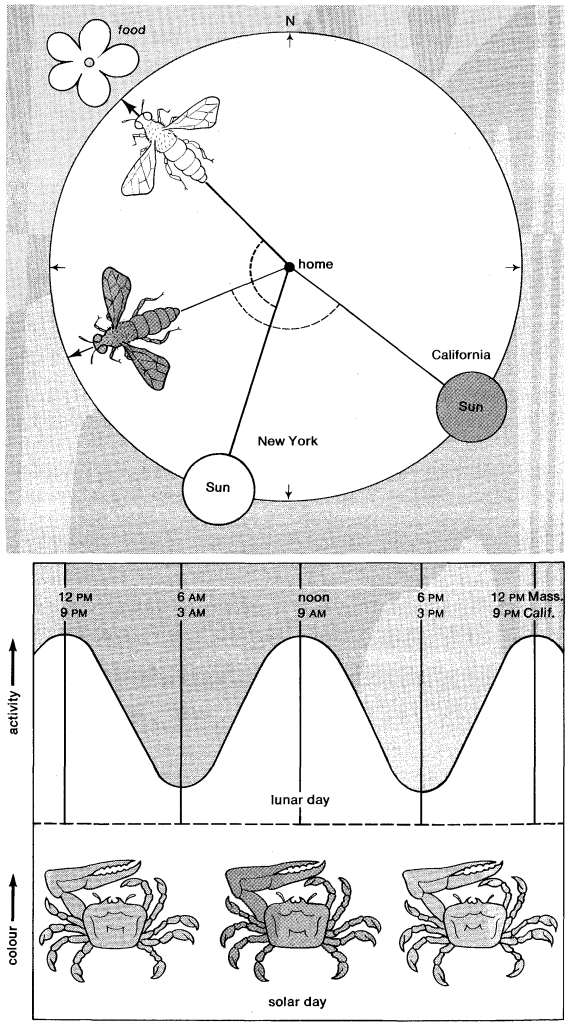

Figure 11: *The persistence of natural rhythms.* (Above) Bees trained in New York to fly northwest to a feeding station at 1 PM fly southwest at 10 AM when transported to California, following the sun's position as learned in New York. (Below) Fiddler crabs, moved from Massachusetts to California and kept in unvarying illumination, show activity rhythms and colour changes identical to their East Coast counterparts, regardless of the local time.

significant ways from the circadian ones. Although they possess the same high degree of temperature and drug independence of their period lengths, they will not synchronize to a 24-hour light–dark environment. Instead, tidal rhythms continue to move over the day at the tidal rate. This failure to follow the light cycles is obviously adaptive, since in nature the phase relationship of the tides to time of day systematically changes.

The clock-timed tidal rhythm can be adaptively adjusted to the tidal schedule of a specific beach. Fiddler crabs transported to a foreign beach with different tidal times gradually, over a few days, reset their tidal rhythms accordingly. The phase-resetting clues for the tidal rhythms remain unknown, though a number of factors such as mechanical wave action and periodic drying have been suggested.

Drifting of tidal rhythms

Clock-timed tidal rhythms commonly exhibit a tendency, under constant conditions of the laboratory, to drift away from their tidal setting until they approximate the actual time of lunar day. Oysters and fiddler crabs taken from their home beaches and kept in the laboratory gradually, during a week or so, reset their tidal rhythms to display their maximum activity at the times of the upper and lower transits of the Moon, as if some subtile synchronizers associated with the lunar tides of the atmosphere were now replacing the unknown local tidal ones.

There are clocked-timed synodic monthly rhythms of 29.5 days, the period from one new moon to the next. This is the period produced by "beats" between the solar days and lunar days—in other words, the interval between the times when the solar day and lunar day begin together. The Moon rises close to the same time of day once each synodic month. The organismic clock-timed monthly rhythms in some instances appear to depend upon a comparable interaction between tidal or lunar-day rhythms and solar-day ones. Interactions between 12.4-hour tidal rhythms and 24-hour circadian rhythms would yield semimonthly "beats," and between 24.8 hour double tidal cycles and 24-hour ones monthly "beats." Evidence for such clock-timed rhythms is seen in the occurrence of semimonthly colour changes in crabs kept under constant conditions. These exhibit phase differences among populations in their semimonthly rhythms accountable in terms of the differing phase relationships between their local tides and time of day.

The clock that times monthly rhythms appears to be just as dependable as those timing circadian and tidal rhythms. Monthly rhythms can, comparably, be phase shifted relative to the actual Moon phases. In addition to the phase setting by changes in some factors associated with local tidal movement, moonlight variations through the month have been suggested as a phase-setting factor for semimonthly and monthly rhythms, particularly the breeding rhythms of sea worms and the menstrual cycle for primates, including women.

Clock-timed annual rhythms, persisting in unvarying regimes of illumination and temperature and every other obvious clue as to the yearly period, have been reported for widely different kinds of organisms and phenomena. An alga, on the one hand, and the laboratory rat, on the other, have displayed annual variations in enzymatic activities. Seeds show annual variations in capacity to sprout, and newly germinated seedlings exhibit annual variations in their metabolic rate. Some birds show rather precise annual, and others *circa*-annual, reproductive cycles. Food intake of woodchucks has been reported to vary systematically with time of year. As for the other periods, the clock that times annual rhythms appears to be independent of temperature and uninfluenced by all attempts to alter its period chemically. The normal patterns of annual variation of many plants and animals can, however, be altered in response to changes in relative lengths of light and darkness (photoperiodism), much in the manner analogous to the phase resetting of the clock-timed circadian rhythm by times of light onset and termination. On the other hand, annual rhythms such as that of woodchuck food intake appear to be unalterable in phase by manipulation of either temperature or light.

Persistent clock-timed rhythms. There is another class of periodicities in organisms, rhythms that persist under the most carefully controlled laboratory conditions but that possess properties different from those described in the preceding account. These have precise solar-day, lunar-day, monthly, and annual periods. These have been discovered for respiratory or activity rates in a wide variety of animals and plants. The activity of an organism, other factors equal, varies systematically with local time of day, time of lunar day, time of month, and time of year. The potato, for example, shows a clear-cut sidereal-day (23-hour 56-minute period of rotation of the Earth relative to the stars) variation in its metabolic processes. These periodisms can not be reset or phase shifted. Moreover, there is no evidence to suggest that they are adaptive. The range of their variations is least for the sidereal-day and most for the annual period.

Fluctuating activity. Aperiodic, hour-by-hour fluctuations in metabolic rate or activity of organisms under presumably constant conditions continue to show correlations with weather changes, indicating beyond reasonable doubt that changing physical factors somehow continue to reach and influence the organisms, even in their experimental isolation. How do these external factors pervade the controlled environments of the laboratory? The answer perhaps may be found in a very highly specialized sensitivity of organisms to weak geoelectromagnetic fields that pervade the universe. Aperiodic biological fluctuations do coincide with fluctuations in such factors as background radiation, terrestrial magnetism, and primary cosmic radiation.

Influence of magnetism and radiation

The exogenous derivation (external to the organism) of these variations is indicated by the universality of response: the rhythmic patterns of these geophysically dependent fluctuations tend to show, among organisms spanning the gamut of kinds of living creatures, either the same general form or mirror images of parts or the whole of them, suggesting that all the organisms are responding to the same specific geophysical changes and that they have freedom only to determine the sign, positive or negative, of their responses to them.

The nature of the biological clock. As more information becomes available, it seems clearer that there are two kinds of rhythms, one resulting from response to the subtle geophysical environment, the other being rhythmic organismic responses to more obvious changes.

The timer for the first of these kinds of rhythms obviously lies outside the organism, and hence these rhythms are termed geophysically dependent. The detailed character of the biological cyclic pattern, however, is just as obviously determined by the nature of the biological response. The widespread general uniformity of the pattern for all organisms suggests that the response is generated at a very fundamental level of cellular organization. It must still depend upon the organism as an organized continuum whose composition and reactivity at any given point in time are related to past and future. The organism is, therefore, not a fully passive system in the generation of its exogenous metabolic periodisms. It may be an effective stimulus-filtering system.

The clock that times the overt, adaptive circadian, tidal, monthly, and annual rhythms is far less evident. Two kinds of hypotheses have been advanced. One, the internal-timer hypothesis, is that living systems can oscillate, fully independent of all environmental periodisms with close to, but not exactly, all major geophysical frequencies. Free-running rhythms are assumed to reflect directly the periods of the somewhat inaccurate internal clocks. Exact organismic solar-day, tidal, monthly, and annual periods are assumed to depend upon continuing corrections of the poorly accurate clocks by the environmental light, temperature, and tidal rhythms. The rates at which the clocks run are believed to be speeded or slowed to a small degree by changed levels of temperature and illumination as well as by certain chemical factors. The clock periods are assumed to be inherited, the approximation to the geophysical periods having resulted from natural selection.

The internal-timer hypothesis

By describing the rhythms as oscillations resembling in properties those of physical systems that become entrained or synchronized to other slightly different imposed

frequencies and treating them mathematically as such, surprisingly satisfactory descriptions of the observed dynamics of biological rhythms and phase setting of the rhythms can be obtained, useful predictions made, and new experiments suggested. Despite intensive research, progress has not yet been made in elucidating an internal oscillator system with the clock properties. The problem is compounded by the inability to differentiate between a biochemical or biophysical reaction that is in reality a clock element and one that is merely timed by the clock.

The external-timer hypothesis

Another hypothesis is that living things have evolved the capacity to use the subtle rhythmic input of geophysical periods to time their own processes to the most adaptive rhythmic patterns. In terms of this hypothesis the clocks are not inaccurate but quite precise (24-hour, 24.8-hour, 29.5-day, and 365 1/4-day clocks, for example). As long as the organism remains in its natural rhythmic environment, the clocks and the environmental rhythms of light, temperature, and tides have the same frequencies. When, however, the organism is placed under constant conditions, its circadian rhythm gradually drifts off phase. There will be phase advances alternating with phase delays in a cyclic manner as the constant light and temperature react at different points along the response curve. The recurring patterns will gradually shift to earlier hours if the advancing response is stronger than the delaying one or shift toward later hours if the delaying one is the stronger. This corresponds well with the observation that circadian periods deviate slightly in practice from 24 hours.

The self-setting to specific clock hour of solar day or lunar day or time of month or of year sometimes observed in constant conditions, as well as the very existence of the geophysically dependent periodisms, would find consistent explanation. The accuracy of the clocks during rapid east–west translocations would require either influence of a universal time-varying geophysical factor, phase-synchronized at all longitudes, as, for example, ionospheric charge, or a capacity to rephase its own rhythmic pattern in relation to a rapidly shifted exogenous local-time cycle effected by the metabolic inertia inherent in a continuing functional system.

In brief, some of the properties of biological periodicities definitely require for their explanation that timing information continuously flows inward from the environment, even in what have commonly been deemed constant conditions. Many other phenomena are equally compatible with either hypothesis, internal or external timing. Possibly both kinds of clocks are utilized by organisms. An environmentally dependent clock element may be responsible for the remarkable resistance to timing interference by temperature and chemical agents and for the long-term, relatively precise persistence of daily rhythms and particularly for the stability of the longer period monthly and annual ones. An environmentally independent clock element, on the other hand, may be essential for bridging shorter intervals of time within cycles but with perhaps a precision by itself inadequate to account for the observed regularity and dependability of clock-timed rhythms.

FACTORS AFFECTING BIOLOGICAL PERIODICITIES

The rhythmic patterns of variation of organisms differ from one species to another and also from one individual to another, even in response to essentially the same external conditions. The nervous and endocrine systems in interaction with the parts of the body that are coordinated and integrated by them contribute to these patterns. Under ordinary circumstances, activities comprising the patterns are arranged to meet an organism's demands anticipated over the period. Pathological or otherwise induced alterations in the organism alter the cycle forms. The periods, following those of the physical environment, usually remain unchanged. Reported, however, have been instances in blinded mice of circadian periods becoming free-running ones differing from 24 hours, resembling the state of affairs commonly seen when comparable mice are held in continuous darkness. Light, operating through the eyes, would appear in such instances to be the essential phase-setting agent.

The role played by the animals' total functional complex in determining the cycle form has been illustrated in respiratory patterns of unhatched chick embryos and in the activity of human infants. In conditions of constant temperature and light, chick embryos up to six days old show a daily activity variation with several peaks each day. By the seventh day, when they have just completed the development of a functioning sensory-neuro-motor system, the daily variation changes to one with a broad daytime higher activity and lower nighttime one. Well known, too, is the change in sleep-activity rhythms of infants. Up to about 15 weeks there are several cycles a day, but afterward the cycle simplifies to essentially a single longer period of wakefulness by day and sleep by night. It might be argued that the infant simply adopts the social pattern of the household, but in the chick the change in pattern with time seems clearly genetically determined.

The sleep-activity cycle of infants

It was mentioned earlier that evolution, involving natural selection, has suited species to fit each niche at a particular time within a cycle. In the continuing course of events a species is usually rigorously held to its rhythmic schedule by the competition of other species present at other times. It is an interesting observation, however, that some large day-active game animals in Africa, whose populations had been decimated by hunters, altered their natural patterns to become night active but resumed diurnal habits when their numbers again had increased. It is likely that comparable adaptive phenomena may be more widespread in nature than has been reported. (F.A.B.)

PHOTOPERIODISM

Photoperiodism is the behavioral response of an organism to changes of duration in daily, seasonal, or yearly periods of light and darkness. It was first reported in 1920 when the flowering of certain plants was demonstrated to be controlled by the daily duration of light.

The photoperiodic response of plants actually depends on the duration of the darkness, and not on light, as the earlier experiments seemed to indicate.

The most conspicuous activities of animals closely correlated with certain seasons of the year, and hence with changes in day length, are bird migration, reproduction, and changes in coat and plumage. Each of these occurs with marked regularity at a particular time each year. By retaining animals in captivity and subjecting them to artificial increases and decreases in day length, bird migration, reproduction, and other activities have been induced out of season. It has been concluded, therefore, that in nature the changing daily periods of light and darkness determine to a great extent when many seasonal activities occur.

Before their northward migration to breeding grounds in the spring, birds undergo a marked change in their physiological state. The change is shown by increased activity of the reproductive organs and deposition of large amounts of fat. When these same changes were induced experimentally in winter by exposing captive birds to artificial increases in day length, the birds migrated northward in winter when released. By employing different schedules of day length at various seasons of the year, it has been demonstrated that the rate of change in physiological state depends on the daily amount of illumination. As little as nine hours of light per day is stimulating. The response is rapid under long days and slow under short days. A gradual increase in the amount of light per day is not necessary. Constant day lengths are effective, as are decreasing day lengths, provided that the daily amount of light is stimulating. Therefore, migratory birds that winter on or near the Equator, where the day lengths are constant, or in the Southern Hemisphere, where the day lengths decrease after December 21, could have the onset of their spring migration regulated by day length. Prerequisite to the response to light that occurs in winter and spring is exposure to short days or long nights in autumn. This phase of the annual cycle is called the preparatory phase, since failure to complete it precludes the subsequent response. Under experimental conditions completion occurs uniformly and more rapidly with longer nights. Day lengths in autumn wind the "clock" within the bird, so to speak, while the day lengths of winter and spring make it run and determine how fast it runs.

Regulation of reproduction

In most birds, mammals, and other vertebrates, breeding is seasonal. By experimental manipulation of day length, reproductive activity has been induced out of season. For the species that normally breed beginning in autumn (*e.g.*, brook trout, deer, sheep, and goats), decreasing daylight or short days following long days will be effective. For species that breed in the spring (*e.g.*, starling, junco, ferret, and mink), increasing daylight or long days following short days will be effective. Changes in breeding season occur in some birds and mammals when they are transported from the Southern to the Northern Hemisphere or from the region of the Equator to temperate latitudes. Although day lengths are constant on the Equator and change but little in the tropics, there is some evidence that day length does regulate the breeding and plumage cycles of tropical birds. Experimental modification of the breeding cycle of invertebrate animals (*e.g.*, snails, crustaceans, and insects) by means of day length has also been demonstrated.

Attempts to discover how the length of daylight affects the breeding cycle have shown that the light stimulates the eye or part of the brain near the eye. The light stimulates the release of special hormones from the brain, which eventually reach the pituitary gland (the master endocrine gland located at the base of the brain). The pituitary, in turn, secretes the hormones that, among other functions, control the growth of the reproductive organs. There is good evidence that the length of the dark period and the ratio of light to darkness are important factors in determining the reproductive response. The effects of day length on the migratory response seem to apply as well to the reproductive response in some birds. Response to light can be modified by temperature, nutrition, and inherent internal factors. Important among the last is a daily rhythm of about 24 hours' duration, which makes it appear as though the organism were keeping track of each day. The response to light–dark cycles seems to depend in part on the time that the light and dark periods occur within these 24-hour periods. A few species of birds and mammals studied did not show any influence of light on the reproductive cycle.

The most conspicuous seasonal change in coat and plumage occurs in those mammals and birds that are white in autumn and winter and brown in spring and summer (*e.g.*, varying hare, ermine, and ptarmigan). By experimental manipulation of light, either of these colours can be produced out of season. Molt into white plumage or coat can be induced by short days. Temperature is not a factor. Day length also influences the time of annual molt in birds, growth of wool in sheep, and production of the winter coat in mink and ferret.

A number of less obvious seasonal activities also occur in response to day lengths. In some aphids, the production of winged individuals (as opposed to wingless individuals) normally occurs in autumn and is dependent on a period of darkness of 12 to 14 hours. In certain other insects the occurrence of sexually reproducing individuals, which occurs normally in autumn, can be produced out of season by shortening the days.

Practical applications of knowledge of photoperiodism are common in poultry management, for the length of daylight affects laying, sperm production, and body weight of the fowl. (A.Wo./Ed.)

BASIC BEHAVIORAL ACTIVITIES OF INDIVIDUALS

Feeding behaviour

The living cell depends on a virtually uninterrupted supply of materials for its metabolism. In multicellular animals the body fluids surrounding each cell are the immediate source of nutrients. The contents of these fluids are kept at a relatively constant level in spite of tolls taken by the cells, primarily by mobilization of nutrients stored in the body; in vertebrates, for example, glucose is stored in the liver, fats in the fat tissues, calcium in the bones. These stores, however, will become exhausted sooner or later, unless the animal takes up nutrients from outside. Movements performed for this purpose are termed feeding behaviour.

NUTRITIONAL REQUIREMENTS OF HIGHER ANIMALS

Catabolism and anabolism

Cells use nutrients as fuel for energy production (catabolism) and as material for processes of maintenance and growth (anabolism). Multicellular animals derive energy solely from the breakdown of complex organic molecules, mainly carbohydrates and fats. Because the fuel for the maintenance of animal life comes only from other living organisms or their remains, animals are known as heterotrophic organisms. All animal life depends ultimately on the existence of organisms (largely green plants) that can use inorganic sources of energy, of which solar radiation is by far the most important; some microorganisms, however, obtain energy from oxidation of simple inorganic compounds.

For anabolic purposes, food must provide adequate amounts of all chemical elements needed by the cells. Of the approximately 35 elements now known to occur in animal cells, four (oxygen, carbon, hydrogen, and nitrogen) make up about 95 percent of the cell weight; another nine (calcium, phosphorus, chlorine, sulfur, potassium, sodium, magnesium, iodine, and iron) contribute about 4 percent. All of these elements have indispensable functions. The remaining 20-odd, together constituting less than 1 percent of cell weight, are called trace elements, because they occur in minute quantities. Although some of them may become incorporated into cells by accident, many fulfill vital functions (see NUTRITION).

It is important to note that animal cells cannot synthesize from simple compounds certain necessary complex molecules. Instead, certain large organic molecules must serve as building blocks; such so-called essential dietary components include the vitamins, some amino acids, and certain fatty substances. In general, higher animals appear to have more restricted synthetic powers than lower ones and to require a correspondingly greater number of essential foodstuffs. Microorganisms in the intestines of vertebrates may synthesize materials essential for the host, so that the food of the latter need not contain these substances.

TYPES OF FOOD PROCUREMENT

Because much of animal evolution, as regards behaviour, as well as anatomy and physiology, involves adaptation for the procurement of food, the extent of the meaning of the term feeding behaviour is not clear. Migratory habits of birds, for instance, no doubt evolved in part as a result of seasonal food shortages; individual birds now, however, start migration before food becomes scarce. Migration, therefore, important though it may be in the feeding ecology of a species, is not considered in this section, which concentrates on food-directed activities that are enhanced by a need for nutrients in the body of an individual. For similar reasons, activities such as host finding and acceptance by internal parasites for themselves or their offspring also are excluded.

A classification of mechanisms of food procurement

Even with these restrictions, the diversity of feeding patterns is bewildering. A useful classification has been put forward by British zoologists Sir Maurice Yonge and J.A.C. Nicol, based on the structural mechanisms utilized, although, as Nicol observed, "many animals make use of a variety of feeding mechanisms, conjointly, or separately as occasion demands":

I. Mechanisms for dealing with small particles.

A. Pseudopodial (*e.g.*, many protozoans). Pseudopods consist of fingerlike projections of the cell membrane and its contents (cytoplasm) that surround and engulf food.

B. Ciliary (*e.g.*, sponges, bivalve mollusks). Cilia are minute hairlike projections of cell membranes that, by concerted beating in wave rhythm, set up water currents or physically move food particles.

C. Tentacular (*e.g.*, certain sea cucumbers). Tentacles are slender, flexible organs on the head. They may function in sensory perception and in actually securing food.

D. Mucoid (*e.g.*, many snails, such as *Vermetus*). In this case, the food particles become attached to a sticky mucous sheet secreted by special cells.

E. Muscular (*e.g.*, certain coelenterates). In the jellyfish *Rhizostoma,* pulsations of the bell-shaped body draw water and food in through perforations in the arms, then expel the water after the food is removed.

F. Setous (*e.g.*, many small crustaceans, such as copepods). Setae are bristlelike projections of the cuticle and are found on the appendages of many invertebrates.

II. Mechanisms for dealing with large particles or masses.

A. For swallowing inactive food, such as bottom deposits (*e.g.*, many polychaete worms, some fishes).

B. For scraping and boring (*e.g.*, some gastropod and bivalve mollusks).

C. For seizing prey.

1. For seizing and swallowing only (*e.g., Hydra,* many polychaete worms, many lower vertebrates).

2. For seizing and masticating (*e.g.*, Crustacea, mammals).

3. For seizing followed by external digestion (*e.g.*, some starfishes, spiders). (In such cases, the secretory and absorptive surfaces of the digestive system may be applied to the food by everting (*i.e.*, turning inside out) the stomach, a method employed by starfish. Alternatively, digestive enzymes may be injected into the prey, liquefying the tissues, which may then be ingested by the predator. This mechanism is found in spiders.)

II. Mechanisms for taking in fluid or soft tissues.

A. For piercing and sucking (*e.g.*, leeches, mosquitoes).

B. For sucking only (*e.g.*, many flies, butterflies).

For absorption through surface of body (*e.g.*, various invertebrates feeding on decaying organic matter, internal parasites such as tapeworms, which lack a digestive tract).

A different classification, often used, rests on the nature of the behaviour for procuring food:

A. Filter feeders strain food from the surrounding medium more or less indiscriminately.

B. Selective feeders analyze the environment with their sense organs before aiming feeding responses at chosen items.

Some feeding patterns, however, cannot be easily fitted into either of these classes alone; spiders, for example, sieve prey from the air with webs but perform directed responses to the insects trapped. Class I of the Yonge–Nicol system comprises mainly filter feeders; most members of classes II, IIIA, and IIIB are selective feeders. Selective feeding requires good sensory and nervous equipment and, in most cases, considerable mobility. It is therefore found mainly among higher animals. Yet the primitive sea anemones are selective feeders in that, capable of paralyzing relatively large prey with their stinging cells, they do not discharge them until informed by chemical and tactile senses that prey is present. At the other extreme, whalebone whales are filter feeders, even though they are highly evolved mammals. Swimming at the surface with mouth open, they filter off large plankton (krill) using several hundred horny plates with hairlike fringes hanging down from the roof of the mouth; availability of a rich food source has caused the evolution of their feeding patterns to diverge widely from that of most other mammals.

Evolutionary forces and limits on feeding pattern

In all cases, the feeding patterns adopted by species are the result of evolutionary interplay between (1) structural properties inherent in their phylogenetic line and (2) the ecological situations to which they have been exposed. These interactions are too complex to make generalizations profitable. The best approach is to study each species as a separate case in the light of its entire biology. A few examples are given below.

Filter feeders occur among sponges, coelenterates, polychaete worms, echinoderms, brachiopods, mollusks, arthropods, protochordates, fish, birds, and several other groups. As might be expected, filtering devices are diverse.

In the oyster, constantly lashing cilia drive a water current—up to 34 litres (about 36 quarts) per hour—through the openings of perforated gill plates. Particles only two microns (0.002 millimetres) in size are wrapped in mucus and transported by other cilia to special food grooves, along which they pass to the mouth by the action of yet further cilia; particles that are too large, too heavy, or capable of producing irritation are sorted out and rejected by various mechanical means.

The polychaete worm *Chaetopterus* uses a bag of mucus, secreted by special body appendages, to strain the water it pumps through its burrow. The mesh openings of the bag, about 40 angstroms (4×10^{-7} millimetres) wide, can even trap single molecules of large proteins. Every 20 minutes the food-laden bag is taken to the mouth, consumed, and replaced by a new one.

The sessile marine snail *Vermetus gigas* secretes mucus strings up to 30 centimetres (12 inches) long that extend away from the shell and entangle fine plankton. At intervals the strings are drawn back toward the mouth and swallowed.

Selective feeders, found among major animal groups, including coelenterates, annelids, echinoderms, mollusks, arthropods, and vertebrates, show even greater diversity of feeding patterns than do filter feeders. One striking point is that different groups deal in different ways with the same food in accordance with special capacities. Animals feeding on bivalve mollusks provide one example. The starfish *Asterias* forces the valves apart by the relentless pull of its sucker tube feet and then everts its stomach through its mouth to digest the soft tissues inside the shell. The snail *Sycotypus* attacks an oyster by stealth: waiting until the valves open, it thrusts its shell between the valves and pushes its tubular feeding organ, or proboscis, into the soft parts. Another snail, *Natica,* supports the scraping action of a filelike structure called a radula with chemical dissolution by sulfuric acid, which is secreted by a gland on the proboscis, and drills a neat hole in a clam. Another snail, *Fulgur,* cracks a clam shell against its own shell by contracting its columellar muscle. Among birds, the oyster catcher (*Haematopus ostralegus*) adroitly cuts the closing muscles of a cockle with its chisel-shaped bill; herring gulls (*Larus argentatus*) break a shell by dropping it onto a rock. A sea otter (*Enhydra lutris*) cracks a clam on its chest, while floating on its back, by pounding it on a stone held between the forepaws.

Various methods of feeding on bivalve mollusks

A few additional examples further illustrate the wealth of adaptations in selective feeding. The sluggish praying mantis (orthopteran insects of the family Mantidae) stalk insect prey until within reach, then carefully orient themselves and accurately and rapidly extend forelegs adapted for grasping. For detecting prey in murky habitats, bats use an ultrasonic echolocation system; some fish use electric pulses in a somewhat comparable manner. Anglerfish dangle a baitlike appendage of the first dorsal spine (luminous in deep-sea species) to lure the fish on which they feed toward their enormous mouths. Certain labroid fishes, which eat parasites off the bodies of other fish, induce their hosts to submit to treatment by a dancing approach; certain blennies treacherously mimic this behaviour and then rapidly bite the fin of the unsuspecting victim. Shrikes perform special wiping movements to remove the sting from certain prey, even without previous experience of stinging insects. The peregrine falcon (*Falco peregrinus*) dives at birds at speeds above 160 kilometres (100 miles) per hour; and the cheetah, or hunting leopard (*Acinonyx jubatus*), pursues antelope at more than 95 kilometres (60 miles) per hour. More than a thousand cormorants may join in a single fish drive. Instead of hunting, some species rob food collected by members of other species; among these robbers are the marauding skuas and jaegers (*Stercorariidae*) and man-of-war birds (*Fregata*), which force weaker cousins to disgorge already swallowed prey, and various tropical flies that take up positions along the line of march of army ants and rob the passing workers.

The driving force for the evolution of each of these adaptations is the survival value to the species of selecting the food sources for which it can successfully compete. For the same reason, closely related species living in the same area may tend to exploit separate parts of the environment; *e.g.*, woodland titmice (*Parus*) forage in different parts of the trees, and the larvae of different species of the moth genus *Eupithecia* prefer different food plants. The result of such evolution may be that a species becomes specialized to one kind of food, as have many internal parasites and phytophagous (plant-eating) insects. Such food may be exotic, as is that of the larva of a moth (*Galleria*) that feeds on beeswax. In other species, such as the herring gull, on the other hand, each individual exploits a broad range of foods, thereby lessening the risk of starvation, as

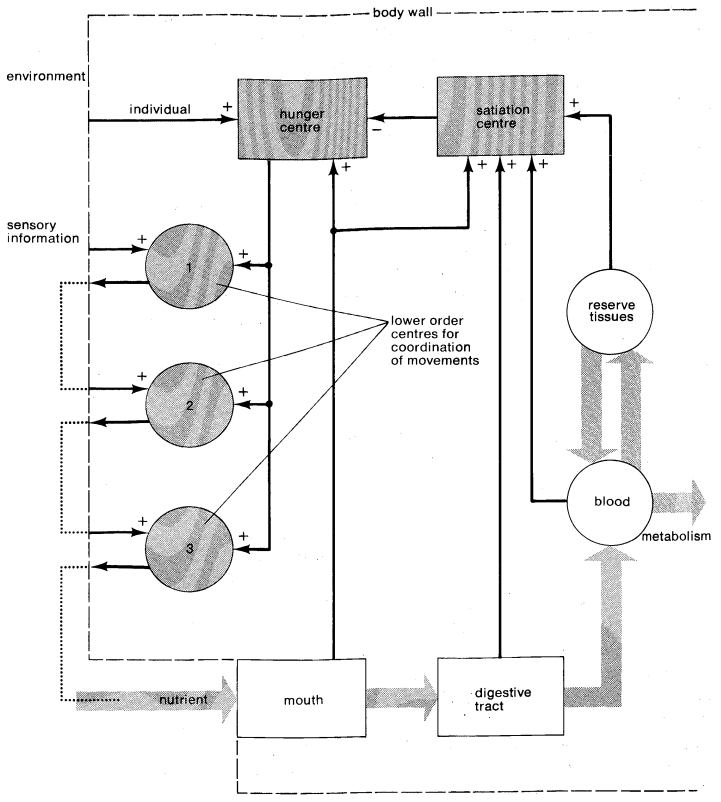

Figure 12: Diagrammatic representation of feeding control in a generalized mammal. Thin black arrows represent information flow; shaded arrows the flow of nutrients. The hunger centre is stimulated by general sensory information (*e.g.*, environment suitable for feeding behaviour). It, in turn, activates lower order brain mechanisms for food searching (1), food getting (2), and eating (3); performance of each of which prepares the animal for the next. Ingested food passes through the various compartments of the body, each of which sends messages to the satiation, or satiety, centre, which inhibits the hunger centre correspondingly. In addition, taste messages from the mouth stimulate the hunger centre.

it is unlikely that all types of food will become exhausted at the same time.

REGULATION OF FOOD INTAKE

Metabolic expenditure cannot exceed food intake for very long if an animal is to survive. One way to equalize the two processes is to decrease metabolism to a level sustainable by maximum intake, which may be limited by the ability to extract food from a meagre habitat. Data for filter feeders suggest that, in certain cases, continuous filtration at maximal rates may be barely sufficient to support normal growth and maintenance. Selective feeders have been found to undergo a more or less drastic reduction of metabolism during temporary starvation. Secondly, the capacity of the digestive system may set a limit on nutrient supply to the body. There is evidence that this is so in the minute filter-feeding crustacean *Daphnia magna*. Such limitations are known to play a role in human feeding behaviour.

In man and many other selective feeders, nevertheless, the capacities of food-gathering and digestive systems exceed all but the most extreme demands of metabolism. To maintain nutritional balance, feeding must then be geared to metabolic rate. Information on the mechanisms and even on the existence of such regulation of intake is scanty, except for mammals and some insects.

Vertebrates. Most information on the control of feeding behaviour in vertebrates has come from studies of mammals, but the general patterns found in mammals appear to be present in fish, amphibians, reptiles, and birds. Food intake requires a well-ordered sequence of searching, food getting, and ingestive activities. Sometimes the behaviour is elaborate. The following elements are distinguished in the various cats: stalking, spying, pouncing, thrusting down with the head, biting the neck, carrying into cover, plucking, and devouring. In grazing animals, the pattern is much simpler. In any case, the movement a feeding animal performs at a given moment depends largely on external stimuli; search and pursuit, for example, are unnecessary when prey is within reach. In this sense, any feeding act is a response to the environment, but it is not a simple "reflex." On repeated presentation of the same food situation, the individual sometimes shows the appropriate response but at other times will fail to do so. These fluctuations in responsiveness are roughly parallel in all elements of feeding behaviour. Responsiveness tends to be higher with increasing lack of food in the body. It appears that responsiveness of the brain mechanisms for feeding is governed by messages reporting the nutritional state of the body. The contents of these messages, in other words, are primary determinants of the level of feeding motivation (for other influences see below *Relation of feeding to other functions*). High and low levels of feeding motivation are the objective counterparts of the everyday concepts of hunger and satiety. Regulation of food intake, then, must hinge on the physiological mechanisms of the feeding motivation.

Elements of feline feeding behaviour

Specific hungers. Lack of any nutrient with a specific anabolic function, such as vitamins or minerals, must be redressed by increased uptake of the particular substance. Little is known thus far of the specific hunger mechanisms that ensure increased uptake, but good evidence exists that a nutrient deficiency causes a specific rise in responsiveness to food containing the substance needed. In the case of thiamine (vitamin B_1), a learning process is involved. The deficient animal tries various kinds of food and concentrates on those that remove the deficiency. Specific appetite for salt in a sodium deficient subject, on the other hand, appears to rest on a genetically determined increase in reaction to the taste of sodium chloride and does not require any learning.

Caloric regulation. Lack of fuel in the body can be corrected by intake of any of a variety of possible substances that provide energy. Most natural food contains a mixture of such substances. Energy deficiencies can be alleviated by increased responsiveness to food in general. Ingested food (*i.e.*, calories) passes from (1) the mouth to (2) the digestive tract to (3) the bloodstream; if not needed at once for catabolic processes, the digested food passes to (4) storage sites, of which the fat tissues are the most important. These four regions are continuously monitored. A considerable amount is known about the monitoring roles of the organs for taste, smell, and touch in the mouth region; in addition, distension receptors in the digestive tract monitor the volume there, and chemoreceptors monitor the nature of the contents. Information concerning the availability of glucose (the most commonly utilized sugar) and possibly other fuels in the blood is recorded by cells located probably both in the brain itself and elsewhere (*e.g.*, in the liver). Finally, circumstantial evidence suggests that the contents of fat tissues are also monitored. All food that passes through the body contributes to each of these four messages in succession, until it is eventually catabolized.

The signals converge on the brain mechanisms for the feeding motivation over nervous and, possibly, humoural (chemical) pathways. Here they have effects of two kinds: (1) if signals from the four regions report increased fuel contents, the feeding motivation is lowered (satiety is raised), and (2) if taste (and perhaps other, *e.g.*, visual) receptors are stimulated by palatable food the feeding motivation is increased. Intake stops when accumulation of signals of the first kind, overriding those of the second kind, causes hunger to drop below a critical level. Feeding is resumed when hunger surpasses this level as a result of fuel depletion by catabolism and emptying of the digestive tract by digestion and absorption. Once started, intake is enhanced by the positive effects of the food stimulus. The net result of this interplay of positive and negative feedbacks from food responses is that caloric intake, observed over a sufficiently long period (at least several days), is equal to energy output over that period, so that body fuel content (body weight in fully grown individuals) remains constant.

The brain mechanisms involved in vertebrate feeding motivation consist of a complex network, not yet well understood, encompassing, among other areas of the brain, the limbic system (the marginal zone of the forebrain) and the hypothalamus. The lateral hypothalamus ("hunger centre") facilitates feeding responses. Electrical or chemical stimulation of this area elicits voracious feeding in satiated subjects, and its destruction causes more or less prolonged noneating (aphagia). If the subject is kept alive by artificial feeding, however, other brain areas may take over and reinstate more or less normal feeding. In contrast, the ventromedial (lower central) nucleus of the hypothalamus appears to be a clearinghouse for satiety signals. Subjects with lesions in this area stop feeding only at an abnormally high level of energy content (obesity) and grossly overeat (hyperphagia) until this level is reached.

Control of feeding behaviour in the blowfly

Invertebrates. One of the few invertebrates in which the physiology of feeding behaviour has been extensively studied is the blowfly *Phormia regina.* Sucking is elicited by food stimuli on taste organs of the tarsi (the terminal sections of the legs) and proboscis. The meal continues until adaptation of these receptors causes their signals to decrease below the threshold of the sucking-response mechanism. This threshold is modulated, in the following manner, by food present in the digestive tract and in body fluids. As long as food is present in the foregut, the threshold is raised by signals from distension receptors in that area. The foregut is kept filled after a meal by release of food from the crop, where food taken up at the meal in excess of the capacity of the gut is temporarily stored. The threshold will remain high, therefore, until the crop is completely voided. The rate of crop emptying is directly related to the nutrient concentration of body fluids. The latter depends on the balance between absorption from the gut and uptake by the metabolizing tissues. The harder the fly works, therefore, the sooner sucking will be resumed, with the result that food intake is kept equal to caloric expenditure through appropriate spacing of meals.

SELECTION OF FOOD ITEMS

Most natural habitats offer a diversity of food objects, and most selective feeders are more or less euryphagic—*i.e.,* they ingest a variety of different foods; strict monophagy is less common. On the other hand, no euryphagic species includes in its diet all potential food objects present in the habitat, nor are those that it does eat taken in proportion to the amounts in which they are available. On what grounds, then, are diets selected?

Vertebrates. A plant species constituting only a fraction of 1 percent of a pasture may make up the greater proportion of the diet of a sheep. Insectivorous birds also take a highly biassed selection from the insect menu offered by the habitat. Although the relative abundance of different kinds of food is reflected in diets to some extent, this does not usually go so far that a single kind of food, however attractive and abundant, will become the sole constituent. Most vertebrates appear to take a varied diet whenever possible.

Responses to encountered food. Diet selection in adult vertebrates proves to be largely the result of individual learning processes that guide the genetically determined response potentialities of the newborn individual into certain definite channels.

Instinctive feeding in young animals

Innate responsiveness appears to be broad in species that forage for themselves from birth and thus must deal with many different food situations. The pecking of newly hatched chicks of domestic fowl at all kinds of small objects, edible or not, is an example. Yet these chicks have certain innate preferences for colour and other features. Such preferences may foreshadow the composition of adult diets. In newly hatched snakes, for instance, feeding responses are more easily elicited with extracts of the natural food of adults of the same species than with preparations of food of closely related species. In contrast, colour preferences of ducklings of different species are similar, although the adult diets differ.

Innate responsiveness may be narrow, however, in young vertebrates for whom the parent is the only source of food. Herring-gull chicks beg for food in response to a few "sign stimuli" provided only by the parent's head among all objects in the natural habitat. Sucking behaviour of newborn mammals is a somewhat comparable example. In such cases, responsiveness must be profoundly reorganized when the individual forages on its own.

Responsiveness is channelled into the adult pattern through experience of taste, nutritional value, and possible noxious properties of various objects. In this way the individual is able to attach a definite palatability rating to each type of food regularly encountered and to associate this with visual or other characters by which it recognizes objects from a distance. As demonstrated in experiments, insectivorous birds may discriminate precisely among as many as 40 different prey species in this manner.

In addition to palatability, detectability of food objects is a factor in diet selection. This has been studied in detail in visually foraging vertebrates. Detectability of an object depends on its degree of contrast with the background as to colour, shape, and movement. The individual predator can learn to detect prey that it finds only with difficulty at first; such "searching image formation" occurs only if the prey is palatable and encountered often.

Finally, responses to encountered prey also depend on (1) the hunger level of the individual and (2) its experience regarding the general food situation. Hungrier predators have lower palatability requirements and may take greater risks to secure prey. At one and the same hunger level, a prey of slight palatability may be rejected if the predator "knows" that further search will probably bring better food but accepted if it "knows" that nothing tastier is available. As a result of these two influences, animals concentrate during scarcity on food scorned in times of plenty.

Determination of search area by a predator

Food searching and diet. The general type of food taken is often determined by the innate search method of the animal and the section of the whole habitat being exploited. A fish-eating bird, such as the osprey (*Pandion haliaetus*), which secures prey by diving into water (but not swimming), is limited in its diet to fish species that are active near the surface. The much discussed question of whether food searching is random is relevant here, for certain kinds of nonrandomness can influence diets. No simple answer can be given. Search must be random in the sense that oriented reactions to food objects can be made only after detection; at the same time, however, the search may be systematic in that (1) places not recently traversed are favoured over those just unsuccessfully explored, and (2) the locality where a prey has just been caught or seen may be searched with special attention. Further, (3) it is most common for individuals to restrict their foraging to parts of the home range where ample food has been previously found, although exploration of other parts is interspersed and may change the destination of further trips if successful. In all, food searching appears to have sufficient nonrandomness to influence diets provided that different kinds of food concentrate in different parts of the home range, as is often the case.

To sum up, vertebrate diet selection is largely molded by learning processes. Insofar as their course depends on chance experiences of individuals, differences in diet may develop even among members of one population of a species. On the whole, however, patterns of food selection are typical of the species, as all its members have similar genetic makeup and live in broadly similar ecological situations.

Invertebrates. Learning processes appear to play a relatively small role in food selection by invertebrates. Diets are largely, though not entirely, determined by genetically fixed preferences. Intensive studies have been made of host-plant selection by phytophagous insects. Here, as in host selection by animal parasites, the question is one of the choice of a place to live rather than of food alone, and the selection criteria may be largely a matter of compromise between nutritional requirements and other ecological functions. Leaving aside these complications, the factors leading to selection of a particular plant as food are predominantly chemical, although other properties, such as structure, also play a role. The chemicals involved in part are the nutrients themselves, but often the feeding responses are largely elicited by token substances that are

not nutritionally essential but are characteristic of the species or family of plants that provide the natural hosts for the insect concerned.

SPECIALIZED ASPECTS OF FEEDING BEHAVIOUR

Relation of feeding to other functions. In principle, feeding must proceed throughout life at a pace equal to that of metabolism, but in many cases intake does not closely follow expenditure. It is permissible for intake to lag when there are reserves in the body. In some cases it is clear that large reserves are present in anticipation of increased metabolic demands or predictable food shortage—*e.g.*, hibernating mammals store large amounts of tissue fat before the onset of dormancy; migrating birds do the same before departure. Insect larvae store nutrients to last them through the pupal stage. Adults of many insects, such as mayflies, do not eat at all and have reduced mouthparts. Other species, such as the hamster, solve similar problems by laying in extracorporeal hoards of food.

Reserves and stores of food

Discrepancies between intake and expenditure, whether large or small, amount to distortion of the basic pattern of caloric regulation for the benefit of other functions.

Like most biological processes, feeding has a diurnal periodicity; *i.e.*, depending on the species, the active period may fall in daylight or during the night. Only in filter feeders is the activity often continuous.

Priority claims of other functions may lead to suppression of feeding even in hungry animals. Thirsty mammals or birds eat much less than normal because food intake would aggravate water shortage in the body in various ways. The same is true of mammals in a hot environment—*i.e.*, food intake increases heat production in the body and would thus intensify the heat stress—and of female mammals during estrus (periods of fertility). In all these cases, more or less marked loss of body weight results.

Social facilitation is a further cause of discrepancies as here considered. Individuals often start feeding when they observe other members of the same (or other) species doing so. Both timing of feeding and choice of food are affected in this way. Unfamiliar food is accepted more readily by individuals observing others eating it. Such phenomena have been noted in mammals, birds, and fish.

Food-directed activities in social situations. A further complication is that food-directed activities may be performed for the benefit of other individuals (see also below *Behaviour of animals in groups*). This may serve their nutrition or some other function. Marked weight loss may occur in songbirds as they feed most of the prey to their nestling young. Courtship feeding in many birds (and insects), in which the male gives food to the female, strengthens the pair bond rather than having a role in nutrition.

Remarkably intricate is the behaviour by which individuals of social-insect species—honeybees, for example—ensure nutrition of the colony. Tropical honey ants store nectar collected by the workers of the colony in the crops (stomachs) of certain workers that remain inside the nest and become so gorged that they are hardly more than storage bins. They disgorge droplets upon solicitation by other ants in the nest. "Dairying" ants keep aphids as suppliers of honeydew, a sugar- and protein-rich secretion. They milk the aphids by gently stroking them and, in return, protect them against enemies. The aphids may even be carried to the nest at the approach of winter and returned to a plant the following spring.

Fungi cultivation

A number of ants and termites cultivate fungi for food. Workers of tropical leaf-cutting ants carry pieces cut off the green leaves of trees to the nest, where other workers use them for making a bed on which the fungi grow. When a queen sets out to start a new nest, she carries a pellet of mycelium (the "root" system of the fungus) in a special pocket on her head during her nuptial flight and subsequent burrowing. After depositing it in the new nest, she manures it with a special secretion until the first workers start bringing in leaf fragments.

The motivational background of behaviour as discussed above has not yet been sufficiently analyzed. Much remains to be done in the more intricate—and even in the more straightforward—cases before satisfactory insight into the functions and causes of the behaviour of animals toward their food is achieved. (L. de R.)

Locomotion

To locomote, all animals require both propulsive and control mechanisms. The diverse propulsive mechanisms of animals involve a contractile structure—muscle in most cases—to generate a propulsive force. The quantity, quality, and position of contractions are initiated and coordinated by the nervous system: through this coordination, rhythmic movements of the appendages or body produce locomotion.

Animals successfully occupy a majority of the vast number of different physical environments (ecological niches) on Earth; in a discussion of locomotion, however, these environments can be divided into four types: aerial (including arboreal), aquatic, fossorial (underground), and terrestrial. The physical restraints to movement—gravity and drag—are the same in each environment: they differ only in degree. Gravity is here considered as the weight and inertia (resistance to motion) of a body, drag as any force reducing movement. Although these are not the definitions of a physicist, they are adequate for a general understanding of the forces that impede animal locomotion.

To counteract the force of gravity, which is particularly important in aerial, fossorial, and terrestrial locomotion, all animals that live in these three environments have evolved skeletal systems to support their body and to prevent the body from collapsing upon itself. The skeletal system may be internal or external, and it may act either as a rigid framework or as a flexible hydraulic (fluid) support.

To initiate movement, a sufficient amount of muscular work must be performed by aerial, fossorial, and terrestrial animals to overcome inertia. Aquatic animals must also overcome inertia; the buoyancy of water, however, reduces the influence of gravity on movement. Actually, because many aquatic animals are weightless—*i.e.*, they possess neutral buoyancy by displacing a volume of water that is equal in weight to their dry weight—little muscular work is needed to overcome inertia. But not all aquatic animals are weightless. Those with negative buoyancy sink as a result of their weight; hence, the greater their weight, the more muscular energy they must expend to remain at a given level. Conversely, an animal with positive buoyancy floats to and rests on the surface and must expend muscular energy to remain submerged.

Buoyancy

In water, the primary force that retards or resists forward movement is drag, the amount of which depends upon the animal's shape and how that shape cleaves the water. Drag results mainly from the friction of the water as it flows over the surface of the animal and the adherence of the water to the animal's surface (*i.e.*, the viscosity of the water). Because of the water's viscosity, its flow tends to be lamellar; *i.e.*, different layers of the water flow at different speeds, with the slowest layer of flow being the one adjacent to the body surface. As the flow speed increases, the lamellar pattern is lost, and turbulence develops, thereby increasing the drag.

Another component of drag is the retardation of forward movement by the backward pull of the eddies of water behind the tail of the animal. As they flow off an animal, the layers of water from each side meet and blend. If the animal is streamlined (*e.g.*, has a fusiform shape), the turbulence is low; if, however, the water layers from the sides meet abruptly and with different speeds, the turbulence is high, causing a strong backward pull, or drag, on the animal.

Aerial locomotion also encounters resistance from drag, but, because the viscosity and density of air are much less than those of water, drag is also less. The lamellar flow of air across the wing surfaces is, however, extremely important. The upward force of flight, or lift, results from air flowing faster across the upper surface than across the lower surface of the wing. Because this differential in flow produces a lower air pressure on the upper surface, the animal rises. Lift is also produced by the flow of water across surfaces, but aquatic animals use the lift as a steering aid rather than as a source of propulsion.

Lift and drag

Drag is generally considered a negligible influence in terrestrial locomotion; and, in fossorial locomotion, the friction and compactness (friability) of soils are the two major restraints. If the soil is extremely friable, as is sand, some animals can "swim" through it. Such fossorial locomotion, however, is quite rare; most fossorial animals must laboriously tunnel through the soil and thereafter depend upon the tunnels for active locomotion.

Movement in animals is achieved by two types of locomotion, axial and appendicular. In axial locomotion, which includes the hydraulic ramjet method of ejecting water (*e.g.,* squid), production of a body wave (eel), or the contract–anchor–extend method (leech), the body shape is modified, and the interaction of the entire body with the surrounding environment provides the propulsive force. In appendicular locomotion, on the other hand, special body appendages interact with the environment to produce the propulsive force.

There are also many species of animals that depend upon their environment for transportation, a type of mobility that is called passive locomotion. Some jellyfish, for example, develop structures called floats that extend above the water's surface and act as sails. A few spiders have developed an elaborate means of kiting; when a strand of their web silk reaches a certain length after being extended into the air, the wind resistance of the strand is sufficient to lift and carry it away with the attached spider. In one fish, the remora, the dorsal (top) fin has moved to the top of the head and become modified into a sucker; by attaching itself to a larger fish, the remora is able to ride to its next meal.

AQUATIC LOCOMOTION

Microorganisms. Most motile protozoans, which are strictly aquatic animals, move by locomotion involving one of three types of appendages: flagella, cilia, or pseudopodia. Cilia and flagella are indistinguishable in that both are flexible filamentous structures containing two central fibrils (very small fibres) surrounded by a ring of nine double fibrils. The peripheral fibrils seem to be the contractile units and the central ones, neuromotor (nervelike) units. Generally, cilia are short and flagella long, although the size ranges of each overlap.

Flagellar locomotion. Most flagellate protozoans possess either one or two flagella extending from the anterior (front) end of the body. Some protozoans, however, have several flagella that may be scattered over the entire body; in such cases, the flagella usually are fused into distinctly separate clusters. Flagellar movement, or locomotion, occurs as either planar waves, oarlike beating, or three-dimensional waves. All three of these forms of flagellar locomotion consist of contraction waves that pass either from the base to the tip of the flagellum or in the reverse direction to produce forward or backward movement. The planar waves, which occur along a single plane and are similar to a sinusoid (S-shaped) wave form, tend to be asymmetrical; there is a gradual increase in amplitude (peak of the wave) as the wave passes to the tip of the flagellum. In planar locomotion the motion of the flagella is equivalent to that of the body of an eel as it swims. Although symmetrical planar waves have been observed, they apparently are abnormal, because the locomotion they produce is erratic. Planar waves cause the protozoan to rotate on its longitudinal axis, the path of movement tends to be helical (a spiral), and the direction of movement is opposite the propagation direction of the wave.

Types of flagellar movement

In oarlike flagellar movements, which are also planar, the waves tend to be highly asymmetrical, of greater side to side swing, and the protozoan usually rotates and moves with the flagellum at the forward end. In the three-dimensional wave form of flagellar movement, the motion of the flagella is similar to that of an airplane propeller; *i.e.,* the flagella lash from side to side. The flagellum rotates in a conical configuration, the apex (tip) of which centres on the point at which the flagellum is attached to the body. Simultaneous with the conical rotation, asymmetrical sinusoidal waves pass from the base to the end of the flagellum. As a result of the flagellar rotation and its changing angle of contact, water is forced backward over the protozoan, which also tends to rotate, and the organism moves forward in the direction of the flagellum.

Ciliary locomotion. Cilia operate like flexible oars; they have a unilateral (one-sided) beat lying in a single plane. As a cilium moves backward, it is relatively rigid; upon recovery, however, the cilium becomes flexible, and its tip appears to be dragged forward along the body. Because the cilia either completely cover, as in ciliate protozoans, or are arranged in bands or clumps, the movement of each cilium must be closely coordinated with the movements of all other cilia. This coordination is achieved by metachronal rhythm, in which a wave of simultaneously beating groups of cilia moves from the anterior to the posterior end of the organism. In addition to avoiding interference between adjacent cilia, the metachronal wave also produces continuous forward locomotion because there are always groups of cilia beating backward. Moreover, because the plane of the ciliary beat is diagonal to the longitudinal axis of the body, ciliate organisms rotate during locomotion.

Metachronal rhythm

Pseudopodial locomotion. Although ciliar and flagellar locomotion are clearly forms of appendicular locomotion, pseudopodial locomotion (Figure 13) can be classed as either axial or appendicular, depending upon the definition of the pseudopodium. Outwardly, pseudopodial locomotion appears to be the extension of a part of the body that anchors itself and then pulls the remainder of the body forward. Internally, however, the movement is quite different. The amoeba, a protozoan, may be taken as an example. Its cytoplasm (the living substance surrounding the nucleus) is divided into two parts: a peripheral layer, or ectoplasm, of gel (a semisolid, jellylike substance) enclosing an inner mass, or endoplasm, of sol (a fluid containing suspended particles; *i.e.,* a colloid). As a pseudopodium, part of the ectoplasmic gel is converted to sol, whereupon endoplasm begins flowing toward this area, the cell wall expands, and the pseudopodium is extended forward. When the endoplasm, which continues to flow into the pseudopodium, reaches the tip, it extends laterally and is transformed to a gel. Basically, the movement is one of extending an appendage and then emptying the body into the appendage, thereby converting the latter into the former. Although the flow of the cytoplasm is produced by the same proteins involved in the mechanism of muscle contraction, the actual molecular basis of the mechanism is not yet known. Even the mechanics of pseudopodial formation are not completely understood.

From T.L. Jahn, *How to Know the Protozoa*

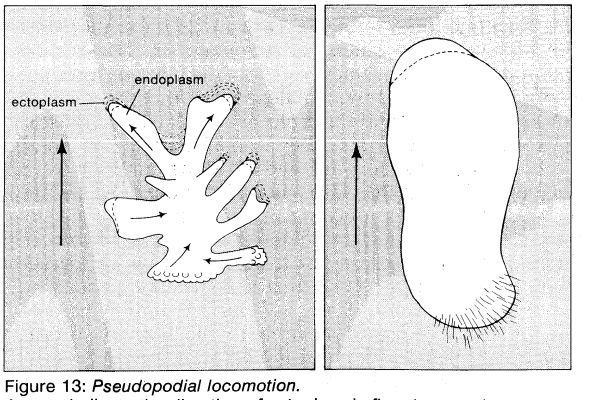

Figure 13: *Pseudopodial locomotion.*
Arrows indicate the direction of cytoplasmic flow (see text).

Undulating and gliding locomotion. Two other types of locomotion are observed occasionally in protozoans. Some protozoans, usually flagellates, have along their bodies a longitudinal membrane that undulates, thereby producing a slow forward locomotion. A gliding locomotion is commonly seen in some sporozoans (parasitic protozoans), in which the organism glides forward with no change in form and no apparent contractions of the body. Initially, the movement was thought to be produced by ejecting mucus, a slimy secretion; small contractile fibrils have been found that produce minute contraction waves that move the animal forward.

Invertebrates. As in the protozoans, aquatic locomo-

tion in invertebrates (animals without backbones) consists of both swimming and bottom movements. In swimming, the propulsive force is derived entirely from the interaction between the organism and the water; in bottom movements, the bottom surface provides the interacting surface. Whereas some bottom movements are identical with terrestrial locomotor patterns, others can occur effectively only in the water, where buoyancy is necessary to reduce body weight.

Bottom locomotion. Small flatworms (Platyhelminthes) and some of the smaller molluskan species move along the bottom by ciliary activity. On their ventral (bottom) surface, a dense coat of cilia extends from head to tail. The direction of the ciliary beat is tailward, causing the animal to glide slowly forward. Generally, all animals that move by this type of ciliary activity secrete a copious stream of mucus over which the animal glides. The mucus not only attaches the animal to the surface but also raises its body so that the cilia can beat. Because ciliary forces are too weak for the movement of large flatworms, they must use muscular contraction for their propulsive force.

Aquatic invertebrates possess several other types of bottom locomotion. In species with well-developed legs, such as crabs and lobsters, bottom walking is common. Whereas the gaits in such cases are identical to those used on land, they tend to be slightly faster in water, because the buoyancy increases the animal's stability. (Walking gaits are described below; see *Terrestrial locomotion.*)

Bottom creeping

Another form of bottom locomotion is bottom creeping, which employs the contract–anchor–extend method of movement. Bottom creeping is best developed in leeches, which have two suckers, one at the anterior end and one at the posterior end. After the posterior sucker anchors the animal, it stretches its body forward and attaches the anterior one. It then releases the posterior sucker and contracts its body toward the anterior end. For effective contract–anchor–extend locomotion, the body musculature must consist of both circular and longitudinal muscles: the contraction of the circular muscles extends or elongates the body; the contraction of the longitudinal muscles flexes and shortens the body. Moreover, the skeleton should be hydrostatic; that is, a fluid skeleton that changes shape but not volume, thereby providing a firm but flexible base.

In pedal locomotion, which is a slow, continuous gliding that is superficially indistinguishable from ciliary locomotion, propulsion along the bottom is generated by the passage of contraction waves through the ventral musculature, which is in contact with the bottom surface. The pedal contraction waves are either direct (in the same direction as the movement) or retrograde (in the direction opposite to the movement). The direct waves produce locomotion in a manner analogous to that in which a caterpillar walks. When a direct wave reaches a muscle, the muscle contracts and lifts a small part of the body; the body is carried forward and set down anterior to its original position as the wave passes. With direct waves, the surfaces of the body touching the bottom surface are not the ones that contract; with retrograde waves, however, these are the surfaces that do contract. As the retrograde wave approaches, the body area immediately adjacent to it is extended upward. The body surface within the contraction area then anchors itself to the bottom surface, after which the body is pulled forward.

Large flatworms use pedal locomotion instead of or in alternation with ciliary activity. In the gastropod and amphineuran molluscans (*e.g.,* snails and chitons, respectively), pedal locomotion is the primary locomotor mode and has become highly complex. The foot of these creeping animals is extremely muscular, penetrated by nerves, and capable of generating one, two, or four laterally adjacent contraction waves. If the foot generates a pair of waves, the lateral halves of the foot may alternate, thereby producing a shuffling movement, or they may be opposite. Generally, a foot can contain no more than one whole and two partial waves moving along a single axis.

Peristaltic locomotion is a common locomotor pattern in elongated, soft-bodied invertebrates, particularly in segmented worms, such as earthworms. It involves the alternation of circular- and longitudinal-muscle-contraction waves. Forward movement is produced by contraction of the circular muscles, which extends or elongates the body; contraction of the longitudinal muscles shortens and anchors the body (see below *Fossorial locomotion*).

Although peristaltic locomotion is frequently used by sea cucumbers, they and other echinoderms, such as sea urchins and starfishes, possess rows of tube feet that provide the main locomotor force. In starfishes, each arm bears hundreds of tube feet. Only one arm, however, becomes dominant in locomotion; while the tube feet on that arm move toward the tip of the arm, the tube feet of the other arms move in the same plane as those of the lead arm. Because there is no apparent metachronal wave of contraction within an arm, the movement of the tube feet is poorly coordinated, but small areas of the tube feet do move in synchrony. Each tube foot is a hollow elastic cylinder capped by a hollow muscular ampulla (a small, bladder-like enlargement). When the ampulla contracts, it forces fluid into the tube foot and extends it. Preferential contraction of muscles in the wall of the tube foot controls the direction of and the retraction of the tube foot. When the tube foot is fully contracted, fluid is withdrawn from it by relaxation of the ampulla, after which the muscles of the tube foot swing it forward in preparation for another step.

Tube feet

Swimming. Invertebrates have developed two distinct propulsive mechanisms for swimming: some use hydraulic propulsion; all others utilize undulations of all or parts of their bodies. The medusa (umbrella-shaped) body of coelenterates and ctenophores (*e.g.,* jellyfish and comb jelly, respectively) is a flexible hemisphere with tentacles and sense organs suspended from the edge; a manubrium (handle-shaped structure) bearing the digestive system hangs from the internal tip of the hemisphere. Enclosed in the outer margin of the medusa is a wide muscular band; when this band contracts, the opening of the medusa narrows. Simultaneously, water is ejected from the medusa through the narrow opening, and the animal is propelled upward. Because the contractions tend to be regular but slow, locomotion is somewhat jerky.

Scallops are the best swimmers among bivalve molluscans that can swim. Locomotion is produced by rapid clapping movements of the two shells, creating a water jet that propels the scallop. The muscular mantle (a membranous fold beneath the shell) acts as a valve and controls the direction of flow of the ejected water, thereby controlling the direction of movement. Nomally, the flow is directed downward on each side of the hinge that joins the two shells, and the resulting water jet lifts the scallop and moves it in the direction of the shell's opening. If necessary, however, escape movement may occur in the opposite direction. The scallop is adapted to swim even though it is two or three times as dense as seawater. The hinge is elastic and opens the shell rapidly; this action, coupled with rapid and repeated contractions of the adductor muscle, which closes the shell, produces a powerful and nearly continuous water jet. Moreover, the body form of a closed scallop is an airfoil (like a wing, the curvature of its upper surface is greater than that of its lower surface); this shape, combined with the downward ejection of water, produces lift.

Cephalopods (*e.g.,* squids, octopuses) are another group of mollusks that use hydraulic propulsion. Unlike the scallops, they have lost most of their heavy shell and have developed fusiform bodies. The mantle of cephalopods encloses a cavity in which are contained the gills and other internal organs. It also includes, on its ventral surface, a narrow, funnel-shaped opening (siphon) through which water can be forcibly ejected when all the circular muscles surrounding the mantle cavity contract rapidly and simultaneously. This water jet shoots the cephalopod in a direction opposite to that in which the siphon is pointed.

Many invertebrates, particularly elongated ones such as open-sea-dwelling annelids and mollusks, swim by undulatory movements produced by contraction waves that alternate on each side of the body. Although the arrangement of the musculature differs between invertebrates and vertebrates, the mechanics of undulatory swimming are the same in both and are described in the following section.

Undulatory swimming

Fish and fishlike vertebrates. Undulatory swimming is roughly analogous to using one oar at the stern of a boat. The side-to-side movements of the oar force the water backward and the boat forward. The undulatory movement of a fish acts similarly, although the motions involved are much more complex.

Anguilliform locomotion. When an elongated fish such as an eel swims, its entire body, which is flexible throughout its complete length, moves in a series of sinuous waves passing from head to tail. In this type of movement, which is called anguilliform (eel-like) locomotion, the waves cause each segment of the body to oscillate laterally across the axis of movement. Unlike the simple side-to-side movement of the oar, however, each oscillating segment describes a figure-eight loop, the centre of which is along the axis of locomotion. It is these oscillations and the associated orientation of each body segment that produce the propulsive thrust.

The undulatory body waves are created by metachronal contraction waves alternating between the right and left axial musculature. During steady swimming, several contraction waves simultaneously pass down the body axis from head to tail; the resultant undulatory waves move backward along the body faster than the body moves forward. As the undulatory wave passes backward, its amplitude and speed increase, thereby producing the greatest propulsive thrust in the tail (caudal) region. Propulsion, however, is not limited to the caudal region, for all undulating segments contribute to the thrust. Because the speed, amplitude, and inclination of each body segment differ, the thrust of each differs. In all segments, the greatest thrust is obtained as the segment crosses the locomotor axis, for here it is travelling at its greatest speed and inclination.

Carangiform and ostraciiform locomotion. All undulatory swimming movements generate forward thrust in the manner described above. Not all swimming animals, however, possess the elongated shape of an eel; only those with a similar body form, in which the surface area of the head end is the same as that of the tail end, have anguilliform locomotion. Fish with fusiform bodies exhibit carangiform locomotion, in which only the posterior half of the body flexes with the passage of contraction waves. This arrangement of body form and locomotion apparently is the most efficient one, for it occurs in the most active and fastest of fish. The advantage of carangiform locomotion appears to be related to the effectiveness of the posterior half of the body as a propulsive unit and the fact that the shape of the body and its small lateral displacement create little water turbulence. In contrast to ostraciiform locomotion, in which only the caudal fin oscillates from side to side in a manner similar to moving a boat with one oar, the length of the propulsive unit of carangiform fish enables the unit to obtain maximum oscillatory speed and inclination.

Locomotion of aquatic mammals

Whales also use undulatory body waves, but unlike any of the fishes, the waves pass dorsoventrally (from top to bottom) and not from side to side. In fact, many mammals that swim mainly by limb movements tend to flex their body in a dorsoventral plane. Whereas the body musculature of fish and tail musculature of amphibians and reptiles is highly segmental—that is, a muscle segment alternates with each vertebra—an arrangement that permits the smooth passage of undulatory waves along the body, mammals are unable to produce lateral undulations because they do not have this arrangement. Nor does the muscle arrangement of mammals permit true dorsoventral undulations; however, with an elongated caudal region, as in whales, they can attain a form of carangiform locomotion as effective as that of any fish.

Stabilization and steering. To stabilize and steer, most aquuatic vertebrates have, in addition to the caudal fin, a large dorsal fin and a pair of large anterolateral fins. Although they may possess other fins, these are of less importance. The balance of a swimming animal may be maintained in several ways. Rolling, or rotation, along the longitudinal axis of the body is reduced or controlled by any fins that extend at right angles to the body. Pitching, or dorsoventral seesawing, movements are counteracted by the anterolateral fins, which are also the major steering organs of fish, whales, and seals. Yawing, or lateral seesawing, is prevented by the dorsal fin and, if present, a ventral fin; for these fins to be effective, however, most of their exposed surface area should be behind the fish's centre of gravity. Because fins of the above type are not common in most invertebrates that swim by undulation, their locomotion is less stable.

Tetrapodal vertebrates. Many of the various types of undulatory locomotion described above are also widely used by aquatic tetrapods (those with walking appendages). Larval frogs, crocodilians, aquatic salamanders, and lizards, for example, have long muscular tails that propel them by undulatory motion. Most aquatic tetrapods, however, move by appendicular locomotion, for which the major propulsive units are the hindlegs. The exceptions are sea turtles, auks, penguins, and fur seals; in these, the hindfeet are webbed and are used as rudders. For propulsion, these animals use their forelegs, which have become bladelike flippers in which the forearm and hand region are dorsoventrally compressed to form a single, inflexible unit. The movements of such flippers are analogous to the aerial flight of birds; by moving synchronously, they provide lift and thrust in the water. Unlike aerial flight, however, the upper arms do not produce lift or thrust; instead, they serve only as a pivotal or leverage point for driving the flippers.

Swimming movements in sea turtles, penguins, and auks are accomplished by the rotation of the flippers or wings through a figure-eight configuration. In the birds, however, the stroke is relatively faster than in sea turtles, because the entire cycle appears to be proportionately smaller in amplitude. Moreover, because the birds' bodies are more streamlined, they can attain greater speeds than the turtles. Penguins may attain speeds of 40 kilometres (25 miles) per hour in water and have sufficient speed and thrust to enable them to leap two metres (six feet) or more above the water. The wings of penguins are so highly modified, however, that they have lost the ability to fly. The auks, on the other hand, are able to use their wings for both aerial and aquatic locomotion.

Aquatic birds

Some of the other aquatic birds, such as ducks and water ouzels, are said to propel themselves underwater through wing movements, but the evidence for such propulsion is incomplete and still open to question. The wing movements of ducks may be for steering and hydroplaning (skimming through the water) rather than for actual propulsion. The wings of the water ouzels, or dippers, were once thought to function as hydroplanes, but investigations have revealed that, although the wings are flapped underwater, the ability of dippers to bottom walk or fly underwater depends upon the velocity of the water flowing past the wings rather than the movement of the wings themselves.

Most aquatic birds are propelled by their webbed hindfeet, which tend to move alternately in surface swimming and in unison when the bird is submerged. Of all the swimming birds that use their hindfeet, the loons show the most extreme adaptations: the body, head, and neck are elongated and streamlined; the hindlegs are at the very posterior end of the body; the lower legs are compressed and bladelike; and the feet are strongly webbed. The webbing increases the surface area exposed to the water during limb retraction and also permits the folding of the foot, thereby reducing water resistance during protraction.

In frogs and freshwater turtles, the hindlegs are elongated and the feet enlarged and strongly webbed. But, whereas the hindlegs of frogs move synchronously, except occasionally in slow swimming, when they alternate, the limb movements always alternate in freshwater turtles. Some aquatic turtles, however, such as snapping, mud, and musk turtles, are very poor swimmers and will swim only under extreme conditions. These turtles are bottom walkers, and their limb movements in water are identical to those on land except that they can move faster in water than on land.

The swimming movements of many mammals are also identical with their terrestrial limb movements. Hippopotamuses spend much of their time in the water, yet

they bottom walk rather than swim. Most of the aquatic mammals—*e.g.*, otters, hair seals, aquatic marsupials, insectivores, and rodents—use their hindlegs and frequently their tails for swimming. The feet are webbed and usually move alternately; the tail tends to be flattened. Fur seals, polar bears, and platypuses swim mainly with forelimbs; only in the seals, however, are the movements of the forelimbs similar to those of sea turtles and penguins.

FOSSORIAL LOCOMOTION

The speed, manner, and ease with which animals move depends directly upon the compactness of the material and its cohesiveness. Many aquatic animals can swim through semisolid mud or muck suspensions, which lack compactness. Some lizards and snakes that live in an arid environment can swim through friable sand, which is compact but lacks strong cohesiveness. Although these swimming movements can be considered a form of fossorial locomotion, the following discussion considers only locomotor patterns in which most of the activity of the animals involved is confined to tunnels that they leave behind.

Burrowing

Fossorial invertebrates. Burrowing or boring invertebrates have evolved a number of different locomotor patterns to penetrate soil, wood, and stone, of which soil or mud is the easiest to penetrate. The soft-bodied invertebrates, such as worms and sea cucumbers, burrow either by peristaltic locomotion or by the contract–anchor–extend method. Their hydrostatic, or fluid, skeleton, combined with their circular and longitudinal musculature, permits controlled deformation of their shape, which allows them to squeeze into narrow spaces and then enlarge the spaces, thus creating a burrow or tunnel. Worms with a protrusible proboscis (a tubular extension of the oral region) generally burrow by the contract–anchor–extend method. Contraction of the circular muscles in the posterior half of the body drives the body fluids forward, causing the proboscis to evert (turn outward) and forcing it into the soil. When the proboscis is fully everted, the part of the body (collar) directly behind it dilates and anchors the proboscis in the soil. The entire body is then pulled forward by the longitudinal muscles and reanchored. This pattern produces the very jerky and slow forward progression typical of most fossorial locomotion.

Peristaltic locomotion (see Figure 14), which is generated by the alternation of longitudinal- and circular-muscle-contraction waves flowing from the head to the tail, is similar to the above pattern. Forward progression is more continuous, however, because of the contraction waves. The sites of longitudinal contraction are the anchor points; body extension is by circular contraction. The pattern of movement is initiated by anchoring the anterior end. As the longitudinal contraction wave moves posteriorly, it is slowly replaced by the circular contraction wave. The anterior end slowly and forcefully elongates, driving the tip farther into the surface as the circular contraction wave moves down the body. The tip then begins to dilate and anchor the anterior end as another longitudinal contraction wave develops. This sequence is repeated continuously, and the worm moves slowly forward. Reversing the direction of the contraction waves enables the worm to back up.

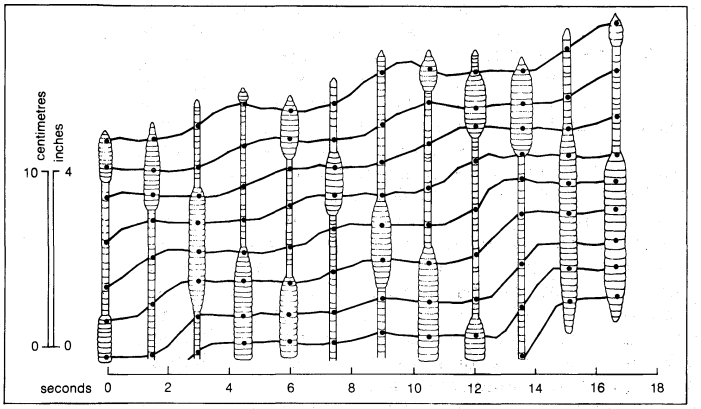

Figure 14: *Peristaltic locomotion in worms.*
Segments move forward except when they are longitudinally contracted (shown as wide areas with large dots). Individual points on the worm's body and their movements relative to each other are shown by the oblique lines.

Burrowing bivalve mollusks, such as clams, use the contract–anchor–extend locomotor mode. Such bivalves have a large muscular foot that contains longitudinal and transverse muscles as well as a hemocoel (blood cavity). The digging cycle begins with the extension of the foot by contraction of the transverse muscles. The siphons (tubular-shaped organs that carry water to and from the gills) are closed, and the adductor muscle of the shell contracts, thereby forcing blood into the tip of the foot and causing it to dilate. With the tip acting as an anchor, the longitudinal muscles then contract, pulling the body down to the anchored foot. Frequently, the longitudinal muscles contract in short steps and alternate between the left and right sides; this causes the shell to wobble and penetrate deeper as it is pulled down.

Rock borers

Some invertebrates are able to bore through rock. Most of the rock borers are mollusks; they bore either mechanically by scraping or chemically by the secretion of acid. The piddock, or angel's wing, bivalves, for example, attach themselves to a rock with a sucker-like foot. The two valves, held against the rock, grind back and forth by the alternate contraction of two adductor muscles; the grinding slowly produces a tunnel.

Fossorial vertebrates. The fossorial vertebrates are found in three classes: amphibians, reptiles, and mammals. Although some fishes and birds dig or bore shallow burrows, they can hardly be considered truly fossorial, as are moles or earthworms. Locomotion of fossorial amphibians and reptiles tends to be axial; it is appendicular only in mammals. Fossorial mammals have strong forelegs with a tendency toward flattening; their hands and particularly the claws are enlarged. Forelegs show the greatest modification in such species as moles and gophers, whose entire lives are spent in burrows. These animals tend to dig with a breast stroke, either synchronously or alternately, by extending the foreleg straight forward in front of the snout and then retracting it in a lateral arc. The loosened soil is compacted against the side walls of the burrow. In those fossorial species that dig burrows as nests but forage above the ground—many rodents, such as prairie-dogs, ground squirrels, and groundhogs—the digging movements tend to be dorsoventral with alternating limb movement. The forelegs are extended forward and then retracted downward and backward; the loosened soil passes beneath the body and is frequently pushed to the surface.

Fossorial reptiles and amphibians are usually legless, or the legs are so reduced that they serve no locomotor function; in most species, the head is flattened dorsoventrally, and the snout extends beyond and somewhat over the mouth. Burrowing is accomplished by one of three patterns analogous to the contract–anchor–extend locomotion of invertebrates. In the most common of these, the snout is driven straight forward along the bottom of the tunnel, the head is then raised, and the soil is compacted to the roof. The head tends to be laterally compressed in animals that use the other two patterns. In one of these patterns, the snout is shoved forward and then swung from side to side; in the other, the snout is rotated as it swings from side to side and seems to shave the walls of the tunnel.

TERRESTRIAL LOCOMOTION

Legs in arthropods and vertebrates

Walking and running. Only arthropods (*e.g.*, insects, spiders, and crustaceans) and vertebrates have developed a means of rapid surface locomotion. In both groups, the body is raised above the ground and moved forward by means of a series of jointed appendages, the legs. Because the legs provide support as well as propulsion, the sequences of their movements must be adjusted to maintain the body's centre of gravity within a zone of support; if the centre of gravity is outside this zone, the animal loses its balance and falls. It is the necessity to maintain stability that determines the functional sequences of limb movements, which are similar in vertebrates and arthro-

pods. The apparent differences in the walking and slow running gaits of these two groups are caused by differences in the tetrapodal (four-legged) sequences of vertebrates and in the hexapodal (six-legged) or more sequences of arthropods. Although many legs increase stability during locomotion, they also appear to reduce the maximum speed of locomotion. Whereas the fastest vertebrate gaits are asymmetrical, arthropods cannot have asymmetrical gaits, because the movements of the legs would interfere with each other.

Cycle of limb movements. The cycle of limb movements is the same in both arthropods and vertebrates. During the propulsive, or retractive, stage, which begins with footfall and ends with foot liftoff, the foot and leg remain stationary as the body pivots forward over the leg. During the recovery, or protractive, stage, which begins with foot liftoff and ends with footfall, the body remains stationary as the leg moves forward. The advance of one leg is a step; a stride is composed of as many steps as there are legs. During a stride, each leg passes through one complete cycle of retraction and protraction, and the distance the body travels is equal to the longest step in the stride. The speed of locomotion is the product of stride length and duration of stride. Stride duration is directly related to retraction: the longer the propulsive stage, the more time required to complete a stride and the slower the gait. A gait is the sequence of leg movements for a single stride. For walking and slow running, gaits are usually symmetrical—*i.e.*, the footfalls are regularly spaced in time. The gaits of fast-running vertebrates, however, tend to be asymmetrical—*i.e.*, the footfalls are irregularly spaced in time.

The different gaits of insects are based on the synchrony of leg movements on the left (*L*) and right (*R*) sides of the animal. The wave of limb movement for each side passes anteriorly; the posterior leg protracts first, then the middle leg, and finally the anterior leg, producing the sequence $R_3 R_2 R_1$ or $L_3 L_2 L_1$. There is no limb interference, because the legs of one side do not have footfalls along the same longitudinal axis. The slowest walking gait of insects is the sequence $R_3 R_2 R_1$ followed by the sequence $L_3 L_2 L_1$. As the rate of protraction increases, the protractive waves of the right and left sides begin to overlap. Eventually, the top speed is reached when the posterior and anterior legs of one side move synchronously. This gait occurs because the protraction times for all legs are constant, the intervals between posterior and middle legs and between middle and anterior legs are constant, and the interval between posterior and anterior legs decreases with faster movements. Other gaits are possible in addition to those indicated above by altering the synchrony between left and right sides.

Limb movements in millipedes and centipedes

The limb movements of centipedes and millipedes follow the same general rules as those of insects. The protraction waves usually pass from posterior to anterior. Because each leg is slightly ahead of its anteriorly adjacent leg during the locomotory cycle, one leg touches down or lifts off slightly before its anteriorly adjacent one. This coordination of limb movement produces metachronal waves, the frequency of which equals the duration of the complete protractive and retractive cycle. The length of the wave is directly proportional to the phase lag between adjacent legs.

Whereas the millipedes must synchronize leg movements to eliminate interference, the tetrapodal vertebrates must synchronize leg movements to obtain maximum stability. Four legs are the minimum requirement for symmetrical terrestrial gaits. Although bipedal (two-legged) gaits require extensive structural modifications of the body and legs, they still retain the leg-movement sequence of tetrapodal gaits (see Figure 15). The basic walking pattern of all tetrapodal vertebrates is left hindleg (*LH*), left foreleg (*LF*), right hindleg (*RH*), right foreleg (*RF*), and then a cyclic repetition of this sequence, which is equivalent to the slow walking gait of insects but with the middle legs removed. Unlike the insects, however, vertebrates can begin to walk with any of the four legs and not just the posterior pair. The faster symmetrical gaits of vertebrates are obtained by overlapping the leg-movement sequences of the left and right sides in the same manner as insects; for example, an animal can convert a walk to a trot by moving diagonally contralateral legs (those on opposite sides) simultaneously, or to a pace by moving the ipselateral legs (those on the same side) simultaneously. Many other symmetrical gaits occur between the walk and the pace and the trot, which are extreme modifications of the walk.

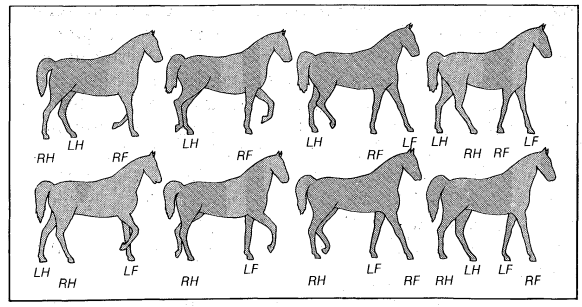

Figure 15: *Walking sequence of a five-gaited horse.* LH and RH refer to left and right hindlegs; LF and RF refer to left and right forelegs.

Running

Cursorial vertebrates. Cursorial (running) vertebrates are characterized by short, muscular upper legs and thin, elongated lower legs. This adaptation decreases the duration of the retractive–protractive cycle, thereby increasing the animal's speed. Because the leg's cycle is analogous to the swing of a pendulum, reduction of weight at the end of the leg increases its speed of oscillation. Cursorial mammals commonly use either the pace or the trot for steady, slow running. The highest running speeds, such as the gallop, are obtained with asymmetrical gaits. When galloping, the animal is never supported by more than two legs and occasionally is supported by none. The fastest runners, such as cheetahs or greyhounds, have an additional no-contact phase following hindfoot contact.

In cursorial birds and lizards, both of which are bipedal, the feet are enlarged to increase support and the body axis is held perpendicular to the ground, so that the centre of gravity falls between the feet or within the foot-support zone. The running gait is, of course, a simple alternation of left and right legs. In lizards, however, bipedal running must begin with quadrupedal (four-footed) locomotion. As the lizard runs on all four legs, it gradually builds up sufficient speed so that its head end tilts up and back, after which it then runs on only its two hindlegs.

Saltation. The locomotor pattern of saltation (hopping) is confined mainly to kangaroos, anurans (tailless amphibians), rabbits, and some groups of rodents in the vertebrates and to a number of insect families in the arthropods. All saltatory animals have hindlegs that are approximately twice as long as the anteriormost legs. Although all segments of the hindleg are elongated, two of them—the tibial (between upper segment and ankle) and tarsal (ankle) segments—are the most elongated.

Types of saltatory patterns

There are at least four different saltatory patterns, but all are similar in that the simultaneous retraction or extension of the hindlegs is followed by an aerial phase of movement. The aerial phase in all patterns is governed by the physical principles of ballistics (the flight characteristics of an object): the height and the length of the jumps are functions of the takeoff velocity and angle. The longest jumps are attained when the takeoff angle is 45°.

Before jumping, the femur (upper segment of the hindleg) of the flea is held perpendicular to the ground, the tibia extends obliquely posterior, and the remainder of the hindleg extends posteriorly along the ground. Just prior to the jump, the middle legs flex and tilt the body upward; then the femur of the hindlegs swings sharply backward simultaneously with the extension of the tibia. This retraction forces the animal upward and forward at an angle of 50°. As the flea approaches touchdown, the front legs are swung forward and downward, the middle legs are held perpendicular to the body axis, and the hindlegs project obliquely posterior. The anterior two pairs of legs thus act to absorb the landing shock.

The frog jump (Figure 16) is initiated with three simul-

taneous movements: the forelegs flex, and the back arches to tilt the entire body upward; the tarsus of the hindleg swings to a vertical position and locks; and the femur, extending anteriorly along the body, swings in a horizontal plane. When the femur is perpendicular to the body, the knee joint snaps open, and the frog jumps forward at a 30° to 45° angle. As the frog begins to land, the forelegs are protracted and held downward in front of the chest. The forefeet touch down first, the forelegs acting as shock absorbers. Simultaneously, the hindlegs are protracted so that they can be in jumping posture by the completion of landing.

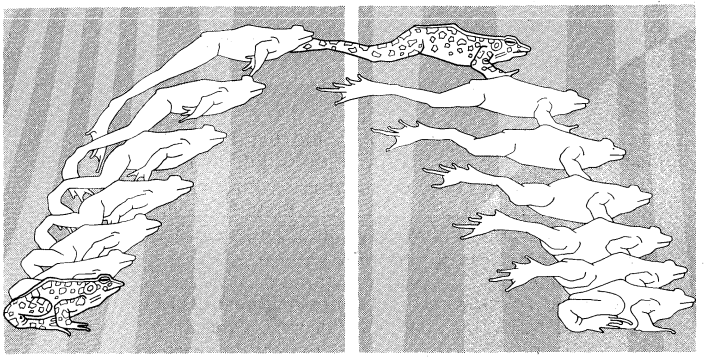

Figure 16: (Left) Jumping and (right) landing sequences of frogs.

The positions and movements of the hindlegs in rabbits and kangaroos are similar to those of the frog. The major difference is that rabbits, kangaroos, and all other mammals move their legs in a vertical plane instead of a horizontal plane, as do the frogs; because the femur and tibia move vertically, the tarsus need not be elevated to prevent the hindleg from hitting the ground. The saltatorial gait of rabbits is quadrupedal, whereas that of kangaroos is bipedal. A jumping rabbit stretches forward and lands on its forefeet; generally, both forefeet do not touch ground simultaneously, however. As the forefeet touch, the back flexes, and the hind end rotates forward and downward. The hindfeet touch down lateral to the forefeet, and, as the back extends, a new jump begins. In contrast, the kangaroo lands on its hindfeet, and the back is held fairly straight through all phases of the jump, although the body inclines forward at takeoff and posteriorly when landing.

Crawling patterns

Crawling. Invertebrates crawl either by peristaltic locomotion or by contract–anchor–extend locomotion, both of which have been described previously (see above *Fossorial locomotion*). Limbless vertebrates, however, crawl in one of four patterns: serpentine, rectilinear, concertina, and sidewinding. The most common pattern, serpentine locomotion, is used by snakes, legless lizards, amphisbaenids (worm lizards), and caecilians (wormlike amphibians). Rectilinear locomotion is used by the giant snakes and almost exclusively by fossorial vertebrates when burrowing. Concertina and sidewinding locomotion are largely confined to snakes.

Serpentine locomotion. In serpentine locomotion, in which the body is thrown into a series of sinuous curves, the movements appear identical to those of anguilliform swimming, but the similarity is more apparent than real. Unlike anguilliform swimming, when a snake starts to move, the entire body moves, and all parts follow the same path as the head. When the snake stops moving, the entire body stops simultaneously. Propulsion is not by contraction waves undulating the body but by a simultaneous lateral thrust in all segments of the body in contact with solid projections (raised surfaces). The muscular thrust against the projection is perpendicular to the axis of the pushing segment. To go forward, therefore, it is necessary for the strongest thrust to act against the side of the projection facing in the direction of movement. Because of this, thrust tends to occur at the anterior end of the concave (inward-curving) side of the loop of the snake's body.

Concertina locomotion. Concertina locomotion is used when there is not enough frictional resistance along the locomotor surface for serpentine locomotion. After the body is thrown into a series of tight, sinuous loops, forming a frictional anchor, the head slowly extends forward until the body is nearly straight or begins to slide. The anterior end forms a small series of loops and, with this anchor, pulls the posterior regions forward, after which the sequence of movements is repeated. This crawling pattern is analogous to the contract–anchor–extend locomotion of invertebrates, but, because snakes lack the body flexibility provided by a hydrostatic skeleton, they must depend upon the body loops.

Sidewinding. Sidewinding, which is also used when the locomotor surface fails to provide a rigid frictional base, is a specific adaptation for crawling over friable sandy soils. Like serpentine locomotion but unlike concertina locomotion, the entire body moves forward continuously in sidewinding locomotion (see Figure 17). Although the body moves through a series of sinuous curves, the track made by the snake is a set of parallel lines that are roughly perpendicular to the axis of movement. This is because only two parts of the body touch the ground at any instant; the remainder of the body is held off the ground. To begin sidewinding, the snake arches the anterior part of the body forward and forms an elevated loop with only the head and the middle of the body in contact with the ground. Because each part of the body touches the ground only briefly before it begins to arch forward again, the snake seems to roll forward like a short, coiled spring. In a continuously repeating cycle, as a segment arches forward, the posteriorly adjacent segment touches down.

Tracks of sidewinders

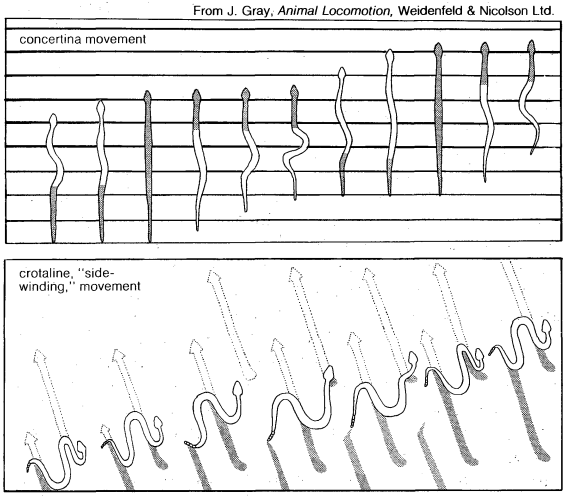

Figure 17: Two modes of locomotion in the snake.

Rectilinear locomotion. Unlike the three preceding patterns of movement, in which the body is thrown into a series of curves, in rectilinear locomotion in snakes the body is held relatively straight and glides forward in a manner analogous to the pedal locomotion of snails. The ventral (belly) surface of snakes is covered by scales elongated crosswise that overlap like roof shingles, with the opening of the overlap facing toward the posterior. Each ventral scale is moved by two pairs of muscles, both of which are attached to ribs but not to ribs of the same segment as the scale. One pair of muscles is inclined posterior at an angle (obliquely); the other is inclined anterior at an angle. As contraction waves move rearward from the head simultaneously on both sides, the anterior oblique muscles of a scale contract first and lift the scale upward and forward. When the posterior oblique muscles contract, the scale is pulled rearward, but its edge anchors it, and the body is pulled forward. This sequence is repeated by all segments as the contraction wave passes posteriorly, and, as a series of contraction waves follow one another, the body slowly inches forward.

ARBOREAL AND AERIAL LOCOMOTION

Climbing. The adaptation for climbing is unique for each group of arboreal animals. All climbers must have

strong grasping abilities, and they must keep their centre of gravity as close as possible to the object being climbed. Because arthropods are generally small and, thus, not greatly affected by the pull of gravity, they show little specific structural adaptation for climbing. In contrast, the larger and heavier bodied vertebrates have many climbing specializations. In both arthropods and vertebrates, however, no leg is moved until the others are firmly anchored.

Arboreal amphibians and reptiles. Arboreal frogs are slender-bodied anurans with tapering legs and feet. The tips of the toes (digits) are expanded into large, circular disks that may function as suction cups, although such an action has not yet been definitely demonstrated. The disks, however, do increase the contact area, thereby improving grasping ability. The leg-movement sequence during climbing is that of a walking gait.

Surface adherence

Arboreal lizards have the same type of climbing gait as arboreal frogs, and their climbing specializations are also similar to those of anurans. They have a different type of climbing foot, however, because of the presence of claws and scales on the digits. Moreover, the entire digits, rather than just their tips, may be expanded. On the bottom of each of these spatula-shaped expansions are one or two rows of transversely elongated scales. Although not visible to the naked eye, the surface of these scales is covered with fine projections that increase their ability to adhere to a surface. Because of this strong adherence, the toes roll off and on the surface on which the animal is walking. Unlike other arboreal lizards, chameleons possess a prehensile (grasping) tail and zygodactylous feet—*i.e.,* the toes are fused into two opposable units. Although these adaptations are inferior for vertical climbing, they are superior for locomotion on vertical or inclined, slender branches. Arboreal snakes tend to have either prehensile tails or extremely elongated bodies.

Climbing birds and mammals. Although the strong, clawed feet of birds permit many of them to climb occasionally, most truly scansorial (climbing) birds cling with their strong feet and brace themselves with stiffened tail feathers. Birds such as woodpeckers and tree creepers usually climb vertically upward, usually with both feet moving simultaneously in short, vertical hops. This mode of locomotion, however, prevents vertical descent. Only the nuthatch can descend as easily as it can ascend; it climbs obliquely, using the upper foot for clinging and the lower foot as a brace. Parrots have developed zygodactylous feet as an aid to climbing; in addition, they frequently use their bills when climbing vertically.

Use of prehensile fingers or claws

Several locomotor patterns for climbing are used by arboreal mammals, the grasping ability of which has been enhanced by the presence of either strong claws or prehensile fingers. Many monkeys use a climbing gait similar to the leg sequence of walking. Occasionally, however, they use a leg sequence equivalent to that of a trot. Small-bodied climbers with sharp claws, such as squirrels, climb by the alternate use of forelegs and hindlegs; essentially, they hop up a tree. Prehensile-fingered climbers descend backward and generally with a walking type of leg sequence. Sharp-clawed species descend with a similar gait sequence but with the head downward.

Leaping. The mechanics of arboreal leaping do not differ from those of terrestrial saltation; the upward thrust in both is produced by the rapid, simultaneous extension of the hindlegs. Because of the narrowness of the arboreal landing site, however, landing behaviour does differ. Arboreal leaping also tends to be a discontinuous locomotor behaviour that is used only to cross wide gaps in the locomotor surface. Leaping from limb to limb, although occasionally employed by most climbers, appears to occur most frequently in animals with opposable or at least prehensile forefeet, particularly tree frogs and primates. Such forefeet enable the animal to grasp and hold onto the landing site.

Brachiation. True brachiation (using the arms to swing from one place to another) is confined to a few species of primates, such as gibbons and spider monkeys. Because the body is suspended from a branch by the arms, brachiation is strictly foreleg locomotion. When the animal moves, it relaxes the grip of one hand, and the body pivots on the shoulder of the opposite arm and swings forward; then the free arm reaches forward at the end of the body's swing and grabs a branch. The sequence is then repeated for the other arm. This locomotor pattern produces a relatively rapid and continuous forward movement but is restricted to areas with thick canopies of trees. Brachiators have arms that may be as long or longer than the body and a very motile shoulder joint.

Gliding. There are two functionally distinct forms of gliding, gravitational gliding and soaring: the former is used by gliding amphibians, reptiles, and mammals; the latter is restricted to birds. All gliders are able to increase the relative width of their bodies, thereby increasing the surface area exposed to wind resistance. The few gliding frogs flatten their bodies dorsoventrally and spread their limbs outward. Gliding snakes not only flatten their bodies but also draw in the ventral scales, thereby creating a trough. The best adapted gliding lizards have elongated ribs that open laterally like a fan.

Gliding mammals, such as the African flying squirrel and the colugo, usually have, on each side of the body, a fold of skin (the patagium) that extends from their wrist or forearm backward along the body to the shank of the hindleg or the ankle. When gliding, they assume a spread-eagle posture, and the patagia unfold.

Gravitational gliding. Gravitational gliding is equivalent to parachuting. Because the expanded lateral surface of the body increases the wind resistance against the body, the speed of falling is reduced. The directions of gliding can be controlled by adjusting the surface area—to curve to the right, the right patagium is relaxed. Gliders can land on vertical surfaces by suddenly turning the anterior end of the body up as it reaches the surface. Mechanically, this stalls the flight—*i.e.,* the horizontal component of flight is eliminated.

Soaring. Gravitational gliding is one of the basic mechanisms of soaring, which is restricted to birds, although birds must obtain their initial elevation by means of flapping flight. The second basic mechanism of soaring involves wind or air currents. Soaring requires that air currents meet one of two conditions: either the air must have a vertical velocity exceeding the rate of descent in gravitational gliding, or it must have a horizontal velocity that is nonuniform in time and space. Whereas static soaring depends upon vertical air currents, dynamic soaring depends upon horizontal air currents. Both types of soaring are described below.

Static and dynamic soaring

Vertical air currents for static soaring are produced when wind strikes an obstruction and is deflected upward. The sites of deflection are very local and discontinuous and seldom extend more than 30 metres (100 feet) above the obstruction. The height of deflection and the vertical velocity of the air are a function of the angle of deflection and the velocity of the wind. If the vertical velocity of the air equals the descent speed of the bird, the bird remains stationary in height relative to the ground. If, however, the vertical velocity is greater, the bird rises, and, if less, the bird falls at a speed equal to the gravitational descent speed minus the air's vertical ascent speed. The horizontal velocity of the air determines the bird's movements relative to the ground in the same manner as that of the vertical velocity.

The soaring flights of vultures and hawks depend upon vertical hot-air currents called thermals. Such currents are not continuous updrafts or downdrafts originating from a specific spot; instead, as a local region of the ground is heated, a vertical, hot-air updraft is created. At the top of the column, a thermal bubble is formed by the hot air curving outward, downward, and then around the bubble. It is then pinched off by cool air flowing into the column and floats upward. The free-floating thermal bubble is doughnut shaped, with the air rising in the centre and cycling outward and downward. Soaring birds spiral downward in the updraft; however, because the bubble rises faster than birds descend, soaring birds are carried upward, but at a speed less than that of the bubble. When a bird reaches the bottom of the bubble, it begins a straight gravitational glide until it reaches the next thermal bubble. Thus, static soaring in a thermal bubble can be

recognized by its alternating flight pattern of circling and straight gliding.

Unlike static soaring, which is done at relatively high altitudes over land, dynamic soaring is done at low levels and is usually restricted to oceanic areas. Dynamic soaring depends upon a steady horizontal sea wind, which is laminated into layers of different velocities because of the frictional interaction between the water and the air; the lower layers have the lowest velocity. The flight path of a bird performing dynamic soaring tends to be a series of inclined loops that are perpendicular to the direction of the wind. A soaring albatross, for example, will begin its gravitational glide approximately 15 metres (50 feet) above the sea. Because it glides downwind, its velocity is increased both by descent and by the wind at its tail. As the bird nears the sea, it makes a turn into the wind, and the forward flight velocity derived from the downwind glide and the tailwind combine to lift the albatross slowly back to its initial gliding height, but with a loss of horizontal velocity. The bird therefore turns downwind again and begins to repeat the soaring cycle.

Because it depends upon the presence of a horizontal air current, the flight of flying fish is more akin to soaring than to true flying. As a flying fish approaches the water surface, its pectoral and pelvic fins, which are analogous to the forelimbs and hindlimbs of quadrupeds, are pressed along the side of the body. The greatly enlarged, winglike pectoral fins then spread out as the fish leaves the water. The wind against the fins provides lift to raise the body above the water, and the tail continues to undulate to provide additional thrust. When the entire body is out of the water, the enlarged pelvic fins extend, and the fish glides for a short distance until its forward velocity is lost. Occasionally, as a fish drops back into the water, it will undulate its tail to initiate another short flight.

True flight. Three animal groups have developed true flight: insects, birds, and mammals. All generate forward thrust by flapping lateral appendages, and all are free of any dependence on gravitational descent or air currents. It should be noted at the outset, however, that, although the aerodynamics of flight are identical in all three, the following cycles of wing movements described for the different animal groups are generalizations; each species in a group has a distinctive flight pattern and, therefore, a distinctive pattern of wing movement.

Wing movements

Flight is produced by the simultaneous rotation of the left and right wings in a circle or in a figure eight. This rotation produces the upward thrust, or lift, necessary to overcome gravity and the forward thrust required to overcome drag. As the downward and backward phase of rotation forces the air backward and the body forward, lift is produced by the unequal velocities of the air across the upper and lower wing surfaces.

Wings of insects. In flies with one pair of wings, the rotation of the tip inscribes a posterior inclined oval. At the top of the wing cycle, the tip lies above the junction of the thorax and abdomen. The wing then beats downward and forward so that the tip ends anterior and below the head. To insure maximum thrust, the broad surface of the wing lies parallel to the horizontal body plane during the downstroke. During the path of the upstroke, which is the reverse of the downstroke, the wing is feathered (turned) by inclining it perpendicular to the body plane. Although the rotational cycle of those insects with two pairs of wings follows a similar path, the upward and downward strokes of the anterior and posterior wings are not simultaneous; the anterior pair usually lags behind the posterior pair.

The wings of insects are rotated by pulsation of the thorax, not by a set of muscles. Basically, the thorax is a rigid box to which the wings are attached by a pair of longitudinal lateral hinges that enable the thorax to move dorsoventrally. Four sets of muscles control the major movements. Contraction of a perpendicular set, which extends from the centre of the floor of the thorax to its roof, depresses the thorax and, because of a reverse linkage between wing and thorax, raises the wing. Contraction of a diagonal set, which extends from the anterior roof of the thorax to its posterior floor, elevates the thorax and lowers the wing. Two diagonal sets of muscles extend laterally from the floor to the wall of the thorax and are responsible for maintaining a relatively constant width in the thorax.

Wings of birds and bats. Unlike insect wings, the wings of birds and bats are linked structures, the lateral extent and regional inclination of which are altered intrinsically by muscular and bony segments. The up-and-down strokes of a bird's wing are produced by large chest (pectoral) muscles that extend from the sternum (breastbone) to the lower surface of the humerus (a bone in the upper arm). When these muscles contract, the wing is lowered; it is raised by the contraction of a small anterior pectoral muscle that is attached to the upper surface of the humerus by a long tendon.

Hovering and propulsive flight

Birds exhibit two major flight patterns, hovering flight and propulsive flight. Hovering flight is of fairly restricted use and is observed most frequently in the hummingbirds. The path of the wings inscribes a horizontal figure eight whose centre is perpendicular to the shoulder joint. The downward stroke of the wings is actually a slightly inclined anterior stroke, and, because the longitudinal body axis is nearly perpendicular to the ground, the upward stroke is a horizontal posterior stroke. Both strokes are power strokes that produce lift: on the downstroke the dorsal wing surface is the top of the airfoil surface; on the upstroke the ventral surface is the top of the airfoil surface.

Most birds and bats, however, utilize propulsive flight. Because the body is not stationary, as it is in hovering flight, the wing always moves forward relative to the air, and its tip generally inscribes an oval or figure-eight path. In a pigeon, for example, the downstroke begins with the wing fully extended and perpendicular to the back (Figure 18). As the wing moves downward and anterior, it draws

level with the body, at which point the upper arm section stops while the distal part completes the downward path. At the bottom of the downstroke, the distal part turns outward and is elevated rapidly by the combined protraction of the humerus and the extension of the distal section.

DIRECTIONAL CONTROL

Although an animal's locomotor pattern may be controlled by its nervous system, directional control is impossible without sensory input. Two factors are involved in directional control: orientation, the ability of an animal to determine and to alter its position in the environment; and steering, the mechanical alteration of the locomotor pattern through which the animal adjusts its position.

Orientation. Orientation of locomotor behaviour is usually categorized as either kinesis or taxis. In kinesis, as previously explained, an animal's body is not oriented in relation to a sensory stimulus; rather, the stimulus causes an alteration in speed or direction of movement. In wood lice, for example, the kinetic response alters only the rate of movement. Because wood lice tend to aggregate in moist areas, their ambulatory activity increases or decreases as the relative humidity decreases or increases, respectively. In the planarian (an aquatic, ciliated flatworm), on the other hand, the kinetic response affects only the rate at

which the planarian changes its direction. Because planaria tend to stay in or return to darker areas, an increase in light intensity causes an increase in their turning responses. Generally, however, animals tend to alter both direction and speed as a single kinetic response.

Taxis

In taxis, an animal orients itself in a specific spatial relationship to a stimulus. The orientation may be simply an alteration of body position or it may be an alteration of locomotor direction so that the animal moves toward, away from, or at a fixed angle to the source of the stimulus. Sources that elicit a taxis response, which may cause a modification of speed, direction, or both, seem to encompass the entire range of environmental stimuli, such as gravity (geotaxis), temperature (thermotaxis), light (phototaxis), or chemicals (chemotaxis). If the response is negative, the animal moves away from the source; if it is positive, the animal moves toward the source.

The control of the response to a taxis is of two types. In open-system control, the initial response to a stimulus has no effect on subsequent responses to the same stimulus. A male firefly, for example, locates a female by the latter's brief flashes of light. When a male sees a female's flash, the male turns in the direction of the female, even though the source is no longer visible. If another female flashes, however, the male responds to the second flash in exactly the same manner as it did to the first. In close-system control, on the other hand, the response is progressively altered by feedback so that all subsequent responses are adjusted to the initial response. A bat chasing a flying insect will alter its flight path to intercept that of the insect. The bat's initial change in direction is only a general alteration of its course, but, as it approaches the insect, the bat constantly modifies its course to obtain an accurate interception.

Steering. Animals obtain accurate directional response (steering) by changing their propulsive response. Because steering relies heavily on continuous feedback (the communication cycle in which the motor output, or behaviour, is constantly being modified by the sensory input, or stimulus), it requires a precise integration of the central and peripheral nervous systems. (The central nervous system—in vertebrates, the brain and spinal cord—is that part of the nervous system that receives sensory impulses and sends out motor impulses; the peripheral nervous system consists of all the nerves that carry impulses between the central nervous system and other parts of the body.) Exteroceptive stimuli (those that originate outside the body) received by the peripheral nervous system establish the animal's spatial position in the environment; proprioceptive stimuli (those that originate inside the body), also received by the peripheral nervous system, establish the relative position of the body units to each other (see further SENSORY RECEPTION). Through integration of these two sets of stimuli, the central nervous system continuously adjusts the contraction of the motor units (*e.g.*, muscles) in order to obtain the desired orientation.

During locomotion, steering is a continual process. The direction of movements must be constantly adjusted to counteract environmentally produced deviations of direction. The apparently simple act of a bird flying from a tree to the ground illustrates the complexity of directional control. As the bird flies to the ground, it must be constantly aware of its height above the ground, the orientation of its body axis relative to the ground, deviations in flight direction resulting from air currents, and its speed of fall. All these parameters are determined primarily by exteroceptive stimuli received through the eyes and inner ears. The downward flight is constantly adjusted in response to these exteroceptive stimuli, and the fine control necessary for these adjustments is obtained by proprioceptive feedback.

(G.R.Z./Ed.)

Avoidance behaviour

In one of its major meanings "avoidance" is any behaviour induced by adverse stimuli. The underlying implication that a single neural mechanism is involved (such as a specific part of the brain, which, under electrical stimulation, seems to inflict punishment) remains only a hypothesis. Clearly, the same kinds of avoidance behaviour might result from different underlying physiological mechanisms. Thus, although the various dichotomies, or polarities, of behaviour such as positive and negative, psychoanalytic life and death instincts, and approach and withdrawal concepts may be logical or philosophical conveniences, they seem, nevertheless, to lack clear meaning physiologically.

Alternative usage defines avoidance behaviour by describing a number of patterns: active avoidance (fleeing), passive avoidance (freezing stock-still or hiding), and a pattern of protective reflexes, as seen in the startle response. There is good reason to suppose that, in cats, for example, each of these patterns is coordinated separately by the brain. One kind of fleeing, in which the cat moves continuously and shows much upward climbing, is produced by electrical stimulation of specific parts of the brain (hypothalamic sites). Stimulation of other sites (in the thalamus) generates other types of fleeing movements, causing the animal to crouch, look around, move, slink close to the floor, and hide, if possible. In general, among birds and mammals, brain sites for fleeing of the first type occur in hypothalamic and mesencephalic zones.

Brain function in coordination of patterns

Protective reflexes in mammals include ear retraction to a position of safety—pressed against and somewhat behind the skull—as when a horse is seen to lay its ears back. Among the monkey-like bush babies (*Galagos*) the outer ear folds up laterally and longitudinally at the same time, under threat. The eyes are closed, and the muscles around the eye are contracted, adding to the protection. During this so-called startle reflex, breathing is checked, and the mouth corners are pulled back to expose the teeth; this prepares both for biting in defense and also for movements of the tongue and for head shaking to free the mouth of any dangerous or distasteful substance that may have been taken in. In most mammals, the limbs flex as if ready for a leap; in the human startle reflex, the arms are thrust outward as if ready to grasp at a support.

It is helpful to consider avoidance behaviour in terms of factors that elicit it (*e.g.*, specific stimuli) and regulate it (*e.g.*, hormones).

FACTORS IN AVOIDANCE BEHAVIOUR

Specific stimuli. Warning calls and visual signals that are unique to different species of birds and mammals effectively and specifically evoke avoidance patterns. In some cases, learning clearly emerges as a factor; thus, members of a colony of birds seem to learn to respond to the alarm calls of all species present in the colony. Among ducklings, a visual model to evoke fleeing and hiding can be fashioned as a cardboard cutout. When moved overhead in one direction, the model resembles a short-necked, long-tailed hawk, and the ducklings flee from it; when moved in the other direction, the model looks like a harmless, long-necked goose, and the ducklings tend to stay calm. The model is effective, however, in eliciting the two kinds of behaviour only when the ducklings are accustomed to geese flying over but not hawks.

Innate factors also contribute to such responses (see above *Instinctive behaviour*). Domestic chicks, for example, show crouching and freezing in response to the long alarm call of their species. Many of the perching birds (passerines) will gather to mob when stimulated by the sight of an owl. The eyes in the characteristic owl face have been found to be especially important; even birds reared in isolation respond to man-made models with appropriate eyespots painted on. It has been suggested that many human beings are specifically (and perhaps instinctively) disturbed by the sight of snakes—the notion of a legless object perhaps being a key stimulus. Human responses to spiders and centipedes with conspicuous legs also may be intense. In the reaction to snakes at least, notwithstanding Freudian explanations that they symbolize male sex organs, the behaviour of people may be compared with owl mobbing among passerine birds.

Specific chemical signals can induce avoidance behaviour; some are released by minnows and tadpoles when their skin is damaged (usually indicating to fellows that there is danger). These chemicals appear to be specific for each species of fish and are highly effective in producing fleeing (see SENSORY RECEPTION: *Chemoreception*). Many

ants produce volatile alarm substances (terpenes) that are attractants to other ants at low concentrations and, in high concentrations near their source, produce rapid locomotion, defense postures, and, sometimes, fleeing. Some invertebrate avoidance responses are reflexes evoked by very specific stimuli; rapid swimming by cockles clapping their shells, for example, is elicited by starfish extract. Shell jerking is produced in a freshwater snail (*Physa*) by contact with a leech, another specific response to a major predator.

Pain, startle, and novelty. Painful stimuli are preeminent among those that produce avoidance. Among mammals (including man) many such responses are patently inborn, as is the reflex withdrawal of one's finger from a hot griddle.

To classify a stimulus as startling or novel requires some comparison with previous stimulation. Human responses (orientation reflex) to startling or interesting stimuli may be studied by presenting a series of repeated tones; the orientation reflex tends to appear at the moment at which some change in the usual sequence (such as a longer or shorter tone) occurs. There is some evidence that the hippocampus (a brain structure) is involved in the human experience of novelty. Surgical removal of the hippocampus in many animals makes avoidance responses to strange objects far more persistent; a comparable operation in small parrots (lovebirds) greatly increases the persistence of calls that gather others for mobbing. Probably the hippocampus takes part in establishing memory of any new stimulus, and once this has occurred, the stimulus is no longer novel. Removal of other brain structures (the amygdala) reduces avoidance of strange objects (*e.g.*, in lovebirds) and also makes fleeing and defensive attack less likely.

Probable role of the hippocampus

Passive and active avoidance. Passive avoidance is achieved by the inhibition of a previously exhibited response. Thus, after a laboratory animal has learned to approach a food dish, it may then be punished by an electric shock whenever a selected visual or auditory stimulus is present. In passive avoidance, the animal may freeze as soon as the stimulus is given; in active avoidance, the animal is given the opportunity of fleeing.

Freezing proper entails general motor inhibition, which, if sustained, may pass into signs of reduced arousal. States of considerable loss of muscle tonus, of eye closure, and many signs of deep sleep have been variously termed feigning death or animal hypnosis. In very young fowl, such signs can be induced simply by holding the animal firmly if the experience is novel (and thus presumably frightening). Such states tend to occur as an alternative to fleeing when the apparently frightening stimulus is difficult to locate or to escape. Among social mammals (*e.g.*, cats or dogs) the status and confidence of an animal may be inferred from its degree of leg extension, arched back (vertebral tonus), and cocky tail elevation. Threat from which there seems no escape may induce a progressive approach to immobility and to general motor inhibition.

Punishment. Inhibitory interconnections have been postulated between the punishment and reward systems within the brain. One line of evidence suggesting a single punishment system rather than a number of them includes behavioral and neurological resemblances in the responses of animals to fear-inducing and to frustrating circumstances. If either fear or frustration is induced during conditioning, both produce resistance to extinction. Both are specifically opposed by barbiturate drugs.

Whatever its physiological basis, negative reinforcement (punishment) can induce in an animal both the inhibition of the response that produced the punishment and the avoidance of the location at which it occurred. Sometimes the tendency to show avoidance behaviour develops further with time, even without additional training. Thus, when being conditioned to discriminate between stimuli (*e.g.*, two tones), some breeds of dog (*e.g.*, Alsatians), if made to wait for food reward or given an impossible discrimination to perform, will howl and show great excitement. On later days, they may first resist mounting the conditioning stand and finally resist approaching the room to which earlier they ran eagerly, presumably for the rewards of food. Stimuli associated with the training room are sometimes said to act as secondary negative reinforcers (secondary punishments) in such a case.

Even a piece of cockroach nervous system (metathoracic ganglion) and the leg it controls have been shown to be capable of avoidance conditioning. If each contact of the leg with a water surface is paired with an electric shock, the leg comes to be retracted on contact with the water; no such change occurs in a control leg receiving the same number of shocks at random. The conditioning is accompanied by a very marked decrease in a chemical (acetylcholinesterase) found in the nervous system; since it greatly facilitates transmission of some nerve impulses, such a chemical may well be basic to this primitive kind of learning.

Avoidance conditioning of the leg of a cockroach

Hormonal effects. Male hormones (androgens) cause the performance of new mobbing calls in the breeding season by many male passerine birds (*e.g.*, chaffinch) and also some other birds (*e.g.*, farmyard cock); it is not certain whether the effect is specific to the vocalization or whether the hormone produces a general change in responsiveness to frightening stimuli. Female hamsters are initially faster than males to emerge from a box and also move about more in a strange place; perhaps females innately tend to be less nervous. Females behave more like male hamsters if given a small injection of male hormone (testosterone) in the second day of life; the adult difference survives castration, so it probably rests on sexual differentiation of the nervous system rather than on adult hormone levels.

The adrenocorticotropic hormone (ACTH) from the pituitary glands of many animals may facilitate avoidance behaviour. ACTH has other direct effects on the nervous system (*e.g.*, facilitating male sexual behaviour).

FUNCTIONS OF AVOIDANCE BEHAVIOUR

Fleeing and escape. Most animals capable of locomotion show a rapid locomotor reflex to painful or startling stimuli. Such a reflex is very ancient in an evolutionary sense; it is present even in such primitive marine animals as the slender, tiny, translucent amphioxus. The rapid propulsion of an octopus or squid by its own jet of water or of a crayfish by a blow of its tail, the sudden leap and flight of a grasshopper, and the retraction of a worm into its hole—all are examples of such avoidance behaviour.

Reflex escape movements

Many invertebrates commonly compete in speed against their vertebrate predators, which tend to have faster conducting individual nerve cells; in order to compete successfully, the invertebrates seem to have evolved giant nerves (bundle of individual cell fibres), for the broader a nerve is, the faster it conducts. Among such lower animals, perhaps one-third or more of the nerve cord running the length of the body is made up of fibres responsible for initiating the escape response of the species. The fibres of a cockroach, for example, activate a mechanism that produces rapid running when the rear end (anal cerci) is disturbed by air movements. Bony fishes also have such structures, the Mauthner cells, that initiate escape swimming when stimulated.

Escape may be facilitated not only by speed of response but also by its explosive onset (*e.g.*, after a period of shamming death), making it difficult for a predator to predict the behaviour of a prospective meal. Escape movements may stop as suddenly as they start. Many animals may even be especially conspicuous in escape (*e.g.*, showing coloured hind wings, as do some grasshoppers and moths), so that their disappearance appears even more sudden. Presumably, the predator, engaged in pursuing and tracking a moving prey, finds its difficult to shift quickly enough to a different kind of search and so is unable to localize the exact point of disappearance.

In many instances, rapid locomotion is enough to frustrate a predator; in others, direction is crucial (*e.g.*, a fish moving upward to the water surface or downward to the bottom or, among birds, a more elaborate celestial orientation). Under threat, insects such as pond skaters (*Vellia*) flee toward the nearest shore; beach fleas (amphipods) flee to the sea; and particular populations of ducks have a preferred compass direction for escape (so-called nonsense orientation).

Freezing. Immobility usually makes detection less like-

ly. For stick insects and other animals resembling twigs or leaves, when immobility itself becomes conspicuous against moving foliage, the animals' compensatory swaying increases the camouflage effect. There seems to be an evolutionary conflict between camouflage and the need for conspicuous signals in communication. Social groups commonly keep in touch by calls or by movements such as tail flicks, which are inhibited during freezing or even under incipient immobility. Movements may be made conspicuous by patches of white or colour on a bird's outer tail feathers, or under a mammal's tail. The well-known white rear patch of hair among antelopes, for example, is hidden when the tail is folded or lowered under conditions of safety.

Protection reflexes, armour, and spines. Facial protective reflexes are usually well developed in flat-faced mammalian predators like cats and tarsiers, whose eyes and ears are especially exposed to injury by prey. The reflexes also are exaggerated in social species for use in communication; thus ear flattening in horse and dog displays has a counterpart in scalp retraction among Old World monkeys. The scalp movements and raised brows are effectively used in communication, despite the greatly reduced mobility of ears among monkeys. Limbs and other appendages (*e.g.*, antennae) are withdrawn or used to protect sensitive areas by both vertebrates and invertebrates. Among mollusks and such groups as sea squirts and barnacles, the whole soft body can be retracted into a protective shell, or carapace; a kind of door (operculum) may be used to stop the entrance (*e.g.*, among snails and barnacles), and trap-door spiders pull the stopper in place behind them. Bone may have evolved in fossil vertebrates as protective armour in jawless ancient fishes (ostracoderms), probably as a result of natural selection in the face of dominant arthropod predators (eurypterids). With the evolution of jaws, the vertebrates themselves gave rise to nearly all later large predators. Evolutionary advantage then apparently came with complex sense organs and behaviour; in most vertebrate lines there is evidence of a progressive reduction in body armour (dermal bone). Thus, although such cartilaginous fishes as sharks and rays do not exhibit such bony skins, they may well have evolved from heavily armoured ancient fishes (placoderms).

The completely armoured turtles and tortoises

Armour nevertheless has evolved repeatedly, particularly among animals incapable of fast locomotion; trunkfish (boxfish), for example, have a body entirely boxed by bony plates; and tortoises and turtles are perhaps the most completely armoured of four-legged animals. The turtles seem to have evolved early from the basal stock of the reptiles; thanks to the shell (carapace) within which they can withdraw head, limbs, and tail, they represent one of the few reptilian orders that have remained consistently successful. The turtle's dorsal carapace appears to consist of newly evolved plates of dermal bones, but the belly plates (ventral plastron) may well be retained in part from fish ancestors. Reptilian land vegetarians usually tended to evolve armour, as in the fossil dinosaurs such as stegosaurs and ankylosaurs.

South American toothless animals (edentates) such as anteaters are probably survivors of a comparable early development in mammals. The armour of armadillos and the presence of bony plates in the skin of the extinct sloths suggest that the whole group may derive from an armoured ancestor. The appearance of hair in the mammal line, partly inferred from the presence of fleas in early evolutionary periods, seems to have led to the evolution of a light, spiny type of armour. Such modern mammals as hedgehogs, echidnas, insect-eating tenrecs, and some rodents and their relatives (lagomorphs) all possess defensive spines that are commonly erectile and are often able to roll into a ball like an armadillo.

Chemical means of defense may be widely distributed in the body, making the animal distasteful to predators. Some of these chemical compounds may be derived from plants eaten or synthesized by the animal itself (*e.g.*, bufotoxin in toads). Although the animal attacked may be killed and thus not benefit, his fellows do since they are likely to be avoided by the predator. Poison or distasteful substances may also be ejected from a bodily reservoir and squirted at the enemy (*e.g.*, the skunk, some ants) or inserted into a puncture made by a spine (*e.g.*, triggerfish) or teeth (*e.g.*, certain snakes). Many poisons act to paralyze muscles by blocking nerve transmission at the neuromuscular junction (*e.g.*, cobra venom).

Warning behaviour. Mobbing behaviour apparently advertises the presence of a predator that is potentially but not immediately dangerous; thus mammalian nest predators can be safely mobbed by flying birds, as can owls in the daytime. From the safety of trees, such mammals as monkeys and squirrels mob predators on the ground. Mobbing calls are typically easy to locate, the calls being short and staccato, and they provide excellent cues of distance and direction. Conspicuous movements, such as tail flicks among small birds and squirrels, accompany the calls.

More urgently, intense warning behaviour is given in response to sources of immediate danger (*e.g.*, hawks actively hunting). Under these circumstances, warning calls are usually long whistles that make location difficult because of their gradual onset and termination and their narrow ranges of pitch. The evolution of warning behaviour that puts the displaying animal in danger (such as these intense warning calls) seems likely to come about only if the benefit to offspring and other members of the species is great. Indeed, it has been calculated that if an individual loses his life as the result of his warning behaviour, increased transmission of his family's genes will result only if the reproductive rate of relatives (as close as sisters) is doubled as a result of his sacrifice. (R.J.A.)

Aggressive behaviour

The term aggressive behaviour is used in so many different ways that no single definition can possibly cover all of its meanings. Behaviour that serves to injure an opponent or a prey animal, or to cause an opponent to retreat, is usually considered aggressive. When considering human aggression, some psychiatrists consider any act that has destructive consequences (including suicide) to be aggressive. (For a discussion of aggressive behaviour in man, see EMOTION AND MOTIVATION.) The role of aggression in behaviour has been—and continues to be—debated by psychologists and ethologists, as does the meaning of the term itself. Frequently, aggressive behaviour encompasses both attack and defense. Other investigators exclude food-gathering behaviour, though it may involve attack on another animal. In order to avoid these ambiguities of definition, a distinction must be made between causation, function, and description of observed behaviour. It is frequently assumed that a single motivational system (aggression) causes all recognizably aggressive behaviour in higher animals. This assumption is certainly invalid for invertebrates and for most higher vertebrates, in which a variety of motivational bases appear to exist. A motivational definition of aggression is thus difficult. The only possible rigorous approach is to list patterns of behaviour, usually held on both functional and causative grounds to be aggressive. Because aggressive behaviour has been most studied in mammals, mammalian behaviour will be examined here first as a basis for comparison with other animals.

BASIC AGGRESSIVE PATTERNS

Most modern theories of aggressive behaviour are based on laboratory experimentation, especially with mice and cats, and on field observations. Mammals show two basic aggressive patterns: attack and defensive threat. Direct evidence from brain-stimulation experiments in marsupials and eutherian (placental) mammals shows that each pattern is a closely coordinated series of events, obtainable in relatively constant form from a wide range of brain sites. Attack behaviour results from stimulating the lateral and anterior regions of the hypothalamus, and defensive threat from some areas near the centre of the hypothalamus and from the central gray region of the mesencephalon (midbrain). In the opossum, attack involves visual fixation on the prey, seizing it with the jaws, and shaking it from side to side through a figure eight. In defensive threat, the jaws

Mammalian attack behaviour

are opened and the animal backs into a corner, hissing. Newborn mice exhibit escape behaviour. Helpless at birth, a mouse will respond defensively to an outside stimulus (*i.e.,* pinching the tail) by squeaking, moving its legs, and moving away. When the mouse is older, its behaviour becomes more offensive in that it will attempt to bite. Still later, at about 12 days of age, it will stand on its hind legs in a posture of defense. Not until it is a month old, however, will it attack. The pattern of fighting in male mice includes kicking, biting, and rolling over until one of the combatants is hurt. The injured mouse might attempt escape, with the attacker in pursuit. If escape is not attempted or is not possible, the injured mouse may show defensive behaviour or feign death, submitting to the attacks of the aggressor. The aggressive patterns in the cat have been studied extensively. There is disagreement about the relation in this species between movements of prey catching and those of attack on other cats, and indeed whether prey catching should be termed aggressive at all. Since the coordination of stalking, biting, seizing with the forepaws, and scratching with the hind legs can be the same in both situations—and the eliciting stimuli also are often similar—it is reasonable to classify them together. The dispute stems from the possibility of the same pattern having two or more rather different causations.

In the cat, it is clear that defensive threat involves a number of component patterns that can occur independently of each other. The patterns include reflexes that protect vulnerable areas, such as narrowing the eyes or flattening the ears and cardiovascular preparations for exertion (*e.g.,* a rise in arterial blood pressure and active dilation of the blood vessels that supply muscles). Hisses and growls, together with erection of back and tail hair, are also typically part of defensive threat, serving to make the animal conspicuous.

Similar patterns can be recognized in birds and can be induced by brain stimulation in roughly the same areas as in the cat. In the collared dove (*Streptopelia decaocto*) attack involves pecks and wing blows, whereas an immobile threat display includes bill opening and feather erection.

Human attack behaviour, defined in this way, might consist of a direct stare, exaggerated by a slight frown, as preparatory behaviour, and then, at full intensity, striking with hand or fist, seizing, and biting. Staccato, loud, or breathy speech, given at such times, may be compared to the violent expiration (hissing, growling) of other primates in threat.

Acquired skilled movements (*e.g.,* boxing, wrestling) could reasonably be included, just as fighting in adults of other species probably also involves skilled movements (*e.g.,* blows with leg spurs in cocks).

CAUSATION

Evocative stimuli. Few stimuli that are highly specific for attack have been described. A scent produced by adult male mice is probably one example. Another is colouring. It has been shown that chaffinches (*Fringilla coelebs*) have a personal territory about them that they protect from intrusion by other chaffinches. This territory may be related to a source of food or water or to space for perching. Invasion of the personal space of one chaffinch by another usually results in either attack or withdrawal. Males may penetrate up to 20 centimetres (eight inches) before either alternative occurs. Females, however, are permitted to penetrate up to 10 centimetres. Experiments have been performed in which the feathers of the female chaffinch's breast are dyed to resemble those of the male. When such a disguised female penetrates the personal territory of a male, attack or withdrawal occurs within 20 centimetres. Experiments with inexperienced birds indicate that the effect is innate.

Members of an animal's own species (conspecifics) that are unfamiliar tend to evoke attack, perhaps partly because they lack the cues that suppress attack in familiar fellows (*e.g.,* group smell in mice; see below *Aggression as a drive*). Another very widely effective stimulus is that of a conspecific approaching within a certain distance, which, in the case of species the members of which ordinarily do not tolerate close approach, may be very uniform; for example, the chaffinches' inviolate personal territory, which has already been mentioned above. This distance may be maintained around objects other than the animal itself. A typical songbird territory includes points, such as song perches or the nest site, that are defended in this way. Approach to the mate often evokes attack; this is particularly clear in species in which paired birds remain in flocks (*e.g.,* some grackles, *Quiscalus*) and approach to the mate is not the same as entry of the territory. Both birds and mammals commonly attack in response to an approach that threatens their offspring. In many ways (*e.g.,* grooming) offspring are treated as an extension of the maternal body, thus, a threat to the offspring is a threat to the parent.

Stimulus of a fleeing animal

A conspecific moving rapidly away tends to evoke chasing and attack in many birds and mammals. In such predators as dogs attacks like this may be partly inhibited, taking the form of aggressive play, but their resemblance to prey catching is so close that any distinction would be artificial. The stimulus is equally effective, however, in such species as baboons, which rarely or never take large prey. For young domestic fowl, inexperienced in attack, repeated rapid retreats and approaches by another individual are the optimal stimuli for sparring and pecking.

Submissive behaviour (*e.g.,* exposing throat or belly) has been described as providing stimuli that specifically inhibit attack. It is more likely that such behaviour is effective either by removing stimuli that tend to evoke attack, or by evoking systems of responses incompatible with attack. Examples of the first category are immobility, as in the resting attitudes assumed by many mammals and birds when persecuted, and the avoidance of behaviour (such as the direct stare) suggestive of intent to attack. The assumption of infantile behaviour (*e.g.,* food begging in many birds) makes attack less likely. Many social mammals, indeed, have evolved special features in their young (*e.g.,* juvenile fur colour of baboons and guenon monkeys) that allow their possessor to behave freely in ways that would certainly produce attack if shown by an adult. The assumption of sexual postures is another example of the second category of submissive behaviour. In baboons and macaque monkeys "presenting" (the type of solicitation used by a sexually receptive female) has become a common response of any subordinate, male or female, when approached by a superior. The Austrian ethologist Konrad Lorenz has argued that predators have unusually effective submissive behaviour because they are so well armed and, extrapolating from animals to man, that it is therefore unfortunate that man is not more genuinely a carnivore. In fact, as with most displays, the clearest correlation is that the more social the species, the more elaborate and easily elicited the communicating displays. Man is even better equipped than other primates with infantile displays (weeping, dependent behaviour) and friendly greetings (smiles) that avert attack.

Dominance hierarchies

Dominance hierarchies, first described in terms of pecking right in the domestic fowl, may be regarded as a means of reducing attack within a social group. Once the hierarchy is established, disputes rarely need arise because the inferior immediately gives way when confronted by a superior.

A dominant animal is best defined as one whose actions are not constrained by possible responses of its fellows. Its position need not derive from earlier successful aggressive behaviour although it usually does, but may instead reflect superior persistence or strength. Although best known in birds and mammals, dominance hierarchies have also been described in crabs and bumblebees. In bumblebees the dominant animal opens its mandibles and butts the inferior one.

Facilitating stimuli. Startling and painful stimuli facilitate attack, which may be directed to objects not associated with the source of pain or startle. The effect has been shown in both rats and squirrel monkeys, following electric shock administered through a floor grid. A clear distinction has usually not been made between attack, defensive threat, and a mixture of the two; but both patterns are clearly facilitated. The human irritability that often accompanies persistent discomfort or pain provides a more familiar example.

The thesis that frustration causes aggression has been very influential since it was first proposed. In a laboratory experiment, a pigeon immediately attacked another whenever a lever that normally delivered food when pressed failed to do so. There is no reason, however, to elaborate such evidence into the proposition that all of the attack is caused by frustration, as has been suggested by some investigators.

Reinforcing patterns. It has been suggested that a number of important patterns of behaviour—most or perhaps all of which have major representation in lateral hypothalamic brain centres—include component responses that produce self-reinforcing stimuli. An animal in which the pattern is activated, either naturally or by hypothalamic stimulation, will learn to run a maze in order to be able to perform the response. This observation has been made of the rat, not only for such obvious patterns as feeding and drinking but also for gnawing on wood and other objects. Following appropriate electrical stimulation, a cat will run a maze in order to be able to attack a rat, even though most cats normally do not respond to rats. This behaviour involves prey catching, rather than attack, if a distinction is to be drawn. There appears to be no direct evidence of this type for attack in animals not artificially stimulated.

Play as aggressive behaviour

It is clear, observationally, that once attack has become likely an animal will search for the opponent and perform a variety of responses in order to reach him. The study of play behaviour suggests that the movements of prey catching (*e.g.*, kittens pouncing on a ball) or attack (*e.g.*, the play fighting so common in primates and other mammals) in themselves can be reinforcing. In such play, hurting or inducing signs of hurt are avoided, but it is possible that these sometimes are sought and serve as reinforcers, as is certainly suggested by human behaviour.

It is almost certain, however, that attack and defensive threat are also performed under the control of quite other reinforcers, such as removing a social fellow who is an inconvenience or an obstacle. It has been shown that a pigeon can be conditioned to attack a cage mate as an operant response to obtain a food reward from a hopper quite remote from the animal attacked. Full intensity attack was given, but other experimenters have found that attack caused in this way shows the simpification and reduction in intensity typical of operant responses. This reduction is obvious in the light peck used by dominant hens to make inferiors retreat from food or to control them in other ways. There is no reason why attack should be used for such a purpose rather than some other behaviour, if some other type of behaviour was more convenient.

Aggression as a drive. Lorenz is the most recent author to treat aggression as a drive that energizes attack (and some other behaviour), is exhausted by performance of the behaviour, and then accumulates afresh, making performance more and more likely. The resemblance to the death wish of Freudian theory is obvious, particularly since both suggest that quite unlikely behaviour may be motivated by the drive. This approach to the causation of behaviour can be traced back through the writing of Charles Darwin to an influential essay by Herbert Spencer on laughter and its role in discharging accumulated nervous energy. No convincing proof for such theories has ever been presented.

There is now direct evidence that threshold (the amount of stimulus required to elicit the response) for attack or threat may be raised or lowered over periods as long as 20 minutes. In the ring dove, following the evocation of either response by a natural stimulus or by brain stimulation, some brain sites that normally give the response show a changed electrical threshold for such a period. In many species, once a stimulus capable of evoking attack has been presented, the individual may remain likely to attack for some time, especially when the attack is evoked by an animal itself too dominant to be attacked. Other conspecifics or, in man at least, inanimate objects may then be attacked instead, a phenomenon called redirection. What evidence there is, however, suggests that such states of readiness, which in man would be termed irritability or anger, will dissipate just as well or better in the absence of actual performance of aggressive behaviour.

There is no reliable evidence that aggressive behaviour becomes progressively more likely over long periods in which it is not evoked, as has been suggested by some workers. Such an increased likelihood is clearly found for feeding behaviour, but the consequences of not eating—such as reduced availability of glucose and free fatty acids to tissues and a reduction of fat stores—provide internal stimuli that make feeding more likely. These effects, of necessity, become more intense the longer a fast is prolonged. In the case of performance of copulation, the act is followed by a reduced likelihood of response to further stimuli. In the male of certain species (domestic cattle, for example) this reduction is almost entirely restricted to copulation with the female just mounted, the bull remaining receptive to stimulation by other cows. In other species there is some contribution from a general rise in the threshold for copulation. There is no evidence for either type of effect in the case of aggressive behaviour, except that isolation promotes fighting. This is well established for male laboratory mice. Attacks on intruders, however, depend largely on odour cues (*e.g.*, male cues increase, female cues decrease, attack). Fighting within a social group of males is much reduced by group cues, and isolation may act to abolish the effectiveness of such cues.

Fighting in laboratory mice

The increased incidence of aggressive behaviour in small groups of isolated men, such as polar explorers or prisoners, has been explained by Lorenz as resulting from a build-up of undischarged aggression. But the comparison is not strictly relevant because the stress and frustration of such situations might well facilitate aggressive behaviour directly.

Physiological effects on aggressive behaviour. It has long been known that the administration of male sex hormones (androgens) makes aggressive behaviour more likely in many male mammals and birds. It has no effect on aggressive behaviour in female rats and mice, apparently because of the general insensitivity of the female central nervous system to androgens. Male individuals castrated at birth are less aggressive than those castrated at the time of weaning, which suggests that masculine aggressiveness is partly determined by early differentiation. Androgens also affect male aggressive behaviour indirectly. In the red deer, testosterone implants cause migration to the rutting (mating) area, which will be defended, and also cause the loss of velvet from the antlers, so that these become effective weapons. The increase in aggressive behaviour caused by the possession of a territory is particularly obvious in passerine birds, the males of which may continue to flock freely with other males on feeding grounds at a time when, if on their territories, they would attack other males fiercely. Hormonal effects on aggressive behaviour also occur in females. The increased aggressivity shown by female hamsters at pregnancy is the result of rising progesterone levels.

Role of hormones in aggression

Lesions of the amygdala, a structure near the base of the forebrain of great importance in motivation, have been long known to produce taming in a wide variety of mammals and in ducks, and the effective area has been localized to the rostral lateral amygdala in cats. Defensive threat, attack, and fleeing are reduced as a result. The amygdala is not exclusively concerned with aggressiveness; it appears to be especially important in cases in which the novelty, intensity, or past significance of a stimulus determines whether the source is approached and eaten or avoided. The amygdala may facilitate aggressive behaviour as part of a determination that a stimulus is intense or unusual.

Lesions of the septum, a part of the base of the forebrain containing important tracts connecting to the rest of the brain, have the opposite effect: in the laboratory rat, such lesions cause defensive attack to be given to such stimuli as handling or a light (but presumably startling) touch, which were previously ineffective. The septum is also implicated in the inhibition of certain responses (*e.g.*, those that have ceased to be rewarded), and this may be related to its role in suppressing attack.

Threat displays. The main modern work on displays has explained their causation in terms of conflict between such major drives as aggression, fear, and sex. There is considerable evidence, especially from experimental brain

stimulation in the cat, that defensive threat is a unitary pattern caused by the same stimuli that evoke attack or fleeing but independent of the latter. Confident threat displays are given by animals unconstrained by the possibility of retaliation, which do not attack because, for example, they do not wish to move. These displays include a wide variety of components. A direct gaze, which may be exaggerated by a frown in mammals with mobile faces, indicates a sustained interest. Protective reflexes indicate that the animal showing them anticipates close and possibly dangerous contact. They are assumed in rough, friendly play; but when they appear during approach—when still at a little distance—they suggest the expectation of attack (*e.g.*, ear flattening in the horse); the greater the distance at which they appear, the less confident the animal showing them. Finally, the animal may perform actual intention movements of attack, such as mouth opening, withdrawing the lips, or striking at the ground.

Many displays, termed threat displays because they are given to strangers at the territorial boundary or during early phases of pair formation when attack is still likely (*e.g.*, long call or choking display of gulls), would be best given a more neutral name.

EVOLUTION OF AGGRESSIVE BEHAVIOUR

It is instructive to attempt to identify attack in the familiar frogs (*Rana*) and toads (*Bufo*) of the amphibian order Anura. Prey catching in most frogs is highly specialized, involving a lunge of the head or a movement of the tongue only and directed only at small moving prey. In this respect, it is quite unlike attack shown by most land vertebrates. The mounting and clasp of females are so obviously related to copulation that they, too, are not readily confused with attack. Males clasped in error use wiping movements of hind legs that also are evoked by dirt on the body surface, and they struggle as they would if caught in some obstruction. There is thus no obvious attack response. Some of the functions of attack, however, are achieved by displays that are not derived from aggressive behaviour: females that have spawned, and all males, when clasped, give a special call that tends to produce unclasping. In higher tetrapods (land vertebrates), such unwanted copulation attempts would certainly evoke and be terminated by attack. In some anuran species, the calls given by males to attract females elicit avoidance by other males, ensuring optimum spacing of breeding males.

Relation of aggression to mating

Iguanid lizards resemble such frogs in possessing a female rejection display (legs extended, back arched, and tail turned toward the male), which appears to be specific in effect. Males give what appears to be an aggressive display to other males from lookout sites, but there is no evidence that it has evolved from movements of attack; it consists of vertical head bobbing that may well be an exaggeration of movements used in depth perception. The movements precede copulation as well as attack, which in lizards involves bites and sometimes tail blows, and the two may have evolved quite separately. The bites presumably derive originally from prey-catching behaviour, which is clearly as ancient in the vertebrates as the evolution of the jaw. As soon as dangerous bites became possible for feeding in vertebrate evolution, there was strong selection for their use in defense, and the facilitation of attack by pain or startle may be as ancient as this selection. The use of prey-catching behaviour to drive off conspecifics from areas offering important resources (*e.g.*, food, mate, nest) would also be strongly selected, for, once the pattern was available (see below), it would require initially only a slight change in evoking stimuli (*e.g.*, response to rather larger moving objects) to allow this result. The crossopterygian ancestors of the tetrapods and their immediate amphibian descendants were dominant predators, so that prey catching and biting in defense can be assumed to have been present. Comparison with present-day inhabitants of muddy shores, both air-breathing fish (*e.g.*, mud skipper) and crabs, suggests that conspicuous displays given to the approach of a conspecific had probably also already evolved. Causally then, as now, some or all of such displays might have been independent of attack. No doubt they already could be followed either by copulation attempts or by attack. There would be strong selection for appropriate hormones to confine the displays to breeding periods; this selection has happened with frog breeding calls and with bird songs, as well as with bird territorial displays, all of which are now facilitated by testosterone. The fact that this is true also of attack and male copulation has been taken mistakenly in the past to indicate causation of the former categories of bird behaviour by aggression and sex.

Prey-catching movements in displays

Aggressive behaviour of invertebrates. An account of invertebrate aggressive behaviour must be based on an analogy with the functions of that of vertebrates, since there can be no question of homology (common origin). Obviously, even in vertebrates, many of these functions are also served by other behaviour as well.

Aggressive behaviour may allow a vertebrate to maintain, exclusively if possible, its access to some important resource such as food, territory, or mate. In some invertebrates, there is the same use of attack derived from prey-catching responses, as in higher vertebrates. The larger dragonflies (Odonata) maintain a feeding territory by hawking at conspecifics in the same way as at prey. The clearest example is that of nest defense in social wasps and bees. Here a sting and a secretion, originally evolved to paralyze insect prey, have come to be used both against conspecifics (*e.g.*, when fighting with "robber" bees attempting to enter the hive) and against vertebrates, which raid bee and wasp nests. Bees are not predatory, so their sting has no food-capturing function. The scent of bee venom strongly facilitates the stinging of large, hairy objects, and a whole hive may pass into a state entirely analogous with that of heightened aggressivity in a vertebrate but with the persistence of lowered threshold (*i.e.*, greater readiness to attack) dependent on the persistence of a chemical signal (pheromone). Both termites and ants have evolved facilitation of colony defense by pheromones released by disturbed individuals, like that described for bees.

Nest defense by social insects

In their attack behaviour, ants and bees show an interesting use of responses evolved to keep the nest clean of dead conspecifics and other debris. Drones (males) are seized and thrown out of the hive entrance. Strangers are treated similarly if they remain passive. If the stranger is identified at a distance (*e.g.*, by the side-to-side flight characteristic of robber bees), the guard bees may open their mandibles in a manner reminiscent of vertebrate threat, although there is no clear evidence that it is effective as a signal.

Freely ranging spiders, such as wolf spiders (Lycosidae), respond to conspecifics as they do to prey; the animal attacked commonly gives a low-intensity version of a display shown at full intensity in courtship, which tends to terminate the attack. Perhaps the least advanced group in which behaviour analogous with attack has been described is that of polychaete worms. Predatory ragworms defend their burrows against conspecifics with biting attacks. In other instances, biting is the analogue of vertebrate defensive threat, which has evolved from prey-catching behaviour; most threatened crabs extend and open their chelipeds (large claws), which evolved for feeding.

The function of defending resources against conspecifics is also served by a variety of adaptations that should not be termed aggressive (*e.g.*, Orthoptera stridulation).

Defensive displays. In addition to territorial defense, aggressive behaviour may function to terminate some behaviour of a fellow animal. The crying of human infants effectively manipulates mothers to remove sources of discomfort or fear; it is misleading to term it aggressive, however. In the chimpanzee, screaming tantrums are known to allow infants to win disagreements with the mother and access to food. Tantrums are also used by adults to some extent. In many primates (*e.g.*, baboons), such behaviour shades into the screeches of defensive threat, but it is probably best separated from aggressive behaviour proper. That the distinction is needed is clear for an analogous series of behaviour patterns, the distress calls of young gallinaceous birds (pheasants, quail, and domestic fowl), which are given when there is marked discrepancy between the stimulation expected or sought after and that obtained. Aggressive behaviour can thus be regarded as a source of only one of a range of reinforcers used by higher vertebrates to punish and manipulate their fellows.

Tantrums

Defense against predation can depend on many adaptations other than attack and defensive threat. Those that involve the infliction of damage, pain, or startle by a response aimed at the predator may be considered here as analogous to aggressive behaviour. A number of mustelids, especially skunks, have evolved a new pattern of defensive threat in which the readiness of the scent glands to discharge is conspicuously advertised, in one species by standing on forepaws to present glands. Various petrels (seabirds of the families Hydrobatidae and Procellariidae) discharge the oily and repellent contents of their crops over substantial distances at nest predators; the accuracy of aim may depend on the fact that they face the predator in order to examine him binocularly.

The loud call given by most tetrapods, including frogs and toads, when seized, apparently serves to startle the predator so that a final opportunity for escape may be given. Such a call may well have been involved in the evolution of the screeches given by many mammals in defensive threat. Many invertebrates have specialized startling displays that are comparable: the sudden display of eyespots by many moths when disturbed by a sudden movement or tap, the forewings typically moving forward to expose markings on the hind wing. (R.J.A.)

Migratory behaviour

Migration can be contrasted with emigration, which involves a change in location not necessarily followed by a return journey; invasion or interruption, both of which involve the appearance and subsequent disappearance of great numbers of animals at irregular times and locations; and range expansion, which tends to enlarge the distribution of a species, particularly its breeding area.

The migration cycle is often annual and thus closely linked with the cyclic pattern of the seasons. The migration of most birds and mammals and many of the fishes are on a yearly cycle. In many cases (*e.g.*, salmon and eels) animals with a relatively long life-span return to the place of birth in order to reproduce and eventually die. In other cases, as in certain invertebrates, where the animal has a relatively brief life-span and reproduces rapidly, migrations may not occur in every generation. The daily movements of certain fishes and invertebrates have also been called migrations because of their regular occurrence. This type of movement, however, is not to be confused with migration in the strict sense.

Most migrations involve horizontal travel. The distance traversed may be a few miles or several thousands of miles.

Some migrations take a vertical direction and involve no appreciable horizontal movement. Certain aquatic animals, for example, move from deep water to the surface according to the season. Certain birds, mammals, and insects migrate altitudinally in mountainous areas, going from the upper zones, where they breed, to the foothills or plains during seasons when the weather is severe and unfavourable. Such vertical travels involve essentially the same type of environmental change as horizontal, or latitudinal, migrations over long distances.

SURVEY OF MIGRATORY BEHAVIOUR IN ANIMALS

Planktonic migration

Lower invertebrates. Many marine invertebrates travel considerable distances during certain seasons. A large proportion of them, however—particularly planktonic organisms, plant and animal aquatic drifters—do not travel deliberately but are carried by ocean currents. Planktonic organisms also travel vertically in a daily rhythm. Very small or microscopic animals remain at great depths during the day and rise at dusk, concentrating in the upper layers of water during the night. Their predators, particularly fishes, follow them in their cycle. The daily activity of pelagic birds (*i.e.*, those living on the open sea rather than along the shore), such as petrels and shearwaters, which feed on planktonic crustaceans and squids, follows this same rhythm.

A seasonal change of habitat, analogous to migration, is made by some Polychaeta (sandworms). Along the coast of Europe, clam worms (*Nereis*) live during the colder months in rock crevices and among algae. During the summer, however, they become planktonic and swim out some distance from the coast, where reproduction occurs. In the South Pacific, near Samoa and Fiji, the palolo worm (*Palola siciliensis*) lives among coral reefs, where it develops posterior segments filled with genital (reproductive) cells. These are cast off, and the worm rises to the surface. The phenomenon occurs regularly on the first day of the last quarter of the October–November moon.

Some of the best known migrations among the invertebrates occur in crustaceans during the reproductive period, when some of them travel as far as 240 kilometres (150 miles). Generally in the crabs, females move into shallow coastal waters to mate and to lay their eggs. After the eggs have been laid, the females return to deep water.

Some freshwater crabs, such as the Chinese crab (*Eriocheir sinensis*), after remaining for three to five years in freshwater, migrate to brackish water, where mating occurs. Females with eggs externally attached then travel to the sea and remain a few miles offshore for several months during winter. The following spring they enter shallower water near the shore. Here the eggs hatch. Young crabs spend a year in brackish water and migrate upstream the following spring, settling in freshwater and growing to maturity.

Some crabs, such as robber crabs (*Birgus*) and land crabs of tropical regions (*Geocarcinus*), have adapted to life on land. They migrate to the sea to reproduce and then return inland and are followed at a later time by the young.

Insects. Migration among the insects is best known in locusts and butterflies; a great number of other insects, however, including some of the smallest, are migrants. Broadly speaking, insect migration is of three types—some insects emigrate on one-way journeys to breed; others migrate from a breeding area to a feeding area; still others migrate from breeding areas to hibernation sites.

Types of insect migration

In the first type, adults with a life-span limited to a single season emigrate from their breeding site, deposit their eggs, and die. Such migratory flights can be very short or very long but, because they are always one-way journeys, cannot be regarded as migration in its strictest sense. The best known examples of such flights are those of locusts, particularly the desert locust (*Schistocerca gregaria*), a species found in tropical and subtropical countries of the Old World. The migratory, gregarious form arises from the solitary form as a result of various conditions—*e.g.*, lack of food, crowding.

The desert locusts breed only when and where seasonal rains permit; as a consequence of climatic conditions, therefore, the insects migrate from one breeding area to another. If the available food decreases and the numbers of insects increase too drastically in a particular area, migratory locusts develop. They differ from nonmigratory forms in colour, structure, behaviour, and physiology. Swarms numbering up to 10,000,000,000 individuals periodically invade territories in Africa, southwestern Asia, and southern Europe, covering areas as large as 1,000 square kilometres (400 square miles).

Other migrant insects travel beyond the limits of their breeding range and either die or return to the breeding range. The painted lady butterfly (*Vanessa cardui*) "migrates" in the spring, when its population becomes too large for local conditions, from the peninsula of Lower California in Mexico to the Mojave Desert in Southern California. Eggs are laid in the desert region, but the species does not become permanently established there and makes no return flight. Such movements are known in about 250 species of butterflies.

In the second type of migration—migration in the strict sense—insects migrate from a breeding area to a feeding area. In the feeding area the females develop mature ovaries and then return to lay their eggs in the place from which they came or a similar region.

Cockchafers (*Melolontha melolontha*), a species of beetle, leave the site where they emerge as adults and move to a feeding area, generally in a forested region, where maturation of the eggs takes place. They then return to the area where they developed from eggs and lay their own eggs. This process may be repeated several times during the life of the insect. Although the distances covered by

the cockchafer may not be great, the regularity of the phenomenon is characteristic of true migration.

In the third type of migration, insects travel from their breeding areas to places where they hibernate or estivate—*i.e.*, pass the summer in a dormant state. The place of hibernation or estivation may be outside the zone where climate permits breeding. The following season, they return to the breeding place and lay their eggs. This type of migration, which can involve great distances, is made by insects with unusually long life-spans. The lives of these insects include a diapause, or period of dormancy during which development is suspended.

In warm countries the coccinellids, a family of beetles, and certain moths leave the hot lowlands and migrate to the mountains, where they estivate and later hibernate. In spring they return to the breeding areas.

Migration of the convergent ladybug

One coccinellid, the convergent ladybug (*Hippodamia convergens*), lives in valley regions of California, where the eggs hatch in March or April and develop into adults one month later. In early summer they migrate to the mountains, particularly to the Sierra Nevada, where they may lay eggs if food is abundant and the weather warm. Generally, however, the adults gather in clusters and remain inactive until October, when rains initiate a period of activity, after which they travel to lower altitudes and hide in forest litter, passing the winter in a state of dormancy. As many as 30,000,000 ladybugs may congregate on a quarter acre. In spring they mate, fly back to the valleys, lay their eggs, and die.

The flight before diapause of some insect groups may cover thousands of miles. In North America, the monarch butterfly (*Danaus plexippus*) is a well-known example of a wide-range migrant with an extensive breeding range. The number of generations varies with the latitude; as many as five generations may occur each year in the south and only one in the north. In summer the insects travel northward to Hudson Bay. Individuals of the last generation of the year migrate southward in autumn to Florida, Texas, and California, where they hibernate after travelling nearly 3,200 kilometres (2,000 miles). They gather in sheltered sites, particularly on trees where they cluster on trunks and big branches. In spring part of the populations migrate back to the northern breeding areas. Some of the returning butterflies are members of the first generation that develops from the overwintered insects; others represent successive generations that develop as the insects progress toward more northern latitudes. The recapture of marked butterflies has revealed that they travel as much as 130 kilometres (80 miles) in one day. The longest distance recorded thus far for the complete flight of a migrant monarch butterfly is 3,010 kilometres (1,870 miles).

From M. Ricard, *The Mystery of Animal Migration*

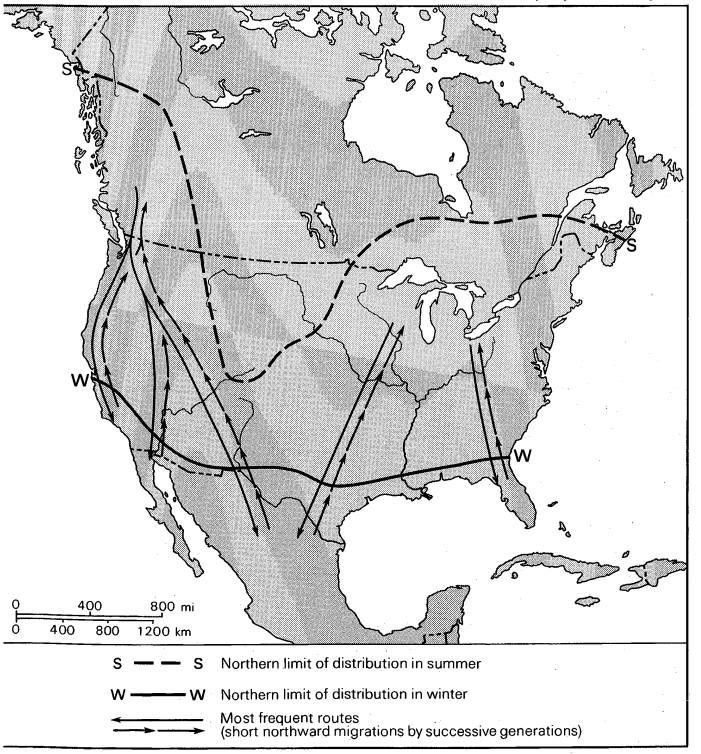

Figure 19: Migrations of the North American monarch butterfly (*Danaus plexippus*).

Fish. Many species of fish wander annually through a particular area of the ocean. Some are true migrants, travelling regularly over great distances. Young fish usually leave the spawning grounds for areas where they develop into juveniles, before joining the adult stock at the feeding grounds. Adults move to the spawning grounds, then return to the feeding grounds. Migratory patterns of fish are related to oceanographic factors and to currents. Eggs, larvae, and young drift passively with the current, although migration of adult fish toward breeding grounds is usually against the current. Adult movements thus are directional rather than passive, and the fish respond to environmental conditions—*e.g.*, climate.

Three categories of migratory fishes can be distinguished: oceanodromous, anadromous, and catadromous.

Oceanodromous fish. Oceanodromous fish, which occur widely throughout the world's oceans, live and migrate wholly in the sea. They differ mainly from one another by the method and extent of their migration.

Herring migratory patterns

Herring (*Clupea harengus*), extensively studied because of their economic importance, are the best known of the oceanodromous type and can be classified into several populations, or local races, which do not mix freely. In addition, each has a particular migratory behaviour. In the North Sea, distinct groups spawn in different seasons and on different grounds: Buchan herring spawn in August and September off the coast of Scotland and migrate to the coast of southwestern Norway; Dogger Bank herring spawn in September and October in the central part of the North Sea and along the English coast and then migrate to the Skagerrak, an arm of the North Sea between Denmark and Norway; Downs herring spawn from November to January off the French coast, mainly between Dunkirk and Fécamp, then feed in summer in the middle and northern parts of the North Sea, sharing the feeding grounds with other populations. The diversity of migration and of reproductive seasons is closely connected with the annual cycle of oceanographic conditions in the North Sea.

Cod (*Gadus morhua*) have migration patterns similar to those of herring. The migrations of other fish cover even greater distances; in the Atlantic, for example, white tuna (*Germo alalunga*) are found in winter around the Azores and the Canary Islands, where they spawn in spring. They then migrate northward to the Gulf of Gascogne and afterward to the waters around Iceland, arriving there in July. Populations of red tuna (*Thunnus thynnus*) occur throughout the Mediterranean Sea and the eastern Atlantic. In May and June they spawn in the western Mediterranean. During summer they spread northward to feed, finally reaching the Arctic Ocean. Similar migrations occur along the North American coast in the Atlantic and throughout the Pacific.

Anadromous fish. Anadromous fish live in the sea and migrate to freshwater to breed. Their adaptations to conditions of different habitats are precise, particularly with regard to salinity of the water.

Salmon (*Salmo, Oncorhynchus*) spawn in the cold, clear waters of lakes or upper streams. Eggs are laid in gravel beds. The young of the Atlantic salmon remain in freshwater for two to three years, sometimes as long as six; Pacific salmon sometimes migrate to the sea in their first year. Adult fish usually remain in the sea for two or three winters, but sometimes only one. Then, as grilse (adolescents) or as adults, they return to freshwater and spawn, after changes occur in colour and other external features. Some Atlantic salmon die in freshwater after a single spawning; others return to the sea.

The tagging of salmon has shown that European types may cross from Norway to Scotland, as well as the reverse. Pacific salmon are probably distributed over the Pacific Ocean and Bering Sea, between latitudes 45° N and 65° N with surface waters of 2° to 11° C (36° to 52° F).

Experiments in Canada and the United States, in which young salmon migrating to the Pacific have been tagged, have shown that a high proportion of the fish return to the river where they hatched. Tagging of Atlantic salmon has shown that a few survivors have migrated two or even three times to a particular river in successive years. Adults reared from experimentally transplanted eggs return to the stream where they were hatched or grew, not to the stream where the eggs were laid. Aside from other means of orientation, such as reference to celestial features, topographical features are believed to play an important part in recognition of the original habitat. The sense of smell, or olfaction, however, has the most important role. Experiments have shown that migrating salmon are attracted to the waters of the stream in which they are going to spawn. Experiential imprinting at an early stage of development enables a grown fish to respond to waters that contain substances with a particular odour or that have a characteristic temperature.

Catadromous fish. Catadromous fish spend most of their lives in fresh water, then migrate to the sea to breed. This type is exemplified by eels of the genus *Anguilla*, numbering 16 species, the best known of which are the North American eel (*A. rostrata*) and the European eel (*A. anguilla*).

Eel migration

European eels and North American eels spawn in warm saline waters of the Atlantic, at depths of 400 to 700 metres (about 1,300 to 2,300 feet), in an area centred near latitude 26° N longitude 55° W called the Sargasso Sea. The pelagic eggs develop into leptocephali—transparent, leaflike forms with relatively small heads—that are carried by the Gulf Stream to the shallow waters of the continental shelves. When they are about two and one-half years old and about eight centimetres long (a little more than three inches), a metamorphosis occurs. The leptocephali are transformed into so-called elvers, which are bottom-dwelling, pigmented, and cylindrical in form. They arrive in coastal waters as glass eels and begin to swim upstream in freshwater streams in spring. Their migration upstream is spectacular, as the young fish gather by millions, forming a dense mass several miles long. In freshwater the eels grow to full size, becoming yellow eels. They live as such for 10 to 15 years before changing into silver eels, with enlarged eyes; they swim downstream to the sea, return to the spawning grounds (Sargasso Sea), and die.

The migration of these eels is not entirely understood, particularly their return to the Sargasso Sea. It may be that European eels and North American eels belong to the same species.

Reptiles and amphibians. The range of seasonal movements of most reptiles and amphibians is probably very limited. Generally incapable of travelling any great distance, they respond to unfavourable conditions by lapsing into a state of lethargy. This type of response makes it possible for them to remain in a particular area for the entire length of the year.

The only migration-like movements of reptiles and amphibians are made during the reproductive period. Frogs and toads then concentrate in particular areas such as ponds and lakes; thousands travel toward these sites from year to year. After reproduction, the animals disperse and again settle over their usual range.

Turtle migration

The South American river turtle, or arrau (*Podocnemis expansa*), migrates along rivers in large masses that may impede the passage of boats. The turtles gather on sandbars of large rivers to lay their eggs. In the Galápagos Islands, giant land tortoises (*Testudo elephantopus*) stay chiefly in the upper humid zone, where food is abundant, but go down to the dry zone to lay their eggs. Despite their great body weight and slow pace, they travel some 50 kilometres (30 miles) across rough country.

Sea turtles, on the other hand, migrate over long distances, lay their eggs on special beaches, and then disperse over a wide area. Green turtles (*Chelonia mydas*), which deposit their eggs on the coast of Costa Rica in Central America, disperse through the Gulf of Mexico and the West Indies. Green turtles that have been tagged on Ascension Island, halfway between Africa and South America, have been recovered on the coast of Brazil, 2,300 kilometres (1,400 miles) away.

Birds. Migration is most evident among birds. Most species, because of their high metabolic rate, require a rich, abundant supply of food at frequent intervals. Such a situation does not always prevail throughout the year in any given region. Birds have thus evolved a highly efficient means for travelling swiftly over long distances with great economy of energy.

The characteristics of migratory birds do not differ greatly from those of nonmigratory forms; many intermediate types exist between the two groups. All transitional forms, in fact, may be manifested in a single species or in a single local population, which is then said to undergo partial migration.

In addition to regular migration, nomadic flights may also occur. This phenomenon takes place, for example, among birds of the arid zones of Australia, where ducks, parrakeets, and seedeaters appear in a locality following infrequent and unpredictable rains, breed, and then move to other areas. Nomadism is a response to irregular ecological conditions.

In Europe. The populations of many northern and eastern European species of birds have pronounced migratory tendencies; the populations of western Europe, on the other hand, are more sedentary.

Some birds are nomadic in winter, others spend the colder months in the southwestern part of the continent or in the Mediterranean region. Many migrant populations migrate to Africa south of the Sahara. Geographical conditions determine several main routes. The Alps are an important barrier to migratory birds. About 150 species travel westward and southwestward; others travel southeastward.

Tits (*Parus*), goldfinches (*Carduelis carduelis*), and blackbirds (*Turdus merula*) are usually sedentary in western Europe; they are usually migratory, however, in northern Europe, where their flights resemble a short migration. Starlings (*Sturnus vulgaris*) are sedentary in western Europe, where large numbers gather from eastern Europe. Large flocks also pass the winter in North Africa.

Insectivorous (insect-eating) species, such as warblers, flycatchers, and wagtails, are highly migratory and spend the winter in the tropics, chiefly in Africa. They migrate to Sierra Leone on the west coast, Tanzania on the east coast, and all the way southward to the tip of the continent. Most of these migrants use different routes to cross the Mediterranean, chiefly in the western portion, although some migrate only southeastward. Golden orioles (*Oriolus oriolus*) and red-backed shrikes (*Lanius collurio*) go to East Africa by way of Greece and Egypt. Swallows—particularly barn swallows (*Hirundo rustica*) and house martins (*Delichon urbica*)—and swifts (*Apus apus*) pass the winter in Africa south of 20° N latitude, particularly in South

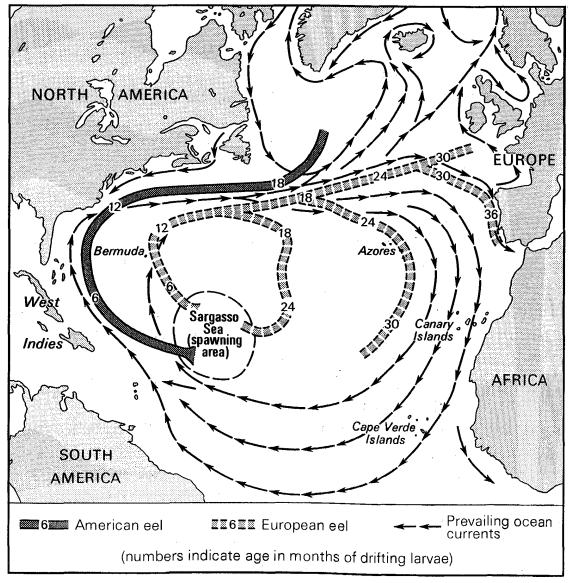

Figure 20: Migration of eels in the Atlantic Ocean.

Africa, in the Congo River region, and in some coastal areas of West Africa.

Migration routes of storks, ducks, geese, and swans

Among nonpasserines—*i.e.*, nonperching birds—one of the best known migrants is the stork (*Ciconia ciconia*), which migrates to tropical Africa along two well-defined flyways. The stork population nesting west of a line that follows the Weser River in West Germany flies southwestward through France and Spain, past the Strait of Gibraltar, and reaches Africa by way of West Africa; the eastern population, by far more numerous, takes a route over the straits of the Bosporus, through Turkey and Israel, to east Africa. These well-separated routes are probably a result of the stork's aversion to long flights over water.

Ducks, geese, and swans also are migrants. These birds winter partly in western Europe and partly in tropical

From J. Dorst, *The Migrations of Birds*; published by Houghton Mifflin Company

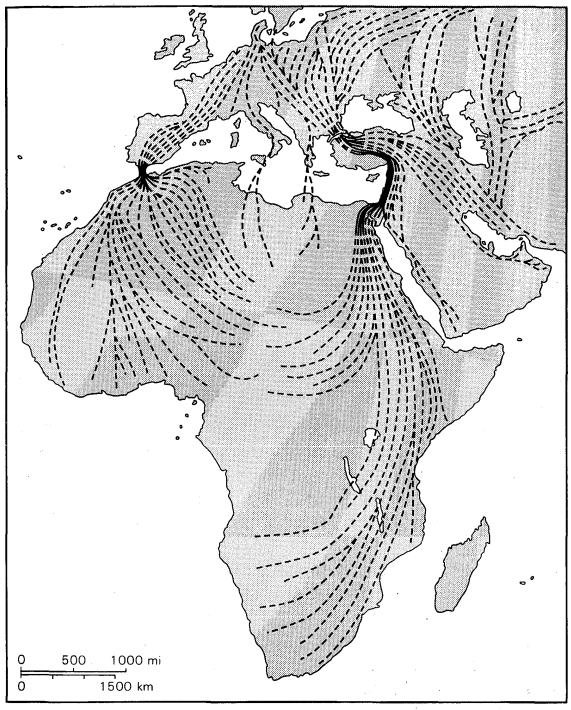

Figure 21: Principal routes taken by the European white stork (*Ciconia ciconia*) between nesting grounds in Europe and wintering grounds in Africa.

Africa. In Africa they are likely to spend the winter in lake and river regions from Senegal in western Africa to the Sudan in eastern Africa, where thousands of garganeys (*Anas querguedula*) and pintails (*A. acuta*) congregate annually. Some ducks leave their breeding grounds to molt (a process by which old feathers are replaced) in areas where they are most secure from predators during the time they are unable to fly; this is known as a molt migration. After molting, the ducks fly to their final winter quarters. Wading birds (Limicolae) also are typical migrants, most of them nesting in tundra of the Arctic region and wintering along the seacoasts from western Europe to South Africa.

In North America. North American birds must endure the same hazards of winter as European species. The geographical arrangement of the continent determines the main routes of migration, which run from north to south and include the Atlantic oceanic route, the Atlantic Coast route, the Mississippi flyway, the central flyway, the Pacific flyway, and the Pacific oceanic route. A great many birds pass the winter in the Gulf States, where the climate is favourable and food is abundant, but the principal wintering area extends through Mexico and Central America to Panama, which has the greatest density of winter bird residents in the world.

The ruby-throated hummingbird (*Archilochus colubris*) nests in southern Canada and winters in Central America as far south as Panama. Some of these birds fly nonstop across the Gulf of Mexico. Because of their food requirements, many American flycatchers (Tyrannidae), which are mainly insectivorous, have the same migratory behaviour as the hummingbirds. Others, like the phoebe (*Sayornis phoebe*), spend the winter in the Gulf States. Birds such as the American robin (*Turdus migratorius*) and several species of grackles assemble in the Gulf States in enormous flocks. The seasonal flights of the American wood warblers (Parulidae) are among the most spectacular on the North American continent. Some spend the winter in the Gulf States and in the West Indies; others, such as the blackpoll warbler (*Dendroica striata*), travel to Guiana, Brazil, and Peru by way of the West Indies. The spring migration routes of the Canada goose span the Continent of North America in an east–west direction from Hudson Bay as far south as Chesapeake Bay.

South America is winter quarters for several tanagers, such as the scarlet tanager (*Piranga olivacea*) and the bobolink (*Dolichonyx oryzivorus*); these birds migrate through the eastern United States and past Cuba to the swampy regions of Bolivia, southern Brazil, and northern Argentina. This area of South America is also winter quarters for the American golden plover (*Pluvialis dominica dominica*), which travels in an enormous loop over much of the New World. After nesting in the tundras of Alaska and Canada, the plover assemble in Labrador in easternmost Canada, then fly to Brazil over an oceanic route (the shortest possible route) about 3,900 kilometres (2,400 miles) long. Their return flight traverses South America, Central America, and the Gulf of Mexico, then follows the Mississippi Valley.

The role of wet and dry seasons

In intertropical regions. Birds of tropical regions migrate according to the rhythmic succession of wet and dry seasons—a profoundly influential factor on the annual cycle of animals and plants alike.

The migratory behaviour of birds has a unique regularity in Africa, where life zones are arranged symmetrically by latitudes away from the equator. Some migrants never cross the equator. The standard-wing nightjar (*Macrodipteryx longipennis*), which nests in a belt extending from Senegal in the west to Kenya in the east along the equatorial forest, migrates northward to avoid the wet season. The plain nightjar (*Caprimulgus inornatus*), on the other hand, nests in a dry belt from Mali in the west to the Red Sea and Kenya in the east during the rains and then migrates southward to Cameroon and the northern Congo region during the dry season.

Other birds migrate across the Equator to their alternate seasonal grounds. Abdim's stork (*Sphenorhynchus abdimii*) nests in a belt extending from Senegal to the Red Sea; after the wet season, it winters from Tanzania through most of southern Africa. The pennant-wing nightjar (*Cosmetornis vexillarius*), in contrast, nests in the Southern Hemisphere south of the Congo forests during the austral, or Southern Hemisphere, summer, then starts north with the onset of the rainy season. It spends its winters in savannas from Nigeria to Uganda.

In coastal and pelagic regions. Among the migrating seabirds, a distinction must be made between the coastal and the pelagic, or open-sea, species. Birds such as guillemots, auks, cormorants, gannets, and gulls—all common to the seashore—stay in the zone of the continental shelf. Except during the breeding season, they are dispersed over a vast area, often preferring specific directions of travel. Gannets (*Sula bassana*) nesting around the British Isles spread in winter along the Atlantic coast of Europe and Africa to Senegal, the young travelling farther than the adults. Pelagic birds, most of which belong to the order Procellariiformes (petrels and albatrosses), cover much greater distances and, from a few small nesting areas, roam over a large part of the oceans.

Wilson's petrels (*Oceanites oceanicus*), which nest in the western sector of the Antarctic (South Georgia Island, Shetland Islands, and South Orkney Islands), spread rapidly northward in April along the coasts of North and South America and stay in the North Atlantic during the summer. In September they leave the western Atlantic, travelling east, then southeast, along the coasts of Europe and Africa toward South America and their Antarctic breeding grounds, arriving there in November. These petrels thus travel in a great loop through the whole Atlantic

The significance of prevailing winds

Ocean, in a flight pattern correlated with the direction of prevailing winds. The same pattern is used by other seabirds normally carried by the winds. Albatrosses, such as the wandering albatross (*Diomedea exulans*) that nests on small Antarctic islands, circle the globe during their migrations. One such bird, banded as a chick at Kerguelen Island in the southern Indian Ocean and recovered at Patache, Chile, travelled in less than 10 months at least 13,000 kilometres (8,100 miles)—perhaps as much as 18,000 kilometres (11,200 miles)—by drifting with the prevailing winds.

In the Pacific, short-tailed shearwaters (*Puffinus tenuirostris*) nest in enormous colonies along the coasts of southern Australia and in Tasmania, then migrate across the western Pacific to Japan, remaining in the North Pacific and the Arctic Ocean from June to August. On the return migration they go east and southeast along the Pacific coast of North America, then fly diagonally across the Pacific to Australia.

Arctic terns (*Sterna paradisaea*), whose breeding range includes the northernmost coast of Europe, Asia, and North America, spend the winter in the extreme southern Pacific and Atlantic, chiefly along Antarctic pack ice 17,600 kilometres (11,000 miles) from their breeding range. American populations of the Arctic tern first cross the Atlantic from west to east, then follow the coast of western Europe. Arctic terns thus travel further than any other bird species.

Modes of migration. The migration flights of birds follow specific routes, sometimes quite well defined over long distances. The majority of bird migrants, however, travel along broad airways. A single population of migrants may be scattered over a vast territory so as to form a broad front hundreds of miles in width. Such routes are determined not only by geographical factors—*e.g.,* river systems, valleys, coasts—and ecological conditions but are also dependent upon meteorological conditions; *i.e.,* birds change their direction of flight in accordance with the direction and force of the wind. Some routes cross oceans. Small passerine (perching) birds migrate across 1,000 kilometres (620 miles) or more of sea in areas such as the Gulf of Mexico, the Mediterranean Sea, and the North Sea. American golden plover, wintering in the Pacific, fly directly from the Aleutian Islands (southwest of Alaska) to Hawaii, the 3,300-kilometre (2,050-mile) flight requiring 35 hours and more than 250,000 wing beats.

The speed of migratory flights depends largely on the species and the type of terrain covered. Birds in migration go faster than otherwise. Rooks (*Corvus frugilegus*) have been observed migrating at speeds of 51 to 72 kilometres (32 to 45 miles) per hour; starlings (*Sturnus vulgaris*) at 69 to 78 kilometres (43 to 49 miles) per hour; skylarks (*Alauda arvensis*) at 35 to 45 kilometres (22 to 28 miles) per hour; and pintails (*Anas acuta*) at 50 to 82 kilometres (31 to 51 miles) per hour. Although the speeds would permit steadily flying migrants to reach their wintering grounds in a relatively short time, the journeys are interrupted by long stops, during which the birds rest and hunt for food. The redbacked shrike (*Lanius collurio*) covers an average of 1,000 kilometres (620 miles) in five days as follows: two nights for migration, three nights for rest, five days for feeding.

Most migrations occur at relatively low altitudes. Small passerine birds often fly at less than 60 metres (200 feet). Some birds, however, fly much higher. Migrating passerines, for example, have been observed at altitudes as great as 4,000 metres (14,000 feet). The highest altitude recorded thus far for migrating birds is 9,000 metres (29,500 feet) for geese near Dehra Dūn in northwest India.

Pelicans, storks, birds of prey, swifts, swallows, and finches are diurnal (daytime) migrants. Waterbirds, cuckoos, flycatchers, thrushes, warblers, orioles, and buntings are mostly nocturnal (nighttime) migrants. Studies of nocturnal migrants using radar on telescopes focussed on the Moon show that most migratory flights occur between 10 PM and 1 AM, diminishing rapidly to a minimum at 4 AM.

Gregariousness during migration

Most birds are gregarious during migration, even those that display a fierce individualism at all other times, such as many birds of prey and insectivorous passerines. Birds with similar habits sometimes travel together, a phenomenon observed among various species of shorebirds. Flocks sometimes show a remarkable cohesion; the most characteristic migratory formation of geese, ducks, pelicans, and cranes is a "V" with the point turned in the direction of flight.

Mammals. Seasonal movements are not widespread among terrestrial species of mammals, because walking speed is relatively slow and energy consumption great. Marine and flying mammals have a much greater tendency to migrate, a tendency that is directly related to their locomotive powers.

Terrestrial mammals. True migration among mammals occurs mostly among large artiodactls (split-hoofed animals) living in habitats with wide fluctuations of climatic and biotic conditions.

In North American Arctic regions, herds of caribou (*Rangifer tarandus*) settle during the summer in the barrens—rather flat wasteland with little vegetation. In July, the animals begin to move irregularly southward and spend the winter in the taiga, or northern forests, through which they wander freely with no general directional trend. Each herd seems to move in accordance with local conditions and without a well-defined pattern. The caribou again move northward as early as late February and return to the barrens. These migrations follow the same routes from year to year.

In former times, American bison (*Bison bison*) migrated regularly through the Great Plains. Herds of as many as 4,000,000 animals moved from north to south in fall and returned when spring rains brought fresh grass to the northern part of their range. Bison travelled over more or less circular routes and spent the winter in areas 320 to 640 kilometres (200 to 400 miles) from the summer range. Other North American mammals, such as elk (*Cervus canadensis*), mule deer (*Odocoileus hemionus*), and dall sheep (*Ovis dalli*) still migrate regularly in areas undisturbed by man.

Large African mammals migrate in accordance with the succession of wet and dry seasons, which can greatly modify the habitat. Some antelope remain in small areas throughout the year, but many species undertake seasonal movements over a large range. In the Serengeti region of Tanzania, plains animals, particularly wildebeests (*Connochaetes taurinus*) and zebras, travel more than 1,600 kilometres (1,000 miles) in their seasonal migrations. Herds spread outward during the rains and concentrate during the dry season around water holes. Elephants (*Loxodonta africana*) wander great distances in search of the best food and water supply.

In southern Africa, hundreds of thousands of springbok (*Antidorcas marsupialis*) once migrated according to the rhythm of rainfall over their vast range. They moved in herds so dense that any animal encountered was either trampled or forced along with the herd. These huge migrations often resulted in enormous losses from starvation, drowning, or disease—natural methods for controlling overpopulation. Such movements, involving lesser numbers, still occur in parts of South West Africa/Namibia and in Botswana.

Flying mammals (bats). A few bats native to Europe and Asia make short flights to winter quarters. In the Soviet Union, the common pipistrelle (*Pipistrellus pipistrellus*) and the frosted bat (*Vespertilio murinus*) withdraw to hibernating places at some distance from their summer range. In Germany, the large mouse-eared bat (*Myotis myotis*) leaves its winter quarters in Brandenburg in March or April and travels as much as 260 kilometres (160 miles) to its summer habitat in northwestern and northeastern Germany. It regularly returns to the same winter locality. Schreiber's long-fingered bat (*Miniopterus schreibersii*) changes its habitat in winter and moves over 160 kilometres (100 miles) or more according to a complex pattern. These local movements represent an adjustment to winter conditions and the search for more habitable caves.

Migratory bats in the United States

Other bats travel even greater distances. In the United States, the red bat (*Lasiurus borealis*), the large hoary bat (*L. cinereus*), and the silver-haired bat (*Lasionycteris noctivagans*)—three species that roost primarily in trees and

shrubs—are true migrants with strong powers of flight. They summer in the northern U.S. and in Canada and winter in Georgia, South Carolina, Florida, and probably also in the southwestern states. The southward movement is made from mid-August to November. Migration flights occur at night, and during the day under favourable conditions. Large numbers follow the coast some distance from land, and all three species are found at sea far from the coast and in Bermuda. Fruit bats and flying foxes (*Pteropus*) native to the tropical regions of the Old World make regular mass migrations, following the seasons for fruit ripening.

Marine mammals. Antarctic whale migrate regularly to the tropics, a fact long known to whalers. By systematically marking whale by shooting into them steel tubes engraved with a serial number, man has obtained evidence of actual movements. A young fin whale (*Balaenoptera physalus*) marked in February in the Antarctic, at latitude 65° S, was captured two years later, in July, off the coast of South Africa, 3,000 kilometres (1,900 miles) north. During the austral (Southern Hemisphere) winter, whale migrate to areas rich in food, particularly the northwestern coast of Africa, the Gulf of Aden, and the Bay of Bengal. Antarctic whale—particularly humpbacks (*Megaptera novaeangliae*), a highly migratory species—can be divided into five distinct populations around Antarctica; each population migrates separately, and individuals usually return to their respective zones, though interchange may occur. The Antarctic population does not, however, migrate entirely into warm waters during the winter, and a segment of the population seems to stay behind at about latitude 50° S.

Northern whale have the same migratory habits as Antarctic whale. Northern blue whale (*Balaenoptera musculus*) migrate northward along the east coast of the United States, then through Davis Strait to Baffin Bay (north of Canada) or Spitsbergen to the waters off northern Scotland or the coast of Norway. They are believed to migrate southward along the same routes. Part of the North Pacific stocks of the northern blue whale winters in the Indian Ocean and in the seas bordering Indonesia.

Smaller cetaceans (porpoises and dolphins) migrate in the same way, as indicated by population fluctuations within a particular area; but little is known about their distribution and migration.

Noteworthy migratory habits occur among the pinnipeds (seals and walrus), some of which disperse over wide areas at times other than the breeding season. The harp seal (*Pagophilus groenlandicus*) lives in summer in northernmost Arctic waters, but reproduces in the White Sea (an arm of the Arctic Ocean extending southward into the landmass of the Soviet Union), in the eastern North Atlantic, and around Newfoundland, where young are born between January and April. The seal then returns to more northern latitudes. Northern fur seals (*Callorhinus ursinus*) reproduce only on the Pribilof Islands, off southwestern Alaska, from May to November, and the colonies then disperse into the open seas. The males stay in the Gulf of Alaska and off the Aleutian Islands; the females go farther south, to southern California, some 4,800 kilometres (3,000 miles) away.

NAVIGATION AND ORIENTATION

Migrants often return to breed in the exact locality where they were hatched or born. This journey homeward, particularly that of birds, may cover thousands of miles.

Homing experiments

Homing experiments have demonstrated the ability of animals to orient themselves geographically. Such experiments involve removing animals from a specific point (usually the nest), transporting them for various distances, and analyzing their speed and degree of success in returning. Starlings have returned to their nests after being transported 800 kilometres (500 miles); swallows have returned a distance of more than 1,800 kilometres (1,100 miles). A Manx shearwater (*Puffinus puffinus*) returned from Massachusetts to Britain, 4,900 kilometres (3,050 miles) across the Atlantic, in 12½ days. Laysan albatrosses (*Diomedea immutabilis*) returned to Midway Island in the Pacific after being released at Whidbey Island, Washington; the journey covered 5,100 kilometres (3,200 miles) and took 10.1 days. Experiments with certain fishes and mammals have demonstrated similar homing ability.

It is apparent that homing animals use familiar landmarks; both random and oriented searches have been observed in birds and fish. Homing experiments with gannets observed from aircraft have demonstrated that, after release, the birds explore the region and hesitate as they apparently look for landmarks. Landmarks vary from topographical (*e.g.*, mountain systems, river systems, coastlines) to ecological (*e.g.*, vegetation zones) to climatic (*e.g.*, air masses differing in temperature and humidity, prevailing winds). Fish may orient themselves by using similar clues in the same way. Passive drifting is an important factor in the movements of larvae and young fishes, such as those of the eel, cod, herring, and plaice, and even in adults that are passive after spawning, such as herring and cod. As a result of drifting with the current, the movements of such fishes are similar from year to year.

Familiar landmarks and exploration do not, however, explain how migrants find their way along routes covering many hundreds or thousands of miles nor do the results of most homing experiments.

Birds. A compass sense has been demonstrated in birds; that is, they are able to fly in a particular constant direction, regardless of the position of the release point with respect to the bird's home area. It has also been shown that birds are capable of relating the release point to their home area and of determining which direction to take, then maintaining that direction in flight. The navigational ability of birds has long been understood in terms of a presumed sensitivity to both the intensity and the direction of the Earth's magnetic field. It has also been suggested that birds are sensitive to forces produced by the rotation of the Earth (Coriolis force); however, no sense organ or physiological process sensitive to such forces has yet been demonstrated to support this hypothesis.

Experiments have shown that the orientation of birds is based on celestial bearings. The Sun is the point of orientation during the day, and birds are able to compensate for the movement of the Sun throughout the day. A so-called internal clock mechanism in birds involves the ability to gauge the angle of the Sun above the horizon. Similar mechanisms are known in many animals and are closely related to the rhythm of daylight, or photoperiodism (see above). When the internal rhythm of birds is disturbed by subjecting them first to several days of irregular light–dark sequences, then to an artificial rhythm that is delayed or advanced in relation to the normal rhythm, corresponding anomalies occur in the homing behaviour.

Two theories have been formulated to explain how birds use the Sun for orientation. Neither theory, however, has thus far been substantiated with proof. One theory holds that birds find the right direction by determining the horizontal angle measured on the horizon from the Sun's projection. They correct for the Sun's movement by compensating for the changing angle and thus are able to maintain the same direction. According to this theory, therefore, the Sun is a compass that enables the birds to find and maintain their direction. This theory does not explain, however, the manner in which a bird, transported and released in an experimental situation, determines the relationship between the point at which it is released and its goal.

The second theory, proposed by British ornithologist G.V.T. Matthews, is based on other aspects of the Sun's position, the most important of which is the arc of the Sun—*i.e.*, the angle made by the plane through which the Sun is moving in relation to the horizontal. Each day in the Northern Hemisphere, the highest point reached by the Sun lies in the south, thus indicating direction; the highest point is reached at noon, thus indicating time. In its native area a bird is familiar with the characteristics of the Sun's movement. Placed in different surroundings, the bird can project the curve of the Sun's movement after watching only a small segment of its course. By measuring maximum altitude (the Sun's angle in relation to the horizontal) and comparing it with circumstances in the usual habitat, the bird obtains a sense of latitude. Details of longitude are provided by the Sun's position in relation

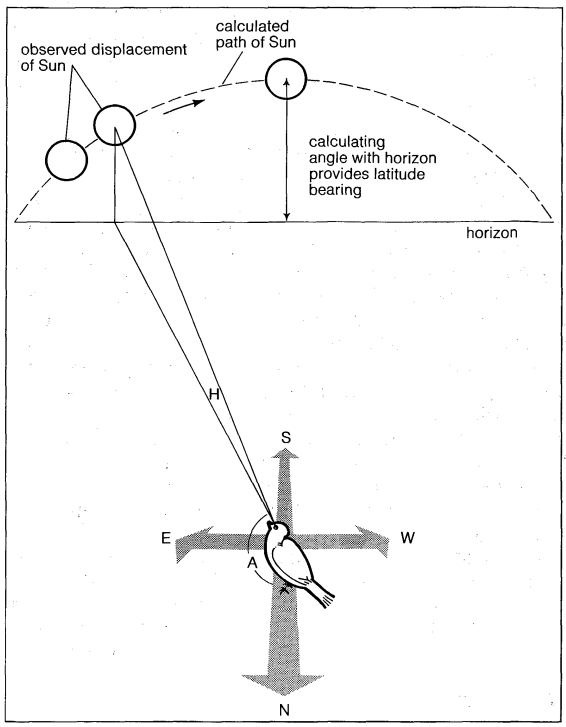

Figure 22: Matthews' hypothesis of solar navigation by birds. Birds can visualize the complete trajectory of the Sun and determine its zenith and altitude at midday (angle H) in order to derive the latitude. Angle A is measured from the north to the point at which a vertical from the Sun cuts the horizon. From this longitude can be derived.
From M. Ricard, *The Mystery of Animal Migration*

to both the highest point and position it will reach—as revealed by a precise internal clock.

Use of celestial navigation by birds

Migrant birds that travel at night are also capable of directional orientation. Studies have shown that these birds use the stars to determine their bearings. In clear weather, captive migrants head immediately in the right direction using only the stars. They are even able to orient themselves correctly to the arrangement of night skies projected on the dome of a planetarium; true celestial navigation is involved because the birds determine their latitude and longitude by the position of the stars. In a planetarium in Germany, blackcaps (*Sylvia atricapilla*) and garden warblers (*S. borin*), under an artificial autumn sky, headed "southwest," their normal direction; lesser whitethroats (*S. curruca*) headed "southeast," their normal direction of migration in that season.

It is known, then, that birds are able to navigate by two types of orientation. One, simple and directional, is compass orientation; the second, complex and directed to a point, is true navigation, or goal orientation. Both types apparently are based on celestial bearings, which provide a navigational "grid."

Other animals. The methods of directional orientation used by birds are similar to those used by other animals. Orientation to the Sun has been demonstrated in various crustaceans, particularly in the sand flea (*Talitrus saltator*). Various insects, particularly bees and certain beetles (families Scarabeidae, Tenebrionidae, and Carabidae) use the Sun to plot their course with remarkable accuracy.

Fishes also are able to use celestial bearings; salmon presumably use the Sun. Experiments with the parrot fish (*Scarus*) have demonstrated a Sun compass reaction that may also occur in other fishes. Localization of the Sun is, however, much more difficult in water than in the air, because of the characteristics of light rays passing through water. Experiments suggest that topographical clues are also used by fishes to recognize their range, particularly their spawning grounds. Visual bearings in this respect have great importance. It is possible that chemical substances also provide clues; the role of olfaction in the salmon has been described (see above, *Anadromous fishes*).

Visible landmarks are used by mammals, at least for orientation within short distances. Scented trails are probably helpful within a limited area, proportionate to the size of the animal; olfaction plays an important role in the life of mammals. Some mammals, however, migrate over enormous distances and are able to return after being taken far away from their home territory; bats, for example, have returned 265 kilometres (165 miles) to their caves. Random exploration plays a part in such movements, but it is possible that some type of true navigation is involved in certain of these movements.

PHYSIOLOGICAL STIMULUS OF MIGRATION

Migration, like reproduction and other phases (as molting in birds), is part of the life cycle and depends on a complex internal rhythm that affects the whole organism, particularly the endocrine glands (glands of internal secretion) and the gonads. Migration must thus be viewed in relation to the entire annual cycle.

Each year birds return to particular areas to breed, and remain there until the members of the brood can care for themselves. There is no relation between the reproductive and migratory stimuli, yet the two phenomena, although independent, are nevertheless stimulated by the same factor.

A physiological study of certain migrants has revealed that metabolic patterns usually change prior to migration, and fats accumulate in the body tissues. The whitethroat (*Sylvia communis*) weighs an average of 12 to 13 grams (about 0.4 ounce) during the breeding season, 16 to 19 grams (about 0.6 ounce) in the autumn, and 20 to 24 grams (about 0.8 ounce) in the winter. Food consumption increases with the autumn molt, reaching a peak at the beginning of the migration season. These fundamental physiological changes, chiefly under the control of the thyroid gland, are correlated with migratory activity. Such fluctuations are not observed in nonmigratory species.

Variations in metabolism and related phenomena are controlled by an endocrine gland, namely the pituitary gland, which is located in the lower part of the brain and acts as a command post, sending out instructions in the form of secretions called hormones. That the pituitary has a cycle independent of environmental factors is demonstrated by the regularity with which phases such as reproduction occur from year to year in the lives of some birds, and by the diverse response of various species and populations to the same environmental factors. That the pituitary is, however, influenced by environmental factors, such as variations in day length and the intensity of the Sun, has been demonstrated experimentally.

The role of the pituitary gland in migration

Gonadal development and the deposition of fat, for example, are influenced by the pituitary, which responds to increasing day length in springtime by accelerating the rate of gonadal development. The pituitary thus governs the development of gonads and, in addition, affects all metabolic processes, including development of the thyroid gland, so as to prepare the animal physiologically for migration. If only the pituitary and variations in day length were involved, migration would be triggered at definite times, because the pituitary cycle is fixed, and photoperiodism is a highly predictable phenomenon; such a lack of flexibility, however, would inevitably cause migrant populations to suffer catastrophes because ecological conditions are irregular—meteorological events, such as the arrival of spring, and biological phenomena, such as flowering, foliation, hatching of insects, and availability of food, are highly variable from year to year. The pituitary thus serves only to prepare the bird for flight; the proper ecological conditions, on the other hand, are necessary to initiate it. The availability of food is an important factor. Temperature and weather conditions also have an influence—a sudden period of cold weather during autumn may induce the immediate departure of many migrants.

Sensitivity to changes in the weather and other environmental conditions varies markedly among species. Some, such as the woodcock, snipe, lapwing, starling, and lark, rely on surrounding conditions to initiate their spring and autumn migrations, and the patterns of their flight depend on temperature and barometric pressure. Others, such as

the swift, cliff swallow, Baltimore oriole, and short-tailed petrel, are less weather dependent, and, since the dates of their arrival and departure are not regulated by the weather, they occur with remarkable regularity each year.

The factors that stimulate migration in animals other than birds are not yet well understood. Ecological conditions play a great part in the migratory activity of mammals, who react to general food shortage by moving to another region. Whale, for example, leave the Antarctic region as winter modifies the oceanographic conditions. Seals disperse when the food supply in the area of their breeding colonies is depleted. Environmental factors are of primary importance in the migration of fishes and marine invertebrates. Annual movements of water masses change physical conditions such as temperature and salinity; biotic conditions are influenced accordingly.

ORIGIN AND EVOLUTION OF MIGRATION

The origins of migration remain in the realm of pure conjecture; neither observation nor experiment has resolved the matter. The explanation, however, must be related to geographical and climatological factors that have prevailed since the Tertiary Period, which ended some 2,500,000 years ago. The great Quaternary ice ages, which came later, were very important in altering the distribution of animals over a large part of the world, but migrations occurred long before.

Migration, as it is now known among modern birds and mammals, probably appeared gradually by stages. Some animals changed their habitat only slightly, never leaving the same general region. The movements of other animals were more erratic, their dispersal being oriented toward the most favourable places. Such movements are the first stages of true migration—a phenomenon characterized by elaborate mechanisms—which gradually acquired stability through natural selection. At first, many populations must have perished rather than attempt to flee from unfavourable conditions. Only a fraction of such populations probably sought more favourable conditions elsewhere, but natural selection favoured the "migrants," and migratory tendencies were retained.

Causes of change of habitat

In some cases, original habitats were in present-day wintering areas, and animals developed a tendency to leave in spring in order to breed in other territories. Seasonal changes of weather and food supply in these newly settled regions forced the animals to migrate in fall, and they thus retreated to their former range. Among birds nesting in the Northern Hemisphere, hummingbirds, tyrant flycatchers, tanagers, orioles, bee-eaters, and swifts have distinct tropical affinities; in recent geological times these birds gradually spread northward as glacial ice receded and the continent became warmer. Other birds, such as plover, ducks, and geese, originally lived in what is now their breeding area. Gradual climatic changes forced them to spend their winters in regions far to the south. Migrations thus appear to be the consequence of invasions or emigrations, during which animals settle in new areas during a segment of the annual cycle.

Migratory birds use the routes by which their ancestors first invaded new regions after the glacial recession. The yellow wagtail (*Motacilla flava*) and the wheatear (*Oenanthe oenanthe*) settled in Alaska; they migrate annually into other parts of the Western Hemisphere but spend their winters in the warm regions of southeastern Asia and even Africa, probably following the migratory route of their ancestors. A typically North American species, the gray-cheeked thrush (*Hylocichla minima*), which has extended its breeding area to northeastern Siberia, returns to spend the winter in the central regions of South America.

ECOLOGICAL SIGNIFICANCE OF MIGRATION

There are many ecological implications of migration. The food resources of some regions would not be adequately exploited without moving populations. The sequence of migratory movement is closely integrated in the annual cycle of ecosystems characterized by productivity fluctuations. Migratory behaviour concerns only species located at specific trophic levels (zones of food availability) where maximal fluctuations occur both in breeding areas and in wintering regions. Migrant birds avoid equatorial forests where productivity is constant throughout the year, and food surpluses do not occur. They do congregate, on the other hand, in savannas where productivity varies with the seasons.

Such a coordinated sequence is particularly apparent in the case of birds migrating from the northern Arctic regions to tropical winter regions; both life zones are characterized by broad fluctuations in productivity. In the Arctic, vegetal and animal production is very high during the summer; ducks and waders nest in great numbers, exploiting these resources. As winter comes, food becomes scarce, and water birds migrate to the tropics, where the rainy season has caused food production to increase to optimal levels. Ducks and wading birds concentrate in the most favourable areas, remaining until spring, when productivity is lowest. By then the condition of breeding areas is again favourable for the birds. The life cycles of these birds are closely attuned with the cycles of their various habitats, and the sizes of bird populations are controlled by the capacity of both areas to sustain them.

Migration, then, has considerable ecological significance. It enables fast-moving animals to exploit fluctuating resources and to settle in areas where life would not be tenable for animals incapable of rapid travel. On the other hand, peaks of food production would be unexploited without the periodic presence of migratory populations.

(J.P.D./Ed.)

Dormancy

There are few environments in which organisms are not subject to some kind of environmental stress. As discussed above, some animals migrate vast distances to avoid unfavourable situations; others reduce environmental stresses by modifying their behaviour and the habitats (immediate surroundings) that they occupy. Arctic lemmings, for example, are able to avoid severe winter weather by confining their life in winter to activities beneath the snow cover. Still another mechanism used by some organisms to avoid stressful environmental conditions is that of dormancy, an inactive state accompanied by a lower than normal rate of metabolism—the chemical processes responsible for the activity, nourishment, and growth of an organism—during which an organism conserves the amount of energy available to it and makes few demands on its environment. Most major groups of animals as well as plants have some representatives that can become dormant; more species hibernate than become dormant, however. Periods of dormancy vary in length and in degree of metabolic reduction, ranging from only slightly lower metabolism during the periodic, short-duration dormancy of deep sleep to more extreme reductions for extended periods of time.

Lowering of metabolic rate

GENERAL OBSERVATIONS

Value of dormancy. In terms of evolution, dormancy seems to have evolved independently among a wide variety of living things, and the mechanisms for dormancy vary with the morphological and physiological makeup of each organism. For many plants and animals, dormancy has become an essential part of the life cycle, allowing an organism to pass through critical environmental stages in its life cycle with a minimal impact on the organism itself. When lakes, ponds, or rivers dry up, for example, aquatic organisms that can enter a period of dormancy survive, while others perish. Moreover, animals that can become dormant during the extreme cold of winter can extend their ranges into regions where animals incapable of dormancy cannot live. Dormancy also ensures that these animals will be free from competition during their periods of activity. Thus, dormancy is an adaptive mechanism that allows an organism to meet environmental stresses and to take advantage of environmental niches that otherwise would be untenable at certain times.

Causes of dormancy. The dormant state that is induced in an organism during periods of environmental stress may be caused by a number of variables. Those of major importance in contributing to the onset of dormancy

include changes in temperature and photoperiod and the availability of food, water, oxygen, and carbon dioxide. In general, because organisms normally exist within a relatively narrow temperature range, temperatures above or below the limits of this range can induce dormancy in certain organisms. Temperature changes also affect such other environmental parameters as the availability of food, water, and oxygen, thus providing further stimuli for dormancy. In Arctic regions, for example, certain animals become dormant during the winter months, when food is less abundant. In desert biomes, on the other hand, the summer months, which may be periods of reduced food availability, intense heat, or extreme aridity, stimulate some desert organisms to become dormant. The lack of water during summer periods of drought or winter periods of freezing, as well as annual changes in the duration and intensity of light, particularly at high latitudes, are other environmental factors that can induce dormant states.

Cyclical environmental changes

Under natural conditions, most of the environmental variables that influence dormancy are interrelated in a cyclical pattern that is either circadian or annual. Fluctuations in the major daily variables—light and temperature—can induce rhythmical changes in the metabolic activity of an organism; annual fluctuations in temperature and photoperiod can influence the availability of food and water. Concentrations of oxygen and carbon dioxide normally do not vary on a cyclical basis but as a result of habitat selection, such as burrowing in the mud, seeking a den, or other similar activities, in which the metabolic responses of the organism can alter the oxygen and carbon dioxide concentrations in its environment.

In an attempt to determine the relative influence of environmental factors upon dormancy, they have been varied experimentally. Investigations indicate that an organism, after it has adapted to a sequence of cyclical rhythms, tends to maintain its adaptive behaviour even though the environmental stimulus that originally elicited such behaviour is no longer present. For example, the Arctic ground squirrel (whose winter period of dormancy is referred to as hibernation), when taken into the laboratory, supplied with adequate amounts of food and water, and exposed to constant temperature and light, exhibits periodic torpor (extreme sluggishness)—an innate behavioral pattern that operates independently of environmental cues. Other animals frequently will continue to respond as if they were exposed to the cyclical changes of their home environments after they are removed from their natural habitats.

DORMANCY IN PROTOZOANS AND INVERTEBRATES

Cysts and cystlike structures. *Protozoans.* Many parasitic and free-living protozoans (one-celled animals) exhibit a dormant stage by secreting a protective cyst. The stimulus for cyst formation in free-living protozoans may be temperature changes, pollution, or lack of food or water. *Euglena,* a protozoan that encysts to avoid environmental extremes, has two kinds of cysts. Apparently one is formed only to avoid stressful conditions; the other is formed for the same reason but also involves asexual reproduction, resulting in a cyst that may contain up to 32 daughter organisms, which emerge under proper environmental conditions.

The role of cysts in parasitic protozoans

Free-living protozoans form cysts around themselves and avoid environmental extremes, but cysts are a part of the life cycle of parasitic protozoans. The causative agent of amebic dysentery, *Entamoeba histolytica,* is found in the intestine of infected individuals, in whom it forms cysts that pass to the outside in feces. When food or water containing cysts enters the digestive tract of another person, the amoebas are released from the cysts and infect the new host. Without encystment, which allows the organism to live in a dormant state in an unfavourable environment (*e.g.,* water), amebic dysentery could be much more easily controlled. Protected by the cyst wall, however, the dormant contents of the cyst can survive for weeks. Although they are not particularly resistant to drying, the cysts of *E. histolytica* can withstand temperatures of up to 68° C (154° F) for five minutes. They are also resistant to certain chemicals.

Invertebrates. Dormant cysts are formed during the life cycles of invertebrate parasites such as the oriental liver fluke (*Clonorchis sinensis*). The cyst stage of this organism develops in fish muscle; if the fish is eaten raw or undercooked, the encysted fluke is transferred to a new host. The encysted stage of the trichina worm (*Trichinella spiralis*), which causes trichinosis, is found in the muscle cells of hogs; it is also an invertebrate parasite in which the dormant stage is an essential part of the life cycle. When undercooked pork is eaten, the cyst wall is dissolved by digestive juices, and the worm is able to make its way into the tissues of a new host.

The cystlike forms found in many other invertebrate groups are all dormant stages that preserve the species during times of environmental stress. All freshwater sponges and some marine species survive cold or drought by forming gemmules within the body of the adult sponge. These structures, which are surrounded by a resistant covering, are released when the sponge dies and disintegrates. When conditions are appropriate, the cell mass escapes from the covering and forms a new sponge.

Rotifers are microscopic aquatic animals that produce winter eggs with thick and resistant coverings similar to protozoan cysts; the eggs may remain dormant for long periods. They can survive drought or freezing and may be dispersed by wind or carried by animals. Thus, the cyst serves not only for survival of the egg under adverse conditions but also for dispersal. Some freshwater bryozoans develop disklike buds, or statoblasts, that are surrounded by a hard, chitinous (horny) shell. These statoblasts are the dormant structures that survive when the bryozoan dies in the fall or during a drought; they form a new bryozoan colony when favourable environmental conditions again prevail.

Among mollusks, land snails remain largely dormant throughout the day, with the soft head and foot withdrawn into the shell. During periods of drought or cold, they retreat into their shells and secrete a membrane (the epiphragm) of mucus and lime that covers the opening of the shell and resists desiccation. Slugs, on the other hand, bore into the ground and secrete a mucus mantle around themselves for protection during periods of unfavourable environmental conditions. Among the arthropods, many freshwater forms develop dormant cystlike stages that resist desiccation and allow the species to survive unfavourable periods.

Diapause in insects. Many insects undergo periods of reduced metabolic activity called diapause. Diapause, which may occur during any stage of the life cycle—egg, nymph, larva, pupa, or adult—is usually characterized by a cessation of growth in the immature stages and a cessation of sexual activity in adults. In some insects, it is a reaction to unfavourable environmental conditions; in others, such as certain moths and butterflies, diapause is a necessary stage of the life cycle. The 17-year larval and pupal periods of the cicada are examples of diapause. This form of dormancy is particularly common among insects that live in arid desert areas, where during the dry and hot summers, the insects usually hide themselves in the soil at suitable depths or under any available protective objects.

Insect survival in winter

Insects may overwinter as egg, larva, nymph, pupa, or adult; because they can stand very low temperatures, few of these forms die if the winter temperatures are within their normal range. Even rather fragile forms, such as mosquitoes and butterflies, survive in sheltered, relatively dry places out of doors. Some butterflies even survive the winter in low shrubbery, where they may be completely covered by snow and ice for three or four months. Other insects prepare for winter by constructing nests or cocoons; still others seek suitable hiding places.

Among some insect species, diapause lasts only until favourable environmental conditions return, after which the insect immediately resumes its normal activities. In other species, favourable environmental conditions alone do not break the diapause; some other stimulus, such as cold or food, is necessary. The eggs of the mosquito *Aedes vexans,* for example, remain in diapause until the damp soil on which the eggs are laid is flooded to form a pool suitable for the larvae. Although the eggs of another mosquito, *Aedes canadensis,* are laid in the same soil as those of

Aedes vexans, they will not hatch—even after flooding—until they have been subjected to cold. Thus, when both species lay their eggs together in early summer, those of *Aedes vexans* hatch in pools formed by late summer rains, but those of *Aedes canadensis* overwinter and hatch in the spring rain pools. Not only are certain conditions required to break diapause but in some species, such as certain cutworms, a specific length of time must elapse before the stimuli are effective.

The onset of diapause depends upon a combination of environmental factors operating on the regulatory mechanisms—*i.e.,* nervous and endocrine systems—of the insect. Photoperiod and temperature influence the endocrine function of the brain, which synthesizes and secretes a substance (hormone) that controls other endocrine organs, specifically the prothoracic glands. Under the stimulation of the brain hormone, the prothoracic glands secrete a hormone called ecdysone. When stimulation by the brain hormone ceases, ecdysone is no longer secreted, and, in its absence, all insect growth and metamorphosis are halted. Thus, provision is made for the overwintering of immature insects in a state of developmental standstill. With the arrival of more favourable conditions, ecdysone is again secreted, and development resumes. Because many insect species have more than one generation of progeny per year, the prothoracic glands do not cease functioning except at some stage in the life cycle of the brood that must overwinter.

DORMANCY IN COLD-BLOODED VERTEBRATES

Two kinds of dormancy can be distinguished in vertebrates on the basis of body temperature. Most vertebrates are poikilothermous, or cold-blooded, because the body temperature follows that of the environment and is not kept constant by internal (homoiostatic) mechanisms. The second group, the homoiotherms, maintain a constant body temperature regardless of the environmental (ambient) temperature; called warm-blooded animals, they include birds and mammals.

Fishes and amphibians. The metabolism of poikilothermous animals is most influenced by the environmental variables of temperature, nutrition, and photoperiod. Photoperiod, the daily length of light exposure, has a marked metabolic effect in both fishes and amphibians; fishes, however, remain active throughout the year, although the activity may be limited by temperature, as in those fish that rest on the bottom or in mud during cold periods. Brief superficial freezing and supercooling (without freezing) to temperatures below the freezing point of body fluids are experienced by resistant species, but it has not been established that fishes that have been frozen solid can become active when thawed. In the Arctic, no fishes are found in lakes that freeze solid in the winter. Because most fishes do maintain some kind of activity year round, they cannot be said to become dormant in the sense in which the word is used in this article.

In addition to light and temperature, another environmental stress imposed upon fish is drought. Lungfishes, as represented by the African lungfish (*Protopterus*), burrow deeply into the mud when their water supply is diminished. They surround themselves with a cocoon of slime and remain inactive. Their gills are nonfunctional during this period of dormancy, and they use a lunglike air bladder for respiratory purposes. They rely on fat reserves as an energy source, and in order to conserve water, they excrete urea rather than ammonia. This is because ammonia as an excretory product is highly toxic; animals that excrete ammonia require large quantities of water to dilute it below toxic levels. Urea is a semi-solid substance of low solubility, and requires little or no water for its excretion. (Desert animals and many insects excrete urea.)

Protective niches

During periods of drought or cold, amphibians seek protective niches in which to remain dormant until the return of favourable environmental conditions. Overwintering of frogs and salamanders frequently involves their aggregation in large numbers in a moist terrestrial niche, such as a rotting log, the mud on banks or bottoms of marshes and ponds, or in springs. The more terrestrially oriented amphibians, such as toads, may pass the winter in solitary burrows on land. During dry seasons, frogs may be dormant in a mud cocoon.

Reptiles. *Effects of temperature.* Because reptiles depend on external sources of heat to keep warm, they survive during periods of low temperature by seeking a place where the temperature will not fall below freezing, except temporarily. The commonest niche for reptilian dormancy is almost always found underground at a depth dependent on the thermal conductivity of the soil relative to the minimum temperature reached. This factor alone can control the distribution of reptiles. None can survive in the Arctic or Antarctic in places in which the subsoil is permanently frozen; and relatively few can exist in areas near these regions, even if suitable sites for dormancy were available, because the short summers would prevent the completion of life cycles. Although the distribution of snakes at high latitudes or altitudes is limited, the adder has been found at 3,300 metres (10,000 feet) in the Swiss Alps and as far north as the Arctic Circle. The Himalayan pit viper has been found at an altitude of 5,000 metres (16,000 feet).

Dormancy in reptiles may display a circadian rhythm, a seasonal one, or both; it is a state of torpor directly induced by low temperature. When the adder, for example, experiences temperatures of about 8°–10° C (46°–50° F), it begins to search out suitable niches in which to rest. Its dormancy ends on the first sunny days after the maximum temperature has reached 7.5° C (45.5° F). Because these conditions vary, the adder's period of dormancy extends from 275 days in northern Europe to 105 days in southern Europe and is about two weeks in the United Kingdom, where the Gulf Stream provides warmth.

Reptiles also normally become dormant during the hottest parts of summer, but the physiology of summer dormancy is quite different from that of winter. As already mentioned, winter dormancy is a state of torpor, induced by a low temperature, that becomes more pronounced as the temperature falls. There is, however, a wide range between the animal's normal, active (coenothermic) temperature and the lowest temperature at which it can exist. At high temperatures, on the other hand, there is a much narrower range between the coenothermic temperature and temperatures that cause death. In other words, reptiles can tolerate colder temperatures much better than they can tolerate higher ones. For this reason, during hot weather they must seek refuge underground or in cool, shady places, where they remain physiologically active but must forego all normal activity because of the restricted nature of the cooler niche. Desert reptiles, in particular, exhibit such temperature responses daily.

During its dormancy, the amount of water needed by a reptile is less than at other times and is normally supplied by water produced from the metabolism of the animal's own stored food reserves, particularly fat. In areas in which alternating wet and dry seasons occur, reptiles maintain a longer period of dormancy during the dry season. This behaviour may be related more to the lack of available water than to temperature, because in such areas the onset of the seasonal monsoons elicits a period of increased reptile activity.

Winter dens of reptiles

Because there is only a limited number of suitable sites available for dormancy, several snakes, usually of the same species, may be found in each niche. As many as 100 or more snakes have been taken from one winter den. Occasionally, lizards and toads may also be found in the same den, but stories of snakes that share denning sites with small birds and mammals have been difficult to substantiate. It is much more usual to find that the entry of snakes into the burrow of a prairie dog or some other warm-blooded animal is followed by the evacuation of the original occupant.

Effects of latitude. Changes in latitude not only alter the lengths of the dormant and active periods of reptiles but also affect their circadian rhythms because of the changes in the proportions of night to day. Many species of snakes, including the adder, are normally active in the early evening. In the northerly latitudes (*e.g.,* northern Europe, such as Scandinavia and Finland), where the length of the active season is reduced by as much as two-thirds, these

snakes are active throughout the day and are able to take advantage of every warm hour in order to complete the necessary portions of their life cycle. Even this increased activity during the shorter summer season, however, does not compensate for the latitude. Growth and development slow to such a point that sexual maturity is delayed, and the reproductive period requires two years rather than one; young are produced only every other year instead of every year, as at lower latitudes.

DORMANCY, HIBERNATION, AND ESTIVATION IN WARM-BLOODED VERTEBRATES

Hibernation and estivation

The term hibernation is often loosely used to denote any state of torpor, inactivity, or dormancy that an organism might exhibit. Properly speaking, however, use of the term should be confined solely to warm-blooded homoiotherms; *i.e.,* birds and mammals whose feathers or fur serve as insulation to reduce heat radiating from the body and aid in the maintenance of constant body temperatures, which normally are independent of those of the environment. Because warm-bloodedness gives animals an internal physiological stability, they are less dependent on many environmental restrictions, particularly those limitations imposed on organisms by ambient temperatures. For example, only two species of reptiles are found north of the Arctic Circle, but great numbers of birds live and breed there. Warm-bloodedness also signifies a high metabolic rate, a factor that undoubtedly influences normal learning, which depends heavily on the frequency and recency of experiences. Because periods of lowered metabolism interrupt continuous learning experiences, they may explain in part why birds and mammals are so much easier to train than any other animal. The benefits of warm-bloodedness require the expenditure of large amounts of energy through the year and make a heavy demand on available food supplies.

The term hibernation is also used to delineate the dormant state only during winter. In arid regions a reverse phenomenon is seen in which the animal becomes torpid during the hot, dry, barren summer; such hibernation is called estivation. As a means of avoiding environmental stresses, hibernation and estivation are not common devices among warm-blooded animals and they are far less common among birds than among mammals.

Some warm-blooded organisms exhibit thermic instability, a heterothermous condition that allows their metabolic rate to be reduced, with a commensurate reduction in body temperature. Heterothermy is a transitional state between cold-bloodedness and warm-bloodedness; the animal is awake and moving during its temperature fluctuations. The body temperature, although not as constant as in humans, is not so low as to force the organism into deep hibernation. Among mammals, two monotremes, the spiny anteater and the duckbill platypus, are thermally unstable; many of the marsupials, including the opossum, the pouched mouse, and the native cat (a weasel-like spotted marsupial of the family Dasyuridae), are also unable to maintain a fixed body temperature.

The true hibernator not only possesses adaptations that enable it to respond as a homoiothermous animal during certain periods of the year but can also adapt to stressful environmental situations and become essentially a poikilothermous animal during other periods. An animal exposed to food shortages, low temperatures, or lack of water, for example, may "turn off its thermostat" and hibernate until the environment becomes more favourable. Unlike poikilotherms, however, hibernators still retain a measure of temperature control and can change their metabolic levels as required. They can arouse themselves to full activity, whatever the environmental temperature, whereas the arousal of a poikilotherm is dependent upon increased environmental temperatures.

Changes in preparation for hibernation

During the period prior to hibernation an animal must make a considerable number of gradual physiological and metabolic adjustments that appear to be correlated with temperature, light, and the availability of food. No one set of conditions applies equally to all hibernators: some store food, others do not; some become excessively fat, others gain a more moderate amount of weight. Generally, as the season advances and as the hibernator becomes progressively more prepared for hibernation, there is an increase of fat deposition and a general readjustment of body temperature, metabolism, and heart rate to lowered levels of activity.

Although no single factor or condition can be said to determine when an animal will go into hibernation, specific changes include an increase in the quantity of magnesium in the blood and a reduction in the activity of endocrine glands, such as the pituitary, thyroid, and adrenals. A reduction in gonadal activity has also been observed; hibernation does not occur when the gonads are in an actively functional state. Perpetuation of the species requires that the animal be warm and active during the mating and pregnancy periods.

There appears to be a relationship between sleep and hibernation; available evidence suggests that hibernation is entered into from a state of sleep. If hibernation is to be considered a form of sleep, then it must be considered a remarkably complex one. Hibernation and sleep are somewhat similar in that essential body processes continue during both periods at a lowered level. In sleep, the heart beats less rapidly, and breathing is slower; the body produces less heat, necessitating that a sleeping person be protected from the cold.

Hibernation in birds. *Temperature variations.* Birds normally have higher and more variable temperatures than do mammals. Whereas mammalian temperatures normally range between 36° and 39° C (97° and 102° F), avian temperatures range between 37.7° and 43.5° C (99.9° and 110.3° F), with the majority between 40° and 42° C (104° and 108° F). Although the nesting temperature of most passerine species (perching songbirds) is about 40.5° C (104.9° F), primitive bird species—like primitive mammals—have lower temperatures than do the more advanced species. The kiwi, for example, has an average coenothermic body temperature of 37.8° C (100° F). In general, the temperatures of small birds fluctuate more than do those of large birds. The temperature of a house wren (*Troglodytes*) may fluctuate 8° C (14° F) in 24 hours, that of a robin (*Turdus*) fluctuates about 6° C (11° F), and that of the domestic duck only about 1° C (2° F).

The circadian period of activity and rest in birds is accompanied by a temperature cycle. Birds active in the daytime have their highest temperatures late in the afternoon and their lowest in the early morning. Nocturnal species, however, such as owls and the kiwi, have their maximum body temperatures at night, when they are most active. Seasonal temperature variations are also found in birds, and, like mammals, certain birds exhibit thermic instability. Although some are capable of maintaining a highly stable body temperature, others have a fluctuating body temperature. A torpid poorwill (*Phalaenoptilus nuttallii*) is an example of a bird that demonstrates both thermic instability and true hibernation. Its coenothermic body temperature is relatively constant; it can, however, through the influence of a thermoregulatory centre (the hypothalamus) in the floor of the brain, become essentially poikilothermous. Under such influence, its body temperatures approximate those of the environment.

Energy conservation. Considering that hibernation and estivation are devices to avoid such factors as stressful extremes of temperature, lack of water, unavailability of food, or lessened photoperiod, they also must be energy-conservation devices for the animals concerned. Even short periods of torpor can conserve energy. The efficiency of this energy-conservation system can be demonstrated by comparing the smallest bird, the hummingbird, which exhibits circadian torpor, with the shrew, the smallest mammal, which remains active throughout a 24-hour period.

Oxygen consumption

Oxygen consumption is an indicator of metabolic rate, and at an environmental temperature of 24° C (75° F) during the day, an awake but resting hummingbird consumes about 14 millilitres of oxygen per gram per hour. At dusk, the rate drops first to a sleeping level and then plunges to a torpid level of about 0.8 millilitre of oxygen per gram per hour. Just before daybreak, the bird awakens for another activity period. The hummingbird has the highest metabolic rate and the greatest metabolic range of

any vertebrate. The shrew, in contrast, consumes about the same amount of oxygen as the hummingbird does during the day and even increases the amount slightly at night.

The hummingbird uses about 10.3 calories (units of heat energy) during each 24-hour period if it sleeps at night without becoming torpid but only 7.6 calories if it becomes torpid. As it wakes from the torpid state, its temperature increases about 1° C (2° F) per minute to a maximum; the entire process takes less than 30 minutes and sometimes as little as 10 minutes. The energy required to warm the tissues of the hummingbird is relatively small; a hummingbird that weighs four grams expends only 0.114 calorie to warm its body from 10° to 40° C (50° to 104° F). This is only 1/85 of the total 24-hour expenditure of energy of a hummingbird in nature.

The behaviour of the hummingbird can be contrasted to that of a larger bird, such as the poorwill, which is a nocturnal, insect-catching bird. During an average 24-hour day, the poorwill has brief periods of activity at dusk and just before dawn, the total of which is scarcely more than an hour. The temperature of the poorwill during these periods of activity, which are correlated with the bird's feeding habits, is between 40.5° and 43.1° C (104.9° and 109.6° F). Between periods of activity, the bird rests quietly, and its body temperature drops 1° to 3° C (2° to 5° F).

During periods when a supply of flying insects is not available, the bird hibernates in depressions in rocks or other suitably protected places, to which it returns each year. When hibernating, the bird's temperature is frequently within 1° C (2° F) of that of the environment; as a result, the energy saved is great. A poorwill whose body temperature is 5° C (41° F) has a metabolic rate only 3 percent of its metabolic rate at normal body temperature. Because the poorwill is a larger bird than a hummingbird, it may take more than an hour for it to emerge from hibernation.

Hibernation in mammals. It takes longer for larger animals than for smaller ones to go into hibernation because heat must radiate from the body before the temperature can be lowered. Thus, it would require a considerable amount of time for large birds or mammals to go into and emerge from hibernation each day, as do bats and hummingbirds. A 200-kilogram (440-pound) bear, for example, would need 5,100 calories to warm from 10° to 37° C (50° to 99° F). Unlike the hummingbird, which uses only 1/85 of its total daily energy expenditure to emerge from hibernation, the amount expended by a bear would be equivalent to its full 24-hour energy budget. Even if there were enough time in 24 hours for a large animal to enter into and emerge from dormancy, therefore, it would be metabolically extravagant, thus defeating a purpose of hibernation.

Actually, the most common misapplication of the term hibernation is in relation to the bear, which is not a true hibernator. Its body temperature, which normally averages 38° C (100° F), drops during its winter lethargy to about 34° C (93° F), seldom getting below 31.2° C (88.2° F). Hence, a bear's temperature during the winter does not approximate that of the environment. This is indicative of winter rest rather than true hibernation. During this inactive period, the bear sleeps but is, nonetheless, warm and capable of activity when stimulated, unlike a true hibernator. Moreover, it is also during this period when females give birth to cubs that suckle and are maintained by maternal warmth until they emerge from the den in the spring. This behaviour is in contrast with that of the Arctic ground squirrel, whose normal temperature is the same as that of the bear but whose temperature during hibernation drops to near freezing and, in some cases, to a degree or two below 0° C (32° F).

Although certain mammals are said to hibernate, they do not necessarily enter a state of deep hibernation during winter. Instead, for weeks at a time they may be inactive and lethargic in behaviour, with a slightly depressed body temperature. The chipmunk (*Eutamias*) is an example of what has been termed a shallow hibernator, as are bears and raccoons. Superficial hibernation, apparently a compromise between the minimum energy requirements of a deep hibernator and the high energy expended by an animal that remains active during the winter, saves energy without the stress of hibernation. The animal can thus conserve food, while still being able to escape from predators and such dangers as flooding of its burrow. The main energy source during the winter in this shallow hibernation state is food stored in the winter nest. There are instances, however, of shallow hibernators, such as the chipmunk, that enter a state of deep hibernation, particularly if without food.

Superficial hibernation

True mammalian hibernation. Omitting the thermally unstable mammals, the true mammalian hibernators are those whose lowered body temperatures approximate that of the environment and those who require extensive and complex physiological changes to turn from a warm-blooded animal into an essentially cold-blooded one for an appreciable length of time. Only three orders of placental mammals display such behaviour: the Insectivora, as exemplified by the hedgehog; the Chiroptera, the bats; and the Rodentia, including the marmot, hamster, dormouse, hazel mouse, and ground squirrel.

A typical mammalian hibernator, such as the Arctic ground squirrel, finds a protected environmental niche—in this case, a burrow beneath the surface—and builds a nest of grass, hair, and other materials to provide still further insulation. The usual hibernating position is one of being curled up in a ball with the extremities tucked tightly against the body so there is a minimal surface-to-volume ratio. After the temperature of the animal has dropped near that of the ambient temperature, it appears to be dead: its respiration is imperceptible, about three irregular breaths per minute; it does not react to outside stimuli in an observable fashion; nor does it react to being handled and uncurled, although such handling will trigger wakening mechanisms.

The internal organs, such as the digestive tract and the endocrine glands, are almost totally inactive. Because the process of hibernation necessitates the mobilization of all body resources, it places great demands on the tissues, all of which are directed toward the problem of maintaining the animal's metabolism at the minimal level necessary for life during the hibernating period. This means that all activity not immediately germane to the process of living at the lowest possible metabolic level ceases. Even bones and teeth deteriorate during hibernation. The hibernator apparently is balanced on a very narrow line between the maintenance of life at a level that makes recovery from hibernation possible and a reduction of metabolism to a level that will lead to death. Evidence obtained from tissues indicates that the process of hibernation is a precarious method of survival at best and one from which many animals do not awaken. As a mechanism of species survival, hibernation seems effective; for the survival of the individual, however, it is an uncertain and dangerous process.

The hibernator does not remain in a continuous state of hibernation from the time it enters in the fall until it emerges in the spring. Hibernating Arctic ground squirrels, for example, awaken at intervals of every three weeks or less. During this time the animals may move about and sometimes emerge from the burrow. These periods of arousal are more frequent at the beginning and end of a hibernation period than in mid-hibernation; and the lower the temperature at which an animal hibernates, the fewer the awakenings.

During the period of hibernation about 40 percent of the total body weight is lost, an average of about 0.2–0.3 percent per day. One period of arousal and wakefulness consumes more heat and energy than many days in hibernation. About 90 percent of the total heat production and weight loss during hibernation takes place during the arousal periods; only 10 percent is required to maintain the animal in hibernation. Thus, in the case of an unusually long or hard winter, the animal may be called upon to use all of its available energy sources in periodic arousals; it then enters one final hibernation period from which it does not awaken. Animals that store food in the nest have a chance to renew their energy requirements by eating when they awaken periodically.

Types of mammalian hibernators

Entrance into hibernation. Hibernating mammals can be divided into four major groups according to the way they enter hibernation. One group is exemplified by the golden hamster; it waits a variable time of from one to three months in the cold and then enters hibernation in one major temperature reduction. This is accomplished when the biochemical and physiological preparations have been sufficient to lower the animal to a level at which it is receptive to the hibernating stimulus, which causes the abandonment of the temperature differential between ambient and body temperatures.

A second group, of which the pocket mouse (*Perognathus*) is an example, prepares for hibernation relatively rapidly, waiting only a few days before becoming torpid in one major temperature decline. The third group, which constitutes most of the mammalian hibernators, includes ground squirrels and marmots. These animals wait only a few days before entering hibernation and then go through a series of steps of torpor and arousal, each one at successively lower body temperatures, until the level dictated by the stage of preparation for hibernation is reached.

The fourth group, which includes most of the bats, becomes inactive in the poikilothermous manner; that is, the body temperature follows the ambient temperature. Even though the bat seems ready to hibernate at any season, survival during hibernation depends upon more adequate preparation than is necessary for the transitory periods of torpor. Bats not only exhibit true hibernation during the winter but also have natural periods of hypothermia (subnormal temperature), which are unrelated to hibernation, during the remainder of the year.

The woodchuck, the dormouse, and the California ground squirrel enter hibernation in successive stages, with a complete or nearly complete awakening between each one. In the woodchuck, an initial decline in temperature is followed by an arousal. During the second decline there is a lower and more pronounced fall in body temperature, followed by a less pronounced rise. This process continues until the body temperature is essentially the same as that of the environment.

Heart rate and circulation. The body temperature of a hibernating mammal is affected by changes in respiration, heart rate, and oxygen consumption; all are apparently mediated by a part of the nervous system. The heart rate decreases prior to a decline in body temperature. In the woodchuck, the rate may drop from 153 to 68 heartbeats per minute within 30 minutes. In the California ground squirrel, the heart may beat as slowly as once a minute at 5° C (41° F). In contrast, the hearts of non-hibernators generally will not beat at all at temperatures below 10°–20° C (50°–70° F).

Preparation of the Arctic ground squirrel for hibernation

As an Arctic ground squirrel prepares for hibernation, its heart rate and its blood pressure decrease. Both may be detected before a decrease in body temperature can be noted. When the animal enters hibernation, temperatures of both the heart and abdominal regions are identical, indicating an even blood flow between the anterior (front) and posterior (rear) parts of the body. As the body temperature drops, the resistance to blood flow in the peripheral parts of the circulatory system increases because of the increased viscosity (resistance to flow) of the chilled blood and the constriction of the distal arterioles (small arteries) of the body. This peripheral resistance maintains blood pressure at relatively high levels in the deeply hibernating squirrel, even when the heart beats only three or four times a minute.

Neural changes. The nervous system of hibernators also is acclimated; certain specific structures and pathways are seemingly maintained to regulate and coordinate metabolism as temperatures drop. This adaptation of the nervous system enables changes in the environment to be perceived, even when the animal is torpid. In the Arctic ground squirrel, measurements of the general electrical activity of the brain indicate a 90 percent reduction when the animal is in hibernation, at which time brain temperatures approximate 6° C (43° F). During hibernation, both the peripheral nervous system (all the nerves outside the brain and spinal cord, which constitute the central nervous system) and the spinal cord have an increased sensitivity to certain stimuli; in addition, the areas of the brain that regulate temperature as well as cardiac (heart) and respiratory function remain active at ambient temperatures, below which the mammalian nervous system normally ceases to function.

Changes in the circulatory system involving constriction (narrowing) of posterior vessels and the favouring of anterior circulation allow the brain temperature of hibernators to remain a few degrees warmer than the environmental level. This enables the temperature of the brain to remain constant despite fluctuations in the temperature of the skin.

Endocrine activity. The male sex hormone testosterone stimulates reproductive activity. The golden hamster will not hibernate if injected with more than five milligrams of a hormonal preparation. Hibernation is also prevented if the animal is fed or injected with thyroid hormones or thyroid-stimulating extracts. The latter would seem to implicate the thyroid as another endocrine gland that plays an important role in hibernation. There is, in fact, a seasonal progression and regression of thyroid activity in hibernators; maximal activity occurs in the spring and minimal activity in the fall. And because hibernation does not take place in the absence of the adrenal glands, it appears that a minimal adrenal activity is also necessary for hiberation and survival.

Importance of timing

The importance of timing in the annual rhythm of activity and dormancy can be demonstrated: when hibernators are exposed to cold temperatures in spring and summer, they react as do all homoiotherms by increasing their thyroid activity and metabolic rate to maintain normal body temperature. But if they are exposed to cold temperatures in the fall, the thyroid activity and metabolic rate of hibernators are lowered. In some species, a combination of decreased food and lower ambient temperature is required to reduce activity of the thyroid gland and to produce hibernation, although cold alone is sufficient in ground squirrels and the dormouse.

Although hibernation does not take place during periods of gonadal activity or stimulated thyroid activity, it can occur during increased activity of the pituitary gland. This would suggest that there is a dissociation of cellular growth and hormone synthesis that is normally controlled by hormone secretion of the pituitary and its target organs. Thus, the triggering mechanism for the resumption of normal endocrine activity apparently resides elsewhere than in the pituitary. The function of the hypothalamic region of the brain in regulating appetite, fat deposition, water intake, and diuresis (increased excretion of urine), as well as in the control of temperature and sleep, would appear to make it a key area in directing life processes of the hibernator. Furthermore, the fact that the hypothalamus regulates the pituitary and other endocrine glands not only supports this thesis but also indicates that this area of the brain is the prime, or master, regulator of the entire hibernation process.

Reproductive cycles. The Arctic ground squirrel may spend more than half its life in hibernation (see Figure 23). It thus must be able to breed, rear young, maintain its home burrow, and prepare for the period of hibernation during an activity period of less than six months. This requires considerable adaptation of both metabolic and behavioral patterns. Prior to entering hibernation in late September or early October, there is a renewal of sexual activity in the testes of males, and, throughout the period of hibernation, they continue to grow. On the Arctic slope in early May, the male ground squirrel emerges from its burrow. As it utilizes the remaining fat and eats the stores of seeds and other food still in the nest, the male reaches a period of reproductive readiness. Mating takes place in the middle of May, and the young are born in the middle of June, after a gestation period of about 25 days. By the middle of July the young are above ground and eating the green Arctic vegetation, which they continue to eat until the onset of hibernation. By October, both the young of the year and the adults from the previous year weigh nearly 1,000 grams (2.2 pounds).

In the bat, the reproductive cycle is interrupted by hibernation. Gonadal activity in the male reaches its maximum

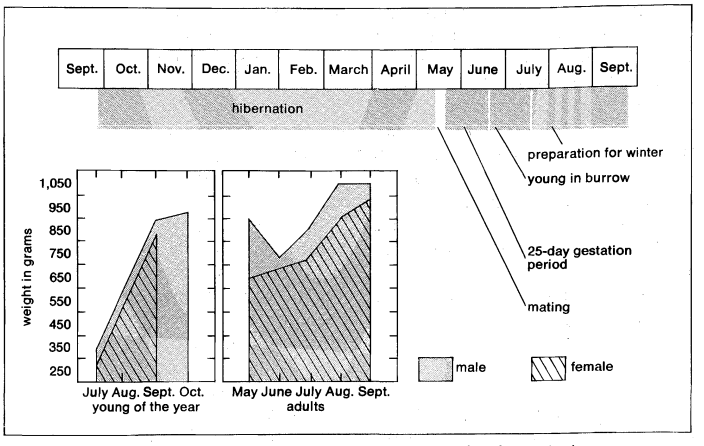

Figure 23: The annual cycle (top) in the life of a typical mammalian hibernator, the Arctic ground squirrel. The graphs show typical weight patterns of young and adult males and females during the aboveground activity period (see text).
From W.V. Mayer, *Hibernation*

in the fall, when copulation with the female occurs. The animals then hibernate, and the production of sperm in the male ceases. The sperm deposited in the female are stored in her reproductive tract throughout the period of hibernation; fertilization occurs the next spring, when the eggs are ovulated (released from the ovaries) within a few days after awakening from hibernation.

Delayed fertilization

The only exception to the general hibernation–reproduction pattern of bats is the vespertilionid bat (*Miniopterus*), in which there is no delayed ovulation and fertilization. In this species the eggs are ovulated soon after copulation, in the fall, and fertilized immediately. During the ensuing period of hibernation embryonic development is initiated and slowed, but it does not actually cease. The young are born in the early summer, soon after hibernation ends. The introduction of hibernation during pregnancy makes the gestation period several months longer than in non-hibernating tropical members of the same genus.

Cyclical reproductive activity has thus become adapted to the shortened activity season available to the hibernator. But although the annual sequence of reproductive events is known, the external stimuli that regulate the reproductive cycles of bats and other hibernators are not known. More knowledge is needed concerning the endocrine and nervous mechanisms that presumably regulate reproductive processes internally. It has been suggested that the pituitary–gonadal relationship influences the hibernating cycles as well as the reproductive cycle, hence both the latter and homoiothermism are controlled by a common mechanism. Such a suggestion is attractive in that the mechanism solves the regulation problems, but more needs to be known of the way in which hibernation directly or indirectly modifies the action of endocrine and neural mechanisms that direct the reproductive cycle.

Protection from disease and radiation. Hibernating organisms have a certain degree of resistance to infectious diseases that appears to be attributable to at least three factors, all of which are related to temperature. One is the fact that the lowered temperature of the host and the commensurate slowing of its metabolic processes prevent the multiplication of parasites to a greater extent than they affect the host's defensive mechanisms. Second, lower temperatures are more harmful to the development of a disease organism than to the host, as has been shown with the parasite *Trichinella spiralis*. In bats hibernating at 5° C (41° F), only larvae have been recovered from the intestines; but mature adult worms have been recovered from the intestines of bats kept at 35° C (95° F). The third factor is that the influence of low temperature on the chemical composition of the host tissues may also affect infectious organisms.

Hibernation also seems to protect animals from radiation. When ground squirrels are irradiated with radioactive cobalt while hibernating, they are found to be more resistant to the effects of the radiation than are squirrels irradiated while warm and active. This resistance, which is apparent over a wide range of doses, suggests that protective mechanisms function in the hibernating animal. In both hibernating and non-hibernating animals, repair processes within cells occur the first day after irradiation; however, when the metabolic requirements of cells are small, as in hibernation, the injured cells seem to be more capable of repair, and survival is greater. The large metabolic requirements imposed on injured cells of warm and active animals appear to render them incapable of an adequate repair response.

Awakening from hibernation. The process of awakening in the Arctic ground squirrel takes about three hours. There is a rapid rise in heartbeat and a decrease in peripheral circulatory resistance; the area around the head and heart warms more rapidly than the posterior part of the animal. This differential vasodilatation (widening of the blood vessels) in the anterior part of the body is a unique and vital part of the awakening process. The concentration of active circulation in this region results in a high blood pressure and an efficient and rapid warming. If a drug is administered during awakening that causes vasodilatation throughout the body, there is a marked drop in blood pressure even though the heart may almost double its rate; thus, the heart cannot maintain a high blood pressure at this time if all blood vessels are dilated. Later during the arousal process, after the anterior part of the body has been warmed, the posterior part of the animal warms rapidly.

Differential vasodilatation

Despite the deterioration of glands and tissues and the drastic reduction of all metabolic activity during hibernation, within 24 hours after arousal, all the squirrel's physiological processes are essentially normal. This rapid repair and recovery mechanism is one that requires further study. (W.V.M./Ed.)

Reproductive behaviour

Reproductive behaviour in animals includes all the events and actions that are directly involved in the process by which an organism generates at least one replacement of itself. In an evolutionary sense, the goal of an individual in reproduction is not to perpetuate the population or the species; rather, relative to the other members of its population, it is to maximize the representation of its own genetic characteristics in the next generation. The dominant form of reproductive behaviour for achieving this purpose is sexual rather than asexual, although it is easier mechanically for an organism simply to divide into two or more individuals. Even many of the organisms that do exactly this—and they are not all the so-called primitive forms—every so often intersperse their normal asexual pattern with sexual reproduction.

BASIC CONCEPTS AND FEATURES

The dominance of sexual reproduction. Two explanations have been given for the dominance of sexual reproduction. Both are related to the fact that the environment in which an organism lives changes in location and through time; the evolutionary success of the organism is determined by how well it adapts to such changes. The physiological and morphological aspects of an organism that interact with the environment are governed by the organism's germ plasm—the genetic materials that determine hereditary characteristics. Unlike asexual methods, sexual reproduction allows the reshuffling of the genetic material, both within and between individuals of one generation, resulting in the potential for an extraordinary array of offspring, each with a genetic makeup different from that of its parents.

Sexual reproduction and adaptation

According to proponents of the so-called long-term theory for the dominance of sexual reproduction, sexual reproduction will replace asexual reproduction in the evolutionary development of an organism because it assures greater genetic variability, which is necessary if the species is to keep pace with its changing environment. According to proponents of the short-term theory, however, the above argument implies that natural selection acts on groups of organisms rather than on individuals, which is

contrary to the Darwinian concept of natural selection (see EVOLUTION, THE THEORY OF: *Natural selection*). They prefer to view the advantages of sexual reproduction on a more immediate and individual level: an organism employing sexual reproduction has an advantage over one employing asexual means because the greater variety of offspring produced by the former results in a larger number of genes being transmitted to the next generation. The latter view is probably more nearly correct, especially in violently fluctuating and unpredictable environments. The former theory is probably correct when viewed in terms of its advantage to individuals that are spreading in geographic range, thereby increasing the likelihood of encountering different environments.

Natural selection and reproductive behaviour. Natural selection places a premium on the evolution of those physiological, morphological, and behavioral adaptations that will increase the efficiency of the exchange of genetic materials between individuals. Organisms will also evolve mechanisms for sensing whether or not the environment is always permissive for reproduction or if some times are better than others. This involves not only the evolution of environmental sensors but also the concurrent evolution of mechanisms by which this information can be processed and acted upon. Because all seasons are not usually equally conducive, individuals whose genetic backgrounds result in their reproducing at a more favourable rather than less favourable period will eventually dominate succeeding generations. This is the basis for the seasonality of reproduction among most animal species.

Natural selection also results in the evolution of systems for transmitting and receiving information that will increase the efficiency of two individuals' finding each other. These attraction systems are usually, but not always, species specific (see EVOLUTION, THE THEORY OF: *Species and speciation*). Once the proper individuals have found each other, it is clearly important that they are both in a state of reproductive readiness. That their sensory receptors are tuned to the same environmental stimuli is usually sufficient to achieve this synchrony (proper timing) in the lower organisms. Apparently, however, this is not enough in the more complex organisms, in which the fine tuning for reproductive synchrony is accomplished chiefly by a process called courtship. Another evolutionary necessity is a mechanism that will guide the partners into the proper orientation for efficient copulation. Such mechanisms are necessary for both internal and external fertilization, especially the latter, where improper orientation could result in a complete waste of the eggs and sperm.

Need for genetic variability

In most organisms, the period of greatest mortality occurs between birth or hatching and the attainment of maturity. Thus, it is not surprising that some of the most elaborate evolutionary adaptations of an organism are revealed during this period. Natural selection has favoured an enormous variety of behaviour in both parents and offspring that serves to ensure the maximum survival of the young to maturity. In some animals this involves not only protecting the young against environmental vicissitudes and providing them with adequate nutrition but also giving them, in a more or less active manner, the information they will need to reproduce in turn.

EXTERNAL AND INTERNAL INFLUENCES

As mentioned at the beginning of this discussion, the anatomical, physiological, and neurological aspects of reproduction and behaviour are dealt with in other articles. It is useful here, however, to consider briefly the external and internal factors that initiate reproductive behaviour.

Environmental influences. Light, usually in the form of increasing day length, seems to be the major environmental stimulus for most vertebrates and many invertebrates, especially those living in areas away from the Equator. That this should be such an important factor is quite reasonable in an evolutionary sense: increasing day length signifies the onset of a favourable period for reproduction. In equatorial regions, where changes in day length are usually insignificant throughout the year, other environmental stimuli, such as rain, predominate.

Superimposed on day length are usually several other factors, which, if lacking, often override the stimulating effect of light. Many insects, for example, will not initiate a reproductive cycle if they lack certain protein foods. Many animal groups have an internal cycle of cellular activity that must coincide with the external factors before reproduction can occur; a familiar example is the estrous cycle in most mammals except primates. Females are sexually receptive only during a brief period when they have ovulated (released an egg from the ovary).

Hormonal influences. Although the exact way by which light affects the reproductive cycle is still disputed, it undoubtedly varies from group to group. In birds, light passes either through the eyes or through the bony tissue of the skull and stimulates the development of certain cells in the forepart of the brain. These cells then secrete a substance that stimulates the anterior pituitary gland, which is located at the base of the brain, to produce an array of regulatory substances (hormones), called gonadotropins, that are carried by the blood to the gonads (ovaries and testes), where they directly stimulate the development of eggs and sperm. The gonads, in turn, produce the sex hormones—estrogen in the female and testosterone in the male—that directly control several overt aspects of reproductive behaviour.

Insect pheromones

Unlike the higher animals, the gonads of insects apparently do not themselves secrete hormones. Instead, stimulation by the corpus allatum, an organ in insects that corresponds in function to the pituitary gland, causes the secretion of liquid substances on the body surface. These substances are transmitted as liquids, or, even more significantly, as gases, to the recipient, in which they are usually detected by olfaction or taste. Such substances, which are called ectohormones, or pheromones, may serve as the major regulation and communication system for reproduction as well as other behaviour in insects.

In the absence of all other stimuli, many types of sexual behaviour can be induced simply by an injection of the appropriate gonadal hormone. Conversely, removal of the gonads usually inhibits most sexual behaviour. The apparent failure of complete hormonal control over reproductive behaviour has been a subject of much investigation and dispute. There is much evidence that many types of reproductive behaviour are or can be controlled solely by neural mechanisms, bypassing the hormonal system and any effect that it might exert on the nervous system to produce behaviour. Several types of reproductive behaviour controlled solely or almost solely by neural mechanisms are involved in or triggered by the processes that are initiated by courtship.

MODES OF SEXUAL ATTRACTION

The chief clues by which organisms advertise their readiness to engage in reproductive activity are visual, auditory, and olfactory in nature. Most animals use a combination of two modes; sometimes all three are used.

Visual clues. The appearance of many higher vertebrates changes with the onset of reproductive activity. The so-called prenuptial molt in many male birds results in the attainment of the nuptial plumage, which often differs radically from that possessed by the bird at other times of the year or from that possessed by a nonreproductive individual. The hindquarters of female baboons become bright red in colour, which indicates, or advertises, the fact that she is in estrus and sexually receptive. Such changes in appearance are less common in the lower animals but do occur in many fishes, crabs, and cephalopods (*e.g.*, squids and octopuses).

The role of aggressive behaviour

Often associated with changes in appearance are changes in behaviour, particularly the increase in aggressive behaviour between males, often a prime feature in attracting females; such changes have interesting evolutionary implications. In certain grouse, for example, females are most attracted to males that engage in the greatest amount of fighting. No doubt, fighting in some groups of mammals also serves this function as well as others (see above *Aggressive behaviour*).

In many animals the rise in aggression takes the form of territoriality, in which an individual, usually a male, defends a particular location or territory by excluding from it

all other males of his own kind. Occasionally, other species are also excluded when it is to the advantage of the defending individual to do so. Territorial behaviour involves many functions, not all of which are directly concerned with reproduction. For purposes of advertising, however, territoriality probably reduces the amount of interference between males and also makes it easier for females to find males at the proper time.

Auditory clues. The fact that sound signals can travel around barriers, whereas visual signals cannot, accounts for their widespread use in indicating sexual receptiveness, especially in frogs, insects, and birds. Like visual signals, a sound for advertising purposes usually encodes several pieces of information; for example, the signals usually reveal to the receiver the caller's species, its sex, and, in some cases, whether or not it is mated. The vocalizations of one type of frog also reveal the number of other males located nearby. This information, a critical clue for females, is a measure of how good the habitat is for depositing eggs. The sounds produced by the wings of mosquitoes attract females and are species specific. Humans have taken advantage of this signal by using artificial sound generators to eradicate certain mosquitoes. Advertising signals also serve to repel other males; a classical example is the territorial song of many songbirds.

Olfactory clues. Researchers have now become aware of the enormous amount of information that is passed between animals by chemical means. Well known are the urine, feces, and scent markings employed by most mammals to delimit their breeding territories and to advertise their sexual state. Males of a number of mammals are capable of determining if a female will be sexually receptive simply by smelling her urine markings. A substance in the urine of male mice, on the other hand, actually induces and accelerates the estrous cycle of females. A female gypsy moth is able to attract males thousands of metres downwind of it simply by releasing minute quantities of its sex pheromone each second. It has been calculated that one female silkworm moth carries only about 1.5 micrograms (0.0015 gram) of its sex attractant, called bombykol, at any given moment; theoretically, this is enough to activate more than 1,000,000,000 males, surely more than exist in any one place at any time. The sex attractant of barnacles, which are otherwise rather sessile (sedentary) organisms, causes individuals to aggregate during the breeding period.

The potency of pheromones

One other possible channel of communication occurs in a few fishes, namely electric discharge. Evidence now accumulating suggests that weak electrical fields and discharges in the Mormyridae of Africa and the Gymnotidae of South America represent the major mode of social interaction in these families.

COURTSHIP

Synchrony is the major factor in achieving fertilization in the lower animals, particularly in aquatic forms. In most of these groups, the eggs and sperm are simply discharged into the surrounding water, and fertilization occurs externally. The parents may never meet, so to speak. It might be assumed that this procedure would be roughly the same in the higher animals, with perhaps more overt behaviour to achieve synchrony, and that, after the two individuals found each other, fertilization would proceed fairly quickly. This is usually not the case, however. Although fertilization in the higher terrestrial forms involves contact during copulation, it has been suggested that all of the higher animals may have a strong aversion to bodily contact. This aversion is no doubt an antipredator mechanism: close bodily contact signifies being caught. Since females are in an especially helpless situation during copulation, they are particularly wary about bodily contact. In addition, males are particularly aggressive during the breeding period, which further increases the uncertainty of both individuals. These difficulties were solved by the evolution of a collection of behaviours called courtship. Courtship has been defined as the heterosexual reproductive communication system leading to the consummatory sexual act.

Courtship behaviour has many advantages and functions, not the least of which is the reduction of hostility between the potential sex partners, especially in species in which the male actively defends a territory. The major aspects of such behaviour seem to be appearance, persistence, appeasement, persuasion, and even deception. Because courtship behaviour involves the transmission of information by means of signals, it is useful to define at this point a peculiar and important group of social signals called displays.

A social signal may be considered any behavioral pattern that effectively conveys information from one individual to another. The term display has been restricted by some authorities to social signals that not only convey information but that, in the course of evolution, have also become "ritualized." In other words, such signals have become so specialized and exaggerated in form or function that they expressly facilitate a certain type of communication. The visual, auditory, olfactory, tactile, or other patterns by which organisms advertise their readiness to engage in reproductive activity provide examples of displays. Clearly, the kinds of displays utilized by organisms depend on the sensory receptors of the receiver. Whereas higher vertebrates tend to use visual and auditory displays, insects tend toward olfactory and tactile displays.

Types of display

In animals in which the male takes on a wholly different appearance during the breeding period, natural selection has eliminated from the female's appearance the "aggressive badges" of males that provoke fighting. It is not without significance that the appearance of the adult female in many species is much like that of the juvenile; this implies to the male a friendly, nonaggressive relationship. When one male approaches another that has intruded into the former's territory, the outsider may either return the aggressive display or flee. Females, however, usually quietly back up slightly and then slowly move forward again. With each approach the male's hostility lessens toward this appeasing, increasingly familiar individual. Often, as in many birds, the females resort to displays that resemble the food-begging behaviour normally seen in the young. Males frequently respond to this display by actually regurgitating food. Male spiders of some species offer the larger and more aggressive females food as bait, and copulation occurs while the female is eating the food rather than her potential mate. Mutual feeding displays, often with nonedible items, are engaged in by a number of insects and birds. In the courtship behaviour of several birds, extremely elaborate displays are utilized to hide the bill from the potential partner, because the bills of these birds are their chief weapons. Some aspects of nest building have been incorporated into the displays of such birds as penguins. Early in the relationship between the individuals, one or both may offer the other stones that are placed in a pile. The actual nest is not constructed until much later, however.

The common denominator in courtships is that the displays resemble functional behaviours that are appropriate to friendly, bonded situations, such as those between parents and between parents and their offspring. The degree of elaborateness of the display is governed by a number of factors. One is to prevent cross-mating between different species, an occurrence that usually results in the waste of the eggs and sperm. Any specific aspect—*i.e.*, one or more displays—used by an organism in species discrimination is called an isolating mechanism. In many species, the majority of the displays between individuals are a series of identity checks.

Species discrimination

Another factor that has an impact upon the complexity of displays is the length of time that the pair bond will endure. Brief relationships are usually, but not always, associated with rather simple courtship activity. In a number of insects, birds, and mammals, the males display on a common courtship ground called a lek or an arena. Females visit these courtship areas, copulate, and leave. The males do not participate in any aspect of parental care; the bond lasts but a few seconds. Yet despite the brevity of this relationship, in no other courtship system is there the development of such elaborate and almost fantastic displays in both the movements and appearances of the courting males.

POST-FERTILIZATION BEHAVIOUR

Various types of behaviour ensure that a maximum number of fertilized eggs or young will survive to become reproductive adults. Clearly, the number of eggs produced and their size represents a balance achieved by natural selection. This balance conforms to some optimum compromise between producing many eggs containing little food for the development of young or fewer eggs with more provisions.

There has been considerable controversy about the factors that limit the number of offspring an organism can produce. It has been suggested that, among animals in which the offspring are dependent on the parents for varying lengths of time, clutch or litter size has been adjusted through natural selection to the maximum number of offspring that the parents, on the average, can feed. There are, on the other hand, organisms that do not practice parental care and produce millions of eggs. According to one school of thought, these species have such a high fecundity (productivity) because the eggs and larvae suffer a very high mortality rate. Hence, it is necessary for such animals to produce thousands, even millions, of eggs just to obtain a few reproductive adults. An opposing school of thought, however, says that such species have high mortality rates because of their great fecundities. By similar reasoning, low death rates would be the consequence of low fecundity.

Protective adaptations. A number of adaptations have evolved to protect the eggs and larvae of species not attended by adults. In one such adaptation, the eggs or larvae are distasteful, inedible, or apparently harmful to potential enemies. The eggs of the jellyfish *Bougainvillia,* for example, contain stinging cells on the surface that deter predators. Many female butterflies deposit their eggs on plants that contain poisonous compounds, which the larvae incorporate into their bodies, making them distasteful. When disturbed many insect larvae, especially those that are camouflaged, give a so-called startle display; several caterpillars, for example, raise their heads as if to bite or their hindparts, in the manner of a wasp, as if to sting. Others suddenly present striking colour patterns previously hidden. Most of these displays have been shown experimentally to be effective deterrents against predators.

Caring for offspring. Animals that do not care for their young must provide for the nutritional needs of their offspring. One way of doing so is by producing an egg with a sufficiently large yolk supply that the young, when hatched, are already at an advanced, almost independent state. A peculiar example of this is found in the incubator birds (Megapodiidae), which cover their large eggs with soil and debris to create a mound of considerable depth, effectively providing heat for the developing eggs. After a very long incubation period, the young emerge as fully feathered miniature adults and are capable of flying in 24 hours. Before sealing the nest that they make for their eggs, many insects, such as certain solitary wasps, stock the nest with food. In a more bizarre manner, other solitary wasps place one egg in the body of an insect or spider previously paralyzed by the wasp. Upon hatching, the larva eats the still living host.

Social parasitism

Social parasitism, another fascinating aspect of post-fertilization behaviour, is found in certain insects and birds. In this case, the true parents do not care for their eggs or offspring; rather, they place them under the foster care of other species, often, but not always, to the detriment of the foster parents' offspring. In certain parasitic species of cuckoos, the females are divided into groups, or gentes, each of which lays eggs with a colour and pattern unlike those of the other groups. The females of each group usually select a particular species as the host, and, more often than not, the eggs of the parasite closely resemble those of the potential foster parent. This mimicry has evolved because many host species throw eggs not resembling their own out of the nest. Some young cuckoos also exhibit a behaviour called backing, in which they push out the other nestlings and monopolize the food supply.

Parental care. Among the organisms that remain with the eggs or offspring, one particular behaviour is striking—that of nest construction to keep the eggs and larvae in one spot and to protect them against predators as well as such environmental factors as sun and rain. The placement of a nest usually serves an antipredatory purpose, as in birds that put their nests near those of social wasps or stinging ants. Although they are not normally thought to do so, many mammals, particularly rodents and carnivores, construct special nests, dens, or burrows solely for reproductive purposes.

A number of fishes build nests made of bubbles that not only hold the eggs together but also provide the oxygen necessary for the developing embryos. Other fishes, particularly those that live in oxygen-poor waters, display elaborate fanning behaviour to keep the water moving around the eggs. In some fishes, the female incubates the egg in her mouth, thus providing protection against predators as well as constant aeration. The fry (young) of some of these mouthbreeders travel in a school near the parent. When danger approaches, they flee into the parent's mouth and later swim out after the danger passes.

Birds have the problem of keeping the eggs at an optimum temperature for development of the embryo. With the onset of egg laying in many species, the feathers of the lower abdomen are lost, and the skin in that area becomes thickened and highly vascularized (filled with blood vessels), forming the so-called brood patches. Usually the female develops these patches, which serve to transfer more effectively to the eggs the warmth from the adult's body. It has been shown that, like much of parental behaviour in the higher vertebrates, brood patches and "broodiness" are controlled by several hormones, combined with visual and tactile stimuli. Chief among these hormones is prolactin, which also controls the production of pigeon milk, a cheeselike substance produced only in the crops of adult doves and pigeons and fed to the nestlings by regurgitation.

Although there are some outstanding exceptions, most young mammals are completely helpless at birth. This helplessness is most striking in the marsupials (*e.g.,* opossums and kangaroos), in which the young are born at a very early stage of development; they crawl through the mother's hair to the brood pouch, where they attach themselves to a nipple and their development continues for many more months.

Licking of newborn

An early characteristic behaviour in mammals following birth is that of the mother licking the newborn. This serves at least two functions—one is general cleanliness to avoid infections or the attraction of parasites; the other would appear to be purely social. If a newborn mammal is removed from its mother and cleaned elsewhere before she can lick it, she usually will not accept it. Thus, licking behaviour also serves, in some manner, to establish a unique relationship between the mother and her offspring. Another characteristic mammalian behaviour is the suckling response of the newborn. Although this behaviour has been claimed to be the perfect instinctive response, it apparently is not so in many species; the trial-and-error period during which the newborn discovers the nipple, however, is quite short.

In birds, especially those that nest on the ground, one of the first adult responses to the hatching of the eggs is to remove the conspicuous eggshells from the area of the nest. It has been shown experimentally that, in gulls at least, this is an important antipredatory measure. When birds hatch, they have the ability to stretch their heads and to gape for food in response to any mechanical disturbance, such as that produced when the parent lands on the nest. Later in development, they stretch and gape only when the parents appear. This is another type of adaptive, antipredatory behaviour, as it would be dangerous for the nestlings to gape and vocalize in response to any environmental disturbance.

Group care. The ability of an animal to identify its own offspring at an early stage is apparently not important in animals that nest or are solitary breeders; offspring in the nest belong to that parent. In colonially breeding species or in those where the offspring of different parents are likely to become mixed, however, natural selection has favoured the evolutionary development of behaviour that makes possible the recognition by the parent of its own

offspring, thereby avoiding the danger of expending energy on offspring that do not possess the parent's genes.

There is, on the other hand, the situation in which the offspring are cared for by individuals who are not the parents. This phenomenon occurs among the social insects in particular and also among several groups of birds and mammals; future investigations may show it to be even more widespread. In such birds as the anis, the effective breeding group consists of several females and males. One nest is constructed in which all the females deposit their eggs, and all individuals participate in the care of the resulting offspring. In certain jays (Corvidae), the offspring of one generation participate in the care of the offspring of the next or another generation, but the exact family relationships among the participants are not clear.

In the social insects, this type of parental behaviour apparently results from the peculiar genetic relationships between the individuals in most social-insect colonies (termites are among the exceptions). The female and, in the termites, both the male and the female can control by chemical means the kinds (called castes in ants and termites) and sexes of the offspring. An outstanding feature of such colonial insects as the honeybee is that the majority of the individuals produced by the queen are sterile; these are the workers, the individuals who care for and feed both the queen and her offspring, the sibs of the workers.

Group care in honeybees

The queen is diploid in genetic makeup; that is to say, half of her genes are derived from her mother and half from her father. The males (drones) are haploid; that is, they have only half the genes possessed by the queen, all of them derived from the mother. A queen produces eggs fertilized by sperm she has retained in her body from the mating flight; thus the individuals produced are diploid, but, unlike the queen, they are sterile. This sterility results indirectly from a chemical secreted by the queen, called the queen substance. It inhibits the workers from building special brood cells that give rise to sexually developed individuals. If the queen fails to secrete this substance because of age or death, the workers immediately construct special brood cells with a substance they secrete; called royal jelly, it is necessary for the development of a larva then destined to be a queen.

How can the evolution of sterility in workers and their care of offspring not their own be accounted for? One possible explanation concerns the coefficient of relationship (the number of genes on the average shared in common) among the individuals of a colony. Because of the peculiar haplo-diploid mode of sex determination, the workers (sisters) share all the genes from their father and, on the average, half of those from their mother. Since each worker receives half of its genes from the father and half from the mother, the average genes shared between any two workers (sisters) is three-fourths. But between mother (the queen) and daughter (a worker) this average is only one-half. The offspring (the sterile workers), therefore, may contribute more to their fitness (the maximum representation of their genes in the next generation) by caring for their sisters than by providing an equal amount of care to their "own" offspring, had they been fertile rather than sterile. A drone, on the other hand, has a coefficient of relationship with one of his sterile sisters of only one-fourth, but retains a relationship of one-half with his mother and daughters (future sterile workers). This explains why workers provide more care for their sisters than for their brothers, and why the workers eventually drive off the almost useless drones, which are relatively scarce (having resulted from unfertilized eggs), from the colony. Because sisters share more genes with each other than with their brothers, they maximize the chances of these genes surviving into the next generation by providing more care for their sisters.

This explanation of group care and extreme sociality does not account for all cases. Indeed, termites are perhaps the most extreme among animals in these respects but lack the haplo-diploid sex determination mechanism. In addition, several groups having this mechanism have not evolved extreme brood care and sociality. Other factors have to interact for these systems to evolve, but it is not yet clear what they are.

REPRODUCTIVE BEHAVIOUR IN INVERTEBRATES

Protozoans and sponges. Most protozoans (one-celled organisms) reproduce asexually, usually by fission (splitting in two); in some species, however, sexual as well as asexual reproduction occurs and may be complex. The colonial organism *Volvox,* which may be either of one "sex" or composed of cells of both sexes, produces true eggs and sperm. A chemical substance released by "females" induces the production of sperm packets; following the union of the egg and sperm, the parent colony dissolves, and the zygote (fertilized egg) is released.

Conjugation

Another form of reproduction in protozoans is conjugation, in which organisms such as *Paramecium* fuse together briefly to exchange nuclear products. This results in a reshuffling of hereditary characteristics just as occurs in true sexual reproduction in higher animals. In some species of *Paramecium,* there are mating types, and an individual is of one type or the other. Opposite types apparently recognize each other by a chemical (pheromone) that is released on their body.

In the lower metazoans (multicellular organisms), reproduction is also by both asexual and sexual means. As befits their sessile life-style and low population densities, sponges that reproduce sexually are usually hermaphroditic; that is, each individual is capable of producing both sperm and eggs, but often at different times to prevent self-fertilization. The sperm are swept by water currents into another sponge, where they are picked up by specialized cells called choanocytes and carried to the egg. Fertilization takes place when a choanocyte fuses with the egg. The free-swimming larval stage that is produced is of short duration, after which the organism settles on the bottom and becomes a new adult sponge.

Coelenterates. Hydroids, jellyfishes, sea anemones, and corals of the phylum Coelenterata, or Cnidaria, reproduce by a variety of mechanisms. A familiar coelenterate animal, the freshwater *Hydra,* usually reproduces asexually by budding, a process by which small portions of the adult structure become new, but genetically identical, individuals. Hydras are also dioecious; that is, each individual produces either sperm or eggs. In many temperate-zone species of *Hydra,* sexual reproduction occurs during the autumn; the fertilized eggs enable the species to survive the winter.

Most of the other hydrozoans are colonial organisms, often occurring in polyp and medusal (umbrella-shaped) forms. In a colony, reproductive individuals called gonophores develop into free-swimming organisms (medusae) that reproduce sexually. Fertilization can be either external or internal; if external, the eggs are shed directly into the water. Internal fertilization results in larvae that swim out of the parent and soon settle on a surface, where they develop into another hydroid colony.

Sea anemones and the polyps of corals reproduce both asexually—by budding—or sexually. In the sexual mode, sea anemones have both dioecious and hermaphroditic species. One interesting aspect of sea anemones, which undergo internal fertilization, is that they are among the first lower animals known to provide parental care. The larvae of sea anemones remain inside the adult until they are ready to metamorphose (change in form), at which time they swim from the parent's mouth and settle on its base, remaining there until they develop tentacles. When they have reached this stage of development, they move away from the parent's protection.

Flatworms and rotifers. The reproductive structures of flatworms (phylum Platyhelminthes) resemble those found in the higher groups. Such flatworms as the land and freshwater planarians are hemaphrodites. Although some species can reproduce asexually by splitting in two, most engage in copulation. Some freshwater planarians can produce both thin-shelled summer eggs, which hatch in a short time, and thick-shelled winter eggs, which are resistant to freezing and hatch in the spring. An apparently unique situation in many planarians is that nutrition for the embryo is supplied by the addition of separate cells to the zygote, after which the entire mass is enclosed in the shell; more commonly, the yolk is incorporated within the structure of the zygote itself.

In the rotifers (phylum Aschelminthes), small but abundant freshwater animals, reproduction is usually sexual, and the sexes are separate. Copulation occurs by injection of sperm anywhere in the body wall of the female. Many species found in temporary ponds and streams exhibit a peculiar reproductive behaviour that is well adapted to their transient environment: they produce different kinds of eggs at different times of the year. One egg type, called amictic, is produced in the early spring. These eggs apparently cannot be fertilized, and the embryo develops without fertilization (parthenogenesis); the result is females with a life-span no longer than two weeks. When the population reaches a peak in the early summer, a second type of egg is produced. If unfertilized, this egg, which is called mictic, results in males. As the male population increases, most mictic eggs become fertilized, resulting in the production of a heavy-shelled dormant egg with much yolk. The dormant egg survives the winter and gives rise to the amictic females of the next spring. Thus, despite the many generations produced in the summer by so-called sexual means, the reshuffling and recombination of genetic material occurs only once a year.

Parthenogenesis

Segmented worms. The marine worms of the class Polychaeta (*e.g.,* clam worms and lugworms of the phylum Annelida) provide the first examples of a kind of courtship behaviour involving both visual and chemical displays initiated by some rather subtle environmental stimuli. Most polychaetes reproduce sexually, and there are two distinct sexes in most species. Either by transformation or budding, many polychaetes produce a reproductive form (epitoke). At a certain time of the year, the epitokes swarm to the ocean surface and engage in mass shedding of eggs and sperm. Some female epitokes of clam worms (*Nereis*) produce a chemical substance called fertilizin that attracts the male epitokes and stimulates the shedding of sperm. Male epitokes of a polychaete found in the Atlantic Ocean emit a flashing light; females emit a steady light. The light may serve to attract male and female and to aid in species discrimination. The swarming of the palolo worm *Palola* in parts of the South Pacific is apparently triggered by an annual and a lunar cycle; the epitokes separate from the parent (atoke) in October or November, during the last part of the lunar cycle.

The class Oligochaeta (phylum Annelida) contains a diversity of both aquatic and terrestrial worms, among which is the familiar earthworm, *Lumbricus.* Although some aquatic oligochaetes reproduce asexually, the majority are sexual, and all of these are hermaphrodites. At mating, two oligochaetes lie side by side so that the head of one is opposite the tail of the other. Sperm then pass reciprocally into small sacs, where they are temporarily stored. This transfer is more complex in the earthworms, however, because the respective male pores are not in direct opposition; each individual forms a temporary skin canal through which the sperm flow to their respective sacs for storage. The body of oligochaetes has a swollen girdle-like structure, the clitellum, which serves an important function in reproduction. After the eggs have matured, a mucous tube, secreted from the clitellum, slides along the body as the worm moves backward. The stored sperm are discharged into this tube, as are the eggs when the tube slides along the section containing them. As the worm literally passes out of the tube, a mucous, lemon-shaped cocoon forms around the now-fertilized eggs. This cocoon serves as a kind of primitive nest, in which the young hatch.

Many leeches (class Hirudinea), all of which are hermaphrodites, have copulatory behaviour much like that of earthworms. Cocoons are formed in a manner similar to that described above, but in some leeches the cocoon is transparent and remains attached to the parent in which the eggs were developed. After hatching, the young leeches remain attached to the "mother" until they become independent. One African leech gives birth to live young and even possesses a special incubating chamber in its body for the developing embryos.

Mollusks. The animals in the phylum Mollusca (*e.g.,* clams, snails, and squid) display a diversity of reproductive behaviour. The majority of the amphineurans (chitons) and pelecypods (*e.g.,* clams, oysters) are dioecious—*i.e.,* individuals are either male or female. Because most species simply shed their eggs and sperm directly into the sea, individuals tend to form dense aggregations during the breeding period. The environmental factor that triggers the release of eggs and sperm has not yet been established with certainty, but, at least in a few species, after one individual has shed its sex products, the others follow in a kind of chain reaction that is clearly chemical in nature. In some mollusks, however, such as the European oyster, the eggs are retained and brooded.

The snails and slugs include hermaphroditic as well as dioecious species. Copulation in the hermaphroditic land snail *Helix* is preceded by a curious courtship involving a bizarre tactile stimulation. When the two partners come together, each drives a calcareous dart (the so-called love dart) into the body wall of the other with such force that it is buried deep in the other's internal organs.

The love dart

To avoid predators, some arboreal slugs copulate in mid-air while each partner is suspended by a viscous thread. In the slipper-shell snails (*Crepidula*), which are rather sessile, all the young are males; their subsequent sex, however, is determined by their nearest neighbour. They remain males as long as they are near a female but change into females if isolated or placed near another male.

Remarkably advanced courtship behaviour in the cephalopods, particularly the squids, involves complex visual displays of movement and changes in colour pattern. Males signify that they are ready for breeding by assuming a distinctive zebra-striped pattern, displaying their fourth arm in a flattened manner, and approaching other individuals with a jerky motion. This fourth arm in squids

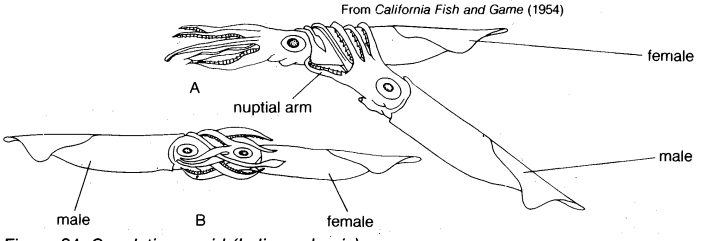

Figure 24: *Copulating squid (Loligo vulgaris).*
(A) Position when spermatophores are transferred to mantle cavity. (B) Position when spermatophores are transferred to sperm receptacle.

and the third arm in octopods, called a hectocotylus, is structurally modified for carrying spermatophores, or balls of sperm. The male cuttlefish (*Sepia*) places the spermatophores in a pocket near the female's mouth, from which the sperm subsequently make their way to the tubes that carry eggs (oviducts). In no squid studied thus far do either of the sexes care for the fertilized eggs, which are laid on vegetation. This is not the case with octopuses, however; at least in *Octopus vulgaris,* the female broods her large number of eggs (about 150,000) for as long as six weeks. During this period she aerates the egg clusters and keeps them free of detritus, exhibiting remarkable behaviour for an animal that produces so many eggs. Brood care such as this is usually associated only with organisms that produce a small number of eggs.

Arthropods. *Crustaceans.* With a few exceptions, barnacles are the only hermaphroditic members of the class Crustacea in the phylum Arthropoda. This is in agreement with the theory that a sessile mode of life tends to be correlated with hermaphroditism. Thus, it is not important for the organism to be near an individual of the opposite sex, but simply to be near any individual of the same species.

Some barnacles are parasitic and have undergone a radical degeneration in form. One, *Sacculina,* is an example of the way in which the reproductive necessities of one species can profoundly affect the reproductive behaviour of another—in this case, the host. Several cells from a larval barnacle penetrate a crab's body and migrate through the bloodstream until they reach the lower portion of its stomach. The cells then send rootlike projections throughout the crab's body. When the crab molts, the barnacle

protrudes a large bulbous portion of its body through the ventral (bottom) surface of the crab. If the crab is a female, its broad shell protects this structure, which contains the barnacle's reproductive organs. The body shape of the male crab, however, is much narrower and does not provide such protection. If the host is a male, therefore, the barnacle first consumes the host's testes; at its next molt, the crab assumes the shape of a female. Should the parasite be removed, the crab regains a male appearance and regenerates its testes.

In the copepods (*e.g.,* sea lice, *Cyclops*) and the amphipods (*e.g.,* beach fleas), the sexes are mostly separate, copulation is brief and without elaboration, and the female of both groups broods the fertilized eggs. The eggs of copepods are usually attached in two clusters to the rear of the female; many amphipods have a special pouch on their ventral surface for brooding the eggs. Many copepods and some amphipods are parasitic on fish and on such marine mammals as whales.

In the crustacean order Decapoda, which includes shrimp, crayfish, lobsters, and crabs, the sexes are separate, fertilization is mostly internal, and egg laying usually occurs shortly after copulation. In terrestrial crabs, however, the females of which migrate to salt water to expel the eggs, the sperm are stored, and fertilization and egg laying are delayed for several months after copulation.

Fiddler crabs of the genus *Uca* and several other decapods show territorial behaviour, an act that is not very common among invertebrates. As in many groups in which males defend territories, male crabs often differ in appearance from the females. Males are much more brightly coloured than the females, and one of their front claws is greatly enlarged; the mostly dull-coloured females have two small front claws. Depending on the species, males perform either simple or complex rhythmic dances in front of their sand burrows. The waving and vertical movement of the large claw is apparently species specific.

The necessity of spermatophores

As in squids and octopuses, the sperm of primitive terrestrial arthropods—millipedes, centipedes, springtails, and silverfish—are often transferred from males to females in structures called spermatophores. During the transition from an aquatic to a terrestrial mode of life, spermatophores became necessary, particularly for those species that had not developed copulatory organs for direct transmission of sperm. Because sperm transfer in these animals is often complicated and takes considerable time, the delicate sperm would be in danger of drying up, were it not for the moisture contained in the spermatophores. It would appear, therefore, that all species that exhibit indirect sperm transfer in which spermatophores are utilized have not achieved complete independence of water.

Males of most primitive soil-dwelling arthropod species place sperm drops on threads in damp locations or use threads or chemical products to guide females to externally placed spermatophores. Most male millipedes have secondary genital appendages called gonopods, by which they transfer the spermatophore directly to the genital opening of the female. One millipede actually uses a "tool" in sperm transfer; the male rounds a fecal pellet, places a drop of sperm on it, and, using its legs, passes the pellet back along its body to a point opposite the female's genital pore. Paired body projections then are used to inject the sperm into the female, and the pellet is dropped. Males of the common bark-inhabiting millipede *Polyxenus* transfer sperm by spinning thin threads on which they place sperm drops; they then construct two parallel thicker threads on which they place a pheromone to attract the female. This chemical and tactile guidance system causes the sperm to become attached to the female's vulva (the external part of the female's genital organs). Males eat the sperm not picked up and replenish it with fresh sperm.

Arachnids. The arachnids (*e.g.,* spiders and scorpions) exhibit the earliest pattern of classical courtship behaviour during which rather ritualized movements are involved. In the true scorpions this behaviour takes the form of the *promenade à deux,* in which the male holds the female by her front claws and apparently stings her in a joint near the base of the claw. The ensuing dancelike pattern apparently results from the male seeking a suitable surface upon which to deposit his spermatophore. After he deposits the spermatophore, the male drags the female over it, releasing her after the spermatophore has passed into her genital pore.

Behaviour of male spiders

As mentioned above, many male spiders have a particular problem in approaching the aggressive and predatory female in order to deposit a spermatophore. The hunting behaviour of most spiders is adapted to react to the slightest movement or vibration of the web, causing the spider to rush forward and bite its prey as quickly as possible. Thus, it is not surprising that male spiders have evolved fairly elaborate display movements and patterns to convey their identity. Many males are quite strikingly coloured, providing additional information about their identity. Some males approach the female only at night and vibrate her web in a highly characteristic manner, different from that caused by the struggling of a trapped animal.

Insects. One puzzling aspect about the courtship behaviour of insects is its sporadic nature. Most insects should exhibit behaviour involving approach, identification, and copulation. Yet, whereas male fruit flies (*Drosophila*) often have elaborate displays preceding copulation, male houseflies and blowflies (*Musca*) simply fly at any object of the proper size and attempt to copulate with it. The reason for these differences in behaviour may be that some insects do not require courtship. Males of some butterflies and moths, for example, simply wait by the pupa and copulate with the female immediately after she emerges.

It is more likely, however, that the majority of insects

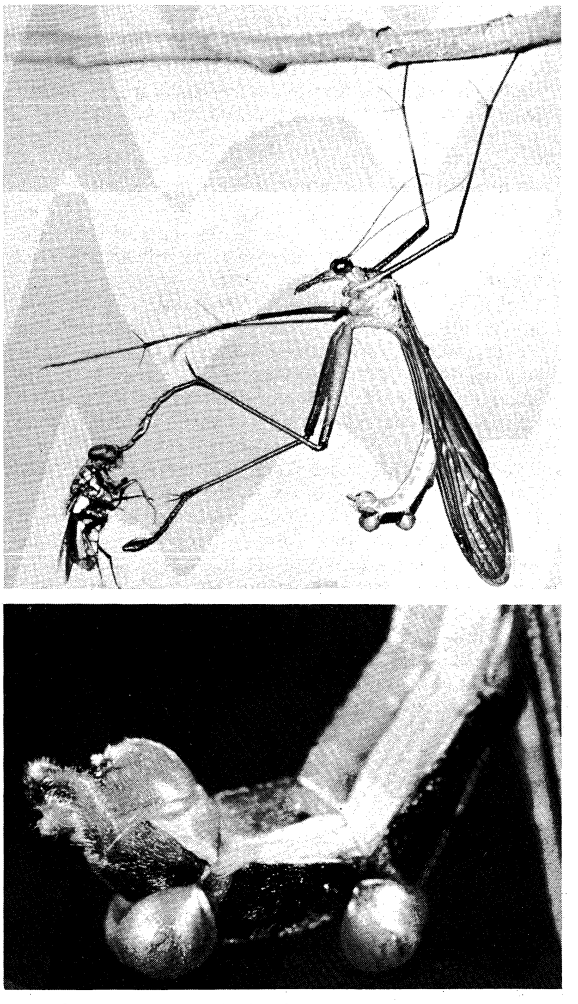

Figure 25: *Reproductive behaviour in mecopterans.* (Top) With his hind tarsi a male mecopteran, *Harpobittacus australis,* captures an insect. Suspending himself he everts two abdominal sacs that release a pheromone that "calls" females. The female, who approaches upwind, is presented with the prey, and copulation follows. (Bottom) Protruding sacs as they appear in magnified view of male abdomen.

have fairly elaborate displays, but man is unable to sense them. The pheromones are, in fact, rather elaborate displays used as sex attractants by many insects; such sensory mechanisms are not usually perceived by man. It has been experimentally demonstrated that the reproductive behaviour of some butterfly species depends heavily on visual clues; similar experiments with other species have failed to show such behaviour. It must be realized, however, that insect vision is quite different from that of vertebrates. Most insects have vision that is sensitive to ultraviolet light, which man and the other vertebrates cannot normally perceive. Butterflies may appear to have identical wing colour patterns under normal light, but, when viewed under ultraviolet light, the patterns differ drastically. Thus, insects that mimic each other in order to appear identical to a vertebrate predator actually possess an unbreakable code by which each species is able to distinguish its own kind.

A reproductive behaviour that is usually misunderstood by those who have observed it is the copulation process in dragonflies. The actual copulatory organ of the male is located close to the thorax, not, as in most insects, near the tip of the abdomen. After a male alights on a plant and transfers sperm from the terminal genital opening to the copulatory organ, he seeks out a female and grasps her behind the head with claspers on his abdomen. Although the two fly in a tandem position, actual copulation occurs only when they alight, and the female bends her abdomen to receive the sperm from the male's organ. Colour, pattern, and movement are important in species recognition. In experiments, it has been found that artificial models acceptable to male *Platycnemis* dragonflies must consist of a female head, thorax, and one wing; the model also must be moved from side to side about once every four seconds to be effective. Complete aerial mating in insects is rare, but it does occur in mayflies, houseflies, ants, wasps, and bees.

Sound displays

Among the cicadas, crickets, and some grasshoppers, females normally mate after they have been attracted to a male by vocalizations of the latter, which, in most cases, are species specific. It has been demonstrated that deafened female grasshoppers do not permit copulation. In many crickets, the specific stridulations (noises) that occur after each copulation keep the female near the male until he is ready to produce another spermatophore. These stridulations also prevent the female from removing the spermatophores before insemination has been completed.

Even some butterflies incorporate sounds into their reproductive displays; in some manner, the butterfly *Ageronia* makes a loud cracking sound when engaged in courtship. Many other insects may incorporate sound into their reproductive displays, perhaps utilizing sounds beyond the sensitivity of the human ear.

Research has revealed that olfactory displays are widespread in insects. The sex attractants for this purpose are usually volatile pheromones. Among certain species of butterflies, such as the queen butterfly (*Danaus gilippus*), the males possess "hair pencils" that project from the end of the abdomen and emit a scent when swept over the female's antennae during courtship behaviour. Copulation does not occur in the absence of this chemical display.

During some stage of their development, a number of insects are either external or internal parasites on a wide variety of animals, including other insects. A particularly bizarre pattern is found in the stylopids, which belong to the order Strepsiptera. Though seldom seen, these insects may be common internal parasites of wasps and bees. The abdomen of the adult females, which never leave their hosts, consists of a bag of eggs that is concealed in the host. The forepart of the parasite, which projects from between abdominal segments of the host, is usually concealed by the host's wings. The females of one stylopid group are apparently unique among animals in having two genital openings—both in the head—in the form of membranous windows. The larvae emerge through these openings, crawl onto a plant, and seek another host. When the host molts its old cuticle (hard skin), the larvae penetrate the soft body. Females extend their heads through the host's abdomen and mature within the host. The males, however, leave the host, pupate in the host's cast-off cuticle, and emerge several days later as adults. The male stylopid then seeks out a host insect and taps it on the side of the abdomen. If no female is present, the male leaves; if a female is present, she somehow signals her presence. The male then inserts his abdomen under the host's wing and enters the genital window of the female.

It is in the orders Isoptera (termites) and Hymenoptera (bees, wasps, and ants), however, that the reproductive behaviour of insects attains its highest level of sophistication. Although dung beetles and some other insect species brood their eggs and care for the young, extreme insect sociality, with its peculiar brood-care system, is found only among the isopterans and the hymenopterans. The principal criterion for such behaviour would appear to be that the female must remain with her brood until after they begin to hatch. Although the phenomenon has been intensively studied, the explanation for the evolution of extreme brood care in ants, many wasps and bees, and termites remains one of the more challenging problems in biology.

Most colonies of social insects reproduce in two ways: either sexual individuals are produced that mate and start new colonies, or the colony breaks up after reaching a certain size. Some species reproduce in both ways. In the first case, the chances of finding new sites are maximized by providing as many individuals of different sexes as possible, each equipped with appropriate guidance mechanisms. In the second, members of the parent colony explore the environment and establish a new colony where suitable.

Another example of reproduction in social insects is that practiced by many ants. Most larvae in an ant colony develop into wingless, sterile workers. Some, however, may get more food (a point that is controversial) and grow more rapidly. These do not pupate when the other larvae do; instead, they become king-sized individuals that eventually metamorphose into sexually mature males or females with wings. Their sex, like that of the wasps and bees, depends upon whether or not the egg was fertilized by the queen.

Mating swarms

The winged sexual forms, or alates, are produced at certain times during the year and swarm in mating flights to establish a new colony, which may actually be no more than a few hundred feet from the old colony. Actual copulation may occur either during flight or after landing on a surface. For most species of ants, it is not known whether a male will copulate with more than one female or if a female will copulate with more than one male. After copulation, the female seeks a location for a new nest and loses her wings within three to five days. Generally, two months are required to rear the first daughter workers. Some females carry a live mealybug with them on the mating flight and take it to the new colony site, where the mealybug's offspring provide the honeydew to feed the ant's initial offspring. Generally, however, the female ant does not provide food for her first offspring; instead, the larvae eat many of the first 100 or so eggs. This egg cannibalism decreases when there are sufficient workers to feed the larvae.

REPRODUCTIVE BEHAVIOUR IN VERTEBRATES

Fishes. The reproductive behaviour of fishes is remarkably diversified: they may be oviparous (lay eggs), ovoviparous (retain the eggs in the body until they hatch), or viviparous (have a direct tissue connection with the developing embryos and give birth to live young). All cartilaginous fishes—the elasmobranches (*e.g.*, sharks, rays, and skates)—employ internal fertilization and usually lay large, heavy-shelled eggs or give birth to live young. The most characteristic features of the more primitive bony fishes is the assemblage of polyandrous (many males) breeding aggregations in open water and the absence of parental care for the eggs. Many of the species in this group, such as herrings, make what appear to be completely chaotic migrations to their breeding areas. Actually, however, each of these huge spawning aggregations is made up of small, coordinated parties consisting of one female and one or more males. On the other hand, a number of fishes are monogamous, form pairs, and care for the eggs or young. In courtship behaviour, in which they utilize all potential

stimuli including sound, chemical, and electrical stimuli, the range and complexity of their displays are not exceeded by any other vertebrate group.

Hermaphroditism in fishes

Although the sexes are usually separate, hermaphroditism is much more common among the bony fishes than in any other group of vertebrates. The reasons for this condition are both physiological and ecological. Whereas the developing gonads of all other vertebrates have an outer and inner layer of tissue, those of bony fishes have a simple origin that lacks any male or female elements. In terms of the evolutionary process, this type of development is likely to be more adaptable to pressures that favour hermaphroditism. When, because of one or several interacting factors, a population density reaches a low point in some species, reproduction may be limited to a low probability of contact with another sexually active individual. In such situations (*e.g.*, very deep sea habitats, tide or stream pools) the evolution of even temporary self-fertilizing hermaphrodites would have the greatest advantage.

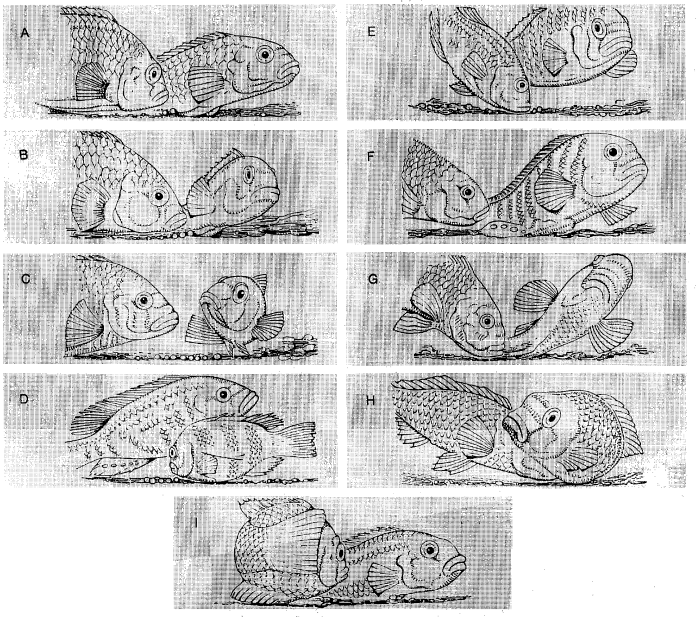

Figure 26: *Phases in the spawning sequence of Haplochromis burtoni.*
(A–C) Female on right deposits batch of eggs; (D,E) female collects eggs in her mouth, where she broods them; (F–H) male emits sperm onto bare surface while female attempts to take up dummy eggs (conspicuous spots near the base of the anal fin of the male) into her mouth; semen enters her mouth in the process and fertilizes the eggs; (I) female deposits another batch of eggs.

One form of hermaphroditism fairly common in bony fishes is the protogynous type, in which the individual functions first as a female and later as a male; it is much more frequent than the reverse situation (protandrous hermaphroditism). The selective reasons for the predominance of the former are presumably associated with the relationship between smaller body size in females and the greater energy requirements needed to produce eggs. In addition, in some promiscuous mating systems, it may be selectively advantageous to be a male when the body size is large and the individual experienced, rather than small and young. Most sea basses, parrot fishes, and wrasses have this sort of hermaphroditism.

Amphibians. Although true viviparity has been described in the African frog *Nectophrynoides,* most amphibians lay eggs. Some salamanders, however, retain the eggs within their body and give birth to live young. Courtship displays in frogs are almost entirely vocal, although in salamanders they may involve tactile, visual, and chemical stimuli. In the European newt *Triturus,* for example, in which mating takes place in the water, the male places himself in front of a female with his back to her. Suddenly, he executes a leap, directs a current of water at her, faces her, and bends his tail forward alongside his body; by waving his tail, he sends toward her a gentle current of water that probably carries a chemical stimulant. If the female responds by approaching the male, he turns and faces away, whereupon she touches his tail and he deposits a spermatophore, which she takes into her cloaca, a common passageway into which waste products and reproductive cells are discharged.

Most frogs and salamanders do not show brood care, but there are exceptions. In the European midwife toad the male rather than the female carries the sticky eggs on its hindlimbs. In a number of Neotropical frogs, the male carries the eggs under a flap of skin on its back. In some species, the young (tadpoles) cling to the back of the male by using their sucker-like mouths.

Lack of brood care

Reptiles. Reptiles are the first vertebrates that, in an evolutionary sense, have evolved an egg that is truly independent of water. Indeed, many snakes and lizards have even gone beyond this stage and have attained complete viviparity. It is difficult to generalize about reproductive behaviour in the reptiles because the various groups differ from each other in the sensitivity of their receptor organs. In many turtles, for example, the males are territorial and are very aggressive during the breeding period. Courtship behaviour involves mainly tactile stimuli, but olfactory clues are also important. It has been recorded that the wood turtle (*Clemmys*) actually emits a low whistle during courtship. Turtles usually bury their eggs and do not brood them.

Lizards appear to use almost every sensory mechanism in their reproductive activities. The nocturnal geckos employ vocalizations, in addition to tactile and olfactory stimuli. Skinks such as *Eumeces* rely heavily on olfactory clues. Lizards of the large family Iguanidae, on the other hand, are almost entirely diurnal creatures and utilize, in the main, visual displays, some of which are the equal in complexity to any known among the vertebrates. Many, such as the anoles, are equipped with a throat flap (dewlap) that is often brightly coloured and specifically marked; it is utilized both in courtship and territorial defense. The skinks and a number of other lizards are known to guard their eggs.

In general, the reproductive behaviour of snakes is not well known. The tongue is apparently an important sense organ for receiving olfactory and other chemical stimuli. The males of some snakes have characteristic skin papillae (nipple-like projections) on the throat; the fact that they rub the papillae over the female's body suggests that tactile stimuli are also important to reproduction. In boas, the rudimentary pelvic bones serve as "claws" for lifting the hind end of the female and for producing a vibration that is said to be important in the process of copulation. Some snakes, the pythons in particular, incubate and guard their eggs.

The bellowing roars of male alligators serve to establish breeding territories and apparently also to attract the females. Female crocodiles remain in the vicinity of their nest and will defend it vigorously.

Birds. Although all birds lay eggs, it is curious that they do so, because the time of highest mortality in most birds usually occurs during the egg-laying period. Apparently, birds lack some adaptation that would permit them to become viviparous.

Most birds build a nest and incubate their eggs, but the incubator birds and such brood parasites as cuckoos are among the exceptions to this rule. Many females that lay a fixed number of eggs are referred to as determinant layers. The pigeons and doves are outstanding examples of this behaviour; for some as yet unknown reason, they never lay more than one or two eggs. Other species are often referred to as indeterminate layers because, in the absence of a suitable stimulus, they continue to produce eggs. More often than not, this stimulus is the presence in the nest of a certain number of eggs. Such behaviour is clearly adaptive—if eggs are lost for some reason and if other environmental stimuli are present, the missing eggs are replaced. The distinction between determinate and indeterminate layers is often blurred, for many indeterminate layers will not replace more than one or two missing eggs.

Number of eggs laid

The duration of egg incubation varies from as little as

nine days in some tropical perching birds to as long as 80 days in some albatrosses. In most species that form pairs, both individuals incubate and feed the young, but the female usually has the greater share of the burden. Among the exceptions to this behaviour pattern are the tinamou (partridge-like game birds), ostriches, some gallinaceous species (*e.g.,* pheasant, grouse, turkeys), and phalaropes. In the phalaropes, the role of the sexes is largely reversed: the females are more brightly coloured than the males and, not surprisingly, are the aggressive ones in courtship and in territorial defense; incubation is carried out solely by the male, but the female aids in feeding the young.

Because many birds begin incubation with the laying of the first egg in the clutch, the eggs hatch at different times. This strategy is often employed by species whose food supply for the young may vary in abundance over a fairly short period. Hence, should food suddenly become scarce, only the smallest chick or chicks will starve rather than the entire clutch. Species in which the young hatch in a relatively well developed, almost independent state tend to have very large clutches, as in many gallinaceous birds. In this case, it might be said that the ultimate size of the clutch is regulated by the abundance and quality of the food available to the female as she produces eggs. The same explanation also accounts for clutch size in parasitic birds—*i.e.,* those that lay eggs in the nests of other species.

Breeding density

The breeding densities of birds vary from one pair in many square miles, as in some birds of prey, to such species as the fulmar, which forms colonies numbering as many as 250,000. Some colonies of the African weaverbird (*Quelea*) have been estimated to exceed 1,000,000 individuals.

One interesting aspect of reproductive behaviour in birds, possibly peculiar to them and to some mammals, is that many courtship displays are learned, or at least perfected through practice, from the parents. An example is the learning of birdsongs. It has been shown in some cases that when chicks are switched from the nest of one species to that of another, they learn some and perhaps all of the songs of the foster parents and do not develop their own species' vocalizations. When mature, such birds often prefer to choose as mates individuals of the same species as their foster parents' rather than those of their own species.

Courtship stimuli in birds are mostly visual and auditory, but it is possible that odour may be important in some petrels and shearwaters. As previously mentioned, most birds form pairs. In these and in many that do not, the males engage in communal, or lek-type, displays on a common courtship ground, such as the familiar strutting grounds of turkeys and many grouse. In addition, there are the incredibly bizarre communal dances of the birds of paradise; the jungle-floor dancing of the cock of the rock; the pasture display grounds of the shorebird, the ruff; and the forest arenas cleared for displaying purposes by the tiny manakins. Many of these display areas are used for many years; in some manakins, for example, certain cleared arenas have existed continuously for at least 30 years. In most lek species, the males are usually brightly coloured, and the females are rather dull in appearance. An exception occurs in some hummingbirds, the so-called hermits, in which both sexes are rather dull in coloration and in which the males group together in singing assemblies.

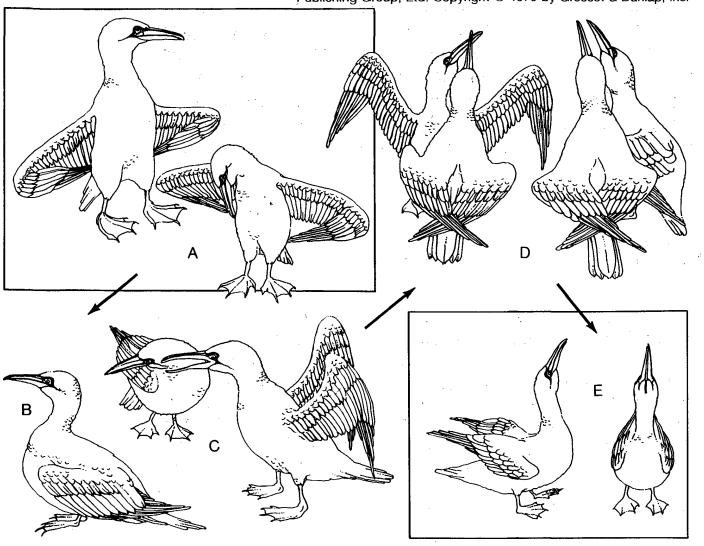

Figure 27: *Courtship behaviour in the North Atlantic gannet.* (A) Bowing; (B) male advertising; (C) facing away; (D) mutual fencing; (E) sky pointing.

Mammals. Most mammals give birth to live young. The outstanding exceptions are the egg-laying monotremes of Australia, the platypus (*Ornithorhynchus*) and the echidnas (spiny anteaters). In the duckbill platypus, a brief courtship involving a chase in the water precedes copulation. The two eggs that are produced are placed in a burrow and hatch in eight to 10 days. In the reproductive behaviour of the spiny anteater (*Tachyglossus*), the female apparently lays her single egg directly into her pouch.

As already mentioned, another general aspect of reproductive behaviour in mammals is the estrous cycle, knowledge of which is essential to an understanding of the mechanisms involved in the reproduction of any mammalian species. Females are usually responsive to males only during that portion of the estrous cycle when they are in heat; that is, when one or more eggs have broken out of the ovary and are in the process of descending to the uterus. The factors causing this event vary greatly, but in some such as rabbits and cats, copulation itself is the main stimulus. In general, however, those mammals, particularly the large ones, that live in temperate areas—*e.g.,* bears, dogs, wolves, foxes, seals, and some deer and antelopes—have one estrous cycle per year. Mammals that live in warmer zones, such as some areas of the tropics, tend to have more than one estrous cycle per year. The sexual cycle in males, the height of which in some forms is referred to as the rut, is, not surprisingly, usually correlated with that of the females. The males of many species of domestic mammals, however, seem to be capable of copulating at almost any time of the year.

Estrous cycle

Another general aspect of mammalian reproductive behaviour is that they do not normally form pairs. Exceptions occur in certain carnivores and in some primates, in which parental care is divided between the sexes. As in many insects, the courtship behaviour of most mammals does not appear to be elaborate; but, just as in the former group, most mammals (humans are an exception) have an acute sense of smell. It is possible, therefore, that many of the chemical attractants wafted into the air by receptive females are actually courtship displays that are more complex than has been realized. This is not to say, of course, that visual, auditory, and tactile displays do not occur. Many deer and antelopes, for example, have rather complex ritualized visual displays employing such movements as strutting and arching of the heads, as well as conspicuous colour patterns. Males in many species discharge urine on females as a preliminary to copulation. Tactile and auditory displays have been shown to be important in aquatic mammals, such as porpoises and whales.

In addition to a number of mammalian pheromones, other odour effects occur in mammals that, aside from their simple advertising value, have an important influence on reproductive behaviour. It has been shown that, when a recently impregnated female mouse is exposed to the odour of a male other than the one with which she has mated, implantation of the egg in the uterus often fails; as a result, there is a rapid return to estrus. The odour of a strange male may signify to a female rodent an unfavourable situation in which to raise young, inasmuch as a number of male rodents attempt to attack offspring not their own. Although it is not yet certain, there might be an adaptive explanation for this behaviour. The population fluctuations of rodents have attracted much attention, and, perhaps correctly, studies have focussed on the ecological parameters of these fluctuations; for example, it has been demonstrated in the laboratory that certain behavioral mechanisms involving odours exercise profound control over the reproduction and population levels of rodents. It has also been shown that the odour of mice can stimulate the production of hormones that cause a decrease

Additional effects of odours

in the reproductive capacity of other mice. In another study, estrus was suppressed and many pseudopregnancies developed when four or more female mice were grouped together in the absence of a male. These results offer a partial explanation for the reduction of population growth in rodent colonies with high population densities.

EVOLUTION OF REPRODUCTIVE BEHAVIOUR

There is a popular tendency to think of primitive animals (in a phylogenetic or descent sense) as lacking "elaboration"; *i.e.*, that the animals of earlier geological periods had simpler displays or perhaps lacked crests or pheromones or elaborate communal displays in comparison with their present-day counterparts. There is no a priori reason for this belief. The fossil record indicates that the societies of which these animals were a part were as diverse and complex as those in which their relatives now live; certainly their display repertoires should have been equally complete. This is not to say, however, that the primitive forms of reproductive behaviour used the same displays for courtship as do the modern forms.

Displays. It has been pointed out that, in general, animals have relatively few displays; in addition, it has been deduced that the relative stability of displays is a dynamic equilibrium—that is, new ones are gained and old ones are lost at about the same frequency. Displays are lost when they no longer convey a selective advantage to the individuals using them; that is, when they are no longer effective in promoting the behaviour that seeks to maximize gene survival in the next generation.

New displays, on the other hand, generally arise by ritualization of previously existing behaviours or functions; that is, when a selective advantage accrues to those individuals who, to convey information, use certain behaviours or functions in a manner that is either partly or totally different from their original purpose. Pheromones, for example, are usually derived from compounds that are natural breakdown products of body metabolism, such as the compounds in urine. Thus, urine, as the precursor of these chemical sex attractants in insects, functions for display purposes, which is far removed from its basic excretory function.

Darwin's theory of sexual selection

Darwin proposed a theory of sexual selection to account for the presence in animals of displays and functions that apparently were not related to survival. He pointed out that two general concepts were involved. First, the evolution of such characteristics as the larger size of males in many species and the development of horns and antlers in mammals could be accounted for by their usefulness in fights between males for their sexual possession of females. This concept has been termed intrasexual selection. For such colourful male structures as the plumes of birds of paradise and the tails of peacocks, Darwin suggested that they resulted from the cumulative effects of sexual preference exerted by the females of the species at the time of mating. This second concept has been termed epigamic selection.

A displaying male has been known to convey information about his relative fitness; that is, his ability, with respect to other displaying males, to maximize the survival of his genes into the next generation. Both the brightness of his coloration and the frequency with which he struts say something about the effectiveness of his genes to produce a "healthy" individual. Once this correlation takes place, selection favours those females who are able to choose the "most fit" males. Correspondingly, sexual selection intensifies the signals up to the point at which any further elaboration of those signals would result in a loss of fitness. When selection goes beyond this point, the male, because of his elaborate ornamentation and other displays, is more likely to suffer from predation before he has the opportunity to reproduce.

Sexual selection. The discussion concerning courtship displays leads naturally to the concept of sexual selection. Why do the males of some species possess elaborate displays? Why, in fact, do some species "elect" to utilize one mating system, say a monogamous one, while others "choose" a polygamous one? It has been suggested that many courtship displays and mating systems, particularly those involving polygamous systems with communal displays in a common courtship area, have an epideictic function—that is, they provide information as to the number of like individuals in a locality. The animals then act according to the information received, often by reducing their reproductive output. Because this concept implies that natural selection is acting for the good of the species rather than for the good of the individual, it has been called group selection. This concept has provoked considerable controversy for two reasons: first, there is no known mechanism by which group selection can function; second, as mentioned earlier, the pertinent behaviours involved can be more simply explained in terms of Darwinian selection dealing with individuals rather than groups.

Polygynous mating systems

In a number of polygynous (mating of one male with more than one female) and promiscuous species, adult females outnumber adult males, sometimes by a factor of five or more. It has been erroneously suggested that this sexual imbalance is the cause of the polygynous mating system, in which one male has several female partners. It has been demonstrated, however, in all polygynous species so far studied, that the ratio of males to females is 50:50 at the time of birth; in many cases, this ratio persists until the cessation of parental care. Therefore, it is the polygynous relationship that causes the imbalance, not vice versa: because sexual selection is the dominant factor in a polygamous and promiscuous species, it results in a greater mortality of males than of females.

Because one male can impregnate many females, thus lowering the selective value of an individual male, females are more valuable than males in an evolutionary sense. It can be seen, therefore, that sexual selection always favours a polygynous and promiscuous system unless it is disadvantageous to the females, as it is in most birds. In most mammals, however, polygyny is the dominant mating system because the male is not needed for parental care. Therefore, monogamy is favoured over polygamy only when some environmental resource (food, for example) is limited and when the maximum survival of young requires the care of both parents. As in all other aspects of reproductive behaviour, the type of mating system that is employed by a species is the result of natural selection.

(N.G.S.)

BEHAVIOUR OF ANIMALS IN GROUPS

Characteristics of social behaviour among animals

Social behaviour among animals takes many forms. The American naturalist and artist John James Audubon observed one of the largest social groups that man has ever known, in the fall of 1813 near Henderson, Kentucky. The species was the passenger pigeon (*Ectopistes migratorius*), once incredibly numerous but hunted to extinction by the end of the 19th century. Audubon wrote:

> The air was literally filled with pigeons; the light of noonday was obscured as by an eclipse; the dung fell in spots not unlike melting flakes of snow.... The people were all in arms.... For a week or more, the population fed on no other flesh than that of pigeons.... The atmosphere, during this time, was strongly impregnated with the peculiar odour which emanates from the species.... Let us take a column of one mile in breadth, which is far below the average size, and suppose it passing over us without interruption for three hours, at the rate mentioned above of one mile in the minute. This will give us a parallelogram of 180 miles by 1, covering 180 square miles. Allowing 2 pigeons to the square yard, we have 1,115,136,000 pigeons in one flock.

SOCIAL AND NONSOCIAL BEHAVIOUR

The largest social organizations ever known are those of desert locusts; the pigeons were second; and present-day

China is probably third, although some pelagic fish schools may be next. Persecution by man is reducing all the large social organizations except his own: the bison and the anchovies off California and Peru have fared poorly compared to smaller groups.

Large numbers or crowding do not in themselves constitute social behaviour. It is usually true, for instance, that a fish that produces a million eggs tosses them out less socially than does a fish that produces a single young and cares for it much more, and that a polygamous bird is less social than a faithfully monogamous one. Overcrowding leads to many social abnormalities. Crowded cats, for instance, develop a "despot" and "pariahs," and there is an almost continuous frenzy of spiteful hissing, growling, or fighting. Crowded rats display, in addition, hypersexuality, homosexuality, and cannibalism.

Effects of crowding

Animals sometimes are brought together by some localized attraction or scarcity, as are moths around an electric light, animals at a water hole in the dry African savanna, birds and bees at a fruit-bearing tree, or iguanas crowding to nest on islands free of predators. To determine if a grouping is social or not, it is necessary to examine the distribution of the animal within the limits of its needed habitat. Most animals require a certain sort of habitat—woodland for a squirrel, or nearly bare ground for a horned lark. Within the correct habitat, the animal also requires certain resources, such as food and water and nesting or roosting sites. The needed habitats and resources collectively form the "niche" of the animal. If an animal's niche is locally distributed, the animal may be found clumped, even if it is not particularly social. If the niche or habitat is patchily or irregularly distributed and the animal cannot move easily from one patch to another, it is said to live in a "coarse-grain" environment or to have a "coarse-grained" niche. Such animals often seem social when they are not. If the niche or habitat of an animal is rather uniform, so that the animal can move about and find what it needs in many places, it is said to live in a "fine-grain" environment or to have a "fine-grained" niche. Such animals often seem solitary when they actually are reacting to each other and hence are social. They tend to be solitary because they do not need to follow others to get to the right environment.

Within a fine-grain environment, or within one "grain" of a coarse-grain environment, animals may occur in groups even when they are not social. A "random" pattern of distribution, in which animals wander without regard to each other, brings asocial animals together at times. An even distribution is much more common, as in territories of many songbirds in which each pair occupies its own plot of ground; these are actually social animals, in the sense that each interacts with its neighbours so as to keep them at a certain long distance. "Clumped" distribution of animals is also common; this usually is truly social in the sense that each animal interacts with its neighbours so as to keep them at a certain short distance. Regularity of the short or long distance an animal keeps from its neighbours is thus as much an indication of sociality as is grouping; only the theoretical (and probably nonexistent) animal that completely ignores its neighbours is truly nonsocial. Time is also a factor in spacing; truly social animals have a tendency to move to the correct distances from each other and to maintain those positions over specifiable time periods, such as for the morning hours each day.

FACTORS INVOLVED IN SOCIAL INTERACTION

Social interaction in time and space is sometimes shown to the ethologist by patterns of following and leadership, although neither of these is necessarily social; following occurs in a dog tracking a rabbit, and leading is seen in an anglerfish luring a smaller fish for dinner by dangling a fleshy protuberance on the snout. In the Eurasian red deer (*Cervus elaphus*), an old female leads the does and fawns about. Spanish merino sheep have been bred to follow each other, while the Scottish highland sheep have been bred to be more independent; following may thus vary within a species according to its needs or to the environmental pressures on it.

Leadership and dominance

Following need not mean there is a leader. The first bird in a migratory "V" of geese or pelicans is not continually the same, and the leaders of a school of fish change every time the school changes direction.

Leadership is sometimes, but not always, associated with a dominance hierarchy or peck order, which may or may not be a sign of social behaviour. Peck order, first noted in bumblebees, means that *A* pecks *B*, *B* pecks *C*, etc., but it does not necessarily mean that *A* leads *C* or *B* or that the three are interacting constructively. The dominant central males of a baboon troop tend to influence the direction taken by the rest of the troop around them; but the bullying dominant stag circling around a herd of red deer has to follow wherever the females decide to go, and his initiative is limited to running straying females back to the herd.

Drawing by Christian D. Olsen

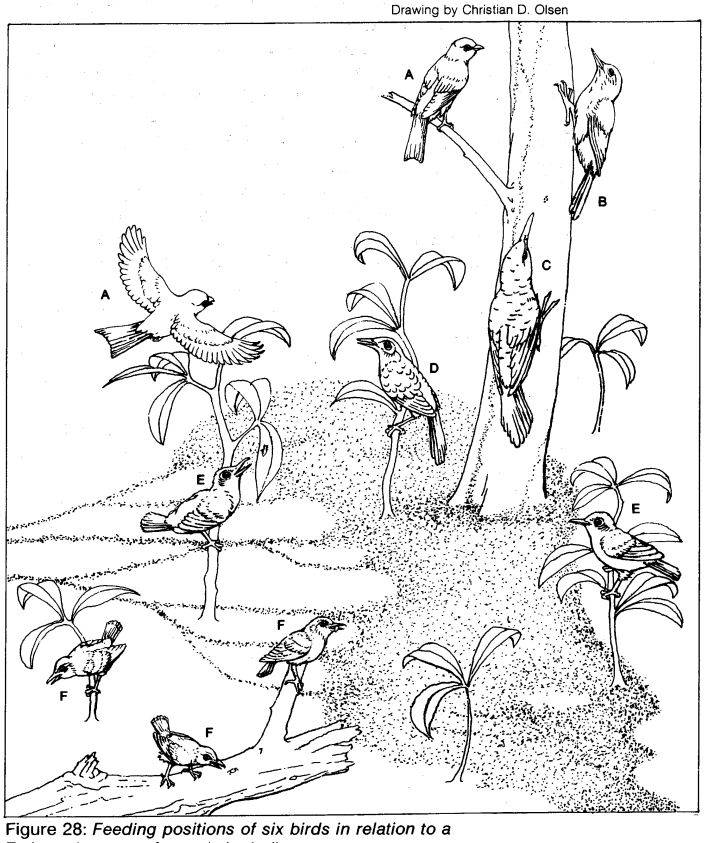

Figure 28: *Feeding positions of six birds in relation to a T-shaped swarm of ants (stippled).* (A) Gray-headed tanager, *Eucometis penicillata.* (B) Plain-brown woodcreeper, *Dendrocincla fuliginosa.* (C) Barred woodcreeper, *Dendrocolaptes certhia.* (D) Ocellated antbird, *Phaenostictus mcleannani.* (E) Bicoloured antbird, *Gymnopithys bicolor.* (F) Spotted antbird, *Hylophylax naevioides.*

Dominance hierarchies may occur whether or not there is social behaviour in the usual sense. Among several species of birds that follow swarms of army ants in Panama to catch insects flushed by the ants, the big ocellated antbird (*Phaenostictus mcleannani*) is dominant, the medium-sized bicoloured antbird (*Gymnopithys bicolor*) is next, and the small, spotted antbird (*Hylophylax naevioides*) is chased by all the other members of the flock (Figure 28).

Crowding almost any two solitary animals together will produce a dominance hierarchy, in which one animal becomes boss or kills the other. This is a major cause of deaths in zoos and aquariums, but it is not necessarily social behaviour. Some biologists even say that dominance hierarchies are evidence of antisocial rather than social behaviour and are expressions of inadequacy in overcrowded social systems. It is certainly true that most peck orders appear in unnatural situations, such as among chickens in a henyard or animals in a cage. In most animals, the absence of a dominance hierarchy, rather than the presence of such, in a crowded context is a sign of a high development of social behaviour.

A further interaction that the ethologist watches for in

Division of labour

social animals is division of labour. Any two animals will, of course, divide up food or any other resource between them. Indeed, no two animals in nature ever have precisely the same niche; if two species have similar niches, they will tend to develop different ways of doing things, or one will exterminate the other. Ecologists call this the "competitive exclusion principle." Man attempts to reduce insect competition by various methods of "control." He kills off other animals by cutting down the trees in which they live. Most animals are less destructive and tend to divide up the world rather than to exterminate other species. Evolution, before the advent of man, seems to have produced continuously more kinds of animals and a greater division of niches, except in periods of environmental disaster. The three antbirds mentioned above tend to specialize in large, medium, and small prey; to the degree that these birds take different foods, they are cooperating better with each other.

Division of labour also occurs within a species. Males and females of some woodpecker species forage in different places in the trees, taking different types of food. Some animals use the same resource but do different things to get it. The male huia (*Heterolocha acutirostris*), an extinct bird of New Zealand, apparently used his short straight beak to open logs while the female, with her long curved beak, removed the insect larvae from the long tunnels he exposed. Male and female birds often build nests together, dividing the labour equally in some cases.

Social insects have more elaborate divisions of labour. Animals that cooperate by division of labour tend to use varied resources and to find more uses for them.

Division of labour seems to be a passing phase in the evolution of most animals other than man. It is evidently of little advantage to most animal societies. The honeybee, the leaf-cutter ants, and other animals with division of labour nearly always occur only where there is little competition from more specialized animals. Few of the most advanced insects or other animals show division of labour. In habitats such as the coral reef and the tropical forest, division of labour tends to be among different species rather than within a species.

Social interactions of various types are more important in determining degree of sociality than are most of the above characteristics. The only interactions between animals that are seldom considered social are behaviours in which animals take something needed by others. The question arises, however, as to how to classify the parasitic relationships of a fetus in the mother and the male anglerfish (*Photocorynus spiniceps*) on his mate, or the fact that killing by predators may help animals to avoid overgrazing their habitats. One could speak of communication of feint and chase in the interaction between moose and wolves. When a bird chases another off its territory, it uses communication and interacts with the other bird very strongly.

Humans often consider chimpanzees or bees as more social than desert locusts, because the locusts have rather simple interactions. Male hummingbirds and birds of paradise, however, have their elaborate plumages and social displays because the females get together with them so seldom that they might not recognize a suitable mate without the displays. It seems generally true that elaborate rituals evolve where social bonds are most fleeting or likely to be disrupted. To determine sociality, one must look at the total spectrum of social interactions as well as at their diversity and productivity, rather than just at a single feature.

Altruistic behaviour

Altruistic social behaviour is often found among animals. An altruistic animal is one that expends some of its energy helping another without direct benefit to itself, be it a mother bear protecting her cubs against their hungry father or a bird giving an alarm call that warns its neighbours of a hawk. An alarm call may help the bird itself, of course, by startling the predator or warning it that this alert bird will be hard to catch.

Psychologists have found that a rat or monkey will slow its rate of pressing a lever for food if that lever also gives an electric shock to a nearby rat or monkey. Rats will take turns sitting on a platform so that others can feed without being interrupted by electric shock. Rats or pigeons can be trained to cooperate in getting food.

Since the altruistic animal always loses something by its behaviour, the question arises why altruism exists. One answer is that, as the evolutionist Charles Darwin suggested, when an animal protects its offspring, it helps its kind to survive the process of natural selection. When porpoises help an injured relative to the surface where it can breathe, they seem to be following a pattern of behaviour that can be accounted for by evolution. Their altruism clearly helps the group and therefore becomes part of the genetic endowment. Altruism, significantly enough, is usually limited to an animal's relatives. Most social animals, such as penguins, feed only their own young. When the individual animal loses more than it or its relatives gain, as when female seals nurse young not their own, the question arises whether this serves the survival of the larger group or the species. Under some conditions, the survival of the group may be more important even than survival of the individual, as when the honeybee dies defending the hive. The worker honeybee, which is not able to reproduce, is in the biological sense not an individual so much as an extra limb of a collective animal.

Reciprocal altruism, in which a benefit is later returned to the benefactor, need not be between related animals and may not even seem altruistic. Alarm calls of birds often alert entirely unrelated kinds of birds, which later may return the favour. An act that seems selfish in the short run is sometimes altruistic in the long run, or vice versa, in the case of maladaptation. Wasps, ants and termites that cannibalize or dominate nestmates at times of food shortage may better keep the colony from starving. Individual ants and bees are often lazy, spending most of their time resting or wandering aimlessly, but these unemployed individuals form an easily mobilized reserve in times of danger.

Individual and group recognition are often important aspects of social structure. Ovenbirds (*Seiurus aurocapillus*) in North America recognize neighbouring males by their songs and react aggressively mainly to songs of strange males. Animals that have long parental bonds often show individual recognition. Herring gulls (*Larus argentatus*), for example, recognize chicks or mates by slight differences in voice or appearance. The larger or more ephemeral the society, the less there can be individual recognition between distant individuals and the more important becomes recognition by group characters, such as the "nest odours" of social insects. Ants, bees, and termites often attack strangers, or even members of their own colony that have been experimentally removed for a few days or washed. Many kinds of parasitic insects (beetles, flies, butterfly caterpillars), however, provide food or scents that gain them entry to a nest, then prey on larvae there.

Other internal characteristics of societies are age structure, birth rates, and death rates. A young wasp or termite colony has few old animals, a mature colony has more, and a declining colony or one that is producing reproductive forms has few young. The old colony has a lower percentage of foraging workers than does the young colony, and has a lower birth rate and higher death rate as a consequence; but only the old colony produces reproductive forms.

Nomadism and migration

Societies also perform movements, such as nomadism and migration (see above *Migratory behaviour*). Army ants wander nomadically after prey. Wildebeest and locusts of Africa emigrate to green areas of local rains; flocking or solitary birds migrate back and forth to escape winter or drought; anadromous fishes, such as salmon, move to the sea for food and to rivers to spawn; catadromous ones, such as eels, do the reverse.

Migrants are often placed at a disadvantage compared to residents, for the latter can take the regular food supplies and leave only ephemeral sources for migrants. Migrants that follow army ants for food in Central America are subordinate to residents and succeed only when residents are absent. The migrant can turn its world from a coarse-grained one to a fine-grained or dependable one by migrating from one patch to the next, and by force of numbers migrants sometimes displace residents.

Societies can make use of seasonal environmental changes by migrating locally, such as sowbugs clustering to estivate in hot weather or ladybugs hibernating in masses. Other societies show food storage; *e.g.,* harvester ants (*Messor*) and wood or pack rats (*Neotoma*). Honey ants (*Myrmecocystus*) have a "replete" caste that bloat their abdomens with stored honey and hang from the roofs of underground chambers until tapped by other workers.

Societies show population fluctuations, from extinction to explosion. Mass emigrations in some, such as lemmings and squirrels, occur mainly after population explosions or periodic extirpations of food supplies. Some populations, such as many protozoans, worms, and insects, normally undergo violent fluctuations, but are resistant to extinction. These are animals in which the adults emigrate or both adults and young emigrate. Animals in which the adults normally occupy a fine-grained habitat and only the young move, such as most higher animals, normally have relatively stable populations, but are easily killed off by a new predator or temporally unpredictable events.

A major external characteristic of the more complex societies is that they construct things, or modify their environments. The elaborate air-conditioned castles of some termites, the path systems of feral house cats, and the patterns of singing at dawn among birds of ephemeral or coarse-grain habitats, all are "structures" created by animals.

Cooperation and competition are major aspects of animal social behaviour. Social facilitation, as when yawning spreads through a pride of lions or chickens eat more rapidly together, shows that cooperative competition can be social. Social animals, which live close together, often interfere and fight more with each other, especially in early stages, than do solitary ones. A fair percentage of the communication between social animals involves "agonistic" or threat–submission behaviour. If this behaviour results in a more adaptive dispersion of the animals, it has been altruistic. Grouped goldfish and other animals survive heat, cold, metallic ions, and other "pollution" better than do isolated animals; but if too many animals aggregate, they pollute each other. Social groups therefore have an optimum size and density, based upon an equilibrium between advantages and disadvantages.

Linking the internal and external characteristics of social systems are flows of energy and materials. Social systems use energy in building structures, or information-rich systems. Physically, one can measure the success of a social system by how efficiently and extensively it uses energy and materials and converts them to physical, biological, or cultural structures. Success in the short run can lead to disaster in the long run, as when elephants or humans destroy an African forest and then must starve or emigrate. Energy and material flows involve an interspecific web, the ecosystem, and must be measured over the long run and in general as well as locally or in the short run.

Social behaviour, therefore, must include interactions between different kinds of animals. A flock of sandpipers in flight is not less social if it includes two species rather than one. If species cooperate, a flock of two species can even be more social than a flock of one species. At African waterholes, baboons keep the lookout while associated antelope are good at scenting predators. Symbiosis is social, even though the late biologist Traian Savesculu of Romania was half right when he joked "Symbiosis is like marriage—a mutual exploitation." Like all social organizations, it is both cooperative and competitive.

Social behaviour may thus be defined as "more or less diverse and constructive interactions among two or more animals." Social behaviour is usually constructive, productive, and adaptive; but it sometimes persists for a time after the evolutionary basis for it is gone. For instance, many kinds of hawks in the eastern United States have almost disappeared, but the flocks of small birds that were formerly their prey still form as vigilante groups.

(E.O.W./Ed.)

COMMUNICATION AS A SOCIAL PROCESS

Social behaviour commonly includes communication, which may be defined as the sending of a message through a medium to a receiver so as to change the status and perhaps the behaviour of the receiver. In general, communication is employed by animals to attract or repel other individuals of particular groups and to establish and maintain distinct forms of social organization that range from relatively simple pair and family bonds to the highly structured troops of some primates and the complex colonies of social insects.

Sources of information

The information involved in animal communication can come from many sources; any facet of the environment perceived is considered information. In linguistic communication the primary function of words is to convey information. Similarly, animals (including man) have modes of behaviour that, in the course of evolution, were selected for their value in providing vehicles for conveying information. During the evolutionary process some of these vehicles also retained more direct functions, but many became specialized for a communicative function alone. These communicative acts, known as displays, include various posturings and movements; sounds; particular ways of making contact among individuals; the release of specialized chemicals called pheromones; and even electrical discharges. Displays have been studied as important means for transmitting information in animal communication. There are, of course, other information sources in animals, some of which have also undergone evolutionary specialization toward a communication function. Among them are what may be called badges—*i.e.,* attributes that are merely structural and nonbehavioral in nature: the red breast of the robin, the red underside of the breeding male stickleback fish, and the mane of the male lion. Many other sources of information can be found in the repeated forms of interaction that develop during prolonged relationships between two individuals and in individual expectations about the nature of the roles in which they encounter others, both familiar associates and strangers. The activities of individuals who interact socially provide a constant and usually rich information source, but, in the study of nonhuman communication, the bulk of systematic research thus far has been directed toward displays and badges; it is, therefore, these highly specialized categories that are of the greatest concern here.

The functions of communication. Because the complexity of social interactions makes experimental manipulation difficult, human understanding of the role of signalling in the social life of animals remains largely based upon inference. It is difficult to repeat an example many times with rigid control of all variables except the one being investigated, and attempts to structure the testing situation to simplify the form of interaction often obviate the interaction. Displays are universal among animals of any degree of structural complexity, however, so that they would not have been evolved and retained if they lacked important functions. But the function of a display is likely to differ, depending upon the individuals involved. A small bird seeing an approaching hawk, for example, may utter a vocal display indicating the high probability that it (the communicator) is, or soon will be, engaged in an attempt to escape. Other small birds, upon hearing this vocalization, may seek cover immediately. Hence, the function of the vocalization is to give them a better opportunity to remain alive and not to increase the immediate chances of survival of the communicator—indeed, its chances for survival may slightly decrease. The display functions for the communicator in that it protects individuals whose continued existence provides a benefit to him greater than the cost of using the display. These individuals may be his offspring or associates whose similar responses to the environment will provide him future protection and, through their alertness in the future, make it possible for him to spend less time scanning his surroundings for predators.

From the ways and circumstances in which displays are used and from the apparent responses of recipients, it is possible to enumerate the general functions of animal communication. First, displays guide animals to one another, thereby enabling one to advertise its presence and behavioral predispositions to potential recipients. Displays enable individuals in a group to respond selectively to particular associates at appropriate times.

Selection of information

Second, communication permits animals to identify one another. Individuals can thus select information of importance to them—usually from members of their own species and often particular individuals. Special cases exist, however; members of different species that normally coexist in the same environment may attend each other's signal. Thus, the maximum alarm communicated by one songbird when it discovers a falcon or accipitrine hawk in its environment is attended by all other songbirds species in the area. In addition, by facilitating identification, communication acts at a premating level to help maintain reproductive isolation among species.

Third, communication reduces the amount of actual fighting and fleeing among animals, an excess of which could disrupt social encounters. In functionally aggressive encounters, such as territorial or dominance disputes, this reduction is achieved by threat displays that often lead to some form of capitulation by one opponent before fighting occurs. In less aggressive circumstances, communication enables animals to appease and reassure one another that each is not likely to be initially aggressive in his present state. Fourth, communication aids in synchronizing the behaviour of individuals who must come into appropriate physiological states in order to breed. This is necessary within pairs and, in some species, among whole colonies of pairs.

Fifth, displays enable individuals to use each other to monitor the environment, not only on a relatively long-term basis but also on a very immediate basis. Thus, in species that spend much of their time living in compact social groups, such as flocks, coteries, or troops, an indication by any one individual that it is fleeing precipitously—often a vocal display in addition to the flight itself—usually correlates with the presence of a dangerous predator and leads to evasion, hiding, or alertness on the part of the other members of the group.

Finally, communication facilitates the maintenance of special relationships between individuals by making available information about the readiness of each to engage in certain activities. The maintenance of individual relationships in cohesive groups is furthered by communication, which keeps members aware both of the behaviour of associates whom they may not be able to see and of the readiness of associates to change their activities. For example, vocal displays usually precede flight by a member of a resting family of geese, and the family then tends to depart as a unit. Within some types of relationship, display behaviour also aids in eliciting general classes of responses; for example, offspring usually signal to arouse various forms of care-giving behaviour from their parents.

The functions in which communication appears to be used vary considerably among different species; each has specialized features, some quite remarkable. It has been demonstrated, for example, that vocalizations and other sounds made during hatching by chicken-like birds (*i.e.*, members of the order Galliformes) influence the rate of hatching of sibling chicks, so that all members of the brood can leave the nest simultaneously. It has been suggested that birds migrating in flocks may use signals in order to inform each other of their position in the night sky, so that the individuals in the flock can perhaps compensate for small individual navigational errors.

Dialectal differences in birdsongs

One interesting aspect of birdsong is the occurrence of dialectal differences (regional variations) among populations of a single species living in different areas. Several such changes that are known to occur between adjacent populations of the South American rufous-collared sparrow (*Zonotrichia capensis*) correlate with relatively major habitat changes. Very few dialectal changes occur over an enormous range on the Argentine pampas, but in this case the habitat of the species also changes little. The habitat changes markedly in the Andes mountains over short distances, however, as elevation rapidly increases, and, concurrently, many more dialectal changes occur there in birds' songs. The suggested function of the correlations between display and features of the habitat is that they provide markers that identify populations adapted to different local conditions; such markers would permit more appropriate selection of mates than would otherwise occur, at least in the marginal areas between populations. It has been suggested that a similar functional explanation may be involved in the evolution of human dialects.

Signals have evolved, the primary function of which lies in communication between, rather than within, species—particularly in cases in which identifying markings or displays of dangerous or distasteful animals provide information to potential predators or in those in which innocuous species mimic the signals. Other species, such as some forest falcons (*Micrastur*) of the New World tropics, apparently employ vocalizations as a kind of lure to attract prey species for capture; in this case the information is of use only to the individual providing it. An American ethologist, Martin Moynihan, has shown that elaborately specialized means of communication have evolved in bird species that join to form large mixed foraging flocks. These signals attract individuals to the flocks and help to maintain the cohesiveness of the assemblages as they move through the trees.

Modes of information transfer. The evolution of animal behaviour and structures toward a communication function has yielded a mode of communication adapted for each externally oriented sensory receptor system—*e.g.*, organs of vision, hearing, and taste. Each mode, although specialized, has limitations with respect to such properties as energy utilization; the ability to surmount environmental obstacles; the ease with which the source of the communication can be located; the persistence or transitoriness of the signal; and the available range of physical complexity. These differences have been exploited during evolution.

Sound. Because sound disseminates and fades rapidly, a given unit of information does not remain to interfere with, or garble, succeeding units. In addition, sound can be varied with regard to pitch, clarity or harshness, duration, loudness, and rate of repetition, with each variable providing greater range of ability to encode. One advantage of sound as a medium of communication is that vocal displays can be uttered by animals who need to keep their appendages free for other activities and can be received by individuals who need not face the communicator in order to receive the signals.

Location of sound

It is usually a simple matter for an animal with two ears to locate the source of a sound, although some modifications (described below) can help to conceal the location of the transmitter from potential dangers. Virtually all of the animals for which sound is important are bilaterally symmetrical and hence have paired hearing organs. Sound is a superb means of encoding information that must pass around environmental obstacles, such as trees or other vegetation. Apparently, some animals utilize frequencies that are particularly good at bypassing obstacles; this appears to be the case at least in the vocalizations of forest birds. Because the highest frequencies are obstructed in the forest and attenuated relatively rapidly by wind and air in open habitats, they apparently are not selected for use in the communication of at least the majority of vertebrate species.

The most obvious examples of the use of sound in displays are the vocalizations characteristic of most of the better known air-breathing vertebrates (*i.e.*, reptiles, birds, and mammals). Many nonvocal means of producing audible displays exist, although none match the potential for elaboration found in vocalizations. Many invertebrates produce sounds by rubbing one body part against another (stridulation); this technique is also used by fishes and is, in some ways, comparable to the chest beating done by the male gorilla (*Gorilla gorilla*). Gorillas also beat upon the ground and upon other objects in their environments; alarmed beavers slap the surface of water with their broad tails. Some vertebrates have elaborated on this sort of behaviour. Many woodpecker species, for instance, seek out certain dead limbs or even the tin roofs of buildings on which to produce their drumming displays. The North American ruffed grouse (*Bonasa umbellus*) produces a sound like the beating of a low drum by beating air toward its chest with its broad wings. Many other birds use specialized wing or tail feathers to produce sounds during display flights—such as the "winnowing" flight of snipe.

Other forms of vibrational signalling

Some forms of vibrational signalling are not perceived as sound, at least not by the relevant participants. Thus, although the sounds employed during the social interactions of honeybees are audible to man, it is likely that the bees perceive them primarily as vibrations through receptors in their feet. Some other displays of this type are not audible to man. Males of some web-building spiders, for example, approach females for mating very cautiously, signalling their presence and identity by strumming on the females' webs.

Vision. Visibly encoded information provides for much easier pinpointing of source than either sound or chemical signals, although visible displays are also much more easily obscured by structures in the environment. Ease of locating the source of a signal is often extremely important as, in a gull colony, for example, in which a large number of individuals are present in small space and it is important for the recipient to identify the individual that is displaying. The sight of the communicator also provides information about his orientation and so functions (like the human signal of pointing) in selection of a relevant recipient. To avoid the problem of being obscured by the environment the communicator is often able to select a display position that makes him more easily seen by the most relevant recipients. When the latter are at a distance, for example, the communicator is likely to display from a highly placed station, or, in the case of many grassland bird species that have no high perches available, to perform a flight display above the vegetation. Visible displays in many species of social birds and in at least some primates (such as baboons) are often combined into relatively complex assortments that are thought to convey unusually precise information.

Unlike sounds, which are usually very transient and can be difficult to maintain, visible posturings can sometimes be maintained with relative ease, although they usually interfere with the communicator's ability to engage in other forms of behaviour. Many animals have surmounted this problem by the evolution of badges—morphological specializations, such as bright patches of skin, fur, or feathers; horns; casques; and crests. Badges convey information about the general identity of the communicator (*i.e.,* species, sex, age) and some information about his physiological state. Animals have also evolved ways to utilize sources of information that supplement displays and badges. Some species provide information of some highly relevant samples of the environment; the honeybee, for example, uses a drop of nectar in the dance at the hive to indicate the identity of the food source. Courting males of many bird species feed their mates or provide them with bits of nest material. Unmated male weaver birds make nests at which they display and which are subsequently used for breeding; male bower birds build "bowers" (a variety of display structures), and male manakins clear leks (special display arenas) that serve only a communicative function. The use of constructions in some cases extends to supplying information in the absence of the communicator, as in territorial marking. Rabbits and other mammals use dung heaps (both visible and scented) for this purpose, and bears scratch marking posts.

Despite their flexibility, visible means of signalling have disadvantages in addition to being easily obscured. They may be too easily located, drawing undesirable attention of predators and other inappropriate recipients to the communicator. Moreover, the signals are available only if the recipient looks at the source directly; this hinders his freedom to do other things simultaneously.

Chemicals. Many species have evolved special chemical products that are released under particular circumstances. Some of these substances are used as defense mechanisms against predators; they apparently function primarily by being distasteful or even injurious, but some may serve to warn the predator that its intended prey can harm it, thus eliminating the need for actual contact. A variety of chemicals called pheromones are used for communication within a species. Fishes and other aquatic animals secrete certain pheromones into the water; moths release pheromones as sexual attractants into the air to be wafted downwind; and various highly social insects mark surfaces with pheromones or spray them into the air, sometimes secreting them onto their own body surfaces so that chemicals can be directly tasted by other individuals. Scents are used by many species to mark territories, as in the well-known urination patterns of domestic dogs.

The role of pheromones

Much research has been done on the use of pheromones by species of ants. It has been found that, depending on circumstances, different pheromones are secreted from different glands; for example, one type is secreted when the ants are laying trails, another when they are indicating alarm. The rate of release and the response thresholds of the different pheromones have been adjusted during the course of evolution so that the fading time of the odour correlates with the functions performed. Alarm pheromones, for example, which cause the ants to congregate,

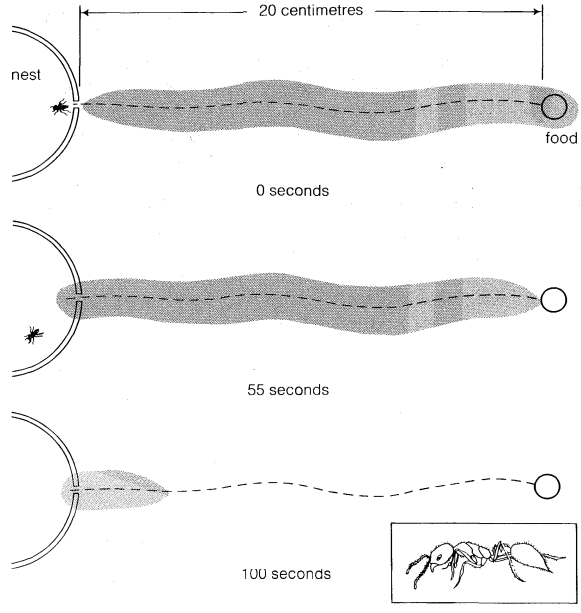

Figure 29: Odour trail of fire ant worker made by exuding a pheromone along its extended sting(s). This experimental situation demonstrates the rate of disappearance and active space of the trail.

diffuse very rapidly and fade quickly, unless continuously renewed by additional secretion from newly attracted individuals who also take alarm. Pheromones used for group identification and for simple assembly (in the absence of alarm), fade much more slowly. Even though pheromones are less persistent than certain structures used for marking, they are used primarily for their persistence—at least in the case of species that have other means of communication available. Extremely rapid fading of the odour is a problem, however, as is the recovery rate of the recipient's chemoreceptors. Pheromones are probably an inadequate means of communication in social events that change rapidly.

Touch. Specialized patterns of touching—*i.e.,* tactile displays—are often overlooked in studies of animal communication unless they involve distinctive movements. Although a recipient animal may be aware of a distinctive touch, an observer may not; nonetheless, many forms of touch are evident. The remarkable dances of honeybees are customarily performed on a vertical comb in the darkness of the hive. Recipients of these displays follow the communicators closely, maintaining contact with their antennae; thus, much of the information is probably received as changing tactile patterns.

Grooming

In many mammalian species, the members of social groups engage in bouts of grooming (called allogrooming when performed on another individual). Although visible to group members other than those in the interaction, allogrooming probably functions largely as a tactile display. Specialized touches with the hands are now suspected to be precopulatory signals in female rhesus monkeys (*Macaca mulatta*). Individuals of the South American monkey

Callicebus moloch rest together in trees with their tails intertwined, a tactile display that probably serves a function similar to that served by allogrooming in social groups of baboons and macaques.

In some cases the communicator leaves information available for individuals it will never meet. Female wasps of at least one species are able to indicate to their offspring the direction in which to seek egress from the cells in which the eggs are laid. The information is stored in the geometry and texture of the walls constructed by the females to seal the nest chambers.

Electrical energy. A number of fishes that live in muddy waters produce regular patterns of electrical discharges as an active sensory system (active in the same sense as a bat's sonar scanning of the environment). There is good evidence that some species respond to electrical discharges of individuals of the same species, and that some aspects of the discharges, including their cessation, may function as displays.

The role of displays. *The display repertoire.* The individual animal may have a repertoire of up to about 40 displays. For most relatively social adult fishes, birds, and mammals, the range of repertoire size for different species varies from 15 to 35 displays. Further, most species have evolved displays adapted for the different sensory modality of their recipients; as a result, their repertoires comprise sets of displays (*e.g.,* both visual and audible) that overlap considerably in the information they convey. A bird can often convey information about the probability of flying by fluttering its wings and by uttering a particular call and may often do both simultaneously. Recipients sometimes are able both to see and to hear the communicator; at other times, however, he may be obscured behind foliage, or, if visible, the sounds may be masked or distorted by wind noise or by the calls of other birds. The redundancy typical of communication systems probably exists primarily to facilitate information transfer in such noisy environments that may unpredictably interfere with any one form of transmission.

Limitations to the number of displays

In view of the immense value of language to man, it is remarkable that evolutionary pressures have not produced a greater elaboration of communication in animals other than man. This implies that further elaboration would impair rather than facilitate communication. Although the nature of this impairment is still a matter of theoretical conjecture, a promising explanation is that of Moynihan, who argues, in part, that it is difficult for a species to evolve the ability to make rapid and finely tuned responses to rare events. Rapid escape from a surprising stimulus (a relatively rare event) has frequently evolved but it is not a finely tuned response. As the size of a display repertoire increases, appropriate circumstances for the use of certain displays would become increasingly rare; Moynihan proposes that the number of displays in an animal's repertoire should not exceed that at which its rarer displays have little usefulness. This number of displays cannot yet be predicted. Other factors also act to limit the number of displays. Among them is the need for each display to be sufficiently distinctive to make it unlikely that a recipient will mistake it for another. Beyond some point, as repertoire size increases distinctiveness requires increasingly elaborate displays that may be time-consuming to produce and require too much attention by the recipient.

The restriction in the size of the display repertoire undoubtedly has had considerable influence on the evolutionary selection of the kinds of information that are encoded. An American zoologist, W.J. Smith, has suggested that this restriction explains two striking characteristics of displays: the paucity of narrowly precise messages and the relative abundance and widespread occurrence of information about such general behavioral patterns as locomotion or social association. Each species has so few displays available to it that only a minimal number can be used in restricted situations. When practical, a display has selective advantages if it conveys information that can be of use in mediating a variety of social interactions. Some types of activities, such as attack and escape, are too critically important in most species to be indicated by ambiguous signals. Others, including many of the acts that bonded (*e.g.,* paired) individuals can perform in each other's company without endangering the fabric of social organization, may be safely left for a recipient to predict based on its experience in similar contexts, provided it has the information that the only likely activities are bond-limited ones. There is strong selection pressure toward both the use of general messages (in situations in which immediacy of correct response is not of overriding importance) and similar messages (for species with a wide overlap of social habits).

The information content of displays. The study of animal displays was once primarily concerned with the motivational states of the animals using the displays. It was recognized that, if an animal uses a display only when in a certain motivational state, then the display informs a recipient that the communicator is in that state; the recipient thus should be able to predict, at least in part, the subsequent activities of the communicator. Because only certain aspects of the communicator's motivational state are common to all uses of a given display, however, these aspects are the only ones that can be said to be encoded in the display. Thus, a recipient must obtain other information in order to establish the presence of other motivational aspects. It is more useful, therefore, to study the behaviour (rather than the motivation) of communicating animals in order to correlate specific behaviour patterns with specific displays. Because communication is a social process, the most productive course of study concerns the nature of the information that can be inserted into social interactions by displays. This information helps to determine the course of the interaction and is concerned primarily with making the behaviour of the interactants more predictable.

Identification

It is important for the recipient to be able to identify the communicator with some degree of precision; if he identifies himself, through displays or some other means, as belonging to a category of individuals important to the recipient, the latter will pay attention to him, insofar as is practical or necessary. Of prime importance is specific identity; the most important communication occurs among members of the same species. Thus, most of the flow of communication among members of other species is irrelevant. Within a species it may be useful for the recipient to know the sex and perhaps the age of the communicator; even the general physiological state (*e.g.,* breeding or nonbreeding condition) may be significant. All of this information, successfully communicated, narrows the range of behaviour that can be expected by the recipient of a display. For bird and mammal species with complex social behaviour, some features of the form of a display may be peculiar to the individual. A female passerine bird (a perching bird) newly arrived from spring migration to the region where she will breed encounters many individuals of several different species. By using certain vocalizations (usually called song), some of the birds identify themselves as males of her species and also communicate to her that they are in breeding condition and probably the information that they are unmated. This information enables the female to predict their responses to any approaches she might make to them. Also, after she begins to form a pair bond with a male, she must be able to identify him.

All displays studied thus far identify the communicator to some degree. The amount or kind of identifying information differs according to the social requirements of the species.

As already noted, identification is not only encoded by animals in displays but also in badges. The strikingly distinctive breeding season plumages of drake waterfowl and of males of many other bird species attest to this. Female birds of many species are less distinctively coloured and it is usually they, not the males, who select a mate; male birds of such species apparently accept any female who attempts to form a bond, but females respond only to males with the correct plumage. The evolution of unusual specializations apparently has been necessary in only a few cases. Gulls, for instance, are able to distinguish species by a combination of eye colour and its degree of contrast with the white head.

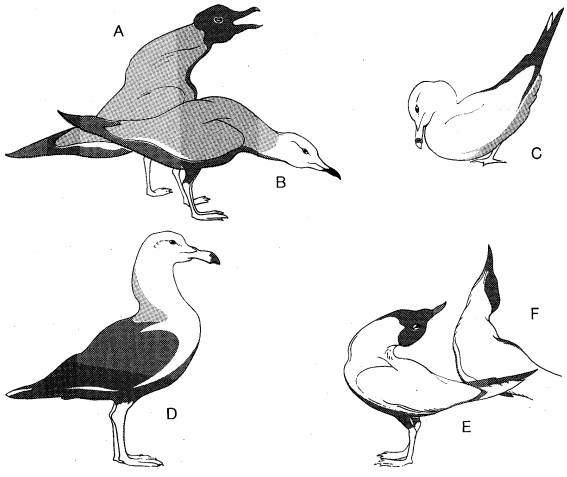

Figure 30: *Visual communication in birds: some display postures that are widely distributed among gulls and terns.* (A) Oblique posture during long call display of the Galápagos dusky gull (*Larus fuliginosus*). Location

Closely related in many ways to information concerning identification is information specifying location. An animal may need to transmit its message without fully revealing its location. It may, for example, use a visible display to a nearby recipient while otherwise concealed by vegetation from potential and undesirable recipients that would perceive vocal displays. In some cases, however, animals provide information about their location in proportion to the need of the recipients. A small bird on fleeing from a hawk, for example, may utter a high-pitched warning vocalization that carries little information about its own location. Natural selection has favoured characteristics of this vocalization that make its source difficult for a two-eared predator to locate. Many small birds hear the sound and are warned that one of their associates has found desperate reason to flee; they need not know his exact location or even why he is fleeing. The hawk, who needs primarily the location information, is denied it, largely since he is unable to locate the source of the vocalization and often has not yet seen the fleeing communicator. It is significant that the begging vocalizations of many nestling birds are similar to the warning call; the reason also is similar—to prevent predators from discovering the location of the nest, which the nestlings' parents, of course, already know.

In certain cases a vocalization can vary in ways that increase or decrease its locatability. One example, which has been studied in detail, is the call given by males of the Panamanian frog *Engystomops pustulosus* as they await females at spawning ponds. The call of a lone male contains fewer clues to his location than does the call of a male in a chorus of other males. The former probably can rely on the persistence of any passing female to find him, but, because he is alone he is more vulnerable to predators and so must give as little information as possible about his location. On the other hand, the male within a group gets some protection from predators by virtue of being among other frogs; not only is the approaching predator likely to encounter one of the other frogs first but, collectively, they are more likely to detect the predator. After the chorus has attracted a female to the immediate region, however, any male that is less easily located than his fellows is at a disadvantage; under these circumstances each male maximizes the ease with which he can be located.

Behavioral information

Much of the remainder of the information encoded by animals in their stylized displays is behavioral—it indicates the likelihood with which a recipient can expect a communicator to engage in different types of activities.

The bared teeth, growls, curled lip, and bristled hair of a watchdog at the approach of a stranger indicate that the animal may attack. The same display components may also indicate that it may not attack, that something, perhaps fear, is holding its aggression in check, however tenuously. Much of the displaying done by animals seems to indicate the probability of attack or escape. Such agonistic behaviour patterns must be controlled in the establishment and maintenance of organized social units such as pairs, families, and troops. A species may encode information about antagonistic behaviour in more than one display. The green-backed sparrow (*Arremonops conirostris*), for example, uses a vocalization that sounds like "chuck" when it is less likely to attack than to escape, but, when both attack and escape are equally probable, it utters either of two calls, which Moynihan has described as "medium hoarse notes" or "hoarse screams." Although the last two vocal displays indicate equal probabilities of the two acts, they do not carry exactly the same information. The "hoarse screams" are used when attack or escape is very likely to happen, and the "medium hoarse notes" are used when the bird's indecision between the two alternatives makes it less likely that either will occur. The two displays thus carry information not only about attack and escape behaviour but also about the probability that some act will occur. In fact, information about the probability of a specific act is apparently encoded in all displays, but not always in the way described above. The eastern kingbird (*Tyrannus tyrannus*) encodes the information that it may attack in a vocalization with a sound similar to "zeer." The likelihood that it may attack when using this call varies, increasing as the abruptness and harshness of the vocalization increases.

Of the information widely encoded among diverse animals in displays, little is apparently as narrowly defined as attack and escape signals. Although the encoding of information regarding attempts by a communicator to engage in social play would seem useful in view of the fact that many mammals (and even some birds such as the hobby falcon, *Falco subbuteo*) play socially, information that an approaching communicator is not likely to be vicious but intends only to play is apparently encoded only by a few primates.

Adults of many vertebrate species appear to lack common reasons for coming into contact with their fellows other than aggressively. Many animals thus have difficulty in approaching one another closely enough to copulate. The displays of only a few species provide information that an individual is approaching specifically to copulate; in fact, the general information provided by the individual in other displays apparently is often sufficient, given the right contextual circumstances, to indicate the intention to copulate. So far as is known, the information provided by most birds and mammals through their displays is in large part of a general nature.

The importance of general information

In many birds and mammals, approach in order to copulate is restricted to individuals who have established a pair bond. In this relationship each partner adopts, and recognizes as appropriate in the other, behaviour patterns that characterize certain roles, special restrictions, and special privileges. Such behaviour patterns are regular in occurrence and apparently expected to some degree by each individual. The complexity of this behaviour varies considerably among species with different degrees of social complexity—*i.e.,* the individuals may be merely temporarily mated or permanent members of a troop of numerous individuals—but the appropriate behaviour will, for some relationships, include the possibility of copulation. Many species employ at such times displays that are used in a variety of behaviour characteristic of closely interacting, bonded individuals. These displays indicate that the communicator will probably select behaviour patterns appropriate to the bonded relationship, without specifying what the behaviour will be.

The somewhat more precise information that may be available among bonded individuals usually appears to specify that appropriate behaviour will not involve physical contact. In these circumstances, the communicator simply associates with the other individual, remaining

in his presence but doing nothing that requires bodily contact. Such information about association is apparently basic and is encoded by many species, at least of birds and mammals. A superficially similar sort of information that may also be widespread indicates that the communicator will engage in a variety of activities, from social encounters to nonsocial acts of individual maintenance (*e.g.*, foraging), but will neither attack nor attempt to escape from the individuals to whom the display is directed. He will thus behave nonagonistically.

Drawing by J. Adamska-Koperska based on M.H. Moynihan, *Journal of Zoology* (1966)

Figure 31: Tactile communication; tail-twining by titi monkeys *Callicebus moloch.*

General information that has been identified in displays of three mammalian species (gorilla, man, and the black-tailed prairie dog) appears to be so basic that it, too, may be widespread among social vertebrates. The communicator provides information that he will probably hesitate to engage in a certain social interaction. This information is usually provided when the communicator is engaged in an activity that would be hampered by interruption. How widespread this sort of information is among animals is not known.

Other kinds of general information known to be widely encoded are less directly social in nature. The best understood information involves the probability that the communicator will engage in some form of locomotion. One kind of display may be used when an unmated male bird moves from point to point along the boundaries of his territory, occasionally stopping to advertise. The same display may be used by a mated male as he approaches his rather aggressive and perhaps sexually unreceptive mate. It may also be used by either mate on approaching a predator near its nest, or later by the nearly independent fledglings when importuning increasingly unwilling parents. Nor does this exhaust the range of situations in which this one display is used. In all cases the display fails to indicate with any precision just what the communicator's probable activities will be, but it is well correlated with a behavioral indication of uncertainty over whether the communicator will initiate or cease flying, or change direction if in flight. In any case the activities of the communicator indicate what it may attempt to do, and the display appears to provide information as to whether or not this apparently probable behaviour will be performed. The information the communicator thus provides indirectly implies that there are factors acting to counter his obvious motivational tendencies, these implications have different social relevance in different circumstances.

Displays are also known that encode even more general information—exactly how general is not yet clear, but the following example is illustrative. The blacktailed prairie dog (*Cynomys ludovicianus*) has a combined visual and vocal display in which the communicator throws its foreparts vigorously into the air, directs its nose straight up, and utters an abrupt, two-part vocalization; the performance has been named the Jump-Yip. Jump-Yips are employed on many occasions, all of which have in common a certain probability (usually less than 50 percent) that the communicator will begin or continue to flee. Other forms of behaviour associated with the Jump-Yip differ greatly, depending on the circumstances; for instance, the communicator may greet or associate with its mate or another individual (such as a member of its family group); approach its mate sexually; challenge a neighbour aggressively; or do one of various nonsocial acts such as foraging or dust bathing. The display seems to function either as an indication that some form of behaviour may be interrupted or prevented by fleeing but that this other behaviour may be socially more important than the fleeing; or that the other behaviour may be negligible and the possibility of flight itself the critical feature of the situation for the particular recipient. The display is not used unless there is an alternative to flight, but it does not provide information about what that alternative is. Such information is usually clear enough contextually, however, The unspecified alternative might be anything in a prairie dog's behavioral repertoire. Jump-Yip

Of widespread occurrence in the displays of birds and mammals is information that the communicator, however strongly motivated to perform a particular act, lacks the opportunity to do so. Thus, when, in a social encounter, a juvenile gorilla tries to flee but finds itself cornered, it adopts a special posture indicative of its frustrated escape. An eastern kingbird or a black-headed gull (*Larus ridibundus*) performs a very stylized and spectacular aerial display when it is strongly motivated to attack but lacks a suitable opponent—such as an intruder into its territory. A Carolina chickadee (*Parus carolinensis*) that appears to be seeking a border encounter with a territorial neighbour employs a special form of song if the neighbour fails to appear in response to its challenges. Various songbirds of the New World tropics have vocal displays that are used only when one bird becomes separated from the companions with which it associates while foraging; the calls cease after reunion occurs. In short, it appears that if an animal is frustrated from engaging in activities of sufficient social importance to merit communication, it may be able to encode its frustration with respect to that activity.

The foregoing describes the types of basic information presently known to be widespread among adult birds and non-human mammals. Other types of information are known to be encoded by other animals: ants provide directional information in odour trails, honeybees in "dances." The fire ant (*Solenopsis*) odour trail appears to indicate specifically the route to a food source, but the honeybee dance is less specific—it can be used to provide information about food sources, water sources, and potential sites for new hives. Both cases reflect the evolution of communication within complex social organizations of invertebrates, based on evolutionary properties quite different from those of vertebrates.

Even among vertebrates, some systems of social organization differ markedly from those of most of the birds and mammals whose communication patterns have been studied. Among nocturnal frogs, for instance, breeding males congregate loosely and call to attract females. They attempt to mate with any individual that comes near them—whether it be a male or a female. A male or a female who has already laid her eggs usually utters a

distinctive call and is released; the encoded information appears to be that the individual that has been clasped does not belong to the class that will shortly lay eggs (*i.e.*, gravid females), a rather precise but entirely suitable sort of information. Precision in such narrowly specific messages may well be the rule in groups in which complexity of social behaviour is minimal.

Information needs of young

Immature animals dependent on adults often have social requirements quite different from those of adults and provide, in part, different information, although they too may have displays encoding attack, escape, and frustration information. At least among infant mammals, much displaying is done to indicate a need state—such as hunger, pain, need for social interaction—for which the infant must depend on others. Some displays do not specify the needs that are relevant—the most common forms of human crying, for instance, are rather imprecise. Others, such as the widely gaping mouth of a juvenile passerine bird, appear to correlate primarily with readiness to eat. Infants, because of their often limited behavioral repertoires, are somewhat difficult subjects for behavioral studies of the kind normally employed by students of animal communication. They provide an important challenge, however, as attempts are made to learn both what they encode in their displays and how this information is altered during development into adult forms of encoding.

Interpretation of information. The information exchanged during social interactions among animals allows them to select their subsequent activities with greater certainty that their actions will be more appropriate than would be possible without the new information. When an animal is offered information through a display, it can select a response that is based, in part, upon this information. Depending upon the abundance and the type of information, the response must be such as to permit flexibility—*i.e.*, a generalized response may be practical. On the other hand, receipt of abundant and varied information permits the individual to choose among less generalized, and probably less flexible, responses with a greater certainty of making the appropriate selection. Complete understanding of animal communication, therefore, requires knowledge of the responses that individuals make to the information communicated. This is the study of what Colin Cherry has referred to as the "meanings" that recipients draw from the circumstances in which communication occurs.

The communication process between two animals is summarized in the following paragraphs. Through displays, badges, and other aspects of his appearance and activities, one individual adds information to another individual's environment, in which much information is already available. The human observer is certain that communication has occurred only when the second individual selects a response, demonstrating the meaning the event has had for him. Unfortunately, the study of responses in social situations is technically very difficult.

The recipient animal certainly ignores most of the many sources of information available and weighs others as he selects his response. In most instances, his response is not directly available to the human observer, for the recipient's mental state or disposition may change without an overt indication. For most displays the response observed most commonly is indistinguishable from that of inattention. When the recipient does alter his activity immediately after exposure to a signal, his first acts may be common to many different kinds of events—he may simply face the source of information, move a little closer to it, or a little farther away.

Initial response

The first response of a recipient to a variety of signals conveying many possible types of information about the communicator (including high probability of attack, intent to escape or to engage in association, social play, or copulation) may be to approach the communicator. The predisposition of the recipient to react further is likely to depend on the signal, and further activity may not occur until the recipient is supplied with further information.

Modified displays. Although the nature of displays and badges and of the types of information that animals encode in them is important in the process of animal communication, it provides only part of the story; for example, a display is a vehicle for a particular type of information transfer, but the communicator, in the manner of its displaying, can modify some aspects of this information. The probability of attack, as encoded in the vocal display of a bird species, can be ascertained by the abruptness or harshness of a vocalization. The intensity of the communicator's involvement in the situation can also be indicated by variations in the rate at which the vocalization is uttered, or in its loudness. Such modifications provide information about the nature of the expected attack—*i.e.*, whether it will be vigorous or perfunctory—and about the communicator's state with the passage of time.

The position of the communicator as it vocalizes may indicate a particular recipient as the most relevant in a given instance. There is little reason to conclude that the orientation of the communicator has become ritualized as a part of the display. Sometimes an intermediate orientation becomes part of a ritualized display, and orientation must very often provide important information.

It appears that the information obtained by most animals about situations in the environment is either associated with stylized displaying or is implied by it with fair probability. For instance, a bird that utters a call when it sights and then flees from a dangerous aerial predator is not specifying the presence of a hawk, even though it is likely that it has been frightened by a hawk; under some circumstances (*e.g.*, if the bird has nestlings) a predator normally less dangerous than a hawk, such as a cat, is responded to with the call usually given for hawks. The bird advertises its fear in the presence of different stimuli at different times. It does not specify what the stimuli are, but instead, what its probable response is or will be. Although a bird does not specify directly that it has a territory, it regularly indicates different degrees of readiness to behave aggressively to inappropriate individuals of (usually) its own species—and so defines a region, which can be labelled its territory, that it will protect from intrusions. A forager bee does not state that it has found food at a certain place; rather, she describes a direction of flight (perhaps a flight she is likely to make again shortly) and, on request, provides a sample of the food. On the other hand, an ant that lays an odour trail only between

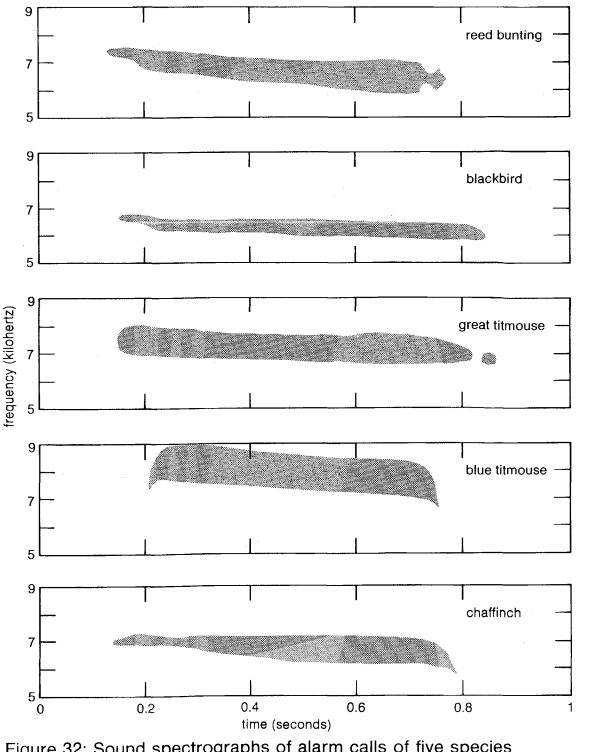

Figure 32: Sound spectrographs of alarm calls of five species of European songbirds showing similarity and broad frequency pattern. Each call is a single, simple, slightly descending note, lasting 0.6 to 0.8 second.

a food source and its home colony is providing information that food is present; such narrow specific use for a display, however, is the exception, at least among birds and mammals.

Evalution of communication. In the evolution of communication within a species, one normal constraint usually is that the exchange of information must be useful to both the communicator and the recipient. The behavioral patterns evolved by the communicator enable him to transmit information that increases the probability of a social response suited to his needs. A recipient evolves the tendency to respond to this information only when the response suits his needs, which often differ, at least superficially, from those of the communicator. When their needs are not compatible, lack of selection pressure for the recipient to respond appropriately usually removes any advantages for the communicator, or at best yields an evolutionarily unstable situation of misinforming, to which recipients are always counter-adapting. Yet, in certain relationships between individuals belonging to different species, particularly in predator–prey relations, selection pressures for providing misinformation are such that it is a widespread phenomenon. In Batesian mimicry, potential prey species advertise that they are actually unpalatable or dangerous to predators, which either learn to leave most of them unharmed or evolve avoidance responses. Other potential prey species, lacking defense mechanisms or unpalatability, may mimic the behavioral and morphological specializations of the unpalatable ones, thus surviving by providing predators with false information. The predators, of course, are under evolutionary pressure to develop means of distinguishing the true from the false information.

Evolutionary precursors of displays

The evolutionary process by which the transmission of information between members of the same species can become specialized has been studied by the pioneer European ethologists Konrad Lorenz and Nikolaas Tinbergen. They have established that displays are specialized activities that have evolved from precursors, or predecessors, of several types. Important among these are intention movements—*i.e.,* incomplete performances of acts, such as taking flight or turning away, which are usually performed by an animal not quite committed to a given course of action. Through the process of ritualization, components of some intention movements become exaggerated and divorced from their directly functional roles. The exaggeration is often evident in an increased conspicuousness (perhaps with the concurrent evolution of morphological badges, to which the display draws attention) or an increase in the conspicuousness of only some components, thus creating a difference between the display and its evolutionary precursor.

A second source of precursors in the evolution of displays lies in inconspicuous but complete movements, such as eyebrow-lowering movements that help protect the eyes; such movements have been incorporated into the facial expressions (frowning) of numerous primate species. Other movements, such as jabbing motions of attack, are ritualized by being aimed in a stiff and often repetitive fashion away from their customary targets; these are called redirected activities. Still other movements appear to be occurring outside their customary functional contexts, as if displaced. Called displacement activities, they remain perhaps the least understood, particularly since it is not always clear that they are as functionally irrelevant as they sometimes appear. Displays apparently derived from displacement activities often resemble the activities devoted to individual maintenance—self-grooming, feeding, and drinking. Such behaviour often occurs in close conjunction with other kinds of socially relevant activities and so is perhaps easily available for evolutionary specialization. Further, some maintenance activities, which are directly related to the physiological results of exertion (as when a bird ruffles its feathers to cool its body) and thus to active social encounters like chasing and fighting, are commonly exaggerated as components of display behaviour. Other autonomic (involuntary) responses, such as urination and defecation by thwarted or frightened mammals, may have been sources for the evolution of some marking displays.

The precursors of ritualization are more easily imagined for visible displays and perhaps tactile displays than they are for other forms, although there is no reason to believe that the evolutionary process is fundamentally different in any case. Chemical displaying seems highly specialized: the chemicals *per se* have in most cases probably originated from metabolic waste products, and the acts of releasing different chemicals (the displaying) may have evolved from precursors classifiable as individual maintenance activities or "autonomic responses." The evolutionary precursors of vocal displays are also conjectural, and many extant vocalizations undoubtedly arose from preexisting ones. Vocalizations must have arisen originally from some form of noisy, controlled breathing; Darwin's suggestion that the breathing patterns of terrified or sexually aroused animals would provide a source for specialization has not been bettered.

Evolutionary origin of vocalization

The evolutionary process of ritualization yields two somewhat distinctive classes of displays. As described above, much ritualization functions to yield a display distinctly different from the act from which it was derived. The act, perhaps a movement preparing a bird to take flight, remains in the behavioral repertoire of the species, serving its original functions, and, to be fully effective, the display must be distinguishable from it. There are, however, cases in which the form of the act is not altered, but its frequency of usage is in one of several ways. This is possible primarily in cases in which the evolutionary precursor is not maladaptive when done to excess (with respect to its original function). Cases in which increased frequency of performance occur are known primarily from social acts, whereas acts that are transformed in the process of ritualization may have social or nonsocial precursors. The best known example of ritualization through increased usage is what is known in mammals as allogrooming and in birds as allopreening—care given by one individual to the condition of the body surface of another individual. In highly social birds and mammals this occurs much more frequently than is necessary for cleansing of the fur or feathers, is done among animals that have bonded relationships, and is often expressed asymmetrically with respect to some feature of the social organization of a species—that is, in one species, subordinate individuals may groom dominant ones more than the former are groomed by the dominants, but in another species the reverse may be true. In addition to being a sanitary procedure, allogrooming apparently expresses the acceptance of bond-limited relationships by both the groomer and the groomed.

The evolutionary process of ritualization operates within a number of limits in addition to those imposed by the process of communication. Each species has a history, in which the origins of its attributes are, ultimately, products of genetic chance.

Closely related species evolve different solutions to the problems and opportunities of communication from those of more distantly related species. Each lineage has developed a working system based on the opportunities it has received, or, having failed to develop such a system, has become extinct. The products of ritualization are not ideal solutions to communication tasks; rather, they are practical ones. The similarities and differences of displays among species contain clues to phylogenetic relationships, although, like all other such clues, they are most safely used when their full functional significances are understood.

Nongenetic differences

By no means do all of the differences among the communication patterns of different species result from the different genetic peculiarities of the different lineages. Species differ in the nature of their social behaviour. Birds, for instance, may be paired through the nesting season and flock in the remainder of the year; be paired only briefly, followed by dispersal on individual territories; be paired for life (year round); or utilize various other types of social structure. The great range of patterns of social organization determines many things about the sorts of behavioral interactions occurring among individuals and, hence, the functions required of communication patterns. The form of social organization is likely to be set, in part, by characteristics of the species' habitat, and the habitat thus must indirectly influence the directions of ritualiza-

tion. Habitats also have a direct influence on ritualization of form, because they differ very much in the degree to which they obstruct information or mask it by noise. The environment of most species also contains other species, some of which communicate with similar displays, creating a need for specific distinctiveness in form.

A basic limitation exists in the nature of the sensory receptor organs available to different kinds of animals. Social insects make much use of chemical and tactile signalling, but visual signals are relatively more important to fishes and visual and auditory signals to birds. Among mammal groups there is considerable specialization, but on the whole mammals make considerable use of all sensory modalities in display behaviour.

(W.J.S./Ed.)

Types of animal societies

To understand social behaviour more fully, it is necessary to examine it throughout the range of animal life. W.C. Allee, in his classic book *The Social Life of Animals,* distinguishes two major types of animal societies. One is the parental, or familial, society, in which parent and offspring stay together for varying lengths of time. The other is the pair bond, or club, society, composed of individuals that come together from different families. This type was much emphasized by the 19th-century English philosopher Herbert Spencer because it corresponded to his social Darwinist ideas. The social Darwinist does not like to admit that a weak son can win out if he has powerful parents; but recent work with rhesus monkeys shows clearly that the son of a high-ranking mother tends to be protected by his mother and hence gets to the top of the hierarchy even if he himself is a weakling. Parental societies are very common.

PARENTAL SOCIETIES

Parental societies are found at all levels, from the cell to the monkey troupe. All animals provide for their young in some way. In every animal there is a period when the young is part of the parent and receives materials from the parent. Later, the young may partly or completely separate from the parent; in some animals, the more or less separate young is then helped by the parent, or helps it.

Parental behaviour among simple organisms. Even some of the simplest organisms show colonial aggregations of the parental type. Some viruses form inclusion bodies in the cells they attack; these bodies are thought to be colonies of daughter viral strands. Other viruses form ordered arrays.

Bacterial colonies

Bacteria, only a few steps up the evolutionary scale beyond viruses, also show parent–young colonies. Diplococci, which can cause pneumonia, are dot-shaped bacteria that have two daughter cells in each group. Streptococci form chains, and staphylococci arrange themselves in grapelike clusters. In all of these, and in a large number of other colonial bacteria, the offspring that are produced by a dividing parent generally stay together for some length of time.

Protozoa, a few steps beyond bacteria, also show parental sociality. Many reproduce by simple division and hence give the daughters help only before the split. Under difficult conditions, protozoans commonly form a protective "cyst" and divide within it. In such divided cysts 2, 4, 8, 16, 32, or even more daughter cells may associate until the cyst "hatches."

Some protozoans form definite colonies in addition to or in place of cysts. *Volvox* and many other slow-moving or sedentary colonial protozoans show differentiation or division of labour between cells of a colony. In *Volvox,* the forward cells have large eyespots and a few rear cells take care of reproduction (Figure 34, top).

Sponges and coelenterates

It is almost certain that sponges evolved from colonial flagellate protozoans. Sponges are integrated networks of cells, some of them amoeboid (amorphous) and some flagellate. It has been shown that if a sponge is strained through cloth so that the cells are separated, they will reunite and form new sponges so long as a flagellate collar cell can rejoin an amoeboid cell. The sponge is thus on the border between colonial organization and integrated multicellular organization (Figure 33, top). One advantage of integrated multicellular organization, with different types of cells performing different functions, was probably that the sponges could become much larger than the largest multinucleate or even colonial protozoans and thus could capture these protozoans. This type of organization also provides strength: some cells can hold on in swift currents, while some can secrete skeletons and others concentrate on food getting. Thus cooperation gave sponges and similar multicellular animals an advantage in competition with even the largest and most aggressive single-celled animals.

Douglas P. Wilson

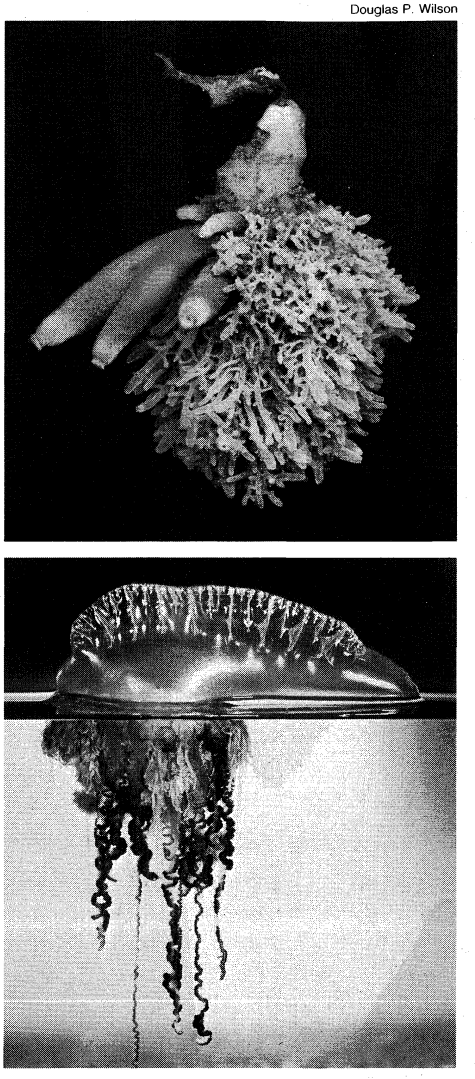

Figure 33: (Top) A colony of three species of sponges, approximately three-quarters life-size. At top of colony is small bread-crumb sponge (Halichondria); branching mass at right is *Leucosolenia complicata;* tubular sponges on left are *Scypha ciliatum.* (Bottom) Portuguese man-of-war (*Physalia physalis*), the body of which may be as much as 12 inches long.

The colonial organization of cells into protozoan colonies or into multicellular animals will be referred to below as the "colonial-1" stage (Figure 34, top), in contrast to the colonial organization of attached multicellular animals—the "colonial-2" stage. The colonial-2 stage is well developed in successful aquatic animals just above the sponges; the coelenterates (hydroids, jellyfishes or medusae, sea anemones). Coral reefs bear witness to the success of colonial-2 growth in other coelenterates (Figure 34, bottom). Many different types of free-swimming colonies, such as the dangerous fish-killing Portuguese man-of-war (*Physalia*), exhibit huge complexity on the colonial plan (Figure 33, bottom). In corals and other colonies, the original individual is linked to its offspring in a network. Food material and chemicals are often exchanged between

individuals over the tubes of this network. Often the different individuals in this network show division of labour. Sometimes, as in *Obelia,* there are only reproductive and feeding individuals. In *Physalia,* there are swimming individuals, stinging ones, and many others, including one that serves as a gas-filled float. The interdependence and communication in such a colony is so extensive that the colony seems almost to be an individual and is sometimes called a superorganism.

Despite the great success of sponges and coelenterates, the main line of evolution goes onward through colonial-1 animals. The link was probably wormlike animals somewhat like present-day flatworms. Most flatworms and higher worms show very little association between parents and young.

From flatworms to insects. The main line of evolution leading from flatworms to insects shows little parent–young cooperation or colonial development. The entoproct Bryozoa, or moss animals, form treelike colonies like those of corals and thus show type-2 coloniality; but it is not certain whether the Bryozoa actually belong to the line leading to insects. A few wheel worms or rotifers, such as the free-floating *Conochilus volvox,* form colonies. A few annelid worms, such as sybellid fan worms, bud off chains of individuals in a manner like the flatworm *Catenula.* This is a common method of breeding in some annelids; the special rear "worm," or "epitoke," breaks off and swims to the surface, where it releases sperm or eggs and dies, often in huge swarms of epitokes as in the Samoan palolo worm (*Palola siciliensis*).

Typically such worms as roundworms and earthworms strew their eggs about or attach them to something as soon as they are fertilized or brood the eggs only briefly. A few nemertine worms are viviparous—*i.e.,* they produce live young. The annelid worm *Ctenodrilus* is said to be truly viviparous, the nutrition of the young coming via maternal blood vessels. Most mollusks take little care of their young. One chiton, *Callistochiton viviparus,* gives birth to young that have undergone development in the ovary. In a few bivalves such as the European oyster (*Ostrea edulis*), the eggs develop in the gill filaments. Most squids release single eggs or chains of eggs, but some members of the octopus group stay near their eggs and remove debris from them. The paper nautilus, *Argonauta,* forms a paper nautilus shell and the mother takes care of her eggs in it. At times the male hides in the shell.

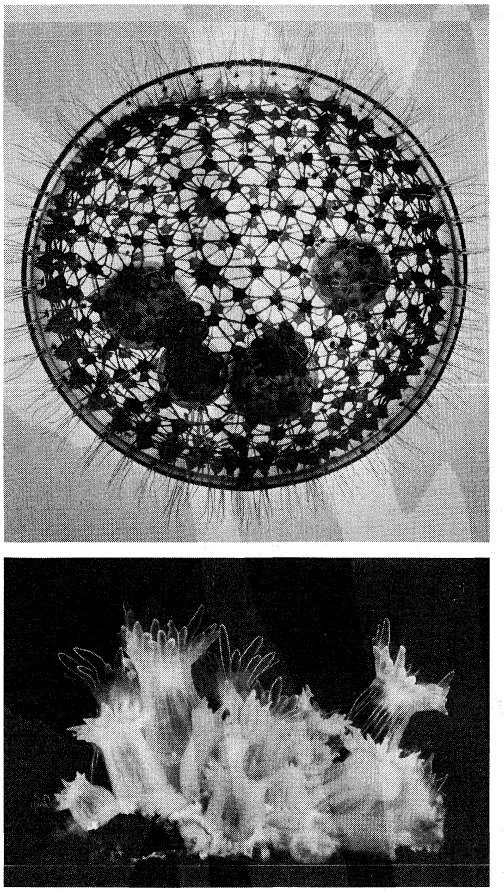

Figure 34: (Top) Glass model of protozoan colony Volvox (magnified about 40 ×). (Bottom) Colony of coral animals *Astrangia danae* (magnified about 1.7 ×).

Peripatus and its relatives, the onychophorans, are intermediate between annelid worms and arthropods and have well-developed parental systems. Some Australian forms lay eggs, but others keep the eggs inside until young hatch; many of these are viviparous, giving the young secretions from the uterus.

Not until one reaches such jointed-legged animals as crabs and insects (arthropods) does one find much extended association between young and their parents. A few scattered arthropods still have no parental care other than production of eggs. The female walkingstick casually drops eggs as she moves about. Many ostracods and copepods, and many of the edible shrimps, shed eggs into the ocean waters. Most arthropods, however, care for their young briefly.

Parental care among arthropods

Scorpions are all viviparous or ovoviviparous (eggs developing in the mother), and many carry their young about. The female pseudoscorpion of the leaf litter often builds a little nest, and the young get nourishment from her in a belly pouch. The female solifugid, or sun scorpion, makes a burrow for her eggs and then brings prey to the young after they emerge from the burrow. The female whip scorpion attaches eggs to herself and carries them until the young go through several molts; she dies as soon as they leave. Spiders generally weave a silken case for eggs and young. The female wolf spider carries her young on her back. Some young spiders build a family or community web together. The harvestmen and mites mostly lay eggs in the environment, but some mites carry eggs until they hatch. Some ticks deposit egg masses, and hundreds of young seed ticks may stay together, to the dismay of a human when such a mass drops on him and starts to spread. Sea spiders (pycnogonids) are strange, for the male takes the egg mass from the female and cares for the eggs until they hatch, or slightly longer. Most crustaceans briefly brood their eggs, or eggs and young, often in special pouches on the body of the female.

Millipedes often form a nest; the young *Spirobolus* later eat the material of that nest. Some female millipedes coil about the eggs for several weeks. Many centipede females brood eggs, but others do not. In symphylans, often considered a link to insects, the female carries eggs in cheek pouches.

Insect families

Social insects. Insects show the greatest development of family structure among animals. Most so-called insect societies are, strictly speaking, families. Sometimes they are called colonies, but the individuals are not directly attached to each other as in the "colonies-1" of protozoa and multicellular animals or the "colonies-2" of corals. They might be called "colonies-3" because they are "attached" by chemicals as well as by social behaviour. The young stay with both parents or with the mother and form social organizations of high complexity. Social behaviour of this type is known among the thrips (Thysanoptera), Zoraptera, book lice (Psocoptera), web spinners (Embioptera), termites (Isoptera), and roaches (Blattoidea) of the more primitive insects, and in some groups of the higher insects—the aphids and lace bugs of the Heteroptera, and especially, in the ants, bees, and wasps of the Hymenoptera. Some of these groups bear little resemblance to the families of vertebrates. A critical observer might say of insect societies that the parents enslave their first children or their sisters, frequently with "drugs," and thereby ensure better care of their later ones.

Societies of lower insects are simple. The female (or male in the case of mole crickets, *Gryllotalpa*), works hard to build a nest and to protect its first offspring. The offspring may reciprocate by helping to build a colony web under a stone or leaf or under tree bark, as in the web spinners and book lice. In wood roaches, such as *Cryptocercus*

Figure 35: Bivouac of army ants (*Eciton*) between trees, which are about 14 inches apart. Inset is detail of bivouac magnified slightly larger than life.

Carl W. Rettenmeyer

punctulatus of the southeastern United States, the young must stay with the adults, because all have symbiotic protozoans inside them that digest wood cellulose: at every molt the roach loses all its protozoa (because the linings of the fore- and hindgut are also molted) and must eat the feces of another roach or die.

In termites, the male and female lose their wings after a dispersal flight and dig a cavity in which they raise the first young. These young have their sexual maturation inhibited by chemical secretions from their parents; instead of reproducing themselves, they work hard to make more chambers and get food for the next young. They often get fecal material from each other full of symbiotic protozoa to digest wood and also use the fecal material to build houses. The more advanced forms masticate wood and grow fungus on the pulp produced in that way. The young have a division of labour, some being workers and some soldiers; there are also nasutes, which have snoutlike processes that eject a sticky substance used in warfare to protect the colony. Such colonies may become huge and build houses higher than a man's head. The first parents are not so much the leaders of the colony as egg-producing machines cared for by their first offspring. Eventually some of the slaves achieve their freedom when the chemical secretion from their parents runs short; they develop wings, fly off, and start new colonies of their own.

Some beetles show behaviour approaching the social. A British rove beetle defends its eggs and young against intruders. Dung beetles dig burrows and store dung for their larvae. The male and female burying beetle cooperate to dig away the soil underneath small dead animals; the female feeds her larvae on regurgitated food. Bark and ambrosia beetles dig tunnels in wood and grow fungal spores; the female feeds her young on pieces of fungus while the male keeps away other males.

Some moths and butterflies associate in the caterpillar stage. Social caterpillars, such as the tent caterpillars (Lasiocampidae) and the larvae of small ermine moths (*Yponomeuta padella*), make webs similar to those of colonial spiders but use them only to hide in rather than to catch prey.

Bees and wasps

The origins of social behaviour can be seen in bees and wasps. There are solitary bees and wasps, all of which prepare a protected place for the egg and later the larva. Some "gall wasps"—as in "gall aphids" and some mites—sting plants, which then provide fleshy galls for the young larvae. The parent often provides food for the larva. The tarantula-killer wasp will sting a huge spider and store it in a drugged state by the egg. The "parasitoid" hymenopterans lay an egg on or in a wandering caterpillar to parasitize it. Some bees or wasps return to put a new spider or other food source into the nest after the first food has been eaten, a process called progressive provisioning. From this it is only a short step to having a single female care for several young in a compound nest, as in *Polistes* wasps, and another short step to having sisters or young stay around the nest and help care for the later young. In some insects, such as wasps of the genus *Polistes,* this is done by having the first or strongest female harass or dominate the later or weaker ones. Their sexual growth is repressed and they cannot lay eggs as long as the dominant female is there. Chemical dominance, or drugging, is the next step; in the more social bees and ants, chemicals produced by the queen are actually needed by the workers, and exchange of food and drugs (trophallaxis) is regular.

Polymorphism and behaviour

Division of labour often occurs in ant and bee societies. Ants are often polymorphic, with small individuals working in the nest and medium or medium-large ones working outside; huge-headed individuals become protective soldiers or even use their heads as plugs to stop up the nest entrance to all besides members of the colony. Honeybees have division of labour by age—the youngest bees feeding larvae, older ones building the comb, and still older ones flying out for nectar and pollen and bee glue. Many of the polymorphic differences are apparently determined by food, as when the new queen bee gets royal jelly regularly, while the smaller workers get royal jelly for only a few days. Other differences are genetic, as in the case of the male ant or bee, which comes from an unfertilized egg.

These family societies of insects are diverse and successful. Termites and ants are among the most common tropical insects, bees and wasps among the common subtropical and temperate ones. The houses of termites—earth castles with shingled construction to shed rain and porous outer layers to control carbon dioxide and humidity—are equalled in their intricacy only by those of man. The honeybees communicate with chemicals and dances to tell each other the distance and direction of flowers.

The ferocious defense of the nest by wasps and hornets avails them little, however, against the onslaughts of marauding hordes of army ants (tribe Ecitonini) in the tropical forests of the Western Hemisphere and of hordes of driver ants (tribe Dorylini) in Africa. The army ants (see Figure 35) do not eat trees or people, as early stories would have it, but they tear apart arthropods. The driver ants, which have scissor-like mandibles that cut flesh, can tear apart humans if given the chance. These are probably the largest of the familial or "colonial-3" societies. It has been estimated that a large colony of the army ant *Eciton burchelli* includes 1,500,000 individuals, and the colonies of the driver ant *Anomma wilverthi* probably contain up to 22,000,000.

The leaf-cutter ants of the Western Hemisphere live in huge underground colonies. They, along with termites and a few beetles and moths, are agriculturalists. The leaf-cutter ants cut strips of green leaves and make a paste of them in which they grow fungus. Their underground chambers may reach several yards. It is hard to realize that such huge colonies are extended families.

From bryozoans to humans. In the other great line of evolution, which leads to man, the social use of the family has taken a different tack. Where the first line began with actively moving, wormlike individuals and ended with drugged, tiny individuals in huge families, the line that leads to humans begins with colonial, attached animals of the general appearance of corals but of the structure of worms and ends with social animals in which families play an important but relatively small role.

Wormlike animals

Some early wormlike animals evidently settled down on the floors of ancient oceans, and to protect themselves had

to develop shells (as in the lamp shells or brachiopods) or colonies with specialized defensive members (as in the moss animals or bryozoans). Brachiopods are solitary and shed their gametes into the seawater. Moss animals form colonies in which there is direct or partially impeded exchange of body fluids. Their societies show more division of labour than do termite colonies. There are feeding individuals, reproductive individuals, special whiplike individuals (vibracula), and bird-head individuals (avicularia) that hit or bite other animals settling on the colony.

It seems incongruous to suggest that active vertebrates developed from tiny wormlike animals living sedentary and colonial lives, but the future does not always belong to the strongest, biggest, or fastest animals of a given age. The moss animals, with their tiny encrustations or filamentous colonies, are internally much advanced over the more abundant corals.

One major side branch of this line of descent does lead to the nonsocial echinoderms—starfish, brittle stars, sea cucumbers. Few of these animals take care of their offspring, and even their gametes tend to be shed broadcast into the seawater. Some sea stars, brittle stars, and sea urchins of the Arctic and Antarctic brood their eggs. In some, as the brittle star *Amphipholis squamata,* the young are attached to the mother and get nourishment from her. Some sea cucumbers, equally divided among cold-water and warm-water forms, brood their eggs externally or, as in *Thyone rubra* of California, inside. A few sea lilies or crinoids brood eggs or young.

There is also little parental care in several of the wormlike side branches of this line of descent. Pogonophoran worms, which even lack a digestive tract, sometimes brood eggs in their tubes in the ocean mud. Arrowworms (Chaetognatha) occasionally carry eggs about, but most release them into the ocean waters where they swim. The arrowworms are successful predators, but the line to vertebrates leads for the most part through the colonial or sedentary filter feeders—the pterobranchs, the acorn worms, and the tunicates or sea squirts.

The pterobranchs are sedentary, colonial wormlike animals, with a central stalk in some colonies but no direct connection in others. The individuals of the latter wander in and out of the colony tubes. Pterobranchs are related to burrowing solitary acorn worms, the hemichordates. All these animals release their eggs and sperm rather casually into the ocean.

The sea squirts (Tunicata) are mostly soft spongelike masses that cling to rocks or pilings in the sea. Most shed eggs into the sea, but some brood eggs or young and release them partly grown. The young are either free-swimming tadpole-like animals or are budded from the adult to form a colony.

The line of descent up to this point is, curiously enough, closely associated with colonial animals, while the line that led to insects produced rather few colonial animals. It has been suggested that advances made during periods of coloniality may produce better free-living individuals and vice versa; the inference is that drastic new changes in a colonial animal can be perpetuated because of feeding by the rest of the colony and later be incorporated in a viable free-living combination.

Some biologists, including Darwin (with his vested interest in competition), have suggested that the sea squirts and all the other colonial animals are unimportant sidelines in evolution. They suggest that the mainline passed through nonsocial, competitive, free-living, wormlike and, later, tadpole-like animals. Wormlike animals led to animals like arrowworms, to the tunicate tadpole, and then to fishlike animals such as *Amphioxus.*

Certainly the next steps were through free-swimming animals with relatively little family life—cephalochordates (lancets) and the jawless fishes. Modern lampreys make a nest for external fertilization, but the hatching larvae make their own way to live as filter feeders in the muddy debris of stream bottoms.

Fish and amphibians

Many jawed fishes take little care of their eggs or young, but there are some major exceptions. Many sharks, skates, and rays give birth to live young, and some have placentas to nourish them. Some fishes make nests; the Siamese fighting fish (*Betta splendens*) and others make bubble nests at the surface, while sticklebacks (*Eucalia*) and a mormyrid fish (*Gymnarchus*) make weed nests, and such fishes as salmon dig spawning nests in the bottoms of streams. Stickleback males fan their eggs until the young hatch, making sure there is enough oxygen. Other fish, such as the black-chinned mouthbreeder, fan their eggs by keeping them in their mouths. Other mouthbreeder fish periodically spit out the young fry and take them back in until the young are feeding well. Mouth-breeders include a freshwater catfish (*Loricaria typus*) and some marine catfishes (*Galeichthys felis* and its relatives), plus cardinal fishes (Apogonidae). There are several fish of a dozen different taxonomic assemblages that bear their young alive, among them the surf perches (Embiotocidae) and the mollies (Poeciliidae). Some have a placenta-like arrangement to nourish the young until birth.

While care of young by the male is frequent in fishes, it is rare among invertebrates (where the sea spiders are the only major example). Care by the males frees the female to obtain more food and hence raise more young per unit of time, which may be necessary in the event that food is difficult to find.

Male care of the young is well developed in lungfishes, predecessors of land vertebrates. Most salamanders and frogs, on the other hand, are not very good parents. The male Surinam toad (*Pipa pipa*) presses the eggs into the back of the female, and the young of *Rhinoderma darwinii* go through development in the vocal pouch of the male. The live-bearing frog (*Nectophrynoides*) of Africa, in which the young hatch within the mother and remain with her for protection, is another exception to the general rule that amphibians release their eggs and care for them little.

Higher vertebrates

Among reptiles the best parental care is in alligators and some crocodiles, where the female makes a mound of dead leaves or sand and stays around to protect the eggs, to release them when they hatch, and to guard the young for perhaps as long as a year.

Birds are well known for parental care. Most build nests, incubate eggs, and care for young. The males commonly help the females in this. Often young birds stay with their parents a year or more, and numerous examples are known of the young of one brood helping to feed the young of later broods. Often the young help the parents defend a "group territory," as among Australian bell magpies (*Cracticus*) and Mexican jays (*Aphelocoma ultramarina*).

The most advanced parental society yet recorded among birds is that of the ocellated antbird, which follows swarms of army ants in order to capture insects they flush in the neotropical forests. This bird's young stay with their parents for several months, then go and find mates, but return to their parents periodically for several years. The

Irven DeVore

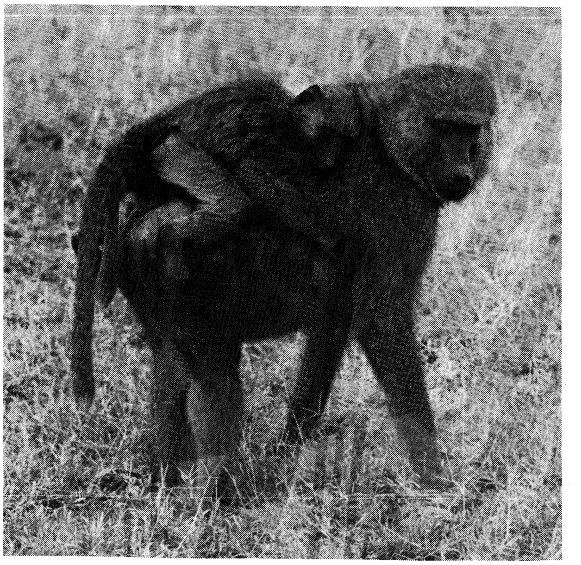

Figure 36: Mother olive baboon (*Papio anubis*) and young.

young bird and its mate are accepted as part of the extended family; they are not chased away as often as are unrelated birds.

An even greater organization of parental care is found in mammals, except that the males seldom help care for the young. The young are usually nourished before birth by the placenta of the mother, except in the egg-laying duck-billed platypus, the spiny echidna, and in marsupials. The young of marsupials are born prematurely and grow in the pouch of the mother for long periods. All mammal young, even the platypus and spiny echidna, must lap or suck milk produced by the mammary glands of the mother. This ensures that there is a strong family association between mother and young (Figure 36).

Commonly, groups develop around a mother and may be joined by other such groups and by males to form bands, troops, and herds. Troops of monkeys and apes are basically families or grouped families. These and wolf bands include males, which may help to raise young. The "extended families" of humans lead to tribes, states, and nations.

Nationalism as a force in human affairs is commonly related to mother and home and family, as well as to interlocking family relationships even more complex than those of ocellated antbirds or wolf societies.

SOCIETIES WITH SEXUAL BONDS

Nonparental social relationships fall into two categories, sexual bonds and nonsexual bonds. Normally, only the latter can involve members of two or more species. Sexual bonds lead in many animals to parental bonds, of course, but differ in that the bond is normally between offspring of different families. The reason for this is that the main advantage of sexual union is to combine the good genetic features of two different lines. Some young, of course, will have the bad features of both lines and will be eliminated—a wastage tolerated in nature as a necessary expense.

Most animals depend on elaborate behaviour patterns to bring the male and female and their gametes together at the right time, rather than using the seemingly more certain processes of asexual reproduction, virgin birth, hermaphroditic self-fertilization, or male parasitism. Many marine animals shed eggs and sperm into the water or into special nests but do so only when chemically stimulated by the presence of substances from the opposite sex. Others use their "internal clocks" to release gametes only at a certain time of day or year. Samoan palolo worms form special gonadal body sections by budding, then release them to swarm in huge numbers at the surface of the ocean on a schedule set by the Moon. The grunion (*Leuresthes tenuis*), a small Pacific fish of the silversides family, is famous for its males and females meeting to fertilize eggs high on the beach at the highest tide each month and at the highest waves of that tide as well. The synchronization of male and female requires them to have an internal lunar clock, such as that known for the colour changes of fiddler crabs.

The functions of courtship

Courtship must basically ensure two things: that the correct male and female get together at the right time with as little loss as possible; and that the offspring have the best possible chance to survive. Ensuring these two things has led to elaborate courtship patterns in animals. Where different kinds of animals that look, smell, or feel alike coexist, each individual must be especially careful not to hybridize with the wrong species. Otherwise it will waste its eggs or sperm in a union that will produce no young, or young that are malformed or maladapted for the world into which they emerge. Animals often develop complicated odours, colours, or voices as means of identification. There are many species of fruit flies of the genus *Drosophila,* and to avoid mismatings, each species has its own pattern of waving the wings by the male. The sight and sound of the wrong pattern of waving is enough to cause a female fruit fly to flee (see also above *Reproductive behaviour*).

Where there is only a limited breeding area or a patchy environment in which the good areas are restricted, strong male–female differences are advantageous. In these cases the males have to advertise, often with song, to help females locate good areas. Males of species whose courtship displays are performed in groups usually have to compete more directly with each other and thus tend to develop large size or striking colours, overpowering scents or voices, or other exaggerated features. Female domestic chickens, sage grouse, and baboons tend to copulate mainly with the lordliest and most dominant males. This is not so evident in other animals, in which the females tend to mate with the male holding the best territory. The dominant male is likely to be the oldest one, the one that has proved he can survive and hence is "fittest."

Supermasculinity

The success of the "supermasculine" or lordly males in a few species may be advantageous only to those males. A few lordly males often usurp the few suitable places to breed, as in male sea elephants (*Mirounga angustirostris*) on Pacific beaches and in male red-winged blackbirds in North American marshes. If the lordly male blackbirds are eliminated, however, other males come in and the females breed with them just as quickly.

The supermasculine males in these species, full of pomp and strutting, seldom care for their young. Baboon males, it is true, do at times stop fights between lesser animals and drive away leopards or other predators. But usually the female takes care of the young herself. It may even be an advantage if she is "ladylike" and unobtrusive, so that the lordly male may draw predators away from the young. Keeping the male away from the young may also allow the female and her young more food. If environments are limited in food, keeping excess males out of the breeding area clearly is an advantage.

Supermasculinity, as well as being correlated with female care of the young, is also associated with polygamy. The mating of several animals of one sex with a single individual of the other sex tends to be associated in birds and mammals with great differences between the sexes. Serial polygamy, or the mating of an animal of one sex with several of the other sex at different times, may also occur. Promiscuity, or the mating of each female with several males and each male with several females, tends in supermasculine animals to resemble serial polygamy. Monogamy, or the mating of each male with one female, tends to occur mainly in animals with little difference between the sexes.

Having many mates does not necessarily mean that an animal is more social than if it has only one mate. In most cases, the polygamous male spends much time driving away other males and little time courting his females. His females spend little time with him, because they are busy raising many young—with little care for each. Among African weaver birds (*Ploceus*), monogamous species of the forest have smaller clutches than do polygamous ones of the savanna.

The whole system of lordly males, ladylike females, polygamy or serial polygamy, and multiple young tends to occur mainly in animals with restricted and undependable sources of food and other necessities. One investigator found that males of the long-billed marsh wren (*Cistothorus palustris*) in Washington, where their marshes varied greatly in quality, had several mates; females went to males with good territories and left neighbouring males, with poor territories, mateless. Another investigator found that in Georgia, where the marshes were everywhere about equal in food supply and nesting cover, the long-billed marsh wrens were usually monogamous. The correlation suggested by many recent studies is this: sexual dimorphism and diethism (behavioral differences) arise in animals in which environmental opportunities are restricted due to undependability or local distribution.

NONFAMILIAL SOCIAL BONDS

Social behaviour also occurs among animals that are not necessarily related by parental or sexual bonds. A "flock" or "band" of animals may be formed of only one family in some cases, but often several families or individuals join together.

Spacing. As previously noted, social organization within a species may be shown not only by the presence of clumping or positive movement of individuals but also by even spacing resulting from negative movements away

from each other. Sociality is shown more by the presence of a definite spacing than by nearness.

Absence of spacing among simpler forms

There is little evidence for social spacing in protozoans and simpler beings, such as viruses and bacteria. Most recorded groups of unicellular or lower animals are probably parental or sexual groups. There seem to be few social interactions among microorganisms, but this apparent dearth of social behaviour may be an artifact introduced by the disturbance of observation.

Most colonies of sponges and coelenterates seem to be parental colonies or aggregations in favourable sites rather than nonfamilial societies. There is little information on nonfamilial social organization among colonial-2 animals, even among those that can move, such as the colonies of Portuguese man-of-wars or the planktonic rotifer or seasquirt colonies. Most worms and their relatives are not known to react to each other or to form social structures of the "flock" type. Little is known about mollusk organization; but the simple fact that mollusks do not pile up on top of each other suggests that they are capable of negative social reactions.

Barnacle larvae prefer to attach next to another member of their own species or on a place where one of their species has just been removed. They avoid settling on top of another member of their own species, even though they readily settle on a member of another species. They react in part to chemicals that are specific to their species. Barnacles, then, aggregate in colonies but within a colony space themselves out. If the multicellular animal is a colony-1, the coral colony a colony-2, and the bee society a colony-3, the barnacle society may be called a colony-4. Colonies-4, in which the interactions take place between unrelated, unmated, and unattached individuals, are regular in arthropods. In many cases the existence or nature of a colony-4 is not obvious or is problematical. Bees form colonies-3 and perhaps also colonies-4, for colonies of bees space themselves out in the environment and avoid establishing themselves too close to other active colonies; but there is no evidence that bee colonies avoid getting too far apart, although if they did then mating between bees from different colonies would become difficult.

Colonies-4 are known among other arthropods. Tube-dwelling amphipods form colonies but chase each other and avoid getting too close. They show the phenomenon of "personal space," or "individual distance," as surely as do swallows sitting on a wire, among whom a new arrival settling will sometimes cause shifting outward by individuals on both sides. Individual distance or personal space is a fairly sharply defined space around each individual that can be penetrated by another individual without hostility only after certain overtures.

Territoriality

The amphipod colonies also show the phenomenon of territoriality. Territoriality differs from personal space in that a territory is centered on some object outside the body of the animal itself. The male bitterling (*Rhodeus sericeus*), a European fish that lays its eggs inside a freshwater clam, will chase male intruders away from his clam even if the clam gets up and moves several feet. The male house finch (*Carpodacus mexicanus*) of North America chases other males away from his female, wherever she moves. More often, however, the external reference for territory is a fixed plot of ground, a nest hole, or some immovable set of objects. The animal may chase out intruders or tolerate them in the territory, but in his territory he is in charge. Work with bicoloured antbirds in Panamanian forests suggests that a territory may be defined as "an external referent in which one animal or group dominates others that become dominant elsewhere." A pair of bicoloured antbirds permits others on its territory, but as soon as the pair crosses a boundary line into another territory, it becomes subordinate to the pair of that territory.

Territoriality is known to exist among insects such as dragonflies and ants, some fish, a few frogs, some lizards, most birds, and many mammals. It probably exists, at least in chemical forms, in tube worms of a muddy beach or rocky shore, and perhaps even among sedentary protozoans.

Swarming. Personal space and territoriality are definite negative signs of coloniality-4, but there are also positive signs. Mutual repulsion is only part of sociality, for mutual attraction must also exist. Mutual attraction is found in many arthropods above the barnacles. Some of the best studied examples are the mating swarms of ants, flies, midges, and, especially, fireflies. Another example of mutual attraction is the migratory horde, of which the African migratory locust (*Schistocerca migratoria*) is the best studied example.

The synchronized communal displays of the fireflies of Thailand are among the most impressive exhibitions of the insect world. The gatherings of thousands of males on the mangroves of the coastal swamps have been described as a city of pulsating glitter, every male anticipating the flicker of his neighbours and flashing in unison with them. Communal mating displays of this type are common in birds such as manakins, sage grouse, ruffs, and birds of paradise, and are called lek displays. Presumably, the communal display enables females to find the males more easily. Seldom do bird leks approach the numbers or synchrony of a firefly lek in Thailand, but several male manakins sometimes cooperate in a synchronized cartwheel dance. It is difficult to explain why males competing with each other for mates should help one another, but the phenomenon has been well documented.

Communal displays

The legendary colonies-4 of the migratory locusts are far larger and more impressive than the migratory colonies-3 of the army and driver ants. When food is abundant, the locusts disperse widely and grow up in what is called the "solitaria" phase. As the locusts crowd and encounter each other, they begin to change colour and enter the "gregaria" phase, in which they look so different that they were once considered a separate species. The "gregaria" locusts behave differently too, for they are excitable and social. They begin to march over the ground as food supplies diminish. Finally they take wing in huge hordes and fly downwind to a low-pressure area where rains have recently fallen. Here they descend on crops and other vegetation, eating it to the ground before flying to the next low-pressure area. The extinct migratory hordes of passenger pigeons were apparently similar in their effects on vegetation.

Many other examples of flocks occur in higher animals, especially insects and vertebrates. Most show little internal structure. The migratory hordes of armyworms that devastated midwestern corn fields in the United States before the days of synthetic insecticides, the swarms of male and female palolo worms in the ocean, the feeding swarms of sharks, and the dense schools of herring are all examples of flocks with little internal structure. The Austrian ethologist Konrad Lorenz calls them "anonymous flocks," because it matters little if individuals change places and bonds are seldom individualized. When the fish school turns, it is like an army platoon turning to the flank, for the former side fishes are now the leaders.

The mating choruses at frog ponds provide an example of an auditory lek. Some salamanders congregate to breed, generally by sight and by odour, in running streams. Snakes form winter dens in which there may be hundreds of individuals rolled up in balls.

Flocks, herds, and packs

Among birds, pigeons (Columbidae), starlings (Sturnidae), and various blackbirds (Icteridae) form dense flocks that wheel about in the sky or mill along the ground during foraging, the rearmost flying ahead to become briefly the leaders. Shorebirds and gulls gather on mud flats or elsewhere to feed. Such birds as the brown creepers (*Certhia familiaris*) reduce the winter cold by clumping together at night. Flocks of geese are made of many families of geese. Many birds gather into huge roosts, containing thousands or even millions of individuals in the case of the red-winged blackbirds (*Agelaius phoeniceus*) of North America. Tricoloured blackbirds (*A. tricolor*) of California are even more colonial than redwing blackbirds when nesting and by sheer force of numbers push into colonies of the more dominant redwings and displace them. The nesting colonies of queleas (*Quelea quelea*) in Africa contain millions of nests. There are many such colonies of birds, such as the phenomenal colonies of seabirds that are found on islands throughout the world.

Mammals often form herds or packs. Many herds are more structured than bird societies, simply because many

mammal groups are combined families plus males. Huge migratory herds of wildebeest and zebra wander the African plains. Each herd of zebra includes many familial harems that are held together by individual males. The herd of Scottish red deer is a matriarchal group led by an old female and composed of her extended family plus other extended families like hers.

Hunting mammals often have even more structured groups. A male and female wolf (*Canis lupus*) and their offspring form a hunting pack that may fuse with another pack or split apart. African hunting dogs (*Lycaon picta*)

George Porter—The National Audubon Society Collection/Photo Researchers

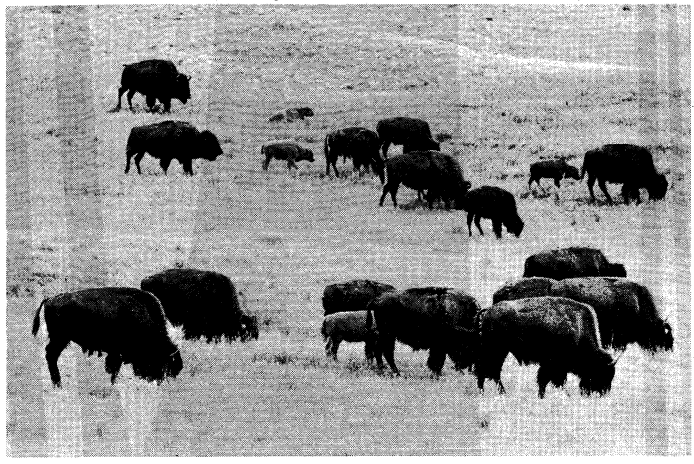

Figure 37: A herd of American bison (*Bison bison*).

and hyenas (*Hyaena* and *Crocuta*) form similarly flexible hunting packs, which are said to be even more effective than lion groups at running down prey.

Primate troops are often as complex as societies of hunting mammals or more so. Superimposed on their parental and sexual bonds is a group organization based on the occupation of a given area. The troop may also accept animals from outside. The society of baboons (Figure 36), as studied on the plains of Kenya, is very highly organized. Around the edge of the troop as it moves are the subadult males, watching carefully for predators and snatching bites of food when they can. Inside, the playful groups of juveniles stay close to the central hierarchy, a cooperating group of two or three big males that keep the subadult males at the periphery. The males of the central hierarchy are replaced, as they get old and toothless, by brash young males moving in from the periphery. With the central hierarchy march the females and their infants, protected both by the big males and by the peripheral younger males. The society is integrated by mutual grooming sessions, in which the big males get most of the grooming, and by domination by the big males.

INTERSPECIFIC ASSOCIATIONS

Individual animal interactions. Associations of animals often include more than one species. These groups may be called colonies-5 or colonies-0, since there is recent evidence that the nucleus and other parts of the cell were originally symbiotic viruses and bacteria. The most intimate form of interspecific association is that known as symbiosis, or mutualism, in which dissimilar organisms live together (see BIOSPHERE: *Biotic interactions*).

Multicellular animals often live on or beside other animals. Small fish live in the tentacles of some jellyfish, sea anemones, and even the Portuguese man-of-war, yet are able to evade or inactivate the stinging cells. Some hydroids and worms live on tubes of other worms or on the shells of other invertebrates. The tubes of worms and shrimp often harbour other worms or fish. At times, the animal will live only on one kind of shell and is found nowhere else. Paleontologists have found some evolutionary sequences in which such an animal first lived on rocks and shells of a wide variety of types, then developed larger forms that lived on one type of animal and probably got food from it.

Complex associations. Slave making is a kind of social relation that verges on parasitism. Certain kinds of ants raid colonies of other kinds of ants, carry off their young, and raise them as slaves. The slaves are perfectly socialized members of the colony and probably do not even realize that their social behaviour is misdirected. They exchange food and drugs with their captors as willingly as they would have with their own species, had they been reared by their own workers.

Associations in ant colonies

One of the most complex associations is that of animals around army and driver ants. In the huge colonies of army ants live dozens of other kinds of insects, millipedes, and mites. Some help clean debris below the nests; some have chemicals that allow them to fool the ant security guards and enter the colony. Mites, beetles, and others ride on the ants or march in their columns. Some may help the ants by cleaning them or by giving them chemicals they crave. Others are like wolves in the fold, eating the food of the ants or even their larvae. The swarms of ants are also waited upon by many kinds of flies and birds. The flies lay eggs on insects and spiders fleeing from the ants. The birds capture animals flushed by the ants. In the tropics of the Western Hemisphere, nearly 50 kinds of birds follow the army ants persistently and would probably die without them.

Some of these associations may not be social in any accepted sense of the word. Humans are not social with rats and fleas merely because they live with them. Some interspecific associations, however, are definitely social. These include the mixed flocks of antelope, zebra, and wildebeest on the African plains, for example, and mixed flocks of birds throughout the world.

One can travel for hours across the African plains or through a tropical forest scarcely seeing an animal and suddenly be surrounded by a herd or flock of many kinds of animals. Usually each animal eats a different kind or type of grass or fruit or insect, although sometimes there is overlap in the foods taken or ways of feeding. The flock moves along together, not spending much time at each concentrated food source. Often it includes parental groups (colonies-2 in the case of mothers carrying young, or colonies-3 after the young separate).

The fact that forest flocks are usually of several species rather than one probably reflects the fact that forests have more species of animals, and hence each species has less of a food supply and must not allow competitors of its own species about it, even its own offspring. In less complex habitats, there are usually very few species, and the animals can tolerate their own young even though these are competitors. They may even use their young—to detect predators (in the case of baboons) or to build a "city" (in the case of bees and ants).

Ecosystems

When a forest is destroyed and begins to grow back, the first animals that come in tend to be kinds that are solitary and very antagonistic or uncommunicative. Later, flocking animals become more common, although they still resist groups of outsiders. Finally, as the mature forest re-establishes itself, one finds mostly paired animals that do not keep their young with them. These paired animals tend to associate with pairs of other species to form mixed flocks. Eventually, every animal links itself with every other in the system, forming what ecologists call a complex "food web," "ecosystem," or "web of life." It is gradually being recognized that such a web is socially cooperative as well as socially competitive. The ecosystem eventually approaches a stage of "colony-6," or what the French biologist and philosopher Teilhard de Chardin called the noosphere.

Dynamics of social behaviour

COSTS AND GAINS

Social behaviour among humans is often regarded as an end in itself, the expression of a basic drive that has no necessary purpose. Biologists doubt that any animal has social tendencies without some adaptive advantage.

The costs. Social behaviour and communication not only take an animal's substance and energy; they impede feeding, drinking, and other inputs necessary for life. The

first cells that associated with other cells to form multicellular filaments lost the ability to absorb on the side by which they were attached. Perhaps the reason most multicellular filaments occur among animals that are attached to the ground or to some other surface is that such animals lose less proportionately than members of free-floating aggregations; attachment on one side to the ground already limits their input. Locomotion is impaired if animals must stay together. The single-celled ciliates could not readily have evolved into higher organisms, because dividing them into many joined cells would have slowed down these fast-moving predators. A speedy golden plover trying to stay with other shorebirds in a mixed flying group near shore constantly turns back to keep with them; it is impeded by its social tendency.

Social behaviour also attracts enemies. Groups of animals have epidemics, while solitary animals seldom do. Many disease-carrying parasites spread much more easily at times when animals are together. Some rabbit fleas are even adapted to the hormonal cycles of the rabbits, so that they reproduce at the times of year the rabbits are reproducing and hence are social.

Predators, like parasites, often have an easier time if animals are crowded together; the animals are often busy reacting to each other and the predator can sneak up without being observed. Their communicatory systems may even attract predators. Tuna prey specifically on fish in schools; a small hawk in tropical America (*Accipiter superciliosus*) mainly on mixed bird flocks.

Conflict and its avoidance

Social behaviour increases the number of interactions between animals and thus the chances of conflict. The conflicts may be solved by fighting, by patterns of dominance and submission (peck orders), or by mutual avoidance. Mutual fighting and mutual avoidance have the same result—a partitioning of resources for which the animals are competing.

The gains. Against these disadvantages of being social, it is possible to set a number of clear advantages. They fall into six broad categories, corresponding to the six possible kinds of animal behaviour. By social behaviour animals gain: (1) food and other resources, (2) reproductive advantages, and (3) shelter and space. They are enabled to avoid (4) physical and other small hazards, (5) competitors, and (6) predators or other large dangers. The first and third of these gains are reactions to desirable things of small (1) and medium to large size (3) respectively; the fourth and sixth are reactions to undesirable things of these sizes.

Food. The value of being social in getting food is obvious in the case of hunting bands. Cooperative hunting has been found among wolves and African hunting dogs, hyenas, lions, killer whales, porpoises, cormorants, white pelicans, pairs of eagles and of ravens, tuna when chasing small fish, army ants, primitive and modern men, and many other animals. Animals that hunt cooperatively can trap, chase, and tear apart prey that would otherwise be too fast, strong, or large for them. In African hunting dogs the chase is run by the leader of the pack, but the rest keep the antelope or other prey from dodging left or right and also help fall on it when the leader catches it. Flocks of wattled starlings (*Creatophora cinerea*) fly after African migratory locusts and surround one group after another, eating every trapped locust from each group. In army ants, the individuals are bound to each other by chemical "trail substances" so that no individual gets far from the group; when one finds prey, it grabs it and emits an "alarm" chemical that causes nearby ants to grab, bite, and sting so that the prey is overwhelmed within seconds. They then tear the prey, usually insects or other arthropods, limb from limb and carry it back to the nest.

Cooperative hunting

Interspecific groups of birds are sometimes food-getting societies. Drongos (*Dicrurus* species) of Africa flush much food, and other birds follow them to get it. Honey-guides (*Indicator* species) of Africa lead honey badgers or men to bee nests and eat wax after the mammals break open the nests for honey. Hawks have been known to follow railroad trains for the same reason, and hornbills and hawks follow monkeys. The birds, lizards, flies, and other animals that associate with army ants offer other examples of interspecific food-providing associations. One animal may steal food from another, as American widgeons (*Anas americana*) steal grass from redheads (*Aythya americana*).

In addition to hunting and flushing food cooperatively, animals sometimes lead others to food or teach them to use it. Parents, especially among mammals, often teach their young to hunt or lead them to food. Animals that must migrate or depend upon seasonally available resources often depend on others to show them what foods are good and where. Vultures and jackals flock to carcasses on the African plains. American robins (*Turdus migratorius*) in California have been observed learning to use certain berries after flocks of cedar waxwings (*Bombycilla cedrorum*) came through and started eating the berries. Tests with a tape recorder show that the recorded calls of some birds that follow army ants will attract unrelated kinds of birds that also follow ants. In the laboratory, some animals learn to push a lever for food by watching others get food that way and learn to avoid distasteful foods by watching others cough it up. In studies of Japanese monkeys (*Macaca fuscata*), the habit of washing potatoes before eating spread from the younger to older monkeys of a troupe. In Britain, a few titmice learned to open milk bottles and drink cream; the habit spread much too rapidly to be a genetic change. (Coverage of learned behaviour is found in LEARNING, ANIMAL.)

Mating behaviour

Reproduction. The reproductive advantages of social behaviour have mostly been discussed earlier. It was noted that sex is a way of combining desirable genes from different lines, genes that otherwise might slowly or never get together. In many lines of animals, parental behaviour is clearly useful in protecting or teaching the young. This normally requires the adult to have fewer young. The careful parent loses in time and energy and number of offspring but comes to prevail in evolution if it has more descendants than does a careless parent that lets its young die. The careless parent prevails if it can get more young out by caring for each one less; some parasites are careless parents because each of the young needs little care and a large number must be produced to get to an extremely distant host.

Shelter. Social behaviour is often used in habitat selection and shelter selection, even to the extent of making it possible for the animal to improve the environment it finds. Male birds that later will fight with each other over territorial boundaries gather first at areas where they hear another bird singing, rather than hunting for a more isolated (and probably unsuitable) place. Certain beetles that attack pines put out a scent that attracts other beetles; only as a result of concerted attack by all beetles can the protective pitch of the tree be reduced so that all may enter. Movement to a flock is a good way to find a patch of habitat or a shelter. It has been suggested that flocking increases the accuracy of migration, since the average direction taken by a flock is more correct than the individual directions taken by individual birds. Small flocks of European starlings returning to a California roost were less accurate in their direction than large flocks. Cooperative building of structures is well known in humans, prairie dogs, rats (whose tunnel systems rival the catacombs in complexity), beavers, certain weaver finches, wasps, bees, termites, and many others; symbiotic use of structures occurs in many animals.

Hazards. Social behaviour can also help animals avoid small hazards. This includes avoiding heat or cold and wet or dry situations as well as preening or grooming to keep off dirt, parasites, and other small environmental hazards. A goose cleaving the air for its companions at the front of a V-shaped flock, a parent bird brooding its young or sheltering it from the Sun, a group of creepers roosting together to help each other survive the cold winter night, and a group of baboons grooming each other to pick off ticks furnish other examples.

Competitors. Dangers from competition are avoided by agonistic behaviour. The five basic types of agonistic behaviour are aggressive display (threat), submissive display (appeasement), attack, avoidance, and fighting.

Agonistic behaviour

Social aggressive display is not common. Males of a troupe of howler monkeys all yell at a neighbouring troupe to make them keep their distance. Baboon males in the

"central hierarchy" cooperate to keep aggressive young males from winning, backing each other up with threats. Social attack occurs in some birds and mammals that keep group territories and may lead to fighting if the other group attacks or threatens.

Highly social submissive display and escape also are not common. A baboon troupe may retreat as another moves in at a water hole. But even when a single animal retreats from a competitor it is a social act. Territoriality is certainly a system in which an animal defends its right to be dominant in part of its home range. The basic feature of territoriality, however, is not aggression in a certain area but submission outside that area. The common idea that strong animals survive and the weak do not is true only in the short run, for in a few generations all reproducing animals are equally strong. Strong animals will begin to lose if they keep on chasing others. An animal that keeps too large a territory will spend more time chasing away intruders than it will in eating or reproducing, unless it can get others to help it. Bees get help by drugging the nonreproductive members of their colony. Most animals limit themselves so that the territory of the most dominant animal or group of animals never exceeds about twice the size of the least dominant animal or group of animals of that species. Most often the young animal has a small territory but defends a larger one as he gains experience, then gradually loses it as he reaches old age.

Grouping and flocking

Predators. The final reason for social behaviour, and one of the most important, is to avoid predators or other large dangers. Just as animals can sometimes overcome large prey by grouping to attack it, so they can sometimes overcome large predators by grouping to defend against them. Cooperative and spirited attacks upon predators occur in most animals that protect their young and are a regular phenomenon in gull and tern colonies, in baboon troupes, in bees and wasps, and many others. "Mobbing" is a similar phenomenon in which the attack is not carried all the way to the predator but so harasses it that it departs or at least is prevented from getting its prey. The massed effect of many mobbing birds is more intimidating to a predator than is mobbing by one or two birds.

Grouping also helps against predators because a predator is distracted by the "confusion effect" of so many shapes, sounds, or smells. Human hunters know that one cannot shoot a duck out of a flock by aiming at the flock; the shot is more likely to pass between the birds than if the hunter aims at one of them. Similarly, hawks have been seen to drive through a flock and miss every bird. Successful predators either dive to break up a flock and then grab a separate animal or pick off an outlying one at the start. Butterflies on tropical trails also swirl up in a confusion effect from a mud puddle. The phenomenon is caused by the difficulty the eye or other sense organ has in analyzing or following very complex motions that cross each other.

Another advantage of the group or flock is that many eyes can see a predator more quickly than can one pair of eyes. Ornithologists have found that social birds are nervous outside of a flock and must spend too much time watching to be able to forage effectively. Certain species that forage by peering in dense vegetation are especially in danger and must associate with other species that look about more actively in open foliage. The peering species often are good at yelling and perhaps help the other birds by scaring or disturbing predators. This suggests that a social organization may have many reasons for being.

DEVELOPMENT FACTORS

Instinct and learning

As noted above, behaviour changes somewhat in the course of evolution. Biologists commonly call the genetic determinants of behaviour in a line of organisms instinct. Every behaviour pattern, however, can be changed somewhat by the individual animal in the course of its experience. The old view that instinct and learning are two different types of behaviour is seldom accepted today, even though some kinds of behaviour certainly have little learning superimposed.

The real question is how social behaviour develops. It is possible to breed animals for aggressiveness or nonaggressiveness, and by further crosses to study the inheritance of behaviour. Mouse strains that show different degrees of aggressiveness are easy to develop. Biochemical imbalances also affect behaviour: in many animals an oversupply of male hormones causes aggressive and antisocial behaviour. Pituitary hormones, especially luteinizing hormone, have the same effect in other animals, such as starlings.

Stimulation of the brain or removal of part of it gives evidence of a structural basis for behaviour; stimulation of the hypothalamus produces many social behaviour patterns, such as sexual activity and aggression. There are even "pleasure centres" that the animal will stimulate on its own, if given a bar to press that sends a shock to its head. Sexual centres are one of the "pleasure centres" that rats are fond of stimulating.

Another approach is to isolate the animal and see if it still develops a particular behaviour. Young pigeons reared in cardboard tubes will fly soon after release, showing that practice is not necessary. Some young songbirds reared in isolation develop normal songs, and many develop normal calls. Many songbirds must listen to songs of their own species at a particular age, however, to learn them.

An animal may develop social behaviour while still in the egg or mother. Baby ducklings peep to the calling mother from the egg. An animal may develop social behaviour soon after it emerges or at some critical period later. A young duckling follows the first object it sees, be it a duck or a duckling or the hand of the experimenter. Young birds, ants, and some mammals "imprint" on the first object they see to such an extent that they may court it or show agonistic behaviour to it later. A mother goat given a lamb in exchange for her kid soon after birth will adopt the lamb and drive away her own kid when it is returned to her.

Later learning also influences social behaviour. Mice that experience defeat learn to run rather than fight; the opposite holds for mice that win. Most animals, however, start at the bottom of a peck order and take defeats in stride, later becoming the dominant animals if they manage to survive. It has been found that association with other young monkeys helps a monkey to behave properly in sexual activity later, although many learn to copulate properly without this opportunity.

THE EVOLUTION OF SOCIALITY

Social behaviour as an adaptation

The fact that bees and ants form complex societies, more complex in some ways than those of apes, shows that social behaviour occurs in small animals as well as in large ones, in animals with small brains or large ones, and in both major lines of evolution. If bacteria can be rather social and humans rather solitary, there is no reason to suppose sociality is more advanced in evolution than is solitary life.

Social behaviour is instead an adaptation to certain environmental opportunities. The evolution of sociality can be glimpsed in the line that leads from the earwig through wood-eating cockroaches to termites, or in the line from solitary bees to social ones. Communication systems also evolve, as may be seen in the line leading from dully coloured monogamous crows to brightly coloured birds of paradise and plain bowerbirds in New Guinea. In this system, the male bird of paradise is brightly coloured to attract the crowlike female. The bright male also attracts predators. The bowerbirds have lost the bright plumage; instead they make elaborate maypoles or bowers decorated with flowers to attract females. One bowerbird even paints the walls of his bower, using a mashed berry or a straw stained in berry juice. These bowerbirds have become safely coloured, for they have replaced bright plumage with bright objects.

The ecological maturity and regularity of a habitat seem to determine to some extent how social its inhabitants will be. Among African weaver finches, the forest-living ones are solitary and monogamous; birds of savannas and marshes flock and nest polygamously; and those of very dry habitats tend to be relatively solitary. The same phenomenon has been noted for cats; leopards of the forest and cheetahs of very open country tend to be less social than lions of open savanna areas. Antelope, deer, monkeys, and apes show similar differences. The general rule

is that, as an environment grows up from the level of bare ground to that of savanna and finally forest, the solitary animals are replaced by social ones and then by solitary ones again. In the forest, however, one-species societies decline in importance and societies of several species form. The same things happen as a marine community goes from bare rock to the complexity of a coral reef.

Societies of the same species, therefore, seem adapted for intermediate habitats that are in transition between bare ground and forest. It may be that the reason for this is that most intermediate habitats are unstable, likely to be limited in space or time. (E.O.W./Ed.)

BIBLIOGRAPHY

General works: KONRAD LORENZ, *Er redete mit dem Vieh, den Vögeln und den Fischen,* 6–8th ed. (1952; Eng. trans., *King Solomon's Ring: New Light on Animal Ways,* 1952; reduced photographic reprint, 1961), is a highly recommended popular treatment; and P.R. MARLER and W.J. HAMILTON, *Methods of Animal Behavior* (1966). Semipopular works include DESMOND MORRIS, *The Naked Ape* (1969) and *The Human Zoo* (1969); NIKOLAAS TINBERGEN, *The Herring Gull's World: A Study of the Social Behaviour of Birds* (1960), *Curious Naturalists* (1958, reprinted 1968), highly recommended to all interested in behaviour, and with the EDITORS OF LIFE, *Animal Behavior* (1965), an excellent résumé of ethology.

Nature and patterns of animal behaviour: IRENAUS EIBLEIBESFELDT, *Ethologie, die Biologie des Verhaltens* (1966; Eng. trans., *Ethology: The Biology of Behavior,* 1970); ANNE ROE and GEORGE G. SIMPSON (eds.), *Behavior and Evolution* (1958); KENNETH D. ROEDER, *Nerve Cells and Insect Behavior,* rev. ed. (1967); and CLAIRE H. SCHILLER (ed.), *Instinctive Behavior* (1957). More advanced are ROBERT A. HINDE, *Animal Behaviour: A Synthesis of Ethology and Comparative Psychology,* 2nd ed. (1970); P.H. KLOPFER, *Behavioral Aspects of Ecology* (1962), and (comp.), *Behavioral Ecology* (1970); KONRAD LORENZ, *Evolution and Modification of Behavior* (1965); WLADYSLAW SLUCKIN, *Imprinting and Early Learning* (1964); and E.L. BLISS (ed.), *Roots of Behavior: Genetics, Instinct and Socialization in Animal Behavior* (1962).

Unlearned behavioral reactions: V.G. DETHIER and ELIOT STELLAR, *Animal Behavior: Its Evolutionary and Neurological Basis,* 2nd ed. (1964); R.A. HINDE, *Animal Behaviour: A Synthesis of Ethology and Comparative Psychology,* 2nd ed. (1970); and W.H. THORPE, *Learning and Instinct in Animals* (1963).

Studies emphasizing stereotyped responses include J.D. CARTHY, *Animal Navigation: How Animals Find Their Way About* (1956); G.S. FRAENKEL and D.L. GANN, *The Orientation of Animals: Kinesis, Taxes, and Compass Reactions* (1940, reprinted 1961); and J. LOEB, *Forced Movements: Tropisms and Animal Conduct* (1918).

Wide-ranging surveys of instinctive behaviour include IRANAUS EIBL-EIBESFELDT, *Grundriss der vergleichenden Verhaltensforschung: Ethologie* (1967); PETER R. MARLER and WILLIAM J. HAMILTON, *Mechanisms of Animal Behaviour* (1966); WILLIAM H. THORPE, *Learning and Instinct in Animals,* 2nd ed. (1963); NIKOLAAS TINBERGEN, *The Study of Instinct* (1951). Papers and books devoted to special aspects of instinctive behaviour are T.H. BULLOCK, "The Origins of Patterned Nervous Discharge," *Behaviour,* 17:48–59 (1961); and in *Nervous and Hormonal Mechanisms of Integration* (1966); ROBERT A. HINDE (ed.), *Bird Vocalizations: Their Relation to Current Problems in Biology and Psychology* (1969) and *Non-Verbal Communication* (1972); KONRAD LORENZ, "The Innate Bases of Learning," in KARL H. PRIBRAM (ed.), *On the Biology of Learning* (1969); and CLAIRE H. SCHILLER (ed.), *Instinctive Behavior: The Development of a Modern Concept* (1957).

Biological periodicity is treated in the following works: F.A. BROWN, JR., *Biological Clocks* (1962), a brief, elementary account of the nature of, and problems related to, the phenomena of plant and animal periodicities; E. BUNNING, *The Physiological Clock,* rev. 2nd ed. (1967), particularly good for the earlier literature and classical views; J.L. CLOUDSLEY-THOMPSON, *Rhythmic Activity in Animal Physiology and Behaviour* (1961), best for its treatment of ecological significances; J.E. HARKER, *The Physiology of Diurnal Rhythms* (1964), emphasizing the periodicities associated with day–night; and B.M. SWEENEY, *Rhythmic Phenomena in Plants* (1969). In a class by itself is A. SOLLBERGER, *Biological Rhythm Research* (1965), a comprehensive, well-indexed, and documented reference work containing more than 2,500 literature citations, well-balanced in distribution over the subject. F.A. BROWN, JR., J.W. HASTINGS, and J.D. PALMER, *The Biological Clock: Two Views* (1970), is a succinct presentation of the two currently held alternative hypotheses, internal and external timing of the rhythms, together with the evidence upon which they are based. G.G. LUCE, *Biological Rhythms in Psychiatry and Medicine* (1970), is a readable, informative, extensively documented account of occurrence and significances of daily, lunar, and annual periodicities for man. The phenomenon of photoperiodism receives thorough coverage in STANLEY D. BECK, *Animal Photoperiodism* (1963), a concise general presentation of the subject on mammals, man, birds, and insects; *Insect Photoperiodism* (1968), an advanced book on all aspects of photoperiodism in insects, with an extensive bibliography of the original research; and BRIAN LOFTS, *Animal Photoperiodism* (1970), a popular work written for the general audience.

Basic behavioral activities of individuals: J.A.C. NICOL, *The Biology of Marine Animals* (1960), gives a good introduction to the classification of feeding patterns with typical examples. W.C. ALLEE *et al., Principles of Animal Ecology* (1949), a classical survey of the entire field, is still useful as an introduction to the relations of animals to their food environment and gives many examples. The best review available of the physiology of feeding behaviour is C.F. CODE (sect. ed.), "Control of Food and Water Intake," in *Handbook of Physiology,* sect. 6, vol. 1 (1967), which is largely though not entirely restricted to vertebrates. A methodologically important systems analysis of the behaviour of vertebrate and invertebrate selective feeders may be found in C.S. HOLLING, "The Functional Response of Predators to Prey Density and Its Role in Mimicry and Population Regulation," *Mem. Ent. Soc. Can. 45* (1965), and "The Functional Response of Invertebrate Predators to Prey Density," *ibid. 48* (1966). An introductory survey of the relations of insects to their food plants (and feeding behaviour of insects in general) is presented by V.G. DETHIER in P.T. HASKELL (ed.), *Insect Behaviour* (1966). More detailed and specialized material on this point is contained in J. DE WILDE and L.M. SCHOONHOVEN (eds.), *Insect and Host Plant* (1969).

R.B. CLARK, *Dynamics in Metazoan Evolution* (1964), discusses locomotor patterns of invertebrates with hydrostatic skeletons. J. GRAY, *Animal Locomotion* (1968), provides a synthesis of most aspects of invertebrate and vertebrate locomotion. H. HERTEL, *Struktur, Form Bewegung* (1963; *Structure, Form and Movement,* 1966), treats the mechanics of flight and undulatory swimming. E. MUYBRIDGE, *Animals in Motion* (1899, reprinted 1957), is a classic work on the subject. R.A.R. and B.J.K. TRICKER, *The Science of Movement* (1966), is a useful introduction to the physics of locomotion.

R.A. HINDE, *Animal Behaviour: A Synthesis of Ethology and Comparative Psychology,* 2nd ed. (1970), and S.P. GROSSMAN, *A Textbook of Physiological Psychology* (1967), both contain valuable material on several aspects of avoidance behaviour.

SILVIO GARATTINI and E.B. SIGG (eds.), *Aggressive Behaviour* (1969), discusses modern theories and experiments on aggressive behavioral responses of animals. KONRAD LORENZ, *Das sogenannte Böse* (1963; Eng. trans., *On Aggression,* 1966), is a highly readable account. S.A. BARNETT, *A Study in Behaviour* (1963), is a general book with particularly useful sections on aggression.

The following works cover all aspects of animal migratory behaviour: G.M. ALLEN, *Bats* (1939), a classic book on bat biology with a chapter on migration; F. BOURLIERE, *Vie et moeurs des mammifères* (1951; Eng. trans., *The Natural History of Mammals,* 3rd ed. rev., 1964), a modern review of mammal biology with a chapter on migration; J. DORST, *Les Migrations des oiseaux* (1956; Eng. trans., *The Migrations of Birds,* 1962), a modern review of all aspects of bird migration; D.R. GRIFFIN, *Bird Migration* (1964), a useful summary with a good chapter on orientation; F.R. HARDEN JONES, *Fish Migration* (1968), a standard book, with many classic references; G.V.T. MATTHEWS, *Bird Navigation* (1955), an original attempt to explain bird orientation; R.T. ORR, *Animals in Migration* (1970), a modern review of migration patterns among animals; E.J. SLIJPER, *Walvissen* (1958; Eng. trans., *Whales,* 1962), a modern review of whale biology, including a chapter on migration; A.L. THOMSON, *Bird Migration,* rev. ed. (1942); and C.B. WILLIAMS, *The Migration of Butterflies* (1930), two classic books, still useful; A. WOLFSON, "Ecologic and Physiologic Factors in the Regulation of Spring Migration and Reproductive Cycles in Birds," in A. GORBMAN, *Comparative Endocrinology* (1959), an accurate review of the physiology of bird migration, somewhat out of date but still useful.

Dormancy and related mechanism are treated in H.W. WOOLHOUSE (ed.), *Dormancy and Survival* (1969), a symposium incorporating a wide variety of review articles covering dormancy in a broad spectrum of organisms from bacteria through mammals; K.C. FISHER (ed.), *Mammalian Hibernation: Proceedings of the Third International Symposium on Natural Mammalian Hibernation* (1967), 25 papers dealing directly or indirectly with the topic of mammalian hibernation accompanied by over 1,300 bibliographical references relative to this topic; X.J. MUSACCHIA and J.F. SAUNDERS (eds.), *Depressed Metabolism* (1969), a variety of studies relative to hibernation, hypothermia, and thermic instability; W.V. MAYER, "Hibernation"

(1964), a popular pamphlet concerned with hibernation in both birds and mammals; J.P. HANNON and E. VIERECK, *Comparative Physiology of Temperature Regulation* (1962), deals with temperature regulation in both cold- and warm-blooded animals, including hypothermia and hibernation; C. KAYSER, *The Physiology of Natural Hibernation* (1961), an intensive look at hibernation in birds and mammals, including hypothermia and estivation, with emphasis on functional changes; and C.P. LYMAN and A.R. DAWE (eds.), *Mammalian Hibernation* (1960), hibernation and hypothermia in birds and mammals, including articles on such thermally unstable forms as bears.

All modes of behaviour related to reproduction in animals other than humans are dealt with in the references cited below: MARGARET BASTOCK, *Courtship: An Ethological Study* (1967), an excellent survey; DESMOND MORRIS, *Patterns of Reproductive Behaviour* (1970), a compilation of some classical papers, all by Morris; N. TINBERGEN and the EDITORS OF LIFE, *Animal Behaviour* (1965), a good introduction; ARI VAN TIENHOVEN, *Reproductive Physiology of Vertebrates* (1968), a good survey with an emphasis on the hormonal and neurophysiological aspects of reproductive behaviour, especially ch. 9, 11, 13, and 14; S.A. ASDELL, *Patterns of Mammalian Reproduction* (1964), a comprehensive survey stressing anatomical and physiological aspects; C.M. BREDER and D.E. ROSEN, *Modes of Reproduction in Fishes* (1966), the best modern survey of reproductive behaviour in fishes; E.O. WILSON, *The Insect Societies* (1971), the best general treatment of this group; and JOHN SPARKS, *Bird Behaviour* (1969), an excellent introduction to the reproductive behaviour of birds, with excellent illustration.

Behaviour of animals in groups: W.C. ALLEE, *The Social Life of Animals* (1938), a readable classic, emphasizing peck order and social facilitation at the expense of other aspects of social behaviour; ROBERT ARDREY, *The Territorial Imperative* (1966), a somewhat tendentious discussion of animal territories by a playwright; R.D. BARNES, *Invertebrate Zoology,* 2nd ed. (1968); J.T. BONNER, *Cells and Societies* (1955), a readable account of social life from the howler monkeys down to the cell; T.D. BROCK, *Biology of Microorganisms* (1970); J.H. CROOK (ed.), *Social Behaviour in Birds and Mammals* (1970), several excellent technical summaries of modern research in social behaviour, including a discussion of habitat and society; FRANK FRASER DARLING, *A Herd of Red Deer* (1937), one of the earliest field studies of a wild society, establishing that deer are matriarchal; IRVEN DEVORE (ed.), *Primate Behavior* (1965), the best collection of relatively nontechnical articles on the behaviour of free-living monkeys and apes; S.J. DIMOND, *The Social Behaviour of Animals* (1970), a discussion of recent experiments on learning of social behaviour in domestic and caged animals; JOHN F. EISENBERG, "The Social Organizations of Mammals," *Handb. Zool.* 10:1–92 (1965), a review of mammalian social behaviour that shows it derives mostly from maternal societies; PEGGY E. ELLIS (ed.), *Social Organization of Animal Communities* (1965), a useful set of rather technical articles, concentrating on social behaviour in insects; WILLIAM ETKIN (ed.), *Social Behaviour and Organization Among Vertebrates* (1964), a set of moderately technical articles on social behaviour; E.S.E. HAFEZ (ed.), *The Behaviour of Domestic Animals* (1969), a set of technical articles on animals such as cats, dogs, sheep, and goats, with an excellent discussion of physiology; S. MARK HENRY (ed.), *Symbiosis,* 2 vol. (1966–67), informative summaries of a few of the many symbioses known to occur, from viruses to man; DAVID LACK, *Ecological Adaptations for Breeding in Birds* (1968), a demonstration that the social behaviour of nesting birds depends on their habitats and their foraging; CHARLES DARWIN, *The Expression of the Emotions in Man and Animals* (1872, reprinted 1965), the first major attempt to trace the evolution of facial signals; WESLEY E. LANYON and W.N. TAVOLGA (eds.), *Animal Sounds and Communication* (1960), accompanied by a phono record; RENE GUY BUSNEL (ed.), *Acoustic Behaviour of Animals* (1963), a general survey; THOMAS A. SEBEOK (ed.), *Animal Communication* (1968); provides good coverage of various aspects of the subject; MARTIN LINDAUER, *Communication Among Social Bees* (1961), a fascinating account of evolution in and experiments on social bees; KONRAD LORENZ, *Das sogenannte Böse* (1963; Eng. trans., *On Aggression,* 1966); LYNN MARGULIS, *Origin of Eukaryotic Cells* (1970), a discussion of the origin of cells by symbiosis; HARRIET L. RHEINGOLD (ed.), *Maternal Behaviour in Mammals* (1963), a set of moderately technical articles on the mother–infant relationship in mammals; JOHN PAUL SCOTT and JOHN L. FULLER, *Genetics and the Social Behaviour of the Dog* (1965), a scientific analysis of heredity and learning that shows how they interact; EDWARD C. SIMMEL, RONALD A. HOPPE, and G. ALEXANDER MILTON (eds.), *Social Facilitation and Imitative Behaviour* (1968), scientific articles on imitative learning in animals and men; NIKO TINBERGEN, *Social Behaviour in Animals, with Special Reference to Vertebrates* (1953), a popular account by a founder of ethology, concentrating on birds, fish, and insects; E.O. WILSON, *The Insect Societies* (1971), one of the best surveys of the behaviour of social insects, but omits locusts; and V.C. WYNNE-EDWARDS, *Animal Dispersion in Relation to Social Behaviour* (1962), a polemic reviewing much of social behaviour to support the view that animals practice birth control by means of social behaviour—but control is usually by agonistic reactions.

The Development of Human Behaviour

Humanists and scientists alike have long speculated about the relative importance of endowment and experience, or of "nature" and "nurture," in the development of human behaviour. During the 19th century, developmental psychology emerged as a discipline devoted to the systematic investigation of these factors. The term "behaviour" may be understood to embrace both the expressed and potential capacity for activity in the physical, mental, and social spheres of life. The "development of human behaviour," in turn, encompasses three interrelated phenomena: the genesis, or origins, of behaviour; continuity, or constancy, of behaviour over time; and discontinuity, or change, in behaviour. The concerns of those who study the development of human behaviour comprise, first, the description of human capacities and activities over the entire life cycle; second, the comparison of human capacities and activities at different points in the life span, across different cultural and ecological contexts, and often among different species; and, third, the explanation of the interaction of the endogenous (internally arising) and exogenous (externally arising) forces that guide and influence the development of human capacities and activities. The breadth of this inquiry places scientists who study the development of human behaviour in a position to provide information about the natural history of behaviour, the growth of individual behaviour, the functions of behaviour, and the causes of behaviour—in short, what develops and when, how, and why. As a consequence, some scientists believe that all biological and social inquiry is circumscribed by the study of the development of human behaviour.

The present article treats both the study and the phenomena of the development of human behaviour. Because of the intimate relation between physical and behavioral aspects of human development, a brief discussion of physical changes is offered for each developmental stage. For further treatment of biological development, see GROWTH AND DEVELOPMENT, BIOLOGICAL. For further treatment of particular facets of behavioral development, see EMOTION AND MOTIVATION, HUMAN; LEARNING AND COGNITION, HUMAN; PERCEPTION, HUMAN; PERSONALITY; SEX AND SEXUALITY.

This article is divided into the following sections:

Theory and practice in research

THEORIES OF DEVELOPMENT

The concept of development is complex and is defined by several characteristics, or principles. One is that development must have an orderly, cumulative, and progressive character. Continuity and discontinuity in life reflect systematic, successive adaptation in organization over time. A second principle is that development is not a straightforward empirical concept; if it were, the direct inspection of data would indicate to any observer whether or not development had taken place. Scientists often disagree about development because the concept is actually a postulation. In fact, whether or not development has occurred in any given instance is generally determined by whether the features of the data fit an implicit or explicit concept of what development entails.

Debates about the character of development arise because different scientists recognize different criteria and, in turn, because they are committed to different philosophical beliefs regarding fundamental aspects of the nature of human life. As a consequence, in discussing orientation, theory, and data about the development of human behaviour, it is necessary to consider the different philosophical perspectives, or metatheories, that stand behind scientific thinking.

A metatheory is a theory about a theory; that is, a philosophical view about what constitutes a good and useful theory. Issues of metatheory arise in debates about what sorts of ideas ought to be included in a useful theory of behavioral development. For instance, should the theory stress ideas about genetic inheritance or about environmental influence, or should it stress the intimate relation between the two? Scientists differ on this question because adhering to different metatheories means espousing different views of the nature of life. In spite of the multitude of differences, though, the study of human behavioral development shows the influences of three distinct metatheories.

Three metatheories of behavioral development

Some scientists advocate the view that human beings do not differ qualitatively from other natural phenomena and that human beings are therefore controlled by the same forces that control nature. Since all natural phenomena are composed of the same units (*i.e.*, atoms and molecules), the mechanical laws of chemistry and physics that explain the actions of these basic units provide information about how human beings act as well. The basic model of this mechanistic metatheory is the machine, in which complex phenomena are ultimately reducible to the workings of elementary parts and their relations. Movement of the parts is initiated by an application of forces outside the unit and results in a chainlike sequence of events. Applied to the study of human development, the mechanistic model postulates human beings who are essentially passive and only reactive to outside forces. The individual is at rest until activity is caused by external forces (stimuli) that bring about change (responses). Complex human activities, such as the mental act of problem solving or even the feeling of emotions, can be measured quantitatively (at least in theory) as the action of a multitude of stimulus–response connections.

A contrasting organismic metatheory holds that mechanism is inapplicable to the study of human beings because atoms and molecules within humans fuse to create char-

acteristics that do not exist in isolated parts. A proper knowledge of human beings is lost if parts or elements are studied by themselves; hence, human development must be apprehended in a holistic rather than mechanistic manner. This organismic view applied to the study of human development yields an active model in which individuals are constantly active and in which qualitative change is evident in the individual's action on the environment.

A third metatheory postulates that human development arises from continuous interaction among different levels of organization, including inner physical and biological phenomena as well as cultural and historical events. The interaction of phenomena at all these levels contributes to human development. In this contextual view, all levels subject to analysis are reciprocally related and are constantly changing. For example, biological changes in the person influence psychological functioning, just as social mores influence psychological and biological characteristics.

The metatheories outlined above exert telling influences on how scientists address basic questions about behavioral development. They also drive deep divisions between scientists over several key issues in the character and sources of development. The purpose of specific developmental theories is to comprehensively explain the origins of and the constancy or change in human behaviour. Three broad perspectives have been articulated in response to these two salient issues. Each perspective is based on one of the metatheories outlined above, and each succeeds to a degree in explaining development, although no single perspective accounts satisfactorily for the development of human behaviour. (Reciprocally, development could never be understood by assessing any individual cause–effect relation.)

Two salient issues: origins and constancy or change

Two of these major perspectives were initiated in the 17th and 18th centuries out of epistemological debate, that is, debate regarding the origins and growth of knowledge. Nativists, notably René Descartes and Immanuel Kant, argued that human beings are created in the image of God and are born with a good nature and worldly knowledge. Empiricists, notably George Berkeley and John Locke, argued that human nature and knowledge are not innate but develop out of experience. Thus, one school contended that behaviour emerges, maintains itself, or changes because of endogenous forces, or forces arising from within the individual; such a view implies an organismic model of the world, according to which individuals are seen as dynamic and change is seen as qualitative. The second school contended that behaviour emerges, maintains itself, or changes because of exogenous forces, or those arising from outside the individual; in the mechanistic worldview implied here, all change merely comprises sequences of cause–effect reactions. A third school argues that development takes place through the interaction over time of endogenous and exogenous influences.

The endogenous view. An organismic view (in modern terms identified with genes, heredity, and the processes of maturation) locates the impetus for developmental genesis, constancy, and change within the individual. Development is seen to reflect an unfolding biological program regarded as largely fixed and universal. Among the features of behavioral development, proponents of this view distinguish species-typical tendencies, those that all human beings share by virtue of being human—such as the propensity to cry when distressed or to attend to novelty—from heritable tendencies, those that individuals possess by virtue of their particular genetic endowment—such as activity level or the disposition to distractibility. Of course, these two sets of tendencies articulate, or occur in systematic interrelation.

Two false beliefs are commonly held about endogenous influences in development. The first is that any behaviour with biological origins must be present at birth; to the contrary, behaviours associated with puberty emerge naturally more than a decade after birth. The second is that behaviours with biological origins are necessarily fixed. Rather, they can change by themselves or be influenced by experience; for example, the readiness to cry may vary naturally among babies, but the actual frequency of any baby's crying can be influenced by the parents' responses.

Fields of investigation

The study of endogenous factors in human behaviour falls within several fields of investigation. Behaviour genetics attempts to chart the influence of genetic programming on the development of behaviour throughout the life cycle. In this field, for example, consanguinity studies (studies of blood relatives) bear out the common observation that the more closely individuals are related the more similar they tend to be in certain physical and behavioral traits (*e.g.,* height and shyness, respectively); heritability quantifies the relative contribution of genetics to behavioral expression. The disciplines of ethology (the study of animal behaviour) and sociobiology place the development of human behaviour in its larger evolutionary framework. These disciplines often argue that human behaviour and its development are best understood in the context of their evolutionary history. For example, ethological comparisons reveal the values of such factors as relative physical immaturity and social play for cognitive growth in the young of different species.

Endogenous forces would appear to account most easily for those aspects of development that are sequenced, or time bound, occurring at particular periods in the life cycle. The development of walking is a good example; the sequence of crawling, toddling, and walking and the ages at which these developments occur are consistent enough among individuals to suggest a genetic timetable for their unfolding. Exogenous forces, however, might also explain such behaviour: environments could uniformly pressure children to start to walk and to follow the same sequence and roughly the same schedule in doing so. It is not difficult, therefore, to attribute motive in development incorrectly, especially in cases where only the behaviour can be observed and where that behaviour unfolds over long periods of time.

The exogenous view. The direct alternative to the endogenous view is a mechanistic one, which locates the forces for development in the individual's environment (*i.e.,* in experience and learning). Behavioral genesis, constancy, and change, according to this view, reflect the operation of a small set of simple, elegant, and powerful principles of learning and socialization, which include associative conditioning and observation. Thus, for example, spontaneous behaviours (*e.g.,* babbling in infants) that elicit positive responses (*e.g.,* parental smiles) tend to recur. Of course, development could not proceed were it governed solely by such principles of reinforcement; actual responses over time are never so consistently appropriate as the theory of learning requires, and development that depended on reward would be remarkably haphazard, slow, or limited. Imitation is a kind of omnibus learning that requires only observation, internalization, and reproduction of what is experienced and so is extremely efficient and ubiquitous.

The roles of experience

In the exogenous view, experience influences the development of human behaviour in three basic ways. The most dramatic form of influence occurs when experience induces otherwise undeveloped behaviours to emerge. If behaviours are partially developed, experience may serve to facilitate their further development. Experience may also be necessary simply to maintain partially or even fully developed behaviours; in the absence of experience, emerging or mature behaviours may be lost.

Doubtless, truths are to be found in each of these extreme positions—the one attributing the development of human behaviour to nature, the other to nurture—and there exist examples of genesis, continuity, and discontinuity in behaviour that support each. But during the past century of developmental study it has become clear that neither nature nor nurture alone wholly accounts for development; environment provides individuals with stimuli and experiences, and genetics contributes sensitivities, propensities, and capacities by which individuals avail themselves of those stimuli and experiences. Endogenous and exogenous factors together determine development, and both must be considered.

The interactionist view. Endogenous and exogenous factors combine to influence development according to three basic patterns: normative age-graded influences, normative history-graded influences, and nonnormative life-

Normative and nonnormative influences

event influences. Normative age-graded influences consist of biological and environmental determinants of individual development that are tied to chronological age. They are normative to the extent that their timing, duration, and clustering are similar for most people. Examples include maturation events, such as growth spurts and changes in endocrine system function, as well as socialization events, such as marriage and retirement. Normative history-graded influences consist of biological and environmental determinants of individual development that are correlated with historical time. They are normative to the extent that they are experienced by most people living in the same era. Examples include historical events such as periods of economic depression and even the noticeable change in modern times in the age at which puberty begins. Sociocultural developments include changes in sex-role expectations and child-rearing practices. Both age-graded and history-graded influences vary with time. Nonnormative life-event influences are not directly indexed by time since they occur more or less at random. Examples include illness, divorce, and the death of a spouse. In short, the life span is filled with events that are common to all people (*e.g.,* birth, puberty, and death), peculiar to certain groups of people (*e.g.,* religious or social ceremonies), and specific to individuals (*e.g.,* encountering a certain role model or having a particular illness). As a consequence, all human beings exhibit certain behavioral developments that are universal and others that are unique; moreover, each new generation develops in a world that shares some features with the world of its parents and some with the world of its children but also has features peculiar to its historical moment.

In essence, then, human beings develop as changing individuals in a changing world. They develop in response to events that occur at all times in life. At any one time, phenomena affecting the life course are present at all levels of being—the inner-biological, the individual-psychological, the social, and the historical. Since events at each plane affect events at every other, the forces at each of these planes interact to influence human development. People may in turn influence the environments in which they live as much as environments influence them. A person is both a product of biological, psychological, sociological, and historical forces and a producer of those same forces. This concept of the nature of human development evokes the idea of a dynamic interaction among the many dimensions of development across the life span.

Both specific and general theories of human development have been constructed around this notion of interaction.

Piaget, Freud, and interaction

Three important specific theories are those of Jean Piaget, Sigmund Freud, and the developmental contextualists. Both Freud and Piaget posited universal, biologically driven stages of development that colour the individual's changing knowledge and interpretation of the environment. (See below *Infant and child development.*)

Piaget's theory is concerned almost exclusively with the development of the mental life of the child. He supposed that at different points in the life cycle human beings interpret their encounters with the world in identifiably distinct ways and that at particular points, based on the interplay of maturation and feedback from the exercise of particular strategies of understanding, they become dissatisfied with immature and inaccurate interpretations and construct increasingly maturer and more accurate ones. In Piaget's structuralist view, equilibration—the process of adjusting and perfecting the balance between mental understanding and function in the world—is the central engine of change. For Piaget an individual pursues and takes advantage of experiences to achieve higher levels of understanding. A young child, for example, may at first draw a chimney top parallel to the angled roof of the house rather than parallel to the ground. Such a feature does not reflect the child's own experience but rather a naive assumption, which as a result of growing interactive experience is eventually modified to conform with reality.

Freud's theory is concerned almost exclusively with social and emotional development. He supposed that development consists of the resolution of confrontations between the evolving individual and the conflicting demands of the social world. According to Freud, individuals are biologically endowed with needs that motivate their behaviours and are modified and transformed through their social experiences. Although for Freud the emergence of psychosexual stages is determined primarily by maturation, experiences during different periods in development forever colour the individual's socio-emotional growth.

Developmental contextualists also argue that development proceeds out of interactions between the individual and the world; in addition, they stress interactions within the person (for example, among cognitive, emotional, and motivational processes) and interactions among biological and physical-environmental processes. Thus, this theory is probabilistic (*i.e.,* based on the assumption that certainty is impossible) with regard to what a person can know, as well as what can be known about that person—knowledge is always a function of a particular set of biological, psychological, social, ecological, and historical conditions.

Prevailing opinion among behavioral scientists posits an even more intricate transaction between nature and nurture, or endowment and environment. According to this view, individuals are born into the world with both cognitive and social propensities that help to shape their experiences, and in turn they are shaped by their experiences to the degree that the environment presents certain events and that the individuals themselves are plastic (responsive) to them. In other words, development is a transactional process in which the individual and the environment continuously affect each other through time. Attributes of the individual have meaning for development only by virtue of their interaction with a particular set of time-bound contextual conditions, and, reciprocally, development can only be understood by specifying relations of the context to specific developmental features of the individual. This position has two significant corollaries. One is that individuals help to produce their own development by provoking significant others in their lives, by processing information and events in the world idiosyncratically, and by actively selecting or shaping the context within which they act or interact. A second is that events in one period of life help to shape and to texture what transpires or how what transpires is understood in other periods of life that come before as well as after.

The theoretical orientations described above have implications for key issues in the study of human development, for what develops, and when, how, and why. In the mechanistic view, development is the quantitative accretion of identical elements; in the case of behaviour, for instance, these elements are stimulus–response connections. The number of such connections changes over time, and there is no a priori direction of change. Moreover, a stage in development merely summarizes the organization of such connections; there is nothing qualitatively distinct about the individual at one or another stage. In the organismic tradition, however, qualitative status and change in both structure and function are emphasized, and change constitutes a specified movement toward a predetermined end state. A stage in development denotes an organization of behaviour that is qualitatively different from those of prior or subsequent stages. Developmental contextualism emphasizes the bidirectional character of both qualitative and quantitative change in structure–function relations. The interactionist view admits of stages, born of an intrinsic interplay between nature and nurture.

The concept of developmental stages

TECHNIQUES OF RESEARCH

All scientific research rests on the pursuit of knowledge by observation and experimentation. To study the development of human behaviour, a scientist must decide, first, the means by which observations and experiments should be made and, second, the designs according to which observations and experiments should be scheduled.

Means of observation and experiment. Scientists observe genesis, continuity, and discontinuity in human behaviour in many different ways. Choice of technique is determined by many factors, including an interest in avoiding reactivity (influences a person experiences as a result of being observed). One useful way to study the development of human behaviour is to observe it natu-

ralistically, either by participant observation (in which the researcher actually becomes a part of the study setting for an extended period of time) or by structured observation (adopting a more detached and rigorous stance with regard to the setting). Either way, the observations must be systematic, and the behaviours investigated must be explicitly operationalized (*i.e.*, they must be defined so that they can be replicated independently). Naturalistic observation is reasonably faithful to everyday life and usually provides valuable information about behaviour. Its role in the study of the development of human behaviour has been important; indeed, modern developmental study was initiated by Charles Darwin's observations of his infant son William ("Doddy"). Limitations of naturalistic observation include the fact that it may be inefficient in that the behaviours of interest may occur only at infrequent or irregular intervals, that researchers may be unable to attend simultaneously to a variety of behaviours of interest (even with the aid of supplementary recording apparatus), that the descriptive data yielded by naturalistic observation often do not serve the purpose of explanation, and that uncontrolled as well as unknown factors may influence the behaviours being observed. Consider, for example, a study of the development of aggression in five-, six-, and seven-year-old children. A researcher may choose appropriate samples of children and then observe predetermined categories of aggressive behaviour while the children are at play in a schoolyard. It is possible, however, that after several days the researcher would find that he had too few observations of the behaviours of interest, that the observed field of action was too great in scope, that the activity itself was too furious, or that the observations yielded only descriptive information that aggressive acts occurred with certain frequencies in children at certain ages but did not explain why they occurred. Furthermore, factors peculiar to the situation but not observed by the researcher could selectively influence the expression of behaviours.

Two other approaches to the study of behavioral development are controlled and experimental observation. In controlled observation, the research situation is naturalistic but structured, and participants' behaviours are not directly manipulated. In experimental observation, the researcher exercises maximum control over the observations and performs direct, calculated manipulations of behaviours.

To illustrate controlled observation, suppose that the researcher is interested in the bases on which adolescents form heterosexual relationships. The researcher may place a group of male and female adolescents unacquainted with each other in a classroom and instruct them to form two-person study groups, ostensibly to examine a topic about which all have little background. Observers may then rate the physical attraction between couples. The situation has been controlled, and some characteristics of participants within the situation have been arranged. To illustrate experimental observation, suppose that the researcher is interested in the extent to which each of three types of instructional techniques influences learning. Since variable factors such as sex, age, social class, intelligence, race, religion, and type of school can also influence learning, these factors must be controlled in order to focus the study on the instructional techniques. Thus, the subjects of the study may be limited to 10-year-old, white, middle-class, Protestant boys of average intelligence, attending a public elementary school in the southern United States. The only factor varied would be the type of instruction to which these children are exposed so that only the precise effects of instructional technique on learning are determined. In this type of experimental observation, conditions are manipulated in such a manner that only those factors whose effects are to be ascertained actually vary, and this variation itself is also controlled, yielding particularly clear data on the phenomenon. Unfortunately, information yielded in such a study would be limited to the conditions of the study, and because of this limitation it may be far removed from everyday life. The effects of the instructional techniques on boys or girls of different racial compositions and social backgrounds, or who attend schools in different places, would be unknown. Moreover, the known effects of instructional technique even on the subjects of the study would be limited; in the real world the factors that the researcher would have controlled would vary and would, no doubt, influence his subjects along with the instructional mode.

Observational techniques are useful only when the behaviours in question are observable and are ethically open to scientific study. Alternative techniques may be required in some circumstances: when it is desirable to study large numbers of people over intervals shorter than those permitted by behavioral observation; when there is no overt behaviour to observe (as when feelings, attitudes, values, or recollections are of interest); when the behaviour may not readily or ethically be seen through observation (as in activities that may be harmful or embarrassing); or when the presence of a researcher may distort the behaviour (as in sexual interactions or voting). Questionnaires and interviews can circumvent these difficulties, although subjects' recollections or predictions regarding their behaviour must not be considered a true index of actual behaviour.

Most methods of studying behavioral development involve an element of compromise. For example, naturalistic observations are inefficient but retain real-life validity; experimental observations are more efficient but risk invalidity for the sake of control. Obviously, both approaches contribute to the scientist's goals of objectivity, reliability, efficiency, replicability, and representativeness. In order to increase both validity and accuracy, scientists often employ what are called converging operations, bringing several different research strategies to bear upon the same problem or question.

Designs of observation and experiment. The basic stages of behavioral development proceed according to a biological timetable measured by chronological age; historical context, however, strongly influences certain expressions of development, as many characteristic behaviours and attitudes of each succeeding generation may differ from those of the previous one. In designing investigations into particular aspects and patterns of behavioral development, scientists must take both of these influences into account. "Design" here refers to the selection of a particular array of individuals for observation or study. Of the many standard designs in developmental research, two are most popular. Each has utility, but each also has weaknesses that must be weighed against its strengths. In the longitudinal design, the scientist observes and compares the same individuals over time. This procedure provides the only means of assessing directly continuity and discontinuity in the individual's behaviour across stages of development, of interrelating development in different domains, and of evaluating the effects of early experience on later behaviour. Longitudinal study is expensive and time consuming, however, and many potential subjects are unwilling to participate in research over long periods of time, so that samples studied tend to be small; also, willing participants may not be representative of the population at large. Furthermore, repeated assessment risks altering the behaviour of participants. The most widely used developmental research schedule is the cross-sectional design, in which individuals of different age groups, or birth cohorts, are studied at the same time. Observations of different ages can be completed relatively quickly in this design, without practice effects (behavioral changes caused by the observation itself) or attrition, and this approach is relatively inexpensive. Cross-sectional design, however, does not permit many of the comparisons (*e.g.*, individual growth) allowed by longitudinal evaluation. Also, in a cross-sectional study it is difficult to control all of the variables that may affect behaviour differences among groups, since such differences may reflect real age changes or initial inequality among age groups. Therefore, whether and the extent to which age-group differences correspond to age changes within individuals over time is left open to question.

Longitudinal design

Cross-sectional design

Alone, neither of these two developmental research designs allows for adequate determination of the contributions of the separate factors of chronological age and birth cohort since each involves a confounding of potential components of change. When variables are confounded,

the influence of one behaviour cannot be separated from that of another since the two may be influencing behaviour at the same time. Thus, findings about development gained from longitudinal study may reflect age-related changes, determined endogenously, or exogenously determined changes related to the historical context of birth and development. Likewise, cross-sectional results confound chronological age and birth cohort, so that at any one time individuals of different cohorts may exhibit different behaviours caused by either their different chronological ages or by their having been born during different time periods.

Some limitations of conventional designs are transcended by combining longitudinal and cross-sectional features in sequential designs. In the so-called cross-sequential design a succession of two or more cross-sectional studies is conducted; in the so-called cohort-sequential design two or more longitudinal studies are conducted in succession. Sequential designs assess the relative contributions of age and cohort simultaneously, but they are difficult and often expensive to undertake.

Sequential designs

Thus, conventional research designs do not allow for unconfounded assessment of the contributions of age and cohort, and less conventional ones are difficult to implement. Because of their respective benefits and shortcomings, the various methods yield variously useful depictions of development. No research method is without limitations, and the general view is that all of the conventional designs of research can contribute to understanding the development of behaviour if they are employed with clear recognition of their limitations.

Development across the life cycle

Any attempt to answer central questions as to what develops, when, how, and why requires two assumptions. First, it is necessary to partition the life cycle; sometimes chronological age (a continuous variable) is an appropriate measure, but at other times some category of the life span is more apt (*e.g.*, infancy and childhood). Second, it is necessary to distinguish among the various domains in which development occurs (*e.g.*, sensation and perception). These two decisions are not as straightforward as they appear. For example, there is some reason to suspect that the concept of "adolescence" as a separate stage in the life cycle is historically relatively new, and there is also debate about whether perception differs from cognition. Nevertheless, certain biological events, such as birth or the onset of reproductive maturity at puberty, or social events, such as the acquisition of language or retirement from work, mark off distinctive and often universal phases of the life span. Likewise, development takes shape in separate physical, mental, and social spheres. With these categories in mind, therefore, it is possible to examine highlights of development in three domains—the physical, mental, and social—during five phases of the life cycle—prenatal life (physiological development only, for the purposes of this discussion), infancy and childhood, adolescence, adulthood, and old age. A common view depicts human development in terms of genesis before birth; growth and maturation during infancy, childhood, and adolescence; stability during adulthood, and inevitable degeneration and decline during old age. However convenient and reasonable such a breakdown may appear, closer examination of each stage reveals disparities and continuities that defy simple categorization.

Phases of development

PRENATAL PHYSIOLOGICAL DEVELOPMENT

In order to examine the development of behaviour throughout all phases of the life cycle, it is necessary to begin with the phase before birth, in which behaviour as it is considered in this article does not yet emerge but in which the "constitution" of the individual, to whatever degree such a concept is regarded as operational, may be said to take shape.

Three periods of prenatal development have been distinguished—the zygotic, the embryonic, and the fetal. The period of the zygote, or fertilized egg, lasts from the moment of conception through the time of implantation in the endometrium, or lining of the uterus. The hallmark of this period is cell multiplication. The succeeding period of the embryo lasts for approximately two months, during which time fundamental morphological and structural developments occur. At this stage, three layers of the organism are distinguishable—the ectoderm, presumptive of mature skin, sense organs, and central nervous system structures of brain and spinal cord; the mesoderm, presumptive of mature muscles, blood, and the circulatory system; and the endoderm, presumptive of mature digestive, respiratory, and other internal organs. At two months after conception the embryo is little more than a couple of centimetres long, but it is morphologically humanoid: all of the major organs are differentiated, although they are not fully developed or maturely proportioned. For example, arms and legs are recognizable, as are fingers and toes; the stomach produces digestive juices; the kidneys filter blood; and the heart beats. The following period, that of the fetus, lasts from two months after conception to the end of gestation and is a time of increasing function and change in bodily proportion. In the fetal period, fingers separate and grow nails, veins develop, muscles interconnect; the fetus has been observed to suck, blink, and even yawn. By four months, fetuses are felt to "quicken," or move in utero; by six months, the expansion and contraction of the lungs and the functioning of the nasolacrimal ducts indicate breathing and crying; and by seven months, fetuses may survive in the extrauterine environment.

It was once believed that a "preformed" human organism resided either in the mother's egg, waiting to be released, or in the head of the father's sperm, waiting for a medium in which to grow. It is now known that each parent endows the offspring with one complementary member of each of 23 pairs of chromosomes that form its genetic constitution, or genotype. The genes that make up chromosomes are themselves composed of chemical codes that guide the development of both structure and behaviour. Although genetic endowment is critically important in the life of the individual, the genotype does not necessarily predict the phenotype (the individual's observed characteristics). Different people with different genetic makeups sometimes look or behave similarly, just as "identical" twins, whose genetic makeups are the same, may look or behave differently. Genetic endowment and experience interact even at the earliest stages of the life cycle to shape the structure and behaviour of the individual.

Genotype and phenotype

Because the time before birth is a period of rapid and extensive development, many factors may influence the course and quality of prenatal growth. These factors include parental age (birth complications tend to increase with parental age), diet (protein is advantageous and malnutrition is perilous since nutrients constitute both the building materials of development and the fuel by which development is propelled), and ingestion of drugs, as well as exposure to disease and environmental toxins. The mechanism of action of such effects is not straightforward: At prescribed times, known commonly as sensitive periods, the organism becomes especially vulnerable to exogenous influences that may temporarily or permanently alter structures or behaviours. These sensitive periods usually occur between the time a particular structure or function emerges and the time it reaches its mature state. For example, the eyes and the visual system develop most rapidly during the second month of pregnancy, and maternal contraction of rubella (German measles) at this time presents a nearly 50 percent risk of causing infant cataracts. Developmental timing is so important that different toxins have similar (often serious) effects during the same phase of prenatal life, yet they may not affect development in identifiable ways at other stages. Further, the effect may be disproportionate to the dose, and it may be delayed.

"Sensitive periods"

Structures related to particular functions emerge at various times during prenatal development. Subcortical structures that control the behavioral state, including the hypothalamus and arousal system of the reticular formation, emerge first. Components of the limbic system and basal ganglia, which govern emotion, instinct, and posture, develop next. Finally, the cortex and its cortical association areas, concerned with awareness, attention,

memory, and thought, emerge last. Because of the nervous system's complexities and astonishing ability to regulate and integrate information, its development in prenatal life is especially remarkable. The adult human brain contains approximately 100,000,000,000 neurons; because virtually no new neurons are generated after birth, some 250,000 cells must be generated every minute before birth. In human beings, genetic programming ensures the cell abundance that is required to perceive, think, feel, and act. The individual cell comes into being, matures, develops sophisticated interconnections with other cells, and subsequently specializes in function. In short order individual neurons aggregate morphologically to initiate meaningful human brain functions. This predetermined specialization does not preclude the plasticity of individual cells or of cell masses since their functions may be modified if they are relocated (through transplantation, for example) before a sensitive period occurs; in addition, some cells may assume the functions of other cells that die, exhibiting further exchange of function. Neurological research suggests that the newborn brain is particularly open or plastic in these regards. Although the neonatal or newborn period is commonly considered a time of growth, expansion, and development, another essential neurological function in early life is the contraction, death, and elimination of initial cell overproduction. Overproduction is thought to underpin plasticity early in the life cycle and the restriction of function later.

Plasticity

Brain function is intimately linked to the development of the sensory systems that enable the organism to register, integrate, and interpret its world. The senses do not lie dormant until they are suddenly switched on at birth; evidence suggests that the sensory systems function well before birth. The different senses seem to achieve structural and functional maturity at different times prenatally—in the order of sensitivity to touch, position, sound, and light—reflecting a staggered developmental schedule that loosely follows the order in which these systems developed during the species' evolution.

Development of the senses

Although it is notoriously difficult to establish causal relations between the brain and behaviour, it would be surprising if behavioral development were not reflected in analogous changes in the structure and working of the human brain. Indeed, in large measure, the psychological accomplishments of infancy reflect impressive prenatal developments of the nervous system. In the space of approximately nine months a single fertilized egg develops into a complex, self-regulating organism, and in an additional nine months it develops further into a sentient child capable of some intelligent feelings, thoughts, and actions. In short, development of the central nervous system prepares the fetus for its new role as a child outside the womb.

INFANT AND CHILD DEVELOPMENT

By definition, infancy is the period of life between birth and the acquisition of language, approximately one to two years later. Despite its brevity, this phase of development has attracted a disproportionate amount of attention and interest, perhaps because the physical and behavioral changes that take place during this time are more dramatic than at any other period in the human life span. The average newborn weighs approximately $7\frac{1}{2}$ pounds (3.4 kilograms) and measures approximately 20 inches (51 centimetres); by the end of the first year of postnatal life the average infant weighs approximately 20 pounds, or nearly three times the birth weight, and measures approximately 30 inches in height, or half again the birth length. Change is equally remarkable in every sphere of development: in the shape and capacity of the body and its muscles, in the advancing complexity of the nervous system, in the growth of sensory and perceptual capacity, in the ability to make sense of and to negotiate the physical world, and in the formation of social affinities and the emergence of personal and social styles. At no other point in the life span do such major changes occur in so many aspects of development so quickly; nor at any other time are they so thoroughgoing. The pervasiveness, rapidity, and clarity of developmental change in infancy help to account for the universal fascination with this stage in the life cycle.

Physiological aspects. After approximately 266 days of gestation, an unknown factor causes the maternal pituitary gland to release a hormone (oxytocin) that in turn initiates muscular contractions of the uterus and the subsequent expulsion of the fetus. The duration of this process, called labour, is influenced principally by maternal age and parity (number of children previously born); it is approximately 17 hours on average for firstborn babies. Significant risks during this period to later psychological development include oxygen deprivation (anoxia) and overuse of anesthetics, both of which have been associated with a variety of adverse long-term sequelae, such as motor defects and impaired cognitive performance. At birth, infants are examined immediately to determine the need for medical intervention and to establish normal functioning. For all its drama, however, birth neither terminates nor initiates development; it is simply one stage in an ongoing developmental process.

The birth process

Newborn activity appears to be spontaneous and random; newborn babies move their eyes, mouths, hands, and feet constantly and without apparent purpose, and they seem to shift abruptly and unpredictably among states of sleep and alertness. Long-term observation, however, reveals considerable regularity in the pattern of cycles of many behaviours in the newborn. Involuntary activity is organized at greatly different rhythms. The rhythms of breathing and sucking are rapid, cycling regularly at frequencies of one or more per second; general bodily movements cycle at periodicities of a minute or two; and waking, quiet sleep, and active sleep are low-frequency phenomena that cycle at periods of one or more hours. At any given time, newborn activity reflects the simultaneous but independent cycles of several complex rhythms.

Periodicity of activity in newborns

In the first month, newborns are awake for about a third of the day. State of consciousness is an important consideration in infancy, since most of what infants learn about the world, about people, and about their own abilities can only be acquired during periods of quiet alertness and attentiveness. Although human neonates appear helpless, they are capable of a small number of integrated and organized (if limited) behaviours: These are reflexes, simple and unlearned stimulus–response sequences that are biologically meaningful and suggest an evolutionary and adaptive significance. For example, approach reflexes serve to maintain sustenance and include breathing, sucking, and swallowing. Avoidance reflexes, which ward off danger, include coughing, sneezing, blinking, and muscle withdrawal. The regularity of reflex function in human infants provides a means of assessing normal neurological development, since both the emergence and disappearance of many reflexes by the end of the first year indicate neurological integrity.

Physical and motor development in infancy and early childhood are impressive because they are so evident and because change is so rapid. Moreover, physical and motor development have both practical and theoretical implications for growth in other spheres of psychological functioning. Because physical growth is so easy to observe and quantify, it was one of the earliest subjects of study by scientists. Its study betrays several general principles, including directionality. Whether in terms of anatomy, complexity of function, or voluntary control, growth tends to proceed cephalocaudally, or from the head of the body to the feet, and proximodistally, or from the centre of the body outward. A second principle of growth is the independence of systems. In the first years of development, the nervous system achieves more than half of its adult status, physical characteristics of the body develop to less than a third of their eventual goal, and secondary sexual characteristics develop hardly at all. A third principle of physical growth and development is canalization, the narrowing or restricting of alternatives so that genetically endowed targets tend to be reached in preference to others. A fourth general principle combines the normal (Gaussian) distribution of many physical, biological, and psychological characteristics with the proviso of individual differences. The normal distribution shows species-typical characteristics. For example, very few adults are four or seven feet (1.2 or 2.1 metres) tall; many more are five and

Principles of physical growth

six feet tall, and most fall in between. These distributions of structure and function are important since they define norms as well as probable ranges for individual differences. For many normal developmental achievements, the age of acquisition has enormous import, but the true range of individual differences is extraordinary especially when considered in proportion to the child's age. For example, some children first walk at 10 months, others at 18 months; some children say their first word at nine months, others at 29 months. Developmental variation in physical growth, as in other spheres of life, may arise in many different ways. Parents particularly tend to be interested in knowing how individual children develop characteristic capacities; scientists, too, find questions concerning the origins and growth of individual differences especially interesting, but they tend more often to focus on general developmental capacities and trends. It is important to keep in mind that, statistically, the central tendency of a distribution does not necessarily best represent that distribution, nor is it necessarily optimal for members of the distribution. Moreover, general developmental trends need not necessarily represent how all or even any individuals develop.

Infant motor development

Like physical growth, motor development is dramatic in the first years of life. From the newborn, unable even to grasp an object or to roll over from the position in which originally placed, emerges the toddler, who is manually deft and able to locomote anywhere at will. Psychomotor development also suggests a program of maturation, although research shows that experiences can channel its course. Depending on the behaviour involved, maturation and experience vary in relative importance. For example, though experience facilitates the coordination and strengthening of muscles generally, experience seems to play a less significant role in the development of gross skills such as walking (in which limits are set largely by the rate of physical maturation) than in the development of finer skills such as skiing (in which earlier and better training seems to make a great difference).

Perception in infants

Although hardly mature, the senses function well at birth. Perception constitutes a necessary first step in experiencing and interpreting what the world has to offer, and for this reason philosophers and scientists have been attracted to the study of perception at or near the beginning of life. Determining how the senses function in infancy also offers a glimpse into the infant's perceptual world and suggests what aspects of the environment can influence that infant's development. No matter how early in life a perceptual capacity manifests itself, it can only manifest itself in terms of actual experience; potential is not observable until it is brought into use. Conversely, no matter how late in an individual's life an ability emerges, its emergence can never be attributed exclusively to experience. Research into the origins of perception has focused on the related goals of, first, determining whether or not particular perceptual capacities are present at the beginning of life and, second, tracing continuity or discontinuity in those capacities as they develop. Perceptual ability is a natural outgrowth of biological sensory function; however, experiences are also critical for normal perceptual growth and development. An experiment conducted with institutionalized newborns, for example, showed that introducing a visually interesting stabile, or fixed sculptural form, into the infants' otherwise bland environment at one month after birth nearly doubled their visual attentiveness and visually directed reaching. Studies of naturalistic mother–infant interaction also suggest that experience influences infants' competence in visual and tactual exploration. Furthermore, it is known that in the development of taste, the greater the variety of infantile experiences, the more open to new tastes the child will be.

Research shows the achievement of extraordinary perceptual sophistication over the first months and years of life. In vision, for instance, newborn babies attend selectively to parts of patterns in which there is information. During the first half year of life there is rapid development in acuity, from 20/800 vision (in Snellen notation) among two-week-olds to 20/70 vision in 5½-month-olds to 20/20 vision at five years. Research shows, too, that well before the end of the first year infants perceive form as form (for example, they perceive an object's shape to remain stable even through transformations of the object's image on the retina), perceive depth in space (showing sensitivity to a "visual cliff" and to an object looming at them), distinguish orientation (smiling at faces on the vertical axis more often than at upside-down or horizontally rotated ones), locate objects in space (reaching in ways that indicate good prediction of location), and display sensitivity to object movement (discriminating among different kinds of motion). Before they are six months of age, infants give evidence that they perceive the colour spectrum in a qualitative, relatively mature fashion, partitioned into categories of hue. In audition, newborns give evidence that they hear, and young infants have been found to display sensitivity to basic dimensions of sound as well as to elemental qualities of human speech. Indeed, young infants are especially attracted to speech as meaningful communication rather than mere noise or a composition of different sounds. Knowledge of the development of taste, smell, and touch in early life is more rudimentary than that of seeing and hearing; nevertheless, by their facial expressions when sweet, sour, and bitter substances are placed on their tongues, neonates give evidence that they discriminate among common tastes and rate them hedonically, or according to their relative pleasurableness. Moreover, by evidence of their facial expressions and attempts to approach or withdraw from diverse odours introduced by means of cotton swabs held beneath the nose, neonates give evidence that they discriminate among common odours and rate them hedonically. Indeed, breast-feeding babies only days old recognize maternal scents. Likewise, infants explore tactually with increasing efficiency. With age, mouthing of objects decreases while fingering and manipulation increase. Exploratory activities rapidly develop to match the characteristics of the object explored; *e.g.,* infants have been observed to respond to a change in an object's shape by rotating the object and to a change in an object's texture by increased fingering.

Integrated perception

Just as an adult at the ocean sees the waves, hears the surf, smells the salt air, and experiences these sensations as an integrated percept, so over the first year does the infant experience the world by means of senses working in concert. For example, manipulation allows tactual exploration and enhances visual investigation. Studies show that infants are extremely sensitive to multimodal information even when it stimulates different senses in distinctly different ways; thus, they can associate a particular face with a particular voice. In uncovering these facts about early perceptual life, investigators have eradicated the once staunchly held notion that infants and young children are perceptually deficient.

Cognition and language. Cognitive development, which takes place against this backdrop of remarkable neurological, physical, and perceptual change, entails the child's growing ability to make sense of the physical and the social environment, that is, to recognize specific objects and persons, to learn the laws that govern their behaviour, and to participate meaningfully in communicative dialogue. What learning, thinking, and language are and how they develop over the first years of life constitute central concerns of scientists interested in the development of human behaviour.

The principle of association

According to the principle of association, two events that occur in close proximity in space or in time tend to be remembered together so that the recurrence of one will bring the other to mind. Because it is a basic mechanism of learning, this principle has long been thought to subserve cognitive and emotional growth. Several types of learned association have been identified; among them are classical conditioning (in which a neutral stimulus assumes the properties of an evocative stimulus through association with it), instrumental conditioning (in which actions that are followed by reward tend to recur and actions followed by punishment tend to be inhibited), and exposure learning (as in the progressive decline in responding to an event that is available continuously or repeatedly). These types of learning are thought to involve the construction of a mental representation of an event

and ongoing comparison of available stimulation with that mental representation. Research clearly demonstrates the very early functioning of these different modes of learning. Newborns can associate a particular orientation of the mother's face with the sweet-tasting substance that is consistently paired with it; they alter their sucking patterns for the reward of mother's voice; and they pay diminishing attention to repeated stimuli. There is even evidence that these modes of learning operate among fetuses in utero.

All of these phenomena indicate that infants from the start of life can avail themselves of many experiences. The fact that human beings can learn so early in life, however, does not preclude development of the learning capacity. Indeed, even in the first years of life, growth in the ability to learn is impressive; for example, the rate of exposure learning shows steady and dramatic change even during the first postnatal year, perhaps reflecting the ongoing physiological maturation of the central nervous system. Factors other than age also influence early learning. These factors include the behavioral state (usually the attentiveness of the infant or child), the elements to be associated (it is by no means self-evident that classical conditioning can be established between any two events or that any behaviour can be strengthened through instrumental learning; rather, human beings are evolutionally "prepared" to learn some associations with greater facility), and the complexity of the learning task. When learning begins, more than associations are learned; knowledge is also acquired about the task of learning. It is widely believed that learning in infants leads to the development of effectance (self-confidence in the ability to control experience), to the motivation to learn more, and thereby to even greater discovery and mastery.

The development of memory

Learning requires memory; the effects of learning are minimal in the absence of any storage and aggregation of knowledge. In considering the growth of memory, scientists distinguish between two pairs of concepts: First, there is the storage, or encoding, of incoming information as opposed to the retrieval of that information later. Second, there is recognition, in which the memory of an experience is cued by repeating the experience, as opposed to recall, in which the memory is retrieved without any cues. Research demonstrates reasonable capacity for recognition even among newborns, as well as rapidly improved encoding and retrieval over the first years of life. For example, infants familiar with one face will later look at a novel face in preference to the familiar one, and toddlers observing the hiding of a toy will later successfully search for it. Again, age combines with conditions of learning to affect the robustness of memory. For example, training conducted over several intervals (distributed practice) typically results in better memory than training conducted all at once (massed practice), and evaluation of memory after a short delay shows more positive results than does evaluation after a longer delay. In general, encoding skills and short-term memory seem to improve rapidly over the first year, and retrieval skills and long-term memory seem to improve gradually over the entire course of childhood.

Two approaches dominate psychological evaluation of the development of thought. One tradition is rooted in the psychometric testing of intelligence, and the other is founded on the Piagetian theory of qualitative changes in mental structure. The two views converge in the beliefs that intelligence implies successful adaptation to the environment and that genetic inheritance and experience interact in contributing to the development of intelligence. Just as it would be disadvantageous for nature to fix an organism's intelligence in advance of its experiences in the world, it would be highly counterproductive to leave the development of intelligence wholly to experience, since individuals' experiences can vary so widely. Although intelligence may manifest itself in many ways, psychological tradition has fixed on verbal and logical skills to evaluate individual achievement.

The mental testing movement was founded at the beginning of the 20th century to study differences in adult perceptual functioning and to identify incipient mental deficiency in childhood. Two compelling questions related to the early development of intelligence soon arose—namely, how early in life intelligence might manifest itself and whether an individual's intelligence early in life was related in a meaningful way to that individual's intelligence in maturity. In general, traditional infant tests applied in the first years of life have shown poor reliability (consistency of test scores over time) as well as poor validity (relation of test scores to independent and objective criteria). Several rationales have been provided by way of explanation: Some have argued, for example, that early development proceeds by fits and starts so that unreliability and unpredictability are inherent to this stage of life; some have argued that early life is a period of such rapid growth that test items appropriate for one age may be inappropriate for another; and some have argued that early life is a period of such extreme susceptibility to experiences effecting rapid change that children affected by different experiences may be inappropriately tested with the same items. By contrast with results of traditional infant tests, new measures of attention in early life that attempt to assess the child's efficiency in acquiring information from the environment exhibit reasonable reliability and validity. Individual differences among infants and young children of given ages, as well as different levels of competence across ages for comparable cognitive tasks, have long been attested, but early psychometric tests repeatedly showed that only after four to five years of age did children's scores begin to stabilize in relation to their performance in maturity. Recent work suggests a degree of predictability in cognitive growth from an earlier period in the life cycle.

Problems of testing infant intelligence

Contemporary research supports the theory of an endowed intelligence that is open to postnatal experience. Studies of both the origins and the maintenance of intelligence from infancy into adulthood show the roles of both endogenous and exogenous factors. On the one hand, identical twins, who share 100 percent of their heredity and most of their environment, are more alike in the pattern and development of their intelligence than are fraternal twins, who also share a good deal of their environment but only half their heredity on the average; likewise, parent and child intelligence test scores are strongly associated. On the other hand, parental intelligence is thought to influence parental behaviour toward children, which in turn is presumed to influence child mental performance. So, for example, institutionalized children and children from lower social classes tend not to score as highly on standardized intelligence tests as do children from intact families or upper social strata, owing presumably to the disparity in formative experiences. The demonstrable success of cognitive interventions with deprived children supports these findings and goes far to discount alternative explanations that the apparent influence of family structure and social class on test scores reflects inherent differences in cognitive ability among the comparison groups. Indeed, research has progressed significantly toward pinpointing the types of experience that affect cognitive development, including the amount, variety, appropriateness, and contingency of stimulation, as well as the interactive quality between child and adult. Research shows, too, how the efficacy of these different types of experiences varies across infancy and childhood. Recognizing the role that experience plays in the development of intelligence is especially important, since, in everyday life, infants and young children normally provoke adults to act in different ways with them, and individual as well as age differences clearly affect the types of learning experiences to which children are exposed.

Complexities of family and social influence

There can never be empirical certainty about which factors contribute to the development of cognition. Environmental and genetic bases for characteristics such as intelligence in children reared by their biological parents cannot be separated because these two sets of forces are ineluctably intertwined.

Based on extensive observations and informal tests of his own three children early in the 20th century, Jean Piaget proposed what he called a genetic epistemology, according to which infants and young children constantly reconstruct their own means of knowing in ways that join their evolutionary history with their particular experiences in the world. In doing so, Piaget rejected both the

Piaget's "genetic epistemology"

nativism and the empiricism then prevailing and introduced a new set of concepts. In contrast to nativists, for whom the basic elements of knowledge are innate ideas, and to empiricists, for whom the basic element is sensation, Piaget introduced the notion of schemes, roughly defined as the various faculties of the central nervous system (including sight, hearing, symbolic thought, and language) by which information about the environment is processed. In Piaget's view, intelligence is a function of adaptation employing the complementary techniques of extracting meaning from data by organizing them according to existing schemes (assimilation) and modifying existing schemes in order to assimilate new information more efficiently (accommodation). Assimilation, for example, predominates during pretend play, in which reality is interpreted as the child wishes, and accommodation predominates during imitation, in which the child mimics new realities as closely as possible.

In Piaget's view, human beings throughout their lives actively adapt their own mental structures, which unfold according to a genetic timetable, in order to maintain equilibrium with the perceived environment. Two examples are the decline in childhood egocentrism and the rise of the concept of objects as independent entities; both are based on the child's transactions with the physical and social environment. Piaget proposed that the development of understanding in the child proceeds through a series of four universal stages, fixed biologically and manifesting distinct dimensions of mental activity: (1) the sensorimotor stage (first two years of life), in which the child experiences his physical self, through reflexes and external stimuli, as an entity in an environment; (2) the preoperational stage (age two to six or seven), in which the child learns to manipulate the environment by means of symbolic thought and language; (3) the concrete operational stage (age seven to 11 or 12), in which the beginnings of logic appear in the form of classifications of ideas and an understanding of time and number; (4) the formal operational stage (age 12 to adulthood), characterized by the manipulation of abstract concepts and the mastery of reasoning. Piaget's theory has been influential in educational policy by suggesting that there are constraints on how significantly the environment can influence cognitive growth if a child has not reached the appropriate stage to assimilate certain experiences. It has influenced linguistic theories by suggesting that aspects of both language acquisition and social attachment attend the cognitive apprehension of the permanence of objects and the development of mental representation. It has also provoked deeper inquiry into processes related to cognition—such as children's play, the development of which has been shown to be orderly, sequential, based on action, and increasingly oriented toward the environment.

Piaget's influence

Piaget's work has an important extension into the study of moral growth in childhood. Piaget hypothesized that all people pass through two phases of moral reasoning. In the first phase an objective and concrete morality is based on the constraints imposed by the powerful (*e.g.,* adults) on the nonpowerful (*e.g.,* children). In the second phase the individual develops a subjective morality based on an abstract understanding of the contracts implicit in cooperative and autonomous relationships. Piaget's stress on the universal ordering of moral growth represents an approach that is quite distinct from relativistic, response-centred approaches. As such, it has stimulated considerable interest among developmental researchers. In particular, the American psychologist Lawrence Kohlberg proposed several stages of development in order to account for the many observable qualitative changes in a person's moral reasoning. Kohlberg's theory of moral development, like Piaget's, is based on the idea that to focus only on the response in a moral situation is to ignore important differences in people's moral reasoning at different points in their lives. These differences in reasoning may, in fact, give different meanings to identical responses evoked at various developmental stages.

In order to investigate the reasoning underlying moral responses, Kohlberg devised a moral development interview based on a series of stories, each presenting imaginary moral dilemmas. On the basis of reasons people give in answering questions about dilemmas in the interview, Kohlberg classified them into three stages of moral reasoning. At the first stage, preconventional moral reasoning, a child uses external and physical events and objects (such as pleasure or pain) as the source for decisions about moral rightness or wrongness. At the second stage, conventional moral reasoning, the child acts as others expect, in accordance with the established order of society. At the last stage, postconventional moral reasoning, moral judgments are made according to the view that there are arbitrary, subjective elements in social rules and that rules and institutions of society are not absolute but relative. Such postconventional reasoning is related to formal operational thinking and thus begins with adolescence (see below *Adolescent development: Cognition*). Kohlberg's stages of moral reasoning follow the social perspective of the person, which moves toward increasingly greater scope (*i.e.,* including more people and their institutions) and greater abstraction (*i.e.,* from reasoning about physical events such as pain or pleasure to reasoning about values, rights, and implicit contracts). Transition from one stage to another is characterized by gradual shifts in the most frequent type of reasoning; thus, at any given point in life a person may function at more than one stage at the same time. Moreover, different people pass through the stages of moral reasoning at different rates. Finally, different people are likely to reach different levels of moral thinking in their lives, raising the possibility that some people may never reach the third, most abstract, stage.

Kohlberg's stages of moral reasoning

Language occupies the central place among early accomplishments in perceptual, cognitive, and social development. In their fourth month, infants indiscriminately respond to social communication; by their 24th month, toddlers comprehend the meaning of prepositions. It is significant that the English words *infant* and *baby* both have their origins in language-related concepts, the former deriving from Latin words meaning "nonspeaker," and the latter sharing a Middle English root with "babble." Many people believe that children enter personhood only when they begin to communicate with others through language.

Language, which has a complex and intricate structure, poses a formidable task for those who try to acquire it, whether they are mature adults or immature children; yet, paradoxically, babies meet the challenge of language learning seemingly with great facility. Language has complex productive (speech utterance) and receptive (comprehension) aspects and operates simultaneously on at least three planes. First, sounds that are to be linguistically meaningful must be produced and perceived as separate from noise. Second, meaning must be grasped in order to say and to understand how symbols are related to the real world as well as to imaginary referents. Third, to ensure meaningful communication, rules must be mastered for encoding and decoding word order.

The mystery of language acquisition has intrigued people throughout history. St. Augustine, for example, wrote that children learn language by imitating, and Constantine the Great supposed that infants could not articulate words because their teeth were not yet firmly rooted. King James I of England, who sponsored a translation of the Bible, sought to identify the original language of Adam and Eve. Toward this end he conceived of a unique experiment, proposing to place two infants on an otherwise uninhabited island in the care of a deaf-mute nurse; the King reasoned that if the two children spontaneously developed speech, theirs would be man's "natural language."

Theories of language acquisition

Some psycholinguists have argued that language learning proceeds on the basis of the child's experiences, whereas others have asserted that language acquisition could only develop on a foundation of biological endowment. This disagreement between empiricist associationism and nativism in so fathomless a domain as language learning has been called "the debate between the impossible and the miraculous." Research shows, however, that infants are surprisingly well prepared in both motivation and competencies to establish communication.

In order to discover how language might be acquired, psycholinguists have listened to and questioned children

as well as consulted their parents as reporters. Observation is the method that dominates this field of study, but the technique is limited, as shown by the exasperation parents often feel at their young child's failure to say with a stranger what the child readily says at home. Standardized assessment tests for the first few years are not yet well developed, and parents themselves (whose diaries have provided much of the earliest detailed information about language development) are often subject to bias.

Dimensions of language

Despite these methodological difficulties, there has been considerable progress in understanding language development. In sound perception, research reveals that, either natively or on the basis of little experience, very young infants divide the speech stream, map correspondences between the eye and the ear, and recognize particular speech. In vocalization, newborn infants sound cries that are distinguishable as signals of pain or hunger; later, infants follow a nearly universal course from babbling through single-word utterances to grammatical speech. Children's earliest sensitivities to sound and their earliest vocal expressions give evidence of a strong biological influence. Yet, even in the first year both the production and the perception of speech sounds are increasingly shaped by the linguistic environment, reflecting the child's exquisite sensitivity and susceptibility to specific experiences.

The acquisition of grammar has sparked some of the longest standing debates in developmental inquiry. Some researchers propose that children learn the rules of language through reinforcement or through imitation; others maintain that, given the enormous requirements of language learning, such a view is hopelessly simplistic and hardly practicable, and they theorize that human beings have innate dispositions toward basic language structure. Again, evidence supports both views. Children everywhere seem to move through a universal sequence of syntactic acquisition, lending support to a biological theory, although children learn the grammar of whatever their local language community happens to be. It is often hypothesized that the human brain has specially developed to meet linguistic requirements, but it is equally clear that adults engage with infants in motor and nonverbal activities that mirror language in structure and that pave the way for the child's comprehending and producing grammatically correct utterances.

Semantics and reference—properly mapping sounds to their meaning—constitutes another aspect of language study. Although the question of reference is not so much plagued by the nature–nurture debate—for the acquisition of meaning cannot readily be attributed to biology—its study is affected by disputes that range from defining exactly what is meant by a "word" to pinpointing the process of matching referents. Whatever the view may be on these issues, it is known that by three years of age children are learning at least two new words per day in an odyssey that has brought them from infancy to a working vocabulary of 3,000 words.

In language, as in other spheres of behavioral development, quantitative as well as qualitative individual differences abound. For example, some 13-month-olds comprehend only a dozen or so words, whereas others comprehend as many as 100; some do not speak at all, whereas others have a productive vocabulary of nearly 50 words. Further, some babies possess vocabularies organized mainly around names of objects, whereas others tend to converse in social formulas principally for the purpose of communicating their feelings and desires. Studies show that heredity and experience both contribute to these striking individual differences. For example, infants' competence in communicating tends to be associated with the competence of their biological (as opposed to their adoptive) parents, yet certain parental activities with infants are also known to assist the development of communication.

The development of language follows a clear and probably universal ontogeny that may, at least initially, be affected by variations in experience. Within limits, normal children seem to follow the same path to basic linguistic proficiency and to travel at more or less the same rate, largely (though not wholly) independent of their general intelligence, the language community in which they are reared, and the amount of early help they receive. Yet nearly all specific manifestations of language learning seem to be prompted and transformed by the child's specific experiences. Critical factors in language development appear to be the amount and variety of verbal stimulation as well as adult sensitivity to infant language levels, especially in dynamic interplay with infants' feedback. Toddlers obviously learn only the particular language to which they are exposed, and differences in experience result in corresponding differences in language competency. To ease this task, parents and teachers readily adjust the language they typically direct to infants. Thus, the processes involved in language acquisition appear to be both rigid and flexible. They assure certain outcomes even in the face of an unstable environment, and at the same time they encourage flexibility in response to a variegated environment.

The foregoing discussion analyzes language acquisition in the child by separating language into sound, syntax, and symbol both in perception and in production. Although each plane entails a separate kind of learning, these components are not independent; rather, they mesh in astonishing complexity to produce what is arguably an entirely new organism.

Personality and social development. Assessing and interpreting the earliest expressions of personality and sociability in human beings have long challenged those who study the development of behaviour. Personality can be thought to include the emotions, their characteristic pattern of expression in individual temperament, and the ways in which experiences and development in growing up enlarge and modify basic temperament and emotions. There is no generally accepted definition even of basic emotions, such as joy, anger, fear, and affection; nonetheless the emotions are recognized as playing a significant role in regulating internal psychological processes as well as in influencing interpersonal interaction—primarily through vocal, facial, or gestural expression. So, for example, the experience of joy not only energizes an individual, but its expression also encourages others around the person to remain near and to keep up a pleasurable interaction. Watching face and gesture and listening to voice, some theorists have argued that the earliest expressions of emotion are learned through experience, presumably through parent–infant interactions. By contrast, others have suggested that emotions are not necessarily outcomes or products of experiences or thought, that emotions are expressed and comprehended universally, and that emotions possess survival value as important means of communication with others of the species; on these bases, these theorists have concluded that basic emotions reflect innate capacities for which no social experience is required.

Earliest expressions of emotion

Developmental studies show that infants both express and interpret many distinct and presumably core emotions in the first years of life, contrary to previous views that they can exhibit only undifferentiated general excitement. Quite frequently in their everyday interactions, for example, newborns clearly respond to pleasant stimuli with facial expressions that may reasonably be interpreted as positive and to unpleasant stimuli with negative ones; this is not to imply that experience plays no role in shaping the expression of emotions, since different cultures obviously socialize different emotional displays in infants and young children. The very young are also recognized to discriminate among expressions of emotion conveyed in face, voice, and gesture. Although the ability to discriminate does not necessarily imply understanding of emotional meaning, research shows that children in the first and second years of life use the emotional expressions of others to regulate their own behaviour, especially with regard to decision making. So, for example, young children are more likely to approach and explore a toy when an adult they "consult" signals joy, as opposed to disgust or fear, and they will even physically position themselves so as to be able to read that adult's expressed emotions more clearly.

The concept of temperament

Most emotions remain available throughout life, but individuals differ in the characteristic patterns of emotions they display, that is, in their temperament. Temperament has many definitions; commonly, it is conceived of as

a constitutionally based source of characteristic socio-emotional elements in the individual, such as affect, attention, and motor activity. Although individual patterns of these components of personality are often thought of as enduring and valid in different situations, they, too, are certainly subject to modification according to the circumstances of life. Presumably personality constitutes the elaboration and transformation of basic temperamental dispositions in development through experience, social interaction, and cognition. Its constitutional base does not mean that temperament is genetically fixed, and models of temperamental variation acknowledge reciprocal influences of environment and organism acting through time so that aspects of temperament are identifiable early in life but may alter with age or environmental change. A convergence of methodologies that combines observing infants and children with interviewing parents has shown moderate agreement in the evaluation of infant and childhood temperament. Research on newborn variation (especially in twins) has strongly supported the appropriateness of a behaviour-genetic model of the origins of temperament. The study of childhood temperament is particularly attractive to clinicians since, if temperament is constitutional and enduring, understanding infant temperament promises to provide clues to understanding mature personality and perhaps to solving parts of the puzzle of pathology in personality. Moreover, individual differences in infant and childhood temperament can be expected to provoke different styles of caretaking and to shape, for good or ill, the nature of children's social interactions.

Infancy and childhood witness the dawning of social awareness, when children come to understand that their behaviour can affect the behaviour of others in consistent and predictable ways (intentionality and effectance) and that others can be counted on to respond when signaled (trust). These basic social characteristics are often born of turn taking (reciprocity) in interpersonal interaction. In their encounters first with parents and later with significant others, infants and young children appear to interact adaptively. Perhaps the central accomplishment in personality development in the first years of life is the establishment of specific and enduring emotional bonds, or attachment. The objects of attachment seem to be the persons who respond most consistently, predictably, and appropriately to the baby's signals, primarily the mother but also the father and eventually others. Interestingly, mothers and fathers have been observed to behave differently with their infants and young children: Mothers hold, comfort, and calm in predictable and rhythmic ways, whereas fathers play and excite in unpredictable and less rhythmic ways. Children quickly learn to expect different patterns of interaction from these two figures.

Attachment

Research suggests that varied social stimulation facilitates the growth of interactional skills in infants and young children. The development of social styles seems to depend on the nature of early interactions, on temperament, and on adult behavioral patterns; moreover, transactions among these factors have ramifications for children's social and cognitive development, including their propensity to explore the environment, the stability of their gender identity, and the facility with which they interact socially with peers. Toddlers who are more secure than others in their attachment to parents approach cognitive challenges such as problem solving more enthusiastically and persistently, and they behave in more socially competent and independent ways in preschool.

Perhaps the preeminent theorist of social and personality development is Sigmund Freud, who, in the first decades of the 20th century, established the modern practice of psychoanalysis. Freud saw a parallel between the transformation of energy in the physical world and events that occur in mental life. Human life, he hypothesized, is governed by a mental energy that he called libido. Libido cannot be created or destroyed; humans are born with a finite amount of it, and instead of its being transformed into another type of energy, its area of localization within the body successively changes over the course of development. Freud postulated a universal, biological progression in which libido is centred in particular body zones for determined lengths of time. Each stage in this progression is, in Freud's terms, a stage of psychosexual development. Where the libido is concentrated determines which stimulation is required to gratify it. Experience can facilitate or hinder the development of certain feeling states, but it is nature that determines where and when libido moves. Freud specified five stages of psychosexual development.

Freud's stages of development

The first psychosexual stage is the oral stage. During the first year of life, gratifying stimulation centres on the mouth region, where libido is concentrated, and pleasure is obtained by sucking and biting. If the baby's attempts at oral gratification are frustrated often enough, some of the libido may become fixated (arrested) at this stage of development; that is, not all the libido will be free to progress to the next stage. Freud believed that adult emotional problems result from fixation, and in the case of oral fixation such problems involve attempts to obtain the gratification missed at the oral stage. As an adult the individual may, for example, overeat. Fixation of libido is a potential problem at any stage.

The anal stage lasts from about age one to age three and occurs when libido centres in the rectal area. Children at this stage obtain pleasure through exercising their sphincter muscles, expelling or withholding bowel movements. The anal stage corresponds to the period when children in many Western societies are toilet trained, and frustration resulting from severe toilet training can result in anal fixation, in which adults are either "loose" (messy and wasteful) or "uptight" (holding back everything, including their feelings).

In the phallic stage, which according to Freud spans years three to five, the libido in both sexes moves to the genital area. For boys, gratification is obtained through manipulation and stimulation of the genitals. Mothers are most likely to provide such stimulation, and boys therefore conceive an incestuous sexual desire for their mothers. Boys recognize that their fathers stand in the way of such desires, and this arouses negative feelings toward them. Freud labeled this emotional reaction the Oedipus complex, after the legendary Greek king who mistakenly killed his father and married his mother. According to Freud's theory, when boys realize that their fathers are rivals, they come to fear that their fathers will punish them by castration. As a result, boys experience castration anxiety. The power of this anxiety forces boys to give up their desires for their mothers and in turn identify with their fathers; that is, boys come to model themselves after their fathers. Although presumably mothers also provide most genital stimulation for girls, girls (for reasons not perfectly clear even to Freud himself) fall in love not with their mothers but with their fathers. Then, analogous to what occurs with boys, girls desire to possess their fathers incestuously but realize that their mothers stand in the way. At this point the similarity with male development ends. Girls are afraid that their mothers will punish them for their incestuous desires, but, although it is possible that girls first fear punishment in the form of castration, their awareness of feminine genital structure causes them to realize that, in a sense, they already have been punished. That is, girls perceive that they do not have a penis but only an inferior (to Freud) clitoris. Hence, girls experience what Freud called penis envy. Penis envy impels girls to resolve the Oedipal conflict by relinquishing their incestuous love for their fathers and identifying with their mothers.

According to Freudian theory, the form of adolescent and adult development is determined in early childhood. The first five years, comprising the first three psychosexual stages, are especially critical for functioning in later life. After the end of the phallic stage (at about five years of age) and until puberty begins (at about 12 years of age), Freud said that the libido is latent. It is not localized in any bodily zone; thus, during the latent stage no zones of gratification emerge or exist. At puberty the libido reemerges, again in the genital area, but this time in a mature adult form of the phallic stage. If the person's psychosexual development has not been too severely restricted during the first five years of life, adult sexuality can now be directed to heterosexual union and reproduction.

Although Freud made great contributions to psycholog-

ical theory—particularly in his concept of unconscious urges—later critics pointed out that actual Freudian research is practically impossible. Such elegant concepts as the theory of psychosexual stages cannot be verified through scientific experimentation and empirical observation. But Freud's concentration on development in early childhood influenced even those schools of thought that rejected his theories.

The study of postnatal behavioral development prior to adolescence has tended to lay stronger emphasis on infancy than on childhood, not because later development is unimportant but because it is widely held by different schools of thought that the most significant developments in behaviour take place early in the life cycle. Psychoanalysis argues for the enduring quality of early experiences; learning theory argues that early experiences are prominent because they are primary, have no competing propensities, and are thus easy to establish and long lasting; ethology proposes that sensitive periods of susceptibility to environmental influence predominate in infant life; and Piaget's theory of genetic epistemology also suggests that advanced cognitive and social capacities build on simple developments that take place very early in life. Infancy and early childhood are thus premiere phases of the life cycle whose characteristics—given, developing, or acquired—are generally fundamental to later experiences that build on or modify them.

ADOLESCENT DEVELOPMENT

Adolescence may be defined as that period within the life span when most of a person's characteristics are changing from what is typically considered childlike to what is typically considered adultlike. Changes in the body are the most readily observed; but other, less definitive attributes such as thoughts, behaviour, and social relations also change radically during this period. The rate of such changes varies with the individual as well as with the particular characteristic.

Physiological aspects. The physical and physiological changes of adolescence do not proceed uniformly; however, a general sequence for these changes applies to most people. It is useful to speak of phases of bodily changes in adolescence in order to draw important distinctions among various degrees and types of change. Bodily changes affect height, weight, fat and muscle distribution, glandular secretions, and sexual characteristics. When some of these changes have begun, but most are yet to occur, the person is said to be in the prepubescent phase. When most of those bodily changes that will eventually take place have been initiated, the person is in the pubescent phase. Finally, when most of those bodily changes have already occurred the person is in the postpubescent phase; this period ends when all bodily changes associated with adolescence are completed.

Phases of adolescence

The bodily changes of adolescence relate to both primary and secondary sexual characteristics. Primary sexual characteristics are present at birth and comprise the external and internal genitalia (*e.g.,* the penis and testes in males and the vagina and ovaries in females). Secondary sexual characteristics are those that emerge during the prepubescent through postpubescent phases (*e.g.,* breasts in females and pigmented facial hair in males).

Several important bodily changes occur specifically within each of the three periods that characterize adolescent physical maturation. The period of prepubescence begins with the first indication of sexual maturation. It ends with the initial appearance of pubic hair. In males, there is a continuing enlargement of the testicles, an enlargement and reddening of the scrotal sac, and an increase in the length and circumference of the penis. These changes all involve primary sexual characteristics. Insofar as secondary sexual characteristics are concerned, there is no true pubic hair at this stage, although down may be present. In females, prepubescent changes typically begin an average of two years earlier than with males. The first phenomena of female development in this period are the enlargement of the ovaries and the ripening of the ova. In contrast with those of males, these changes in primary sexual characteristics are not outwardly observable. However, changes involving secondary sex characteristics can be seen (*e.g.,* the rounding of the hips and the first phase of breast development). The latter begins with an elevation of the areola surrounding the nipple, which produces a small cone-like growth called the breast bud. As with the male, there is no true pubic hair, although down may be present.

The onset of pubescence in both sexes occurs with the appearance of pubic hair, and this period ends when pubic hair development is complete. The peak velocity (speed) of growth in height and weight also occurs during this phase. This so-called growth spurt occurs about two years earlier in females than in males. Another key change of pubescence in females is menarche, or the onset of menstruation, which occurs about 18 months after the maximum height increase of the growth spurt and typically is not accompanied initially by ovulation. In pubescence the primary sexual characteristics continue the development initiated in prepubescence. In females the vulva and clitoris enlarge; in males the testes continue to enlarge, the scrotum grows and becomes pigmented, and the penis becomes longer and increases in circumference. In regard to secondary sexual characteristics, in females there is increased breast development, with the breast buds enlarging to form the primary breast; in males, the voice deepens and pigmented axillary and facial hair appear, usually about two years after the emergence of pubic hair.

The "growth spurt"

The phase of postpubescence starts when pubic hair growth is complete, there is a deceleration of growth in height, changes in the primary and secondary sexual characteristics are essentially complete, and the person is fertile. Some changes in primary and secondary sexual characteristics occur in this phase. For instance, in males, it is during this period that the beard begins to grow; in females, there may be further breast development.

Although, as noted, the ordering of these bodily changes is fairly uniform among individuals, there is considerable variation in the rate of change. Some adolescents mature more rapidly and others more slowly than most of their peers. Of course, there are also youths who pass through the periods of bodily change at the average rate. Variations in the rate of bodily change in adolescence often affect psychological and social development. Early-maturing adolescent boys are typically better adjusted than late maturers and have more favourable interactions with peers and adults. These advantages of early maturation and disadvantages of late maturation tend to continue through the middle adult years for males. For females, however, early maturation is associated with more psychosocial disadvantages than is late maturation. Maturing at an average rate seems to be most advantageous for females. However, the relations between female maturation rates and personality and social functioning in later life have not been determined.

Variations in rate of change

Bodily changes among adolescents can also differ according to sociocultural and historical influences. The age of menarche, for example, varies among countries and even among different cultures within one country. Moreover, there has been a historical trend downward in the average age of menarche, translating into a decrease of several months per decade from about 1840 to the present. This phenomenon is generally ascribed to the improved health and nutrition of children and adolescents.

Cognition. The dramatic physical and physiological changes characteristic of adolescence have an equally dramatic impact on cognitive and social functioning. Adolescents think about their "new" bodies and their "new" selves in qualitatively new ways. In contrast with sensorimotor and more limited spatiotemporal modes of thinking, which according to Piaget characterize infancy and childhood, beginning at about puberty the formal operational, or hypothetico-deductive, mode of thought emerges, characterized by reasoning and abstraction. In the formal operational stage, adolescents begin to discriminate between their thoughts about reality and reality itself and come to recognize that their assumptions have an element of arbitrariness and may not actually represent the true nature of experience. Thus, adolescent thinking becomes somewhat experimental in the scientific sense, employing hypotheses to test new ideas against outward reality.

Formal operational thought

In forming hypotheses about the world, adolescent cognition can be seen to grow along with formal, scientific, logical thinking. Consider, for example, a problem of combinatorial thought: An adolescent is presented with five jars, each containing a colourless liquid. Combining the liquids from three particular jars will produce a colour, whereas using the liquid from either of the two remaining jars will not produce a colour. The adolescent is told that a colour can be produced but is not shown which combination produces this effect. Children at the concrete operational stage typically try to solve this problem by combining liquids two at a time, but after combining all pairs, or possibly trying to mix all five liquids together, their search for the workable combination usually stops. An adolescent at the formal operational stage, on the other hand, will explore all possible solutions, systematically testing all possible combinations of two and three liquids until a colour is produced. As another example, consider adolescent thinking in respect to certain types of verbal problems—for instance, as represented by the question "If Jane is taller than Doris and shorter than Francine, who is the shortest of the three?" Concrete operational children may be able to solve an analogous problem (*e.g.*, one using sticks of various lengths, with the sticks actually present). Abstract verbal problems, however, are usually not solved until the capacity for formal operations has emerged.

Formal operational thought does not seem to be a stage characterizing all adolescents. Studies of older adolescents and adults in Western cultures show that not all individuals attain formal operations. In turn, in some non-Western groups there is a failure ever to attain formal operations. Some researchers have attributed these differences to the differences between rural and urban societies and the different kinds of schooling offered by each. There is, however, little evidence for socioeconomic or educational differences being associated with the achievement of formal operational thought.

Formal operational thinking also has limitations, predicated in part on the fact that adolescents often think about their own thinking. Just as the infant is preoccupied with his physical self in a world of new stimuli, so the adolescent may be preoccupied with his own thinking in a world of new ideas. Such preoccupation often leads to a kind of egocentrism, which can manifest itself in two ways: First, the individual may presume that his or her own concerns, values, and preoccupations are equally important to everyone else; second, the urgency of this new thinking may paradoxically give rise to an overestimation of one's uniqueness, often resulting in feelings of alienation or of being misunderstood. Although the formal operational stage is the last stage of cognitive development in Piaget's theory, the egocentrism of this stage diminishes over the course of the person's life, largely as a consequence of interactions with peers and elders and—most importantly—with the assumption of adult roles and responsibilities.

The social context. The adolescent's social context is broader and more complex than that of the infant and the child. The most notable social phenomenon of adolescence is the emergence of the marked importance of peer groups. The adolescent comes to rely heavily on the peer group for support, security, and guidance during a time when such things are urgently needed and since perhaps only others experiencing the same transition can be relied upon to understand what that experience is. Contrary to cultural stereotype, however, the family is quite influential for adolescents. Indeed, no social institution has as great an influence throughout development as does the family. Most studies indicate that most adolescents have few, if any, serious disagreements with parents. In fact, in choosing their peers adolescents typically gravitate toward those who exhibit attitudes and values consistent with those maintained by the parents and ultimately adopted by the adolescents themselves. For instance, while peers influence adolescents in regard to such issues as educational aspirations and performance, in most cases there is convergence between family and peer influences. While it is the case that adolescents and parents have somewhat different attitudes about issues of contemporary social concern (*e.g.*, politics, drug use, and sexuality), most of these differences reflect contrasts in attitude intensity rather than attitude direction. That is, rather than adolescents' and parents' standing on opposite sides of a particular issue, most generational differences simply involve different levels of support for the same position. In sum, there is virtually no evidence supporting the cultural stereotype of adolescence as a period of storm and stress. Most adolescents continue their close and supportive relationships with their parents, and their relationships with peers tend to support parental ideals rather than run against them.

Influence of the family

Personality. The dramatic changes that characterize puberty present the adolescent with serious psychosocial challenges. A person who has lived for 12 years has developed a certain sense of self as well as of self-capacity. In adolescence, however, this knowledge of self is challenged. As has been discussed, the rather sudden bodily changes in this period are accompanied by equally dramatic changes in thoughts and feelings. Thus, all the assumptions adolescents held about the self in earlier stages may no longer be relevant to the new individuals they find themselves to be. Because a coherent sense of self is necessary for functioning productively in society, adolescents ask a crucial psychosocial question: Who am I?

At precisely the time that adolescents feel unsure about who they are, society begins to ask them related questions. For instance, adolescents are expected to make the first steps toward career objectives. Society asks adolescents, then, what roles they will play as adults, that is, what socially prescribed set of behaviours they will choose to adopt. Thus a key aspect of this adolescent dilemma is that of finding a role, which is generally taken to be the outward expression of identity. The emotional upheaval provoked by this mandate is called the identity crisis. In order to resolve this crisis and achieve a sense of identity, it is necessary to synthesize psychological development and societal directives. The adolescent must find an orientation to life that not only fulfills the attributes of the self but at the same time is consistent with what society expects of a person; that is, a role cannot be something that is self-destructive (*e.g.*, sustained fasting) or socially disapproved (*e.g.*, criminal behaviour). In the search for an identity the adolescent must discover what he or she believes in and what his or her attitudes and ideals are. For commitment to a role entails, to a greater or lesser degree, commitment to a set of values.

The identity crisis

If the adolescent fails to resolve the identity crisis by the time of entry into adulthood, he or she will feel a sense of role confusion or identity diffusion. Some young adults waver between roles in a kind of prolonged "moratorium," or period of avoiding commitment. Others seem to avoid the crisis altogether and settle easily on an available, socially approved identity. Still others resolve their crises by adopting an available but socially disapproved role or ideology. This latter option is called negative identity formation and is often associated with delinquent behaviour. Resolution of the adolescent identity crisis has a profound influence on development during later adulthood.

All societies traditionally prescribe stereotyped roles to each sex. These roles have adaptive significance; that is, they allow society to maintain and perpetuate itself. From this reasoning, it follows that differences in sex-role behaviour, at least initially, arose from the different tasks males and females performed for survival—especially those tasks centred around reproduction. Differing biologies exert differing pressures on psychosocial development; however, these pressures do not occur independently of the demands of cultural and historical milieus. The biological basis of one's psychosocial functioning is believed to relate to adaptive orientations for survival. Many differences exist between males and females, but the nature of individual differences between the sexes is dependent on interactions among biological, psychological, sociocultural, and historical influences.

DEVELOPMENT IN ADULTHOOD AND OLD AGE

In sheer number of years, the periods labeled adulthood and aging constitute the major portion of the human life span. Historically, however, these periods were seen as less significant and interesting developmentally than infancy,

childhood, and adolescence. Adulthood was viewed as a time of continuity, a period when what had been developed earlier was utilized. Aging was viewed as a time of decline, a period when what had been developed earlier was lost. Contemporary opinion is that adulthood and aging are just as significant and interesting as are earlier periods of the life cycle. Adulthood and aging are characterized by both growth and decline.

Central nervous system processing. There is relatively clear evidence that, with advancing age, individuals show a tendency toward decreasing speed of response. This is a gradual change occurring across the entire life span that shows up in a variety of so-called speeded tasks (those in which errors would be unlikely if the individual had an unlimited amount of time to complete the tasks). For example, reaction time tests (which measure the time elapsing between the appearance of a signal and the beginning of a responding movement) are usually viewed as a measure of central nervous system processing. Mean speed of response on such tasks increases with age until the late teens, remains constant until the mid-20s, and then declines steadily throughout the remainder of the age range.

Considerable evidence has accumulated to link changes in brain electrical activity to the slowing of behaviour. The electroencephalogram (EEG) provides a record of the brain's electrical activity. The normal human EEG displays continuous rhythmic activity in the form of wavelike patterns varying in frequency and amplitude. The dominant rhythm is the alpha wave, which reaches its maximum frequency in adolescence and begins to slow gradually after young adulthood. This slowing may be related to disease processes (particularly vascular disease) as well as to basic aging processes. The older adult's central nervous system appears to be in a state of under-arousal in comparison to that of the younger adult.

Cognition. Decline in the rate of central nervous system processing does not necessarily imply a similar change in learning, memory, or other intellectual functions. However, considerable evidence indicates that the learning ability of young adults is superior to that of older adults and that the faster the pace of the task the more difference age makes. Older learners benefit more from slower pacing of tasks than do younger learners. When allowed to regulate the pace of the task themselves, older learners often show an improvement in performance, whereas this is not necessarily the case with younger learners.

Memory functions

However, in regard to memory, as opposed to the learning or acquisition of information, research suggests that there are relatively few age-related differences within the primary-memory system, the temporary maintenance system for conscious processing of information. Age is a significant factor, however, in the functioning of the secondary-memory system. Secondary memory depends on the elaboration and organization of information in terms of its semantic content or meaning. Compared to younger adults, older adults appear to be deficient in these processes. Generally, they do not spontaneously use organizational strategies as extensively as do younger adults, or, if they use them, they do so less effectively. However, when various organizational strategies are built into the situation, the performance of older adults improves significantly.

Most studies examining memory for general knowledge have found that older adults retrieve such information as well as or better than do younger adults. Within some contexts, older adults appear to integrate and retain the meaning of sets of sentences and texts as well as do younger adults. For example, when young, middle-aged, and elderly adults are asked questions covering such topics as famous people, news events, history, geography, the Bible, literature, sports, mythology, and general information (*e.g.,* "What was the former name of Muhammad Ali?"; "What is the capital of Kampuchea?"), their answers typically show no evidence of age differences in the retrieval of knowledge. In fact, elderly people may actually answer more questions correctly than do younger groups. Older adults also appear to have accurate knowledge about their own memory processes—knowledge that has been labeled metamemory. For example, research has found no age differences regarding subjects' assessments of the relative reliability of visual and verbal memory, regarding the use of memory strategies (*e.g.,* reminder notes), or regarding memory monitoring (*e.g.,* prediction of the number of items that would be recalled following various memory tasks).

Fluid and crystallized intelligence

Psychometric approaches to cognition suggest that intelligence is characterized by two distinct properties. Fluid intelligence, measured by tests that minimize the role of cultural knowledge, reflects the degree to which the individual has developed unique qualities of thinking through incidental learning. Crystallized intelligence, measured by tests that maximize the role of cultural knowledge, reflects the degree to which the individual has been acculturated through intentional learning. Fluid intelligence shows a steady decline from adolescence through middle age. Across the same age range, however, a steady increase occurs in crystallized intelligence. When measures of both properties are taken, few age-related differences appear.

Finally, there are age-related differences on several measures of cognitive functioning. In general, older adults perform more poorly than do younger adults on tasks requiring both concrete operational thought and formal operational thought.

Some features of cognitive functioning—speed of response, secondary memory, and fluid intelligence—seem to decline with age. Others—contextual memory and crystallized intelligence—increase. Aging does not inevitably precipitate a decline in cognitive functioning. Indeed, there is growing evidence that older persons can largely modify their intellectual performance, documenting a clear lifelong capacity for cognitive change in human beings.

Personality and social development. Several theories of personality development stress that adulthood and aging are periods of qualitative change, of discontinuity, and of transformations of earlier life patterns. These changes are believed to arise in relation to the demands of the person's changing biological status and social context—the family, the workplace, and society in general. Thus, personality development is both an individual and a social phenomenon.

Erikson's theory of crises

In the view of the German-born U.S. psychoanalyst Erik Erikson, certain psychosocial demands, or crises, confront the individual at distinct intervals throughout life. The young adult, for instance, is expected to enter into an institution—*i.e.,* marriage and family—that will perpetuate the society. The degree to which the basic need for intimacy on all levels—physical, emotional, and others—is met in such a relationship determines in most individuals the conception of the self as belonging or as isolated. In middle adulthood the crisis develops between the sense of generativity and the sense of stagnation. In this stage the individual is expected to play the role of a contributing, generative member of society. Generativity can take the form of providing the goods and services by which society functions or of producing, rearing, and socializing future members of society. The inability to develop a productive self-conception results in a feeling of stagnation. In maturity, according to Erikson, a crisis arises with regard to the sense of ego integrity versus the sense of despair. In this stage, individuals realize that they are reaching the end of life. If they have successfully progressed through the previous stages of development, they can face old age with satisfaction in the feeling that a full and complete life has been led. Individuals for whom this integrity of life is lacking often feel a sense of despair over "wasted" opportunity.

The American psychologist Daniel J. Levinson also divides adult life into qualitatively distinct periods. Confining his study to men, Levinson identified five eras within their lives that are not stages of biological, psychological, or social development but that together constitute a life-cycle structure. The eras are: (1) preadulthood (birth to age 22); (2) early adulthood (age 17 to 45); (3) middle adulthood (age 40 to 64); (4) late adulthood (age 60 to 85); and (5) late late adulthood (age 80 and over). Each of these eras is in turn made up of a series of developmental periods and transitions. For example, in early adulthood a first major transition, ordinarily beginning at

age 17 to 18 and extending until age 22 to 23, represents a developmental link between preadulthood and early adulthood. The young man in this early adult transition faces two major tasks. The first task is to modify relationships with his family and with other persons, groups, and institutions significant to his preadult world. The second task is to take a preliminary step into the adult world. This requires making initial explorations and choices for adult living. Major life events within this transition may include graduating from high school, moving out of the family home, seeking gainful employment, or attending college. Entering the adult world begins in the early 20s and extends until the late 20s. The focus of this period is on exploration and provisional commitment to adult roles and responsibilities. The young man faces two antithetical tasks. On the one hand, he must explore alternate possibilities for adult living, keeping options open and avoiding strong commitments. On the other hand, he must create a stable life structure, becoming responsible and "making something" of himself. Crucial life events during this period include occupational choice, first job, marriage, and the birth of children.

The age range of 28 to 33 years represents a transition between the period of entering the adult world and the next period of settling down. This transition provides the young man with an opportunity to adjust and enrich the provisional adult life structure that he created earlier. For most men, however, a moderate to severe crisis is common; divorce and occupational change are frequent during this time. A settling down period then follows, beginning in the early 30s and extending until about age 40. This period, during which the man's task is to become a full-fledged adult, emphasizes stability and security. The individual makes deeper commitments to his occupation, family, or whatever enterprises are significant to him. In addition, he generally concentrates on "making it." This involves long-range planning toward specific goals with a timetable for their achievement. Most men fix on a key life event, such as a promotion or new job, as representative of ultimate affirmation or evaluation by society. During the last years of the settling down period, there is a distinctive phase designated as "becoming one's own man," ordinarily occurring at age 36 to 40. The man's major task during this phase is to achieve greater independence and authority by striving for the goals of his various enterprises.

The mid-life transition spans four to six years, reaching a peak in the early 40s. It forms a developmental link between early adulthood and middle adulthood and, being part of both eras, represents a beginning and ending, a meeting of past and future. A task of the mid-life transition is to work on and partially resolve this discrepancy between what is and what might be. The transition may be relatively smooth, but it is more likely to involve considerable turmoil. The period of entering middle adulthood begins at about age 45 and extends until about age 50. Sometimes the start of this new life structure is marked by a significant life event, such as a change in job or occupation, a divorce or love affair, or a move to a new community. In other instances, the changes are more subtle.

Evidence of constancy in adult personality

Research evidence does not unequivocally support the discontinuous, stagelike changes in adult personality proposed by theorists such as Erikson and Levinson. In fact, several major studies of personality development during the adult and aged years present evidence for both change and constancy. For instance, studies of healthy adults between the ages of 40 and 80 residing in the Kansas City area during the 1950s found evidence for both continuity and change of adult personality. On the one hand, personality structure was stable; four personality types—integrated, defended, passive-dependent, and unintegrated—emerged among respondents regardless of age. Similarly, characteristics dealing with the socio-adaptational aspects of personality (*e.g.*, goal-directed behaviour, coping styles, and life satisfaction) were not age-related. It seems, therefore, that the ways in which healthy adults interact with the environment may be stable even though the roles they adopt alter with age. On the other hand, individual styles of coping with the inner world of experience showed marked age differences. For example, 40-year-olds felt in charge of their environment, viewed the self as a source of energy, and were positive about risk taking, whereas 60-year-olds saw the environment as threatening and even dangerous and viewed the self as passive and accommodating.

Other studies of personality development from birth through early adulthood have also found evidence for constancy and change. For example, behavioral dispositions of the early school years, including passive withdrawal from stressful situations, dependency on family, arousal of anger, involvement in intellectual mastery, sexual behaviour and sex-role identification, and anxiety over social interaction, have been found to carry over into adulthood. The degree of stability in these behaviours exhibited from childhood to adulthood seems to be closely related to cultural expectations of appropriate sex-role behaviour. If a pattern of childhood behaviour is consistent with sex-role expectations, it will more likely remain stable over time.

Other studies, concentrating on the development from adolescence into adulthood among people born in California in the late 1920s and early 1930s, found different personality types for males and females that showed substantial stability over time. Personality characteristics reflecting socialization and self-presentation, for example, tended to remain stable. On the other hand, two major types of personality characteristics, those reflecting information processing and those reflecting interpersonal relations, tended to change. There were differences between the sexes both in what was constant and in what changed across life. For example, life-style patterns among the parents of the California children were more continuous between young adulthood and old age for fathers than they were for mothers. Fathers who in early adulthood were unwell and disengaged from their families showed these same characteristics in late adulthood. In regard to personality, however, there was more apparent continuity between young adulthood and old age among mothers than among fathers. For example, mothers who were group-centred showed a more psychologically healthy personality and had a more satisfying life in later years than in earlier years, whereas non-group-centred mothers were happy and healthy at age 30 but lost their health and physical stamina by age 70.

In general, older adults tend to engage in greater introspection and self-reflection than do younger adults, showing a general movement from the outer world toward the inner world. They tend to withdraw emotional investments, be less assertive, and avoid challenges. Adulthood and old age involve both constancy and change. These periods of life are continuations of the past as well as new phases in their own right.

CONCLUSIONS

This article treats as separate various substantive spheres of human development—physical, perceptual, cognitive, linguistic, personality, and social—as it does various temporal phases of development—prenatal life, infancy, childhood, adolescence, adulthood, and old age. However, human beings are coherent wholes, and behavioral development is unified, so that development in any one arena of life at any one time is ineluctably interrelated with development in other arenas at the same and at other times in patterns of mutual influence. In the life course, genetic endowment and biology interact with cultural context and experience to shape the development of human behaviour. Each of these powerful sources of influence on development has distinctive characteristics, and it is their transaction over time as well as the degree of congruence between the two that influence outcome. Our elucidation of the processes that underpin human growth is central to understanding normal as well as abnormal development. Study of the development of human behaviour is unwieldy; life does not submit to elegant scientific analysis or to precise prediction. Therefore, developmental study takes as its goals the general description and explanation of origins, of constancy, and of change in perceiving, thinking, feeling, and behaving. Any such undertaking requires constant reconsideration in light of new data and new insights.

(M.H.Bo./Ri.M.L.)

Beirut

Beirut (Arabic Bayrūt; French Beyrouth) is the capital, largest city, and main port of the Republic of Lebanon. It occupies a metropolitan area of approximately 26 square miles (67 square kilometres) on the Mediterranean coast, at the foot of Mt. Lebanon. It comprises two hills, al-Ashrafiyah (East Beirut) and al-Muṣayṭibah (West Beirut), that protrude into the sea as a roughly triangular peninsula; in the immediate hinterland lies a narrow coastal plain (as-Sāḥil) that extends from the mouth of the Nahr al-Kalb (Dog River) in the north to that of the Nahr ad-Dāmūr (Damur River) in the south.

The article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city plan. Under the Ottoman *vilâyet* administration and the French Mandate, the growth of Beirut was planned, but after independence in 1943 it was as haphazard as it was rapid. It is estimated that the population of the city increased tenfold between the early 1930s and early 1970s and the city's area grew to three times the size it had been in 1900. By the 1950s, few traces of the old city were left, and most of those were destroyed in the 1974–76 Lebanese civil war and its aftermath.

The neighbourhoods. Street plans and block arrangements in the city and its suburbs are not consistent or uniform. In most quarters, modern high-rise buildings, walk-up apartments, slum tenements, modern villas, and traditional two-story houses with red-tiled roofs—all in varying states of repair—stand side by side. After 1974, countless houses and apartments, particularly in West Beirut, were forcibly occupied by refugees from rural areas, especially from the Shīʿī areas of South Lebanon.

Civil war destruction

The downtown area of central Beirut (the old city) was destroyed during the civil war and remained in ruins, a vacant belt between East and West Beirut that could not be reconstructed because of sporadic fighting there between rival factions. As a result, all business moved out of the area to establish new premises in the Christian and Muslim sides of the city. While few areas of Beirut were purely residential before 1974, none was by 1980.

THE PEOPLE

Ethnic and religious groups

The resident population of Beirut is more or less evenly divided between Muslims and Christians. The overwhelming majority in both religious groups is ethnically Arab and includes Palestinian refugees, Syrian residents, and others. The most important ethnic minority is the Christian Armenians; there is also a Kurdish ethnic minority among the Muslims. East Beirut is almost solidly Christian, West Beirut is predominantly Muslim, and a number of mixed neighbourhoods (notably in the district of Ra's Bayrūt) are cosmopolitan in character. The Jewish community is concentrated in the neighbourhood of Wādī Abū Jamīl. The larger Christian communities are the Maronites and the Greek Orthodox; the Christian minorities, apart from the Armenians, include Greek Catholics, Protestants, Roman Catholics, and others. Originally, the Sunnīs were the dominant Muslim community, but Shīʿī Muslims began moving into the city in increasing numbers from the 1960s. Small numbers of Druzes live in parts of West Beirut.

ECONOMIC AND POLITICAL CONDITIONS

Between 1952 and 1975, Beirut was the hub of economic, social, intellectual, and cultural life in the Arab Middle East. In an area dominated by authoritarian or militarist regimes, the Lebanese capital was generally regarded as a haven of liberalism, though a precarious one. With its seaport and airport—coupled with Lebanon's free economic and foreign exchange system, solid gold-backed currency, banking-secrecy law, and favourable interest rates—Beirut became an established banking centre for Arab wealth, much of which was invested in construction, commercial enterprise, and industry (mostly the manufacture of textiles and shoes, food processing, and printing). Foreign banking and business firms found in Beirut an ideal base for their operations in the Arab Middle East. The "free zone" of the Beirut port was a leading entrepôt for the region. A skilled professional class provided varied sophisticated services for a pan-Arab clientele. Beirut was also a centre for tourism. The large number of daily and weekly newspapers, journals, and other periodicals, which were normally uncensored, kept the Arab world informed about regional and world developments and provided a full array of editorial opinion. Beirut's schools, colleges, and universities—the American University of Beirut, Université Saint Joseph, Université Líbanaise (Lebanese University), and Beirut Arab University—attracted students from many Arab countries. An underlying lack of consistency and organization, however, and an undercurrent of social and political unrest never escaped notice.

Political terrorism

Beirut became a prominent centre for Palestinian resistance organizations after the Arab–Israeli War of 1967,

and became the headquarters of the movement after the Palestine Liberation Organization (PLO) in Jordan was crushed in 1970. The Lebanese government failed in repeated attempts to bring the Palestinian movement in Beirut and the rest of Lebanon under control. Arab nationalist and leftist political parties established armed militias for themselves, frequently in association with the Palestinian resistance movement. When the PLO was trapped by Israeli troops in West Beirut in 1982, the organization was removed from Lebanon by multinational forces. Sectarian violence continued after the Israeli withdrawal, destroying the established order of the city.

Beirut's destruction

Beirut is no longer the hub of the Arab Middle East. The incessant fighting that began with the civil war, the Israeli bombing of West Beirut, and the chronic shelling that continued after the Israeli withdrawal ate away at the city's infrastructure. The Green Line established in the 1970s to separate the Christian and Muslim factions in East and West Beirut, respectively, became a dangerous barricade permanently dividing the city. Businesses and residents alike left the city as hopes for a cease-fire waned, and even basic services such as water and electricity came to be only sporadically available.

History

THE EARLY PERIOD

The antiquity of Beirut is indicated by its name, derived from the Canaanite name of Be'erōt (Wells), referring to the underground water table that is still tapped by the local inhabitants for general use. Although the city is mentioned in Egyptian records of the 2nd millennium BC, it did not gain prominence until it was granted the status of a Roman colony, the Colonia Julia Augusta Felix Berytus, in 14 BC. The original town was located in the valley between the hills of al-Ashrafīyah and al-Muṣayṭibah. Its suburbs were also fashionable residential areas under the Romans, who constructed an aqueduct to augment the city's water supply. Between the 3rd and 6th centuries AD, Beirut was famous for its school of law. The Roman city was destroyed by a succession of earthquakes, culminating in the earthquake and tidal wave of AD 551. When the Muslim conquerors occupied Beirut in 635, it was still mostly in ruins.

Arab and Christian rule. Beirut was reconstructed on a small scale by the Muslims and reemerged as a small, walled garrison town administered from Baalbek as part of the *jund* (Muslim province) of Damascus. Until the 9th or 10th century, it remained commercially of no significance and was notable mainly for the careers of two eminent local jurists, al-Awzāʿī (died 774) and al-Makḥūl (died 933).

The Crusaders

A return of maritime commerce to the Mediterranean in the 10th century revived the importance of the town, particularly after Syria passed under the rule of the Fāṭimid caliphs of Egypt in 977. In 1110 Beirut was conquered by the military forces of the First Crusade and was organized, along with its coastal suburbs, as a fief of the Latin Kingdom of Jerusalem.

As a crusader outpost, Beirut conducted a flourishing trade with Genoa and other Italian cities; strategically, however, its position was precarious because it was subject to raids by the Druze tribesmen of the mountain hinterland. Saladin reconquered Beirut from the crusaders in 1187, but his successors lost it to them again 10 years later. It was the Mamlūks who finally drove the crusaders out of the town in 1291. Under Mamlūk rule, Beirut became the principal port of call in Syria for the spice merchants from Venice.

Ottoman rule. Beirut, along with the rest of Syria, passed under Ottoman rule in 1516, shortly after the Portuguese had rounded the African continent (1498) to divert the spice trade of the East away from Syria and Egypt. The commercial importance of Beirut declined in consequence. By the 17th century, however, the city had reemerged as an exporter of Lebanese silk to Europe, mainly to Italy and France. Beirut at the time was technically part of the Ottoman province (*eyalet*) of Damascus, and after 1660 of Sidon. Between 1598 and 1633, however, and again between 1749 and 1774, it fell under the control of the Maʿn and Shihāb emirs (feudal suzerains and fiscal agents) of the Druze and Maronite mountain hinterland. From the mid-17th to the late 18th century, Maronite notables from the mountains served as French consuls in Beirut, wielding considerable local influence. During the Russo-Turkish War of 1768–74, the town suffered heavy bombardment by the Russians. Subsequently it was wrested from the Shihāb emirs by the Ottomans, and it soon shrank into a village of about 6,000.

The growth of modern Beirut was a result of the Industrial Revolution in Europe. Factory-produced goods of the Western world began to invade the markets of Ottoman Syria, and Beirut, starting virtually from nought, stood only to profit from the modern industrial world. The occupation of Syria by the Egyptians (1832–40) under Muḥammad ʿAlī Pasha provided the needed stimulus for the town to enter on its new period of commercial growth. A brief setback came with the end of the Egyptian occupation; by 1848, however, the town had begun to outgrow its walls, and its population had increased to about 15,000. Civil wars in the mountains, culminating in a massacre of Christians by Druzes in 1860, further swelled Beirut's population, as Christian refugees arrived in large numbers. Meanwhile, the pacification of the mountains under an autonomous government guaranteed by the great powers (1861–1914) stabilized the relationship between the town and its hinterland, where traditional silk production was mechanized by French and local industrial concerns. In 1886 Beirut was made the capital of a separate province (*vilâyet*) comprising the whole of coastal Syria, including Palestine. By the turn of the century, it was a city of about 120,000.

Egyptian occupation

Meanwhile, Protestant missionaries from Great Britain, the United States, and Germany and Roman Catholic missionaries mainly from France became active in Beirut, particularly in education. In 1866 the American Protestant Mission established the Syrian Protestant College, which later became the American University of Beirut. In 1881 French Jesuit missionaries established the Université Saint Joseph. Printing presses, introduced earlier by Protestant and Roman Catholic missionaries, stimulated the growth of the city's publishing industry, mainly in Arabic but also in French and English. By 1900 Beirut was in the vanguard of Arabic journalism. A class of intellectuals sought to revive the Arabic cultural heritage and become the first spokesmen of a new Arab nationalism.

MODERN BEIRUT

Beirut was occupied by the Allies at the end of World War I, and the city was established by the French mandatory authorities in 1920 as the capital of the State of Greater Lebanon, which in 1926 became the Lebanese Republic. The Muslims of Beirut resented the inclusion of the city in a Christian-dominated Lebanon and declared loyalty to a broader pan-Arabism than most Christians would support. The resultant conflict became endemic. The accelerated economic growth of Beirut under the French Mandate (1920–43) and after produced rapid growth of the city's population and the rise of social tensions. These tensions were increased by the influx of thousands of Palestinian refugees after 1948. The political and social tensions in Beirut and elsewhere in Lebanon, coupled with Christian–Muslim tensions, flared into open hostilities in 1958, and even more violently in 1974–76. The conflict continued to simmer, with sporadic eruptions of violence, and Beirut became a divided city.

Muslim–Christian tensions

West Beirut was largely destroyed by heavy fighting between Israeli forces and members of the Palestine Liberation Organization (PLO) in 1982, when Israel launched a full-scale attack on PLO bases operating in the city. Israeli troops surrounded West Beirut, where most PLO guerrilla bases were located, and a series of negotiations brought about the evacuation of PLO troops and leaders from Lebanon to other Arab nations.

Divisive sectarian loyalties only increased after the Israeli withdrawal. Neither the continued Syrian military presence nor the formation of a coalition government could defuse the violence. The shelling persisted, and much of the population fled. (K.S.S./Ed.)

BIBLIOGRAPHY. SAID CHEHABE ED-DINE, *Géographie humaine de Beyrouth* (1960), though slightly outdated, is the only study that surveys the human geography of Beirut and accounts for its growth patterns. C.W. CHURCHILL, *The City of Beirut* (1954), is a descriptive, socioeconomic survey that provides detailed information on household composition, education, mobility, occupations, housing, income saving, and expenditure. FUAD I. KHURI, *From Village to Suburb* (1975), is a detailed account of the social life and organization of two peripheral villages engulfed by the Beirut metropolis. The BEIRUT EXECUTIVE BOARD OF MAJOR PROJECTS, *Comprehensive Plan Studies for the City of Beirut* (1968), a preliminary but comprehensive survey report, provides detailed information on the physical features, land use patterns, utilities, population, and economic characteristics of the city. See also S. KHALAF and P. KONGSTAD, *Hamra of Beirut: A Case of Rapid Urbanization* (1973), an empirical study that explores the ecological transformation and the social structure of one of Beirut's urban communities; and HARVEY PORTER, *The History of Beirut* (1912), a brief but instructive historical sketch of the city from the earliest times to the beginning of the 20th century.

Belgian Literature

The literature of Belgium falls into two main divisions by language: Flemish (the Netherlandic language as spoken in Belgium, and equivalent to Dutch in The Netherlands) and French. To this may be added a third, Walloon, a literature written in local dialects of French and Latin origin that are spoken in the provinces of Hainaut, Liège, Namur, Luxembourg, and the south of Brabant. (These provinces together were known as Wallonia.) This article provides a brief historical account of the development of each of these three literary traditions.

The article is divided into the following sections:

Flemish

EARLY LITERATURE

Relationship with Dutch literature. When considering the literature of Flemish-speaking (Dutch-speaking) Belgium it must be remembered that the Belgian territories were united with the Netherlands politically, economically, and culturally until 1579, when, as a result of the Reformation, the northern (Reformed) provinces seceded from the Roman Catholic south. Thus until the early 17th century the literature of Flanders and Holland must be considered as a whole (see DUTCH LITERATURE). It was in Flanders that the literature of the medieval Low Countries flowered most profusely. It was, moreover, in Flanders and Brabant that learning showed new vigour under the influence of the Renaissance and the Reformation. In literature inspired by the Reformation the tone was set by the glowing satiric verse of the Catholic Anna Bijns and the polemical satire on the Catholic Church, *Biencorf der H. Roomsche Kercke* (1569; "The Beehive of the Roman Catholic Church"), of the Calvinist Philips van Marnix van Sint Aldegonde. The Renaissance in the Netherlands began with Lucas de Heere, Karel van Mander, and Jan Baptista van der Noot, all of whom, significantly, had fled from the south for religious reasons.

Decline. Many left the south as a result of the religious and political troubles before 1579, and the literary revival in Flanders and Brabant was interrupted. Whereas Holland was approaching its golden age, in the south a decline set in. But Justus de Harduwijn, a lyrical poet in the Classical style of the French Pléiade; Richard Verstegen, a polemicist and writer of prose characters; Adriaen Poirters, a popular moralist; the dramatists Willem Ogier and Cornelis de Bie, and, especially, Michiel de Swaen, the last important poet and playwright of the Baroque period, who was deeply inspired by his religion, compare favourably with most writers of their time. The decline was most noticeable in the early 18th century, when the aristocracy and intellectual elite came increasingly under French influence.

Revival. Before the end of the 18th century, however, Willem Verhoeven and Jan Baptist Verlooy had started a reaction against this French influence. Like contemporary historical and scientific writers they reverted to the work of the 16th-century Humanists but neglected the medieval masterpieces. Revival was helped by the *rederijker*s (rhetoricians), who continued, more or less successfully, to use Flemish, not French. Karel Broeckaert wrote dialogues modelled on Joseph Addison's *Spectator* essays in a spirit of rational liberalism, creating a literary figure, "Gysken," the ironic representative of the ancien régime; he also wrote the first Flemish prose story, *Jellen en Mietje* (1811). The poet Pieter Joost de Borchgrave embodied the transition from Classicism to Romanticism, and Jan Baptist Hofman, a prolific playwright, introduced middle-class sentimental tragedy, or *drame bourgeois*.

19TH-CENTURY LITERARY TRENDS

The Romantic movement. Romanticism made its influence felt in the 19th century and was linked to a revival of nationalist consciousness. The older generation—Jan Frans Willems, Jan Baptist David, Philip Blommaert, and Ferdinand Snellaert—while remaining rationalists, rediscovered the rich medieval inheritance. To their group belonged two important poets of the new age, Karel Lodewijk Ledeganck and Prudens van Duyse. The younger generation was more spontaneously Romantic, as was illustrated by the work of Hendrik Conscience, creator of the Flemish novel. Theodoor van Rijswijck and Johan Alfried de Laet freed poetry from Classical concepts and forms, and the ultra-Romantic stories of Eugeen Zetternam and Pieter Frans van Kerckhoven denounced social evils.

Realism and other post-Romantic trends. Led by a Realist, Domien Sleeckx, a reaction against Romanticism set in about 1860. Writing became characterized by acute observation, description of local scenery, humour, and, not infrequently, a basic pessimism, as could be seen in novels such as Anton Bergmann's *Ernest Staes* (1874) and Virginie Loveling's *Een dure eed* (1892; "A Dear Oath"). The poets Johan Michiel Dautzenberg, Jan van Beers, and Rosalie Loveling, together with the first important Flemish critic, Max Rooses, also reflected a new Realistic approach.

The reaction of Flemish Realism

Parallel to this Realism was a remarkable revival in poetry in West Flanders, headed by a Roman Catholic priest, Guido Gezelle, undoubtedly the greatest Flemish poet of the 19th century. Albrecht Rodenbach wrote militant songs, thoughtful lyrics, monumental epics, and a verse tragedy, *Gudrun* (1882).

The review *Van Nu en Straks* (1893–1901; "Of Now and Later"), which was to make Flemish literature of European importance, was influenced more by Gezelle and Rodenbach than by the Dutch generation of the 1880s. Led by Pol de Mont, an already complex modern poet, the writers of the 1880s had, however, widened horizons and, by emphasizing individualism and "art for art's sake," prepared the ground for their successors.

THE 20TH CENTURY

The turn of the century. The writers grouped around *Van Nu en Straks* helped to bring about a true revival of Flemish culture. Though they held a wide variety of opinions, they all strove for an art that would comprehend all human activity, and in which individual feelings would be given universal significance. In his masterly essays and his symbolic novel *De wandelende Jood* (1906; "The Wandering Jew"), their leader, August Vermeylen, advocated a rationalism infused with idealism. Prosper van Langendonck, on the other hand, interpreted the incurable suffering of the *poète maudit.* In 1898 Emmanuel de Bom published *Wrakken* ("Wrecks"), the first modern Flemish psychological novel, and *Starkadd,* an early Wagnerian drama by Alfred Hegenscheidt, was produced.

The poetry and prose of Karel van de Woestijne formed a symbolic autobiography of a typical fin de siècle personality, the sophisticated, world-weary sensualist striving for spiritual detachment. His work, a passionate confession of human frailty, represents one of the great achievements of European Symbolism.

Stijn Streuvels, a master of prose, made the West Flemish rural landscape his microcosm, a visionary world in which man is dwarfed by nature (*De Vlaschaard,* 1907; "The Flax Field"). The polished work of Herman Teirlinck, novelist, dramatist, and essayist, was characterized by imagination, sensuality, and a sonorous vocabulary. In the stylistically refined stories of F.V. Toussaint van Boelaere there were often tragic undertones.

As well as that resulting from the influence of *Van Nu en Straks,* other important tendencies developed. Naturalism found a first representative in Reimond Stijns. It reached its height in the robust tales and pithy plays of Cyriel Buysse and in the regional novel, as exemplified by the evocations of Bruges by Maurits Sabbe and the vivid treatment of Antwerp life by Lode Baekelmans. The pictorial verse of Omer Karel de Laey and the vigorous rhythms of René de Clercq have permanent value. The poems, plays, and essays of Cyriel Verschaeve are passionate expressions of his Augustinian outlook.

The group associated with the review *De Boomgaard* (1909–11; "The Orchard"), which included André de Ridder and Paul Gustave van Hecke, strove to be more cosmopolitan than *Van Nu en Straks* and defended a more dilettante attitude to culture. The elegiac poet Jan van Nijlen had affinities with this group.

After World War I. During World War I there was a new flowering of the picturesque regional tale: *Pallieter* (1916), by Felix Timmermans, and the roguish *De witte* (1920; *Whitey*), by Ernest Claes, became known outside Flanders. From the poetry of August van Cauwelaert and the prose of Franz de Backer it could be seen that the generation that fought in the war stressed life rather than literature. But a trend first revealed during the German occupation found its most direct outlet in revolutionary Expressionism, and the review *Ruimte* (1920–21; "Space") published its manifesto: ethics must take priority over aesthetics, and the art of the community over that of the individual. Expressionism was most apparent in lyrical poetry and drama. Wies Moens' poetry reflected this humanitarian trend, whereas Gaston Burssens remained less pathetic and more playful. The outstanding lyricist of the movement was Paul van Ostaijen, who expressed faith in humanity in *Het sienjaal* (1918; "The Signal") but soon went through a crisis of Dadaism, adopted rhythmic typography (*Bezette stad,* 1921), and wrote pure poetry concentrating on word and sound, grotesque verse and prose, and penetrating essays on art and poetry. The review *'t Fonteintje* (1921–24; "The Little Fountain"), whose editors included Richard Minne and Maurice Roelants, reacted against Expressionism. Expressionism also gave new life to drama. In the 1920s the Flemish Popular Theatre became one of the foremost avant-garde theatres in Europe. The standard of drama was raised by Herman Teirlinck and Anton van de Velde.

Flemish Expressionism

By 1930 the tide of Expressionism had run out and the novel came into its own. The regional novel was replaced by the psychological novel, introduced by Roelants with *Komen en gaan* (1927; "Coming and Going"), and was raised to great stylistic heights by Maurice Gilliams (*Elias,* 1936) who was also a subtle poet and essayist. Gerard Walschap wrote of man's social, religious, and moral problems, and Lode Zielens wrote about the lives of the poor.

The focal point of the novel was man. The skeptical Raymond Brulez and the disenchanted humanist Marnix Gijsen were both more or less detached observers of human weaknesses.

In Willem Elsschot's short but superb novels, such as *Lijmen* (1924; *Soft Soap*) and *Kaas* (1933; "Cheese"), caustic irony and an astringent style mask the underlying compassion. The new tone was set by the "personalistic" poets of the *Vormen* (1936–40; "Forms") group, of whom Pieter Geert Buckinx is representative.

After World War II. The major writers of World War II and the postwar period were novelists. The range of subjects and styles in the novel was remarkable. The problem novels by Paul Lebeau and Gaston Duribreux, the "magic-realist" work of Johan Daisne and Hubert Lampo, the Social Realism of Piet van Aken (*Het begeren,* 1952; "Desire") and Louis-Paul Boon (*De kapellekensbaan,* 1953; *Chapel Road*), the Existentialism of Jan Walravens (*Negatief,* 1958; "Negative"), and Hugo Claus's experimental novels are but a sample. Boon, Walravens, and Claus belonged to a review group called *Tijd en Mens* (1949–55; "Time and Man"), which was marked by postwar chaos, rebellion, and Experimentalism. Boon and Claus eventually became recognized as the outstanding postwar novelists.

In the 1960s the experimental trend in the novel led to new prose either based on stream-of-consciousness association (Hugo Raes, Ivo Michiels, and Paul de Wispelaere) or consisting of introverted "texts" dwelling largely on the act of writing itself (Willy Roggeman and Daniel Robberechts). Nevertheless, the tradition proved to be fertile; *e.g.,* in the satiric and allegorical novels by Ward Ruyslinck and in Jef Geeraerts' violent colonial novels. Walter van den Broeck later emerged as an accomplished writer, employing a mixture of autobiography and social history.

In postwar Flemish poetry the impact of Experimentalism made itself felt in the work of Albert Bontridder and Hugo Claus, whose *Oostakkerse gedichten* (1955; "Oostakker Poems") has remained a milestone. The playful Paul Snoek and the sombre Hugues Pernath continued the experimental line. In the 1970s a Neorealist reaction set in (Herman de Coninck, Roland Jooris), followed by a Neoromantic revival (Eddy van Vliet). The poetry of Freddy de Vree, on the other hand, is more intellectual.

Postwar drama, at first still dominated by Teirlinck, saw new talent emerging in Jozef van Hoeck (*Voorloping vonnis,* 1957; "Provisional Verdict"), in the literary plays of Herwig Hensen, and in the political theatre of Tone Brulin, but especially in the many original plays and adaptations of Claus, such as *Suiker* (1958; "Sugar") and *Vrijdag* (1969; *Friday*). Van den Broeck later made his mark with socially committed and naturalistic work.

French

BEGINNINGS

In the history of French literature, that by Belgian writers in French forms an important chapter. Even before Belgium achieved independence in 1830, many outstanding works were written in French by writers of Flemish

origin. They were responsible for some of the medieval chansons de geste. In the Middle Ages too, didactic, religious, and lyrical poetry, plays, and chronicles began to be written. The names of Jean Le Bel, Jean Froissart, Georges Chastellain, and Philippe de Commynes indicate the wealth of early historiography by Flemish writers, while Jean Lemaire de Belges was one of the great late medieval poets and rhetoricians (*rhétoriqueurs*).

The death of Margaret of Austria (1530) was followed by a period of literary sterility, prolonged until the end of the ancien régime by unstable economic conditions, the indifference to native culture of successive foreign governments, and the strong influence of 17th- and 18th-century French literature. Only a few writers are remembered, and notable among them is Charles Joseph, prince de Ligne.

Between the end of the 18th century and 1880 attempts were made to create an original, native literature. The poet André van Hasselt is still remembered. More important were the novelist Charles de Coster, whose *Légende . . . d'Ulenspiegel* (1867; *The Glorious Adventures of Tyl Ulenspiegel*) has attained the status of an epic of Flanders, and the influential essayist Octave Pirmez.

THE "JEUNE BELGIQUE" MOVEMENT

Impetus for the long-awaited literary renaissance came from Max Waller, founder in 1881 of an influential review, *La Jeune Belgique* ("Young Belgium"), which indicated a possible national literary consciousness; essentially, however, the review was the vehicle of expression of individual writers dedicated to the idea of art for art's sake.

Of novelists early associated with the movement, Camille Lemonnier, Eugène Demolder, and Georges Eekhoud were the most influential. A later *Jeune Belgique* novelist was Georges Rodenbach, celebrator of silence and spirituality, whose *Bruges-la-morte* (1892; "Bruges the Dead City") was the epitome of decadent fiction.

Stimulated by the *Jeune Belgique* movement was a group of poets much concerned with style and language. Among them were Grégoire Le Roy, a gifted lyrical Symbolist poet; Charles van Lerberghe, who explored the potential of Symbolist verse; and Albert Mockel, founder of an influential Symbolist review, *La Wallonie.*

They were overshadowed, however, by three poets of international stature: Émile Verhaeren, Maurice Maeterlinck, and Max Elskamp. Verhaeren extolled humanity's struggle toward social justice; Maeterlinck, creator of the Symbolist poetic drama, illuminated life's inner meaning; and Elskamp treated themes from folklore and legend.

Outstanding dramatists were Maeterlinck (*L'Oiseau bleu,* performed 1908; *The Blue Bird*) and Verhaeren. Edmond Picard, a playwright, novelist, and critic, propounded Socialism, Symbolism, and Impressionism. The period also saw a beginning, in the work of Godefroid Kurth, of modern historiography and criticism. An outstanding historian was Henri Pirenne. Art and literary criticism flourished, and an atmosphere for a flowering of scholarship culminated in the foundation (1920) of the Belgian Académie Royale de Langue et de Littérature Françaises.

THE MODERN PERIOD

Between World Wars I and II. A new generation of Belgians who wrote in French arose between World Wars I and II. The novels of André Baillon showed keen yet compassionate observation of life. Jean Tousseul was concerned with human suffering, whereas Charles Plisnier wrote powerfully analytical novels (*Mariages,* 1936; *Nothing to Chance*). Constant Malva was a radical socialist writer. Jean de Bosschère displayed a multifaceted talent. Other talented novelists were Marie Gevers and the visionary Franz Hellens. Paul Nougé and Marcel Lecomte were important figures in Belgian Surrealism, and Jean Ray was a pioneer of fantastic literature in Belgium. Somewhat later, Georges Simenon imbued the detective story with exceptional psychological penetration.

French-language novels

The poetry of this period was characterized by increased stylistic experiment and the development of a neoclassical poetry of great fluency. Henri Michaux, influenced by Surrealism, revolutionized the poetic language. Marcel Thiry and Edmond Vandercammen, whose lyrical style harmonized traditional and modern, and Géo Norge were chief exponents of an experimental use of words. Clément Pansaers was influenced by Dada. Another group was headed by Odilon-Jean Périer, an original poet of unusual clarity who was the leading light of his generation.

In drama Fernand Crommelynck wrote savage farces laced with poetry. Michel de Ghelderode astonished audiences by a love of anachronistic character and situation and puppetlike characters, and Herman Closson reinterpreted historical events and characters.

Developments after World War II. After World War II the novel became less regional than formerly, often set in foreign surroundings; generally it subordinated action to detailed psychological analysis of characters' reactions in somewhat contrived situations. Albert Ayguesparse, Hubert Juin, and Maud Frère were all ultimately concerned with the theme of man. Breadth of subject matter and meticulous style characterized the work of Suzanne Lilar and of Françoise Mallet-Joris, who won instant success with *Le Rempart des béguines* (1951; *Into the Labyrinth*). Gaston Compère and Dominique Rolin displayed both technical prowess and emotional intensity. Notable younger novelists included René Kalisky, Pierre Mertens, Conrad Detrez, and Marcel Moreau.

Postwar poetry often reverted to regular metrical forms in poems on the eternal themes of love and death. Christian Dotremont, Jean-Pierre Verheggen, Jacques Izoard, and Werner Lambersy investigated the frontiers of poetic language. Outstanding dramatists were Georges Sion, who wrote comedy, religious and historical plays, and translations from Shakespeare; Charles Bertin, whose *Prétendants* (1947), a modern version of the Ulysses story, was played abroad as *Love in a Labyrinth;* and Jean Mogin, whose plays, successful in both Paris and Brussels, explored "being" and "nonbeing." Later dramatists of note were Kalisky, Jean Sigrid, and Paul Willems.

Literary periodicals, which were usually organs for political or literary groups of writers, were influential, especially *Le Journal des Poètes,* which in 1952 founded a biennial international conference of poets and critics, held at Knokke–Het Zoute and later at Liège.

Walloon

EARLY WRITINGS

The origins of dialect literature in Wallonia are obscure. From the 9th to the 11th century Latin held sway in the abbeys, the only intellectual centres of the period. With the exception of the *Cantilène de Sainte Eulalie* (*c.* 900), the first vernacular writings date only from the middle of the 12th century. They are chiefly anonymous tracts, among which the *Poème moral,* consisting of nearly 4,000 alexandrines, stands out. During the next three centuries Walloon literature is marked by the importance of its local chronicles and certain aspects of its religious drama.

At the beginning of the 17th century, Wallonia—particularly the district of Liège—became conscious of the literary possibilities of dialect, and from then on the number of writings increased. An "Ode" in the Liège dialect appeared in 1620, and *pasquèyes* (*paskeyes, paskeilles*), poems describing local life and history, enjoyed a vogue.

THE 18TH AND 19TH CENTURIES

Use of the patois broadened in the 18th century. The success of comic opera at Liège resulted in several noteworthy librettos. *Li Voyadjue di Tchaudfontaine* (1757; "The Journey to Chaudfontaine"), *Li Lidjwès egagî* ("The Enlisted Liégeois"), and *Les Hypocondres* ("The Hypochondriacs") resulted in the formation of the Théâtre Liégeois. In lyric poetry the cramignon (a type of song for dancing) and the *Noëls* (Christmas carols and dialogue) adopted a genuine realism.

The number of Walloon poets and other dialect writers increased during the 19th century. Charles-Nicolas Simonon wrote the moving stanzas of "Li Côpareye" (the name of the clock of the cathedral of Saint-Lambert), François Bailleux his charming "Mareye," and the first great Walloon lyric poet, Nicolas Defrêcheux, his famous "Leyiz-m'plorer" (1854; "Let Me Weep"). The establish-

The Société Liégeoise de Littérature Wallonne

ment at Liège, in 1856, of the Société Liégeoise de Littérature Wallonne had considerable influence on both language and literature. The number of poems, songs, plays, and even translations into Walloon of such authors as La Fontaine, Ovid, and Horace increased.

Other parts of Belgium, apart from prolific Liège, still remained active centres of dialect writing. In the 19th century, Namur could boast especially of Charles Wérotte and Nicolas Bosret, poet of the touching song "Bia Bouquet." The works of Jean-Baptiste Descamps and others originated in Hainaut. Walloon Brabant was the home of a truculent Abbé Michel Renard.

By the end of the 19th century many writers working in Walloon dialects chose a rather doctrinaire Realism to depict workaday existence and remained somewhat hidebound by social conventions. Poets included Joseph Vrindts and, above all, Henri Simon, who sang of working peasantry. Successful playwrights included André Delchef and Édouard Remouchamps, whose vaudeville comedy in verse, *Tâtî l'pèriquî* (performed 1885; "Tati the Hairdresser"), married observation and technical dexterity.

THE 20TH CENTURY

Walloon literature explored new paths in the 20th century. Dialect studies were undertaken by an army of scholars, and the literary possibilities of the dialect were extended as a result of a standardizing of rules of spelling and grammar, as well as of attempts by Émile Lempereur and some other writers to renew the sources of inspiration. Alongside several veteran authors, such as the talented prose writer Joseph Calozet of Namur, the younger generations sought to achieve a strict unity of thought and technique. Among poets the following were to be noted: Franz Dewandelaer, Charles Geerts, Willy Bal, Henri Collette, Émile Gilliard, Jean Guillaume, Marcel Hicter, Albert Maquet, Georges Smal, and Jenny d'Invérno. Widely praised storytellers and novelists were Léon Mahy, Dieudonné Boverie, and Léon Maret, among many others. The dramatists included François Roland, Jules Evrard, Georges Charles, Charles-Henri Derache, François Masset, and J. Rathmès.

The work of dialect writers continued to be assisted by the Société de Littérature Wallonne, with its associations and publishing centres at Liège, Namur, Mons, La Louvière, Nivelles, and Brussels.

BIBLIOGRAPHY

General works: Among works useful to the general reader are JETHRO BITHELL, *Contemporary Belgian Literature* (1915); PAUL HAMÉLIUS, *Introduction à la littérature française et flamande de Belgique* (1921); SUZANNE LILAR, *The Belgian Theatre Since 1890,* 3rd ed. (1962); JAMES A. RUSSELL, *Romance and Realism* (1959); VERNON MALLINSON, *Modern Belgian Literature 1830–1960* (1966).

Berlin

The capital and chief urban centre of Germany, Berlin lies at the heart of the North German Plain, athwart an east–west commercial and geographic axis that helped make it the capital of the kingdom of Prussia and then of a unified Germany. Berlin's former glory ended in 1945, but the city survived the destruction of World War II. It was rebuilt and came to show amazing economic growth. Germany's division after the war put Berlin entirely within the territory of the German Democratic Republic (East Germany). The city itself echoed the national partition—East Berlin being designated the capital of East Germany and West Berlin being a *Land,* or state (though not constitutionally incorporated as such), of the Federal Republic of Germany (West Germany), from the rest of which it was physically isolated. This unique status, later enforced and symbolized by the concrete barrier erected in 1961 and known as the Berlin Wall, made Berlin a continuous focus of crisis and confrontation between the Eastern and Western powers for some 40 years. The sudden downfall of the East German communist regime—and the accompanying opening of the wall—in late 1989 unexpectedly raised the prospect for Berlin's reinstatement as the all-German capital. That status was restored in 1990 under terms of the reunification treaty, and subsequently Berlin was designated a *Land* (state), one of the 16 constituting unified Germany. In addition to their political significance, these developments heralded the city's return to its historic position of prominence in European culture and commerce.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Berlin is situated about 112 miles (180 kilometres) south of the Baltic Sea, 118 miles north of Czechoslovakia, and 110 miles east of the border that partitioned Germany from 1949 to 1990. It lies in the wide glacial valley of the Spree River, which runs through the centre of the city. The mean elevation of Berlin is 115 feet (35 metres) above sea level. The highest point near the centre of Berlin is the peak of the Kreuzberg, a hill that rises 216 feet above sea level northwest of the Tempelhof Airport.

Measuring about 23 miles from north to south and 28 miles from east to west, Berlin is by far the largest German city. It is built mainly on sandy glacial soil amid an extensive belt of forest-rimmed lakes, formed from the waters of the Dahme River to the southeast and the Havel to the west; indeed a third of the Greater Berlin area is still covered by sandy pine and birch woods, lakes, and beaches. "Devil's Mountain" (Teufelsberg), one of several hills constructed from the rubble left by World War II bombing, rises to 394 feet and has been turned into a winter sports area for skiing and sledding.

"Devil's Mountain"

Climate. Berlin lies where the influence of the Atlantic Ocean fades and where the climate of the continental plain begins. This climatic crossroads gives the city what the inhabitants call *Berliner Luft,* a type of air colder than but not as damp as that of western Germany and fresher, despite increasing industrial smog, because of quick replenishment from across lake-studded flatlands. The political events of 1989 and 1990 made possible the development of citywide pollution-control programs. Berlin's mean annual temperature is about 48° F (9° C), and mean temperatures range from 32° F (0° C) in winter to 65° F (18° C) in summer. The average precipitation is 23 inches (598 millimetres). About one-fifth to one-fourth of the total falls as snow.

The city layout. The original twin towns of Berlin and Kölln developed from the 13th century on an island of the Spree River (the site of Kölln) and a small portion of land on the north bank of the river facing the island (the site of Berlin). An independent Hanseatic city in the Middle Ages, Berlin, still a small town, became the capital of the electors of Brandenburg from the 15th century onward. The narrow streets and alleys of the medieval town remained largely intact until they were destroyed during the massive aerial bombing of World War II.

From the late 17th and early 18th centuries, when the electors of Brandenburg (also kings of Prussia from 1701) developed into powerful figures on the European political stage, the central quarter expanded and was embellished with broad avenues, handsome squares, and grandiose stone buildings. The central area acquired broad north–south avenues, such as Wilhelmstrasse and Friedrichstrasse, and also its characteristic east–west road axis. Supplementing this main axis are several great exit roads that now serve as major traffic arteries. The developing suburbs of the later 19th century grew up around these arteries and their subsidiary streets. Where destruction during World War II was massive, there has been large-scale construction of modern high-rise apartment and office buildings. Although the only major park near the centre of Berlin is the Tiergarten, which lies just west of the Brandenburg Gate, Berlin has always been a surprisingly green city, with luxuriant trees softening the effect of the stone apartment blocks in most streets. Water is even more prevalent. With the Spree River running through the city's centre, the broad belt of lakes spreading out east and west, canals running through much of the city, and several artificial ports, Berlin is very much a city on water.

Until the political eruption of 1989, the most notorious and pervasive feature of Berlin's topography was the Berlin Wall, originally erected by the East German government on Aug. 13, 1961, to stop free movement between East Berlin (and indeed East Germany) and West Berlin. The boundary between East and West Berlin and the boundary between West Berlin and East Germany, for a combined length of 103 miles, were closed until 1989 by a solid ring of barriers, consisting mostly of wall. There were several heavily guarded crossing points between West and East Berlin, the most famous of which was Checkpoint Charlie on Friedrichstrasse.

The city divided

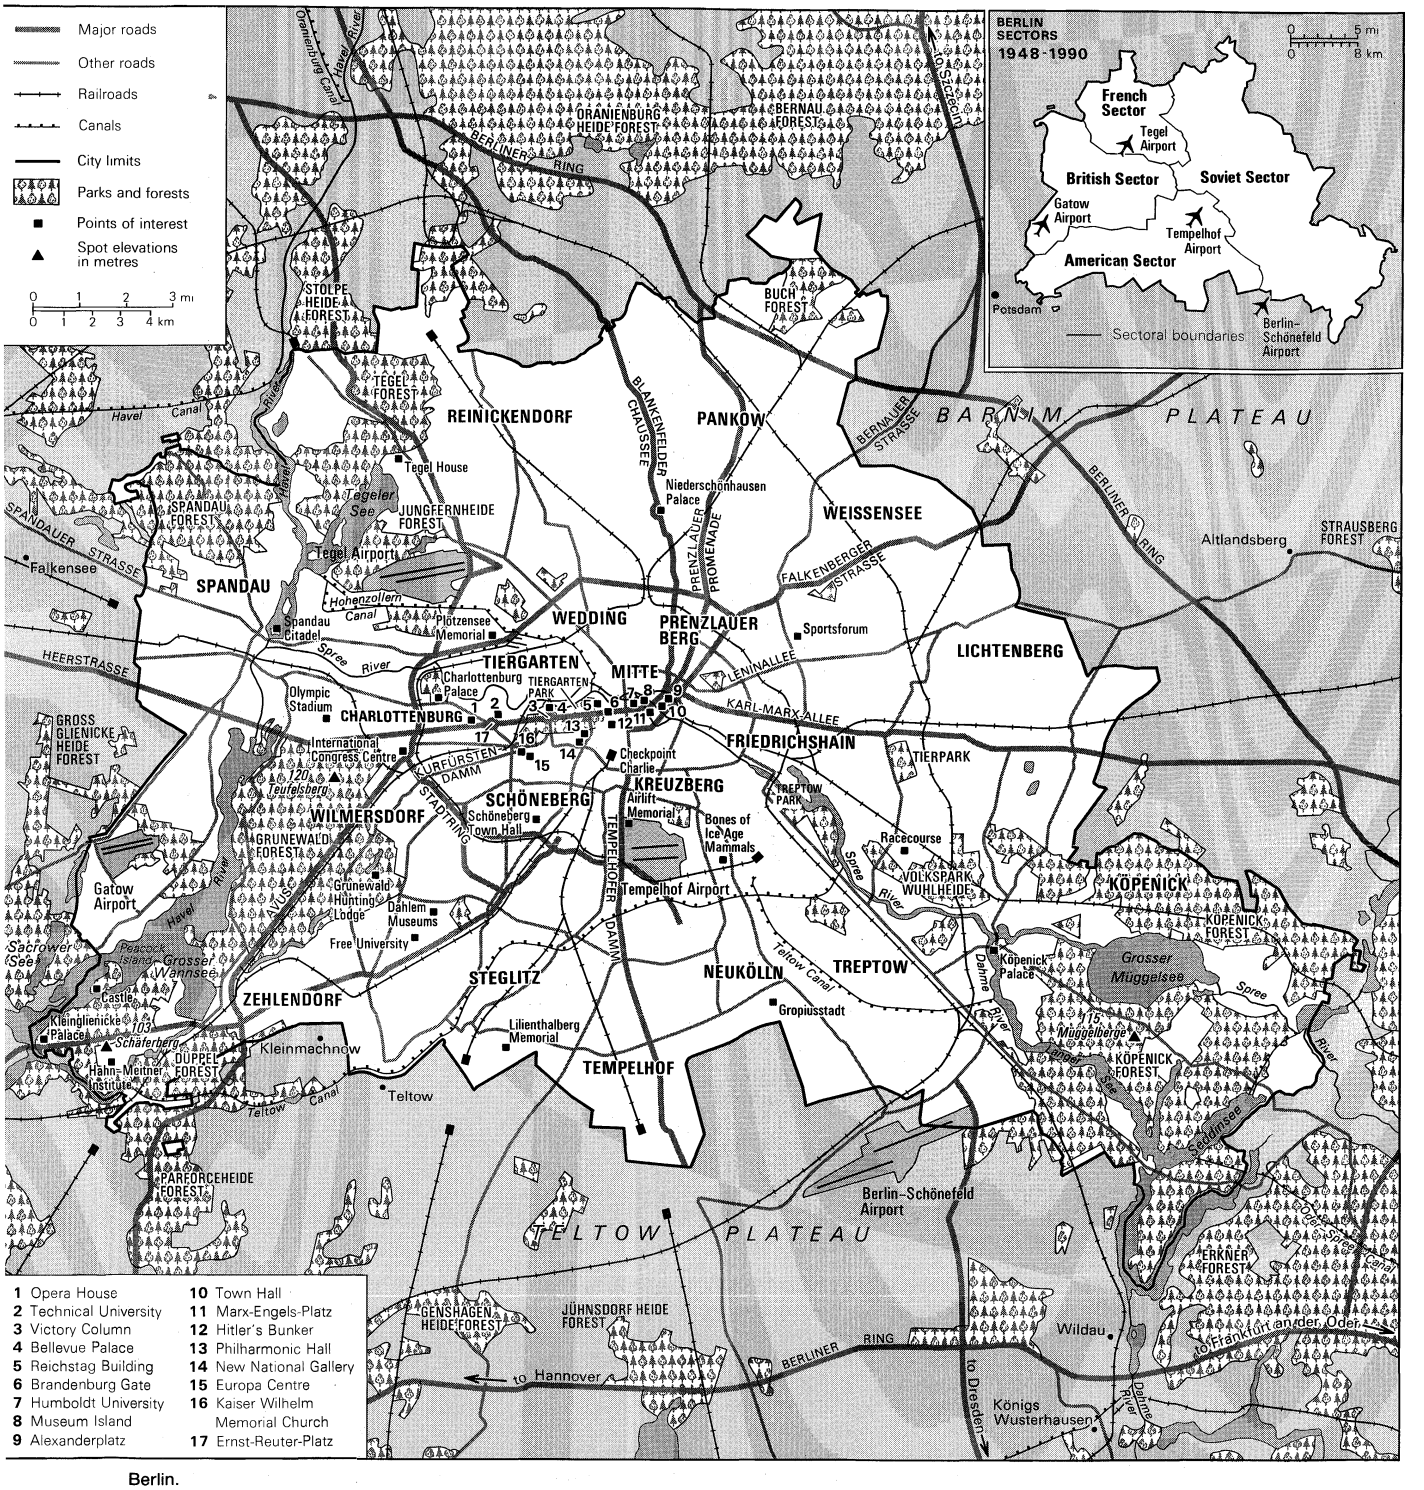
The landscape immediately next to the wall became one of the distinctive features of a divided Berlin. In East Berlin, a closed zone, guarded by watchtowers and armed patrols, flanked the wall, with the area closest to the wall constituting the so-called "death strip." On its western side, the wall was accessible from the start, and many visitors, Germans and non-Germans alike, endowed it with graffiti, ranging in quality from crude to artistically significant. Over the years, the original wall structure of steel-girded concrete was replaced incrementally (up to three times in some sections) with prefabricated concrete slabs set between steel pilings. After the opening of the wall on Nov. 9, 1989, new crossing points, such as that at Potsdamer Platz, were created by simply lifting out whole sections with cranes. Enterprising individuals from both sides who broke through with hammers and chisels—or who salvaged fragments for the souvenir market—received the nickname *Mauerspechte,* or "wall woodpeckers." Alongside the remnants of the wall lie open spaces and tracks of abandoned streetcar lines. In some places buildings had immediately adjoined the wall, and in the early days of division some people died attempting to jump to freedom from their upper floors. Today, crosses mark the places where these and other would-be refugees, numbering at least 80, lost their lives.

In terms of urban planning, the effects of the political and physical division of Berlin were many and pervasive, partly because the walled boundary created, in effect, an urban frontier immediately west of what had been the city's central administrative quarter, Berlin Mitte, which became part of East Berlin. West Berlin was thus forced to develop a new central area of its own around the Kurfürstendamm and the nearby Zoo railway station in the former suburb of Charlottenburg, separated from Berlin Mitte by the broad expanse of the Tiergarten. The area had been a distinctive commercial and entertainment district since the late 19th century, but rebuilding following extensive damage from World War II gave it a decidedly modern character.

Throughout the city, an effort to blend the modern with the traditional is evident. The most striking example in the western part is the Kaiser Wilhelm Memorial Church (Kaiser-Wilhelm-Gedächtniskirche), which incorporates the bell tower of the original 19th-century structure (ruined in World War II) into a dramatic glass and concrete church built in 1961. A landmark of more conventional historic preservation in the west is the restored Reichstag building. The decision to restore the former parliament house in the 1970s at a cost of 100 million deutsche marks was a controversial one—the building had been torched in the early days of Hitler's chancellorship (a key event in his assumption of dictatorial powers) and heavily bombarded during the final Soviet offensive in April 1945. Following the events of late 1989, the future role of the Reichstag in the new Berlin became a focus of national speculation. In early 1990, work was completed to make the building's plenary session chamber suitable for parliamentary use. Other buildings of note in the western part of the city include the Philharmonic Hall (Philharmonie; 1963) and the New National Gallery of modern art (Neue Nationalgalerie); the gallery was the last creation of the architect Ludwig Mies van der Rohe, who first worked in Berlin before World War I. The Hall for Chamber Music (Kammermusiksaal), a companion facility to the Philharmonic Hall, opened in 1987. The Charlottenburg Palace, dating from the late 17th century, is perhaps the city's most outstanding example of Baroque design.

Buildings in the east

The eastern part of the city has its own architectural symbol and war-memorial church—St. Nicholas Church (Nikolaikirche), dating from about 1200. Only the red-brick shell of Berlin's oldest building remained standing after a bombing attack during World War II, but restoration was completed in 1987, the 750th anniversary of Berlin's founding. The church, capped by two steeples brought from West Germany, serves as the centrepiece



Berlin.

of the old city enclave, the St. Nicholas Quarter (Nikolaiviertel), which includes replicas of townhouses from three centuries.

Two structures erected by the communist state dominate central Berlin—a 1,197-foot (365-metre) television tower (the Fernsehturm) and the Palace of the Republic (Palast der Republik), both adjacent to the Alexanderplatz. The tower, completed in 1969 to mark the 20th anniversary of the founding of East Germany, commands the Berlin skyline and has a revolving restaurant at the 800-foot level. The Palace of the Republic was opened in 1976 as the new seat of the East German parliament (Volkskammer), occupying the site of the former palace of the Prussian and German kings and kaisers. The decision to raze rather than to restore that badly damaged residence met with wide public disapproval. Also on the Alexanderplatz, which has prospects of once more becoming a crossroads of a united Berlin, rises the 39-story hotel Stadt Berlin, one of the city's tallest buildings.

In the same general area stand Berlin's oldest surviving church, St. Mary's Church (Marienkirche), and the Museum Island, on which are located the Old (Altes) and New (Neues) museums, the National Gallery (Nationalgalerie), the Bode Museum, and Pergamon Museum with its famous Greek altar of Zeus. Also in this area are the Town Hall, built of red brick; the State Council Building; and the rebuilt St. Hedwig's Cathedral, which dates from 1747 and which was the first Roman Catholic church to be built in Berlin after the Reformation.

The cultural district centred on Unter den Linden, the

broad avenue leading from near the Alexanderplatz to the Brandenburg Gate, also reflects the old and new. At its eastern end stands the Berlin cathedral (Berliner Dom), restoration of which did not begin until the late 1970s. For its entire length the avenue features modern hotels and shops and landmarks including the restored Arsenal (Zeughaus), New Guardhouse (Neue Wache), Berlin Palace (formerly the Crown Prince's Palace), Princesses' Palace (Prinzessinnenpalais), Opera House, National Library, Kaiser Wilhelm Palace, and Humboldt University. The Brandenburg Gate's sculptured chariot with four horses was restored in 1958; damage incurred during the celebrations marking New Year's Eve 1989 necessitated another restoration, to be completed by 1991, the 200th anniversary of the gate's construction.

South of Unter den Linden is the old Gendarme Market, renamed Academy Square, one of the finest architectural centres in Berlin, where restoration of the German cathedral and the Schauspielhaus, the former royal playhouse, was completed in time for the city's 750th anniversary. By 1990, restoration of the French cathedral, the dome of which matches the German one, also was nearing completion. Wilhelmstrasse, which runs north–south and which retains its name in the western part of the city, was once the site of Prussian and Reich government buildings. Removal of the wall west of the street exposed the remains of Hitler's bunker and the nearby Potsdamer Platz, once the city's busiest traffic hub. Before its sudden collapse, the East German government had bulldozed the bunker area and begun erecting a series of apartment buildings. Souvenir hunters and others reopened the underground complex, which has again become a focus of historical examination. Potsdamer Platz, a storied place in the memories of older Berliners, was the site where the wall was breached on Nov. 12, 1989. Since then, city planners, architects, and commercial enterprises have proposed various schemes for the area's revitalization.

Restored cathedrals

THE PEOPLE

Although the two sectors divided by the wall were approximately equal in area, the population of East Berlin numbered less than two-thirds that of West Berlin. Because the average age of West Berliners was higher than that of other West Germans, West Berlin encouraged the immigration of younger West German workers. With the end of partition, new or restored patterns of population growth quickly emerged. Some from the west sought cheaper housing in the east. Property values soared throughout the city. Many international firms sought Berlin locations. Some projections estimated that Berlin's total population would reach or exceed 5 million by the year 2000, as compared to a total of 3.4 million in mid-1990.

THE ECONOMY

Industry and trade. To a large extent, traditional economic activities, greatly reduced by World War II, have been revived throughout Greater Berlin. These include the production of textiles, metals, clothing, porcelain and china, bicycles, and machinery. Electronics became a principal postwar industry in both city halves. The cigarette and confectionery manufacturing that developed in West Berlin continues to flourish.

During the years of partition, West Berlin was a typical Western city, with plentiful consumer goods and luxury items. East Berlin authorities, on the other hand, tried to maintain morale through provision of cheaper basic elements in the cost of living, although salaries and pensions were lower than in the West. Central to the creation of a unified German state was the introduction of the deutsche mark, the West German currency, as the only legitimate monetary unit in the whole of the country on July 1, 1990.

Transportation. In urban transportation, the bus is now the mainstay, although East Berlin maintained streetcar service as well. Modern rapid-transit systems brought some postwar unity to the sphere of transport. The S-Bahn (Stadtbahn), an elevated railway system started in 1871, serves the whole city and metropolitan area. Through trains are few, with only one major station in the western part of the city. Construction of the subway, or Untergrundbahn (called the U-Bahn), began in 1897, and by World War II the city had one of the finest systems in Europe.

Rail systems

Air traffic has played an important role since 1945, particularly in the West in 1948, at the time of the Soviet blockade of the Western sectors. Tempelhof, the main field of the airlift, lost its traditional role as the centre of Berlin's air traffic during the 1970s. The airfield remained in use under the control of the U.S. Air Force, but outlying Tegel, created as an auxiliary airfield by the Western Allies during the Soviet blockade, became West Berlin's primary field, handling all civilian traffic. Berlin-Schönefeld in East Berlin was developed to handle the largest of modern aircraft. During the partition, only planes of the United States, Great Britain, and France were able to use the air corridors to the West. German reunification was expected to bring a general revision of Berlin's commercial air traffic pattern. Planners studied proposals to build a still larger third major airport outside the city.

The Reichsautobahn (National Expressway) in Berlin is part of a national superhighway network inaugurated before World War II. The system is linked with the Berliner Ring, a circle of autobahns around the city, putting Berlin in the centre of access spokes. Even before the events of November 1989, both Germanys had cooperated in developing road and rail traffic to and from Berlin. An autobahn connecting West Berlin with Hamburg was financed largely by West Germany.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. In the East and West separately, district government after World War II continued much as before, with a chief burgomaster, or mayor, a city assembly, or parliament, and district mayors and councils, although a trend toward centralization ran strongly in such matters as citywide integration of primary and secondary education.

The parliamentary and municipal elections held throughout East Germany in the spring of 1990—the first free elections in this part of Germany since Hitler's rise to power in 1933—initiated changes that were intended to reunify both Germany and Berlin politically as well as practically. The central East German communist government, whose presence had long overshadowed East Berlin's city council, was quickly turned out of power by the freely elected delegates of the People's Chamber (Volkskammer). The Social Democratic Party, which had originated in what became East Germany but was subsequently ousted or absorbed by the communist regime, made the strongest showing in East Berlin. The mayor of West Berlin, also a Social Democrat, soon thereafter called for a joint city administration to seat itself in Berlin's traditional Town Hall in the eastern sector.

Joint city administration

In most respects, West Berlin was considered the 11th *Land* of West Germany. The city's delegates to the Bundestag in Bonn, however, lacked full voting powers, because the *Land* Berlin remained under occupation status, not constitutionally a part of West Germany. Formal reunification ended four-power jurisdiction in Berlin, and the city then became one of Germany's 16 *Länder*.

Overt postwar remilitarization by Germans was apparent only in East Berlin. The West German Bundeswehr (Federal Defense Force) was barred from West Berlin, and, although West Berliners could volunteer for military service, they were not eligible for the draft. For this reason, there was a steady movement of young West German males to West Berlin. East Germany openly drafted East Berliners, but by early 1990 this whole system had broken down.

In matters of justice, East Berlin was fully integrated within the overall East German court system. In West Berlin the Allies forbade the West German Constitutional Court from exercising jurisdiction. In practical law, however, West German justice and legislation applied in West Berlin under the federal constitution just as the East German system applied in East Berlin.

Health. Far-reaching health insurance is available throughout the city, which forms Germany's largest centre of medical activity. In the eastern part the Charité, which was founded as a royal hospital in 1710, was among those institutions hard hit by a shortage of medical professionals following the massive emigration in 1989. Authorities in

both sectors hoped that the opening of the wall would contribute to the stabilization and improvement of health services throughout the east. In the western part a modern Klinikum, or teaching hospital, has introduced new methods to medical practice.

Education. Berlin has traditionally played a leading role in German education. Communist ideology formed the basis of education in East Berlin until the fall of the regime made necessary an overhaul of both curriculum and the teacher-selection process. East Berlin had an earlier start in rebuilding its university system through physical control of the Frederick William University, now Humboldt University. Because of communist hegemony, noncommunist academics left East Berlin in 1948 and founded the Free University in West Berlin. From its inception, the Free University drew political activists from all over Germany. At first, many students participated in daring operations to bring refugees out of the East. By 1965 a new left had emerged whose militancy was carried into the streets, leading to clashes with the police. After a decline in student activism in subsequent decades, the events of 1989 and the movement for reunification brought a resurgence of political participation on West Berlin campuses. In East Berlin student dissidence had been limited until reform groups, often led by academics, emerged throughout the city in the late 1980s, notably under the protection of Protestant churches. It was these groups who first protested the falsified results of a municipal election in May 1989, triggering a wave of similar demonstrations elsewhere in East Germany. By November 1989, these efforts had coalesced into a centralized movement, which shortly before the opening of the wall brought more than one million demonstrators into the centre of East Berlin on a single afternoon.

Students and politics

With more than 100,000 students already enrolled in the three major universities in the west, the coming together of both the city halves and their respective educational systems posed new questions regarding acceptance of academic credentials and the management and accommodation of an east–west flow of students and teachers.

Several noteworthy libraries operate in the city. Two libraries of acclaim in the west are the American Memorial Library, built with U.S. aid after the Berlin blockade, and the Art Library, a state museum founded in 1867. The National Library in the east is also a major cultural and educational centre.

CULTURAL LIFE

When Berlin was a provincial capital, it only rarely rivaled cities such as London and Paris as a cultural magnet and, because of the regionalism of German life, seldom monopolized talented individuals as did other national capitals. From the 18th century, however, its cultural contribution became distinctive, and, if its 19th-century title "Athen an der Spree" ("Athens on the Spree") seems exaggerated, the contribution of Berliners to the arts and sciences, nevertheless, has been considerable. By 1750 the Prussian State Opera on Unter den Linden was rated among the finest opera houses in Europe, and the city's link with musical excellence was firmly established. Berlin never rivaled Vienna as a centre for German composers, although Felix Mendelssohn, a scion of one of the city's distinguished Jewish families, lived much of his life in Berlin.

Literary renaissance

The renaissance of German literature, dating from the late 18th century, found at least one of its homes in Berlin. Among the finest 19th-century writers associated with Berlin was Theodor Fontane, who wrote for the city's newspapers the *Kreuzzeitung* and *Vossiche Zeitung* and who perfected the German realistic novel. Other noted 19th-century writers who flourished in Berlin were the playwright Heinrich von Kleist and E.T.A. Hoffmann, who is best known for his fantastic short stories.

From the 18th century the Prussian state was served by a line of distinguished architects. Among these were Andreas Schlüter, who initiated the late German Baroque style; Georg Venzeslaus von Knobelsdorff, who built Sanssouci Palace outside Berlin for Frederick the Great; and Karl Friedrich Schinkel, who gave the centre of Berlin its characteristic Neoclassical grandeur. The court painter Antoine Pesne and the sculptor Christian Daniel Rauch, among lesser talents, lived in Berlin.

From the founding of the Frederick William (now Humboldt) University in 1810, Berlin became one of the foremost centres of German intellectual life. The city once rivaled Leipzig as a centre for German publishing, but its publishers' row was almost wiped out by wartime bombing. In the 19th century Berlin was also the centre for German newspaper publishing, and it still has more daily newspapers than most large cities.

The Weimar period

Berlin's role as a city of the imagination, of myth and symbol, reached its zenith not during the years of imperial splendour but during the era that followed, the period of the troubled Weimar Republic in the 1920s, when Berlin developed an extraordinary reputation for cultural brilliance and intellectual ferment. For many foreigners Berlin's more garish image of the period was epitomized by the British novelist Christopher Isherwood in such works as *Mr Norris Changes Trains* and *Goodbye to Berlin.* The clubs, cabarets, and other amusement enterprises that made Berlin notorious in the 1920s continued into the postwar period. The image of Weimar cultural brilliance was to be succeeded by another image of Berlin: the city of smoking and charred ruins when the Nazi regime crashed into defeat. Some of the loss brought by the Nazi interregnum could never be entirely regained—for instance, the cultural impact of the decimated Jewish community. Berlin has made strenuous efforts, however, to salvage and rebuild its cultural life.

The new Opera House (Deutsche Oper Berlin) was opened in West Berlin in 1961, and it quickly established a position as one of the leading opera houses of the Western world. The Opera House in East Berlin, burned down in 1843 and destroyed again by World War II bombs, was rebuilt in 1951; it is home to the long-established Deutsche Staatsoper (German National Opera). East Berlin's Comic Opera also gained fame. Classical music in general still finds a distinguished home in Berlin. Foremost among many notable musical ensembles is the world-famous Berlin Philharmonic Orchestra, founded in 1882 and reaching new heights in the postwar period under the leadership of the conductor Herbert von Karajan.

In the theatre of East Berlin, international acclaim was won by the Berliner Ensemble, founded by the playwright Bertolt Brecht after he returned to the city in 1948 following wartime exile. In the western part are three state theatres—the Schiller-Theater; its associated theatre workshop, the Schiller-Theater-Werkstatt; and the Schlosspark-Theater—as well as numerous privately operated theatres. In the early 20th century Berlin became the German centre of film production. From the 1960s a notable revival of filmmaking began in West Berlin. The Berlin Film Festival, founded in 1951, became one of the most important in the world.

Berlin is famous for its many excellent museums (see above *The city layout*). Because the prewar museum sites and parts of the old collections were located in what became East Berlin, a magnificent new museum complex, collectively called the Dahlem Museums, was built in the western district of Dahlem. The Egyptian Museum, in the western part, is also noted for its outstanding collection, which includes the celebrated bust of Queen Nefertiti. In the Reichstag building there is a permanent exhibition illustrating German history. The transfer of art works among formerly estranged institutions began in 1990 even before unification was formalized.

History

THE EARLY PERIOD

Founding

Origins. The name Berlin appears for the first time in recorded history in 1244, seven years after that of its sister town, Kölln, with which it later merged. Both were founded at about the beginning of the 13th century. In 1987, both East and West Berlin celebrated the city's 750th anniversary. Whatever the date of foundation, it is certain that the two towns were established for geographic and mercantile reasons, as they commanded a natural east–west trade route over the Spree River.

The way for their founding was opened by a Germanic resurgence in the area, which had been abandoned to the Slavs by the original Germanic tribes as they migrated westward. The Slavs were subdued by Albert I the Bear, a Saxon who crossed the Elbe River from the west. His successors took the title margrave of the mark (border territory) of Brandenburg. Berlin still retains as its symbol a defiant black bear standing on its hind legs.

The settlements of Spandau and Köpenick, now metropolitan districts, preceded the establishment of Berlin-Kölln. The Ascanians, followers of Albert I the Bear, established their fortress in 1160 at Spandau in the north where the Spree flows into the Havel River; by 1232 the fortress had earned the privileges of a town. Berlin-Kölln emerged between Spandau to the northwest and Köpenick to the southeast. By 1250 Berlin-Kölln dominated the mark of Brandenburg east to the Oder River, where a fort had been built in 1214, and in the 14th century it joined the Hanseatic League of northern German towns.

The Hohenzollerns. In 1411 the mark of Brandenburg came under the governorship of the Nürnberg feudal baron Frederick VI, beginning Berlin's association with the Hohenzollerns, who from the end of the 15th century as prince electors of Brandenburg established Berlin-Kölln as their capital and permanent residence.

The Thirty Years' War of 1618–48 laid a heavy financial burden on the city, and the population was reduced from 12,000 to 7,500. When Frederick William the Great Elector assumed power in 1640, he embarked on a building program, including fortifications that enabled him to expel Swedish invaders. His rule also marked the beginning of the development of canals, which by 1669 provided a direct link between Breslau (now Wrocław, Pol.) in the east and Hamburg and the open sea in the west. In 1709 the framework of Greater Berlin was laid when Berlin-Kölln and the newer towns of Friedrichswerder, Dorotheenstadt, and Friedrichstadt were put under a single magistrate. The population grew from 12,000 in 1670 to 61,000 in 1712, including 6,000 French Huguenot refugees.

The role of Frederick the Great

During the first half of the 18th century, Berlin expanded in all directions. Frederick II the Great adorned the city with a number of new buildings, and, soon after his death, the Brandenburg Gate was completed (1791). In 1810 the scholar Wilhelm von Humboldt founded what became East Berlin's Humboldt University. It early attracted such outstanding thinkers as the philosopher Georg Wilhelm Friedrich Hegel and the father of communism, Karl Marx. Berlin had its first popular uprising in 1830 when tailors' apprentices took to the streets over working conditions. The Revolution of 1848 produced 200 dead in a clash between soldiers and citizenry. By this time the city's population had risen to 415,000, from about 100,000 a century before. With the opening of the Berlin–Potsdam line in 1838, Berlin became the centre of an expanding rail network.

The period of railway growth was also that of Otto von Bismarck, whose successful military ventures as prime minister of Prussia paved the way for the creation of a united Germany. The Second Reich came into being when the king of Prussia was crowned Kaiser (Emperor) William I in 1871, at which time the population of Berlin, his capital, was 826,000.

THE 20TH CENTURY

The republic and Hitler. Three times in the 20th century, the date of November 9 has marked dramatic events in the history of Germany and Berlin. On that date in 1918, Berlin became the capital of the first German republic. Exactly 20 years later, Nazi storm troopers (Sturmabteilung) vandalized Jewish synagogues, shops, and other properties in the night of violence known as Kristallnacht (Night of Broken Glass). And on Nov. 9, 1989, East German authorities opened the barricade that had divided the city for 28 years.

The period 1918–33, in Berlin as elsewhere in Germany, was one of great disorder, runaway inflation, mass unemployment, and the rise to power of Adolf Hitler. Political and economic chaos spurred his ascendancy. By 1932 the unemployed in Berlin alone totaled 636,000, and on Jan. 31, 1933, Hitler became chancellor, his storm troopers marching through the Brandenburg Gate with massed flags and torches. He took absolute power in February and March of that year.

In 1936 Berlin was the scene of the most spectacular of modern Olympic Games, held in a specially built 100,000-seat stadium complex. Two years later, Kristallnacht, so called after the shattered windows of Jewish-owned buildings, was a landmark event of another kind. This rampage initiated a wave of persecution that in Berlin reduced a Jewish population of 170,000 to 5,000 by 1945. In May 1990, drawn by the momentous changes sweeping central and eastern Europe, the World Jewish Congress met in Germany for the first time in the organization's history, holding sessions in both East and West Berlin. Already in late 1989, both halves of the city had announced that they would vigorously pursue a bid to bring the Olympics back to Berlin in the year 2000.

Impact of World War II

Allied aerial bombing during World War II cost Berlin an estimated 52,000 dead. Another 100,000 civilians died in the battle for Berlin launched by the Soviet Army on April 16, 1945. Berlin's residential districts, factories, military facilities, streets, and cultural buildings were pounded into the sandy plain (one-sixth of all the wartime rubble in Germany lay in Berlin). The war left Berlin with a population that was 70 percent female, and in the aftermath of bombardment, the *Trümmerfrauen* ("rubble women") cleared the refuse. On April 30, 1945, Hitler committed suicide in his bunker below the Chancellery. On May 8 Soviet officials staged an elaborate German surrender ceremony in Berlin, rivaling that held by the Western Allies the day before in Reims, Fr. This divided ritual began the drama of the postwar city, the focal point of an East–West political struggle.

Berlin divided. On Oct. 1, 1920, the creation of a metropolitan Berlin took place through the fusing of 7 districts, 59 country communities, and 27 landed estates into a single association. Twenty resultant districts became integral parts of metropolitan Berlin but still remained largely autonomous. At the end of World War II the Soviet Union took eight of Berlin's districts as its sector of occupation: Berlin Mitte, Prenzlauer Berg, Friedrichshain, Treptow, Köpenick, Lichtenberg, Weissensee, and Pankow (Lichtenberg and Weissensee later being re-formed into the three districts of Hohenscheinhausen, Marzahn, and Hellersdorf). What was called the New West End, developed after old Berlin had outgrown its space, became West Berlin. The U.S. sector was formed by the southern districts of Zehlendorf, Steglitz, Tempelhof, Neukölln, Kreuzberg, and Schöneberg. The British sector embraced the central and western districts of the Tiergarten, as well as Wilmersdorf, Charlottenburg, and Spandau. The French were allotted the northern Wedding and Reinickendorf districts.

This apportioning was based on an agreement reached in London in 1944 by the United States, Britain, and the Soviet Union, acting on a British plan that divided Germany into occupation zones and Greater Berlin into sectors within, but not part of, the Soviet zone of occupation. A significant feature of the agreements concerning Berlin was the inability of the Western side to get a written Soviet guarantee of access.

Blockade and airlift

In March 1948 the Western powers decided to unite their zones of Germany into a single economic unit. In protest, the Soviet representative withdrew from the Allied Control Council. In June 1948, the West introduced a currency reform in the western sectors of occupied Germany, including West Berlin. The Soviet Union responded by launching a land blockade of West Berlin.

A great airlift broke this attempt to cut off the city from vital supplies, Western Allied planes hauling 1,831,200 tons of food, coal, and other necessities. The Soviets abandoned the blockade on May 12, 1949, but the Western Allies kept flying until September, building up a year's supply of essential goods. From time to time afterward access by road to West Berlin was denied for short periods as a form of harassment. In the meantime, on Nov. 30, 1948, a separate municipal government with its own chief burgomaster, or mayor, was set up in East Berlin, and this

completed the splitting of Berlin between East and West.

On June 17, 1953, some 50,000 workers, reacting to restrictive policies, rebelled in East Berlin. The uprising, which spread throughout East Germany, was crushed by Soviet intervention. In August 1961 West Berlin was physically separated from East Berlin by the erection of a wall topped with barbed wire and was isolated from the East German countryside elsewhere mainly by an encircling wire-mesh fence surmounted by watchtowers overlooking a strip of cleared ground. All of the 103-mile barrier was lighted at night. Patrols on foot and on small vehicles passed regularly. Trained dogs on long leashes guarded areas difficult to monitor by sight. Before its sudden transformation into an anachronism, the Berlin Wall had grown to about 12 feet (3.7 metres) in height, uniformly whitewashed on its eastern side, in contrast with the lively graffiti on the west. The barrier had reduced escape attempts to a trickle, until the changed political condition of Germany's neighbours to the east and south made indirect flight possible, notably through Hungary into Austria and then West Germany. In an effort to ease tensions, the United States, Britain, and France had joined the Soviet Union in signing a Berlin agreement in 1971. The working out of practical details for easier access to West Berlin from the West and for visits beyond the wall by West Germans and West Berliners was left to officials of the two German states. This resulted in an eastward flow by West Germans and West Berliners that numbered 9 million visits inside East Germany and another 27 million overland transit trips to and from West Berlin by car or train in 1988.

However, small steps toward normalization were not nearly enough, especially for the shut-in East German populace. In East Berlin and elsewhere, tens of thousands of demonstrators took to the streets in the autumn of 1989, demanding first the removal of the communist regime and then reunification with West Germany.

The opening of the wall

On November 9 the partition of Berlin dissolved with a speed few had thought possible. During the three days following, more than two million East Berliners and East Germans engulfed West Berlin, coming by car, on foot, and by subway and elevated trains. A provisional East German government then permitted West Berliners and West Germans to enter East Berlin freely, so that by New Year's Day 1990 east–west movement in Berlin had become an uncontrollable flood.

By mid-1990, whole sections of the wall, including that paralleling the mid-city Brandenburg Gate, had been removed. With crossing points proliferating, Berlin became in effect one city, although two governments still separately governed. Under the terms of the treaty enacting the reunification of the two German states, Berlin once again became the national capital.

Beverage Production

The preparation of potable liquids from water and plant matter reflects a recurrent human predilection for variety, stimulation, and conviviality, as well as an ingenuity in exploiting resources toward those ends. This article treats beverages made by infusion, such as tea and coffee; alcoholic beverages, including beer and wine, made by fermentation; distilled spirits, requiring fermentation and distillation; and soft drinks, consisting of carbonated water flavoured with sweetened syrup.

For information on the cultivation of tea, coffee, and other crops important to beverage production, see the *Macropædia* article FARMING. For information on milk beverages, see FOOD PROCESSING. Information on fruit juices may be found in the entries on individual fruits in the *Micropædia.*

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 731. (Ed.)

This article is divided into the following sections:

Tea

Tea is made from the young leaves and leaf buds of the tea plant, *Camellia sinensis*. Two principal varieties are used, the small-leaved China plant (*C. sinensis sinensis*) and the large-leaved Assam plant (*C. sinensis assamica*). Hybrids of these two varieties are also grown.

HISTORY OF THE TEA TRADE

According to legend tea has been known in China since about 2700 BC. For millennia it was a medicinal beverage obtained by boiling fresh leaves in water, but around the 3rd century AD it became a daily drink, and tea cultivation and processing began. The first published account of methods of planting, processing, and drinking came in AD 350. Around 800 the first seeds were brought to Japan, where cultivation became established by the 13th century. Chinese from Amoy brought tea cultivation to the island of Formosa (Taiwan) in 1810. Tea cultivation in Java began under the Dutch, who brought seeds from Japan in 1826 and seeds, workers, and implements from China in 1833.

Tea in India and Ceylon

In 1824 tea plants were discovered in the hills along the frontier between Burma and the Indian state of Assam. The British introduced tea culture into India in 1836 and into Ceylon (Sri Lanka) in 1867. At first they used seeds from China, but later seeds from the Assam plant were used.

The Dutch East India Company carried the first consignment of China tea to Europe in 1610. In 1669 the English East India Company brought China tea from ports in Java to the London market. Later, teas grown on British estates in India and Ceylon reached Mincing Lane, the centre of the tea trade in London.

By the late 19th and early 20th centuries, tea growing had spread to Russian Georgia, Sumatra, and Iran and extended to non-Asian countries such as Natal, Malawi, Uganda, Kenya, Congo, Tanzania, and Mozambique in Africa, to Argentina, Brazil, and Peru in South America, and to Queensland in Australia.

CLASSIFICATION OF TEAS

Teas are classified according to region of origin, as in China, Ceylon, Japanese, Indonesian, and African tea, or by smaller district, as in Darjeeling, Assam, and Nilgris from India, Uva and Dimbula from Sri Lanka, Keemun from Chi-men in China's Anhwei Province, and Enshu from Japan.

Teas are also classified by the grade, or size, of the processed leaf. Traditional sifting operations result in larger leafy grades and smaller broken grades. The leafy grades are: flowery pekoe (FP), orange pekoe (OP), pekoe (P), pekoe souchong (PS), and souchong (S). The broken grades are: broken orange pekoe (BOP), broken pekoe (BP), BOP fanning, fannings, and dust. Broken grades usually have substantial contributions from the more tender shoots, while leafy grades come mainly from the tougher and maturer leaves. In modern commercial grading, 95 to 100 percent of production belongs to broken grades, whereas earlier a substantial quantity of leafy grades was produced. This shift has been caused by an increased demand for teas of smaller particle size, which produce a quick, strong brew.

Black, green, and oolong teas

The most important classification is by the manufacturing process, resulting in the three categories of fermented (black), unfermented (green), and semifermented (oolong or pouchong). Green tea is usually produced from the China plant and is grown mostly in Japan, China, and to some extent Malaysia and Indonesia. The infused leaf is green, and the liquor is mild, pale green or lemon-yellow, and slightly bitter. Black tea, by far the most common type produced, is best made from Assam or hybrid plants. The infused leaf is bright red or copper coloured, and the liquor is bright red and slightly astringent but not bitter, bearing the characteristic aroma of tea. Oolong and pouchong teas are produced mostly in southern China and Taiwan from a special variety of the China plant. The liquor is pale or yellow in colour, as in green tea, and has a unique malty, or smoky, flavour.

PROCESSING THE LEAF

In tea manufacture, the leaf goes through some or all of the stages of withering, rolling, fermentation, and drying. The process has a twofold purpose: (1) to dry the leaf and (2) to allow the chemical constituents of the leaf to produce the quality peculiar to each type of tea.

The best-known constituent of tea is caffeine, which gives the beverage its stimulating character but contributes only a little to colour, flavour, and aroma. About 4 percent of the solids in fresh leaf is caffeine, and one teacup of the beverage contains 60 to 90 milligrams of caffeine. The most important chemicals in tea are the tannins, or polyphenols, which are colourless, bitter-tasting substances that give the drink its astringency. When acted upon by an enzyme called polyphenol oxidase, polyphenols acquire a reddish colour and form the flavouring compounds of the beverage. Certain volatile oils contribute to the aroma of tea, and also contributing to beverage quality are various sugars and amino acids.

Caffeine content

Only black tea goes through all stages of the manufacturing process. Green tea and oolong acquire their qualities through variations in the crucial fermentation stage.

Black tea. *Withering.* Plucking the leaf initiates the withering stage, in which the leaf becomes flaccid and loses water until, from a fresh moisture content of 70 to 80 percent by weight, it arrives at a withered content of 55 to 70 percent, depending upon the type of processing.

In the traditional process, fresh leaf is spread by hand in thin layers onto trays or sections of coarse fabric called tats. It is then allowed to wither for 18 to 20 hours, depending upon several factors that include the temperature and humidity of the air and the size and moisture content of the leaf. Withering in the open air has been replaced by various mechanized systems. In trough withering, air is forced through a thick layer of leaf on a mesh in a trough. In drum withering, rotating, perforated drums are used instead of troughs, and in tunnel withering, leaf is spread on tats carried by mobile trolleys and is subjected to hot-air blasts in a tunnel. Continuous withering machines move the leaf on conveyor belts and subject it to hot air in an enclosed chamber, discharging withered leaf while fresh leaf is simultaneously loaded.

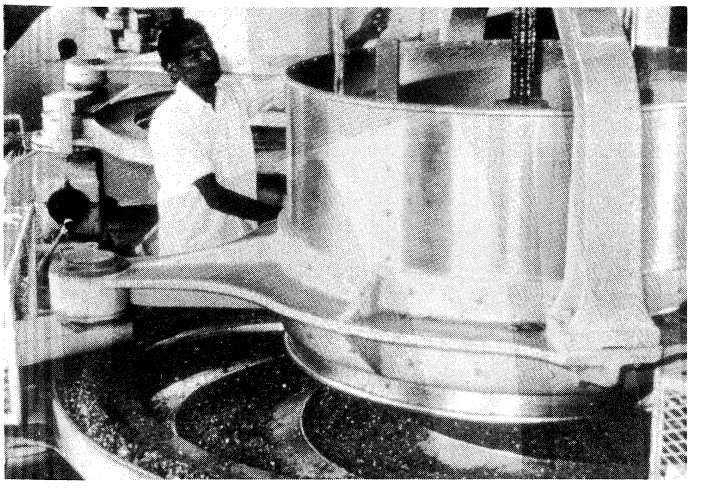
Importance of withering

Mechanized systems greatly reduce withering time, but they can also lower the quality of the final product by reducing the time for chemical withering, during which proteins and carbohydrates break down into simpler amino acids and sugars, and the concentration of caffeine and polyphenols increases.

Rolling. At this stage, the withered leaf is distorted, acquiring the distinctive twist of the finished tea leaf, and leaf cells are burst, resulting in the mixing of enzymes with polyphenols.

The traditional method is to roll bunches of leaves between the hands, or by hand on a table, until the leaf is twisted, evenly coated with juices, and finally broken into pieces. Rolling machines consist of a circular table fitted in the centre with a cone and across the surface with slats called battens. A jacket, or bottomless circular box with a pressure cap, stands atop the table. Table and jacket rotate eccentrically in opposite directions, and the leaf placed in the jacket is twisted and rolled over the cone and battens in a fashion similar to hand rolling. Lumps of rolled leaf are then broken up and sifted. The smaller leaf passing through the sieve—called the fines—is transferred to the fermentation room, and the remaining coarse leaf is rolled again.

In many countries, rolling the leaf has been abandoned in favour of distortion by a variety of machines. In the Legg cutter (actually a tobacco-cutting machine), the leaf is forced through an aperture and cut into strips. The crushing, tearing, and curling (CTC) machine consists of two serrated metal rollers, placed close together and revolving at unequal speeds, which cut, tear, and twist the leaf. The Rotorvane consists of a horizontal barrel with a feed hopper at one end and a perforated plate at the other. Forced through the barrel by a screw-type rotating shaft fitted with vanes at the centre, the leaf is distorted by resistor plates on the inner surface of the barrel and is cut at the end plate. The nontraditional distorting machines



A rolling machine twisting tea leaves, coating them with juices, and breaking them into pieces; Sri Lanka.

can burst leaf cells so thoroughly that in many cases they render the withering stage unnecessary. However, unlike traditional rolling, they do not produce the larger leafy grades of tea.

Fermentation. Fermentation commences when leaf cells are broken during rolling and continues when the rolled leaf is spread on tables or perforated aluminum trays under controlled conditions of temperature, humidity, and aeration. The process actually is not fermentation at all but a series of chemical reactions. The most important is the oxidation by polyphenol oxidase of some polyphenols into compounds that combine with other polyphenols to form orange-red compounds called theaflavins. The theaflavins react with more units to form the thearubigins, which are responsible for the transformation of the leaf to a dark brown or coppery colour. The thearubigins also react with amino acids and sugars to form flavour compounds that may be partly lost if fermentation is prolonged. In general, theaflavin is associated with the brightness and brisk taste of brewed tea, while thearubigin is associated with strength and colour.

The formation of flavour and colour

In traditional processing, optimum fermentation is reached after two to four hours. This time can be halved in fermenting leaf broken by the Legg cutter, CTC machine, and Rotorvane. In skip fermentation, the leaf is spread in aluminum skips, or boxes, with screened bottoms. Larger boxes are used in trough fermentation, and in continuous fermentation the leaf is spread on trays on a conveyor system. In all of these fermentation systems the leaf is aerated by forced air (oxygen being necessary for the action of the enzymes), and it is brought by automated conveyor to the dryer.

Drying. At this stage, heat inactivates the polyphenol enzymes and dries the leaf to a moisture content of about 3 percent. It also caramelizes sugars, thereby adding flavours to the finished product, and imparts the black colour associated with fermented tea.

Traditionally, fermented leaf was dried on large pans or screens over fire, but since the late 19th century, heated forced air has been used. A mechanized drier consists of a large chamber into the bottom of which hot air is blown as the leaf is fed from the top on a series of descending conveyors. The dried leaf is then cooled quickly to prevent overdrying and loss of quality. Modern innovations on the drier are the hot-feed drier, where hot air is supplied separately to the feeder to arrest fermentation immediately as the leaf is fed, and the fluid-bed drier, where the leaf moves from one end of the chamber to the other over a perforated plate in a liquid fashion.

Prevention of fermentation

Green tea. In preparing unfermented tea, the oxidizing enzymes are killed by steamblasting the freshly plucked leaf in perforated drums or by roasting it in hot iron pans prior to rolling. The leaf is then subjected to further heating and rolling until it turns dark green and takes a bluish tint. The leaves are finally dried to a moisture content of 3 to 4 percent and are either crushed into small pieces or ground to a powder.

With the inactivation of polyphenol oxidase, the polyphenols are not oxidized and therefore remain colourless, allowing the processed leaf to remain green. The absence of theaflavins and thearubigins in the finished leaf also gives the beverage a weaker flavour than black tea.

Oolong tea. After a brief withering stage, the leaf is lightly rolled by hand until it becomes red and fragrant. For oolong it is then fermented for about one-half, and for pouchong for one-quarter, of the time allowed for black tea. Fermentation is stopped by heating in iron pans, and the leaf is subjected to more rolling and heating until it is dried.

PACKAGING

Sorting and grading. The first step in packaging tea is grading it by particle size, shape, and cleanliness. This is carried out on mechanical sieves or sifters fitted with meshes of appropriate size. With small-sized teas in demand, some processed teas are broken or cut again at this stage to get a higher proportion of broken grades. Undesirable particles, such as pieces of tough stalk and fibre, are removed by hand or by mechanical extractor. Winnowing by air removes dust, fibres, and fluff.

Packing. Teas are packed in airtight containers in order to prevent absorption of moisture, which is the principal cause of loss of flavour during storage. Packing chests are usually constructed of plywood, lined with aluminum foil and paper, and sealed with the same material. Also used are corrugated cardboard boxes lined with aluminum foil and paper or paper sacks lined with plastic.

Preventing exposure to moisture

Blended teas are sold to consumers as loose tea, which is packed in corrugated paper cartons lined with aluminum foil, in metal tins, and in fancy packs such as metallized plastic sachets, or they are sold in tea bags made of special porous paper. Tea bags are mainly packed with broken-grade teas.

Instant tea. Instant teas are produced from black tea by extracting the liquor from processed leaves, tea wastes, or undried fermented leaves, concentrating the extract under low pressure, and drying the concentrate to a powder by freeze-drying, spray-drying, or vacuum-drying. Low temperatures are used to minimize loss of flavour and aroma. Instant green teas are produced by similar methods, but hot water is used to extract liquor from powdered leaves. Because all instant teas absorb moisture, they are stored in airtight containers or bottles.

PREPARING THE BEVERAGE

Blending. Tea sold to the consumer is a blend of as many as 20 to 40 teas of different characteristics, from a variety of estates, and from more than one country. Price is an important factor, with cheap teas (called fillers) used to round off a blend and balance cost. Blends are often designed to be of good average character without outstanding quality, but distinctive blends—for example, with a flavour of seasonal Ceylon tea or the pungency and strength of Assam tea—are also made.

Brewing. A tea infusion is best made by pouring water just brought to the boil over dry tea in a warm teapot and steeping it from three to five minutes. The liquor is separated from the spent leaves and may be flavoured with milk, sugar, or lemon.

Tasting. Professional tasters, sampling tea for the trade, taste but do not consume a light brew in which the liquor is separated from the leaf after five to six minutes. The appearance of both the dry and infused leaf is observed, and the aroma of vapour, colour of liquor, and creaming action (formation of solids when cooled) are assessed. Finally the liquor is taken into the mouth with a sucking noise, swirled around the tongue, brought into contact with the palate, cheek, and gums, and then drawn to the back of the mouth and up to the olfactory nerve in the nose before being expectorated. The liquor is thus felt, tasted, and smelled. Tasters have a large glossary of terms for the evaluation of tea, but the less-demanding consumer drinks it as a thirst quencher and stimulant and for its distinctive sour-harsh taste. (S.Si.)

Professional tea tasting

Coffee

Coffee, a beverage brewed from the roasted and ground seeds of the tropical evergreen coffee plant of African origin, is consumed either hot or cold by about one-third of the people in the world, in amounts larger than those of any other drink. Its popularity can be attributed to its invigorating effect, which is produced by caffeine, an alkaloid present in green coffee in amounts between 0.8 and 1.5 percent for the Arabica varieties and 1.6 to 2.5 percent for Robusta.

Two principal coffee plants

Two species of the coffee plant, *Coffea arabica* and *C. canephora,* supply almost all of the world's consumption. Arabica coffee, which is divided between Brazilians and milds, is considered to brew a more flavourful and aromatic beverage than Robusta, the main variety of *C. canephora.* Arabicas are grown in Central and South America, the Caribbean, and Indonesia, while Robustas are grown mainly in Africa.

HISTORY

Wild coffee plants, probably from Kefa (Kaffa), Ethiopia, were taken to southern Arabia and placed under cultivation in the 15th century. One of many legends about the discovery of coffee is that of Kaldi, an Arab goatherd, who was puzzled by the queer antics of his flock. About AD 850, Kaldi supposedly sampled the berries of the evergreen bush on which the goats were feeding and, on experiencing a sense of exhilaration, proclaimed his discovery to the world.

Whatever its historical origin, the stimulating effect of coffee undoubtedly made it popular, especially in connection with the long religious service of the Muslims. The orthodox priesthood pronounced it intoxicating and therefore prohibited by the Qur'ān, but despite the threat of severe penalties, coffee drinking spread rapidly among Arabs and their neighbours.

During the 16th and 17th centuries, coffee was introduced into one European country after another; many accounts are recorded of its prohibition or approval as a religious, political, and medical potion. Coffee gained popularity as a beverage in the London coffeehouses, which became centres of political, social, literary, and eventually business influence. The first coffeehouse in London was established about 1652. In Europe, too, the coffeehouse flourished later in the 17th century. In such North American cities as Boston, New York City, and Philadelphia, coffeehouses became popular beginning in the late 1600s.

Until the close of the 17th century, the world's limited supply of coffee was obtained almost entirely from the province of Yemen in southern Arabia. But, with the increasing popularity of the beverage, the propagation of the plant spread rapidly to Java and other islands of the Indonesian archipelago in the 17th century and to the Americas in the 18th century. Coffee cultivation was started in the Hawaiian Islands in 1825.

By the 20th century the greatest concentration of production was centred in the Western Hemisphere—particularly Brazil. In the late 19th and early 20th centuries, industrial roasting and grinding machines came into use, vacuum-sealed containers were invented for ground roasts, and decaffeination methods for green coffee beans were developed. After 1950 the production of instant coffee was perfected. The popularity of instant coffee led to increased production of the cheaper Robusta beans in Africa.

(T.C.W./Ed.)

PROCESSING GREEN COFFEE

Hulling. The ripened fruits of the coffee shrubs, known as coffee cherries, are processed by disengaging the coffee seeds from their coverings and from the pulp and by drying the seeds from an original moisture content of 65–70 percent water by weight to 12–13 percent. Two different techniques are used: a wet process (used mainly for the mild Arabica coffees) and a dry process (used for Brazilians and Robustas).

Two methods of hulling

The wet process. First the skin and pulp of the fresh fruit is removed by a pulping machine, which consists of a rotating drum or disk that presses the fruit against a sharp-edged or slotted plate, disengaging the pulp from the seed. Pulp still clings to the coffee, however, as a thin, mucilaginous layer. This is eliminated by fermentation, actually a form of digestion in which naturally occurring pectic enzymes decompose the pulp while the wetted seeds are held in tanks for one to three days. Washing clears all remaining traces of pulp from the coffee seeds, which are then dried either by exposure to sunlight on concrete terraces or by passing through hot-air driers. The dry skin around the seed, called the parchment, is then mechanically removed, sometimes with polishing.

The dry process. In this process, the fruits are immediately placed to dry either in sunlight or in hot-air driers. Although mechanical drying is replacing the labour- and time-consuming sun drying, more time and equipment are required than in drying pulped seeds in the wet process. When the fruits have been dried to a water content of 12 percent, they are mechanically hulled to free the seeds from their coverings.

Grading and storage. The practice of grading coffee gives sellers and buyers a guarantee concerning the origin, nature, and quality of the product to aid their negotiations. Each country has a certain number of defined types and grades, but there are no international standards outside the contract market.

The prolonged storage of coffee in the producing countries presents problems, especially in the warm and humid coastal regions, where molds and parasites may develop and cause damage; for this reason coffee from these areas is exported as quickly as possible. In moderate climates, the conservation of dry lots does not pose a problem as long as they are stocked in well-ventilated places.

PROCESSING THE BEAN

Decaffeination. Caffeine can be removed from the green coffee by a variety of methods. In the most common, solvent extraction, the beans are steamed to raise the moisture content and bring the dissolved caffeine to the surface of the beans. They are then washed by an organic solvent such as methylene chloride, which extracts the caffeine. The solution is removed by steam, and the beans are dried.

Roasting. The aromatic and gustatory qualities of coffee are developed by the high temperatures to which they are subjected during roasting or broiling.

Temperatures are raised progressively to about 220°–230° C (430°–440° F). This releases steam, carbon dioxide, carbon monoxide, and other volatiles from the beans, resulting in a loss of weight between 14 and 23 percent. Internal pressure of gas expands the coffee beans by 30 to 100 percent. The beans become a deep, rich brown, and their texture becomes porous and crumbly under pressure. But the most important phenomenon of roasting is the appearance of the characteristic aroma of coffee, which arises from very complex chemical transformations within the bean. Roasting too long can destroy volatile flavour and aroma compounds. For this reason, Robusta beans are often over-roasted (as in the dark French and Italian roasts) to rid the coffee of its natural harshness.

Effects of over-roasting

In the oldest method of roasting, a metal cylinder, or sphere, containing the coffee is rotated above a source of heat such as charcoal, gas, or electricity. In modern roasters, hot air is propelled by a blower into a rotating metal cylinder containing the coffee. The tumbling action of rotation ensures that all beans are roasted evenly.

Regardless of the method used, the coffee, after leaving the industrial roasters, is rapidly cooled in a vat, where it is stirred and subjected to cold air propelled by a blower. Good-quality coffees are then sorted by electronic sorters to eliminate those seeds, either too light or too dark, that roasted badly and whose presence depreciates the quality.

Grinding. Some coffees are left as whole beans to be ground at the time of purchase or by the consumer at home. But a large part of the coffee is ground, or milled, by the manufacturer immediately after roasting. In most modern roasting plants, grinding is accomplished by feeding the coffee through a series of serrated or scored rollers, set at progressively smaller gaps, that first crack the beans and then cut them to the desired particle size.

The degree of fineness is important. If a coffee is too coarse, water filters through too fast to pick up flavour; if it is too fine, water filters through too slowly and retains particles that deposit at the bottom of the cup.

PACKAGING AND BREWING

Packaging. Effective packaging prevents air and moisture from reaching the coffee. Ground coffee alters rapidly and loses its aromatic qualities within a few days if it is not put into hermetically sealed containers immediately. The air, especially in humid atmospheres, causes rancidity through oxidation of fatty components. Modern packaging materials, plastic films like polyethylene and complexes of aluminum and cellulose, are capable of conserving the quality of coffee for a time. But the most satisfactory solution to the problem is packing under vacuum or in an inert gas, in rigorously impervious containers.

Brewing. There are several methods of extracting flavour and aroma from ground coffee. In steeping or boiling, pulverized coffee is measured into hot water, which is set or boiled before being poured off the grounds. In percolation, water is brought to the boil in an urn and fed up a tube to a basket holding the coffee. After filtering through the coffee, the water drips back to the urn, where it is forced back up the tube and recirculated until the brew reaches the desired strength. In the filter, or drip, method, hot water is slowly filtered through the coffee and dripped into a receptacle; it is not recirculated. The espresso machine forces boiled water under pressure through finely ground coffee; because the water has only brief contact with the grounds, it extracts a highly flavoured brew with little bitterness.

Caffeine content

Caffeine content varies with the variety of bean and method of brewing. One serving (five fluid ounces) of Arabica instant coffee contains about 70 milligrams of caffeine, while a serving of brewed Robusta may contain 200 milligrams.

Instant coffee. In the manufacture of instant coffee (called soluble coffee in the industry), a liquid concentration of coffee prepared with hot water is dehydrated. This can be done by spray drying in hot air, by drying under vacuum, or by lyophilization (freeze drying). The operations are complex and methods vary among manufacturers. The resulting soluble powder, on the addition of hot water, forms reconstituted coffee. The average yield is 25 to 30 percent by weight of the ground coffee. Because it picks up moisture readily, instant coffee needs special vacuum packages. (R.C./Ed.)

Beer

Beer is an alcoholic beverage produced by extracting raw materials with water, boiling (usually with hops), and fermenting. In some countries beer is defined by law—as in Germany, where the standard ingredients, besides water, are germinated barley, hops, and yeast.

HISTORY OF BREWING

Before 6000 BC, beer was made from barley in Sumeria and Babylonia. Reliefs on Egyptian tombs dating from 2400 BC show that barley or partly germinated barley was crushed, mixed with water, and dried into cakes. When broken up and mixed with water, the cakes gave an extract that was fermented by microorganisms accumulated on the surfaces of fermenting vessels.

The basic techniques of brewing came to Europe from the Middle East. The Roman historians Pliny (in the 1st century BC) and Tacitus (in the 1st century AD) reported that Saxons, Celts, and Nordic and Germanic tribes drank ale. In fact, many of the English terms used in brewing (malt, mash, wort, ale) are Anglo-Saxon in origin. During the Middle Ages, the monastic orders preserved brewing as a craft. Hops were in use in Germany in the 11th century, and in the 15th century they were introduced into Britain from Holland. In 1420 beer was made in Germany by a bottom fermentation process; before that, yeast rose to the top of the fermenting product and was allowed to overflow or was manually skimmed. Brewing was a winter occupation, and ice was used to keep beer cool during the summer months. Such beer came to be called lager (from German *lagern,* "to store"). The term lager is still used to denote beer produced from bottom-fermenting yeast, and the term ale is now used for top-fermented British types of beer.

Lagers and ales

The Industrial Revolution brought the mechanization of brewing. Better control over the process, with the use of the thermometer and saccharometer, was developed in Britain and transferred to the Continent, where the development of ice-making and refrigeration equipment in the late 19th century enabled lager beers to be brewed in summer. In the 1860s the French chemist Louis Pasteur established many of the microbiological practices still used in brewing. The Danish botanist Emile Hansen devised methods for growing yeasts in culture free of other yeasts and bacteria. This pure-culture technology was quickly taken up by continental lager brewers but not until the 20th century by the ale brewers of Britain. Meanwhile, German-style bottom-fermented lagers fermented by pure yeast cultures became dominant in the Americas.

Brewing in the 20th century is a large-scale industry. Modern breweries use stainless-steel equipment and computer-controlled automated operations, and they package beer in metal casks, glass bottles, aluminum cans, and plastic containers. Beers are now exported worldwide and are produced under license in foreign countries.

TYPES OF BEER

Beverages similar to beer are produced in Japan (sake, from rice) and Mexico (pulque, from cactus). In Nigeria and South Africa, malted sorghum is used to produce *burukutu* and Kaffir beers.

In the West, the properties of the water used for brewing, the types of malt, the brewing practices, and the yeast strains have contributed to traditional distinctions between beers. Early British beers were made from successive extracts of a single batch of brown malt. The first and strongest extract gave the best quality beer, called strong beer, and a third extract yielded the poorest quality beer, called small beer. In the 18th century London brewers departed from this practice and produced porter. Made from a mixture of malt extracts, porter was a strong, dark-coloured, highly-hopped beer consumed by the market porters in London. Brewers in Burton upon Trent, using the famous hard waters of that region and pale malts roasted in coke-fired kilns, created pale ales, also called best bitter. Pale ale is less strong, less bitter, paler in colour, and clearer than porter. Mild ales—weaker, darker, and sweeter than bitter—are a common variation; more colour is obtained by special malts, roasted barley, or caramels, less hops are used, and cane sugar is added to impart sweetness and aid maturation. Stouts are stronger versions of mild ale; some, such as milk stouts, contain lactose (milk sugar) as a sweetener.

Pale ale, mild ale, and stout

Bottom-fermented lagers have their origins in different regions of continental Europe. Brewers in Plzeň (now in Czechoslovakia) used local soft waters to produce the famous Pilsner beer, which became the standard for highly hopped, pale-coloured, dry lagers. *Dortmunder* is a pale lager of Germany, while Munich has become associated with dark, strong, slightly sweet beers with less hop character. The dark colour comes from highly roasted malt, and other characteristic flavours arise during the decoction mashing process. Bock is an even stronger, heavier Munich-type beer that is brewed in winter for consumption in the spring. *Märzbier* ("March beer") is a lighter brew produced in the spring. While all German lagers are made with malted barley, a special brew called weiss beer (*Weissbier;* "white beer") is made from malted wheat. In other countries such as Denmark and The Netherlands, other cereals are used in lighter coloured larger beers.

The 20th century has seen the erosion of traditional distinctions based on place of manufacture, raw materials, and brewing methods. This has caused a reaction among a small body of consumers. In Britain it has encouraged support for smaller, traditional ale breweries. In the United States a growing number of "microbreweries" make beers with more flavour and colour.

The strength of beer may be measured by the percentage

by volume of ethyl alcohol. Strong beers are in excess of 4 percent, and so-called barley wines 8 to 10 percent. Diet beers or light beers are fully fermented, low-carbohydrate beers in which enzymes are used to convert normally unfermentable (and high-calorie) carbohydrates to fermentable form. In low-alcohol beers (0.5 to 2.0 percent alcohol) and "alcohol-free" beers (less than 0.1 percent alcohol), alcohol is removed after fermentation by low-temperature vacuum evaporation or by membrane filtration.

THE BREWING PROCESS

Beer production involves malting, milling, mashing, extract separation, hop addition and boiling, removal of hops and precipitates, cooling and aeration, fermentation, separation of yeast from young beer, aging, maturing, and packaging. The object of the entire process is to convert grain starches to sugar, extract it with water, and then ferment it with yeast to produce the alcoholic, lightly carbonated beverage.

Malting. Malting modifies barley to green malt, which can then be preserved by drying. The process involves steeping and aerating the barley, allowing it to germinate, and then drying and curing the malt.

Barley. In order to be fermented by yeast, the food reserve of barley, starch, must be converted by enzymes into simple sugars. Two enzymes, α- and β-amylases, carry out the conversion. The latter is present in barley, but the former is only made during germination of the grain. Specially bred strains of barley (generally low in nitrogen content) are used for malting. Other important characteristics are yield, even germination, ability to produce enzymes, and a highly extractable malt.

Steeping. Malting begins by immersing barley harvested at less than 12 percent moisture in water at 12° to 15° C (55° to 60° F) for 40 to 50 hours. During this steeping period, the barley may be drained and given air rests, or the steep may be forcibly aerated. As the grain imbibes water, its volume increases by about 25 percent, and its moisture content reaches about 45 percent. A white root sheath, called a chit, breaks through the husk, and the chitted barley is then removed from the steep for germination.

Germination. Activated by water and oxygen, the root embryo of the barleycorn secretes a plant hormone called gibberellic acid, which initiates the synthesis of α-amylase.

Conversion of starch into sugar

The α- and β-amylases then convert the starch molecules of the corn into sugars that the embryo can use as food. Other enzymes, such as the proteases and β-glucanases, attack the cell walls around the starch grains, converting insoluble proteins and complex sugars (called glucans) into soluble amino acids and glucose. These enzymatic reactions are called modification. The more germination proceeds, the greater the modification. Overmodification leads to malting loss, in which rootlet growth and plant respiration reduce the weight of the grain.

In traditional malting, the steeped barley was placed in heaps called couches and, after 24 hours, spread on a floor to permit germination. Because respiration of the grain causes oxygen to be taken up and carbon dioxide and heat to be produced, control of aeration, ventilation, and temperature was achieved by manually turning the grain. Large-scale floor maltings with mechanical turners were introduced and then replaced by pneumatic maltings, in which germination occurred in boxes with the bed automatically turned, aerated, and ventilated with forced air. In some malting operations gibberellic acid is sprayed onto the barley to speed germination, and bromates are used to suppress rootlet growth and malting loss. Although less-modified malts are traditionally used in lagers, and well-modified malts in ales, it is now usual to produce well-modified malts regardless of whether lager or ale is to be made.

Kilning. Green malt is dried to remove most of the moisture, leaving 5 percent in lager and 2 percent in traditional ale malts. This process arrests enzyme activity but leaves 40 to 60 percent in an active state. Curing at higher temperatures promotes a reaction between amino acids and sugars to form melanoidins, which give both colour and flavour to malt.

In the first stage of kilning a high flow of dry air at 50° C (120° F) for lager malt and 65° C (150° F) for ale malt is maintained through a bed of green malt. This lowers the moisture content from 45 to 25 percent. A second stage of drying removes more firmly bound water, the temperature rising to 70°–75° C (160°–170° F) and the moisture content falling to 12 percent. In the final curing stage, the temperature is raised to 75°–90° C (170°–195° F) for lager and 90°–105° C (195°–220° F) for ale. The finished malt is then cooled and screened to remove rootlets.

Roasting special malts

Special malts are made by wetting and heating green malt in closed drums at high temperatures. Made in this way are crystal (caramel), chocolate (black), and amber malts; used in small and varying proportions (2 to 3 percent of brewing malt), they introduce considerable variations in colour and flavour to finished beers. Chocolate malt and roasted ungerminated barley are used at a high proportion (25 percent) to make stouts and porters. The use of unmalted cereals has also become common, because they are less expensive sources of starch and can be used to dilute malt colour and flavour, thereby yielding fresher, lighter beers.

Modernization. Modern maltings can produce malt in four to five days, and technological improvements give precise control over temperature, humidity, and use of heat. Tower maltings have been developed with an uppermost floor for steeping and lower floors for germination and kilning, producing a compact, semicontinuous operation that is also fully automated.

Mashing. After kilning, the malt is mixed with water, and the enzymatic conversion of starch into fermentable sugar is completed.

Milling. For efficient extraction with water, malt must be milled. Early milling processes used stones driven manually or by water or animal power, but modern brewing uses mechanically driven roller mills. The design of the mill and the gap between the rolls are important in obtaining the correct reduction in size of the malt. The object is to retain the husk relatively intact while breaking up the brittle, modified starch into particles.

Mixing the mash. The milled malt, called grist, is mixed with water, providing conditions in which starch, other molecules, and enzymes are dissolved and rapid enzyme action takes place. The solute-rich liquid produced in mashing is called the wort. Traditionally, mashing may be of one of two distinct types. The simplest process, infusion mashing, uses a well-modified malt, two to three volumes of water per volume of grist, a single vessel (called a mash tun), and a single temperature in the range of 62° to 67° C (145°to 150° F). With well-modified malt, breakdown of proteins and glucans has already occurred at the malting stage, and at 65° C the starch readily gelatinizes and the amylases become very active. Less well-modified malt, however, benefits from a period of mashing at lower temperatures to permit the breakdown of proteins and glucans. This requires some form of temperature programming, which is achieved by decoction mashing. After grist is mashed in at 35° to 40° C (95° to 105° F), a proportion is removed, boiled, and added back. Mashing with two or three of these decoctions raises the temperature in stages to 65° C. The decoction process, traditional in lager brewing, uses four to six volumes of water per volume of grist and requires a second vessel called the mash cooker.

Two mashing methods

Other sources of starch that gelatinize at 55° to 65° C can be mashed along with malt. Wheat flour and corn (maize) flakes may be added directly to the mash, whereas corn grits and rice grits must first be boiled in order to gelatinize. Their use requires a third vessel, the cereal cooker.

Modern mashing systems use mixed grists and mash mixers, which are efficiently stirred and temperature-programmed mashing vessels. Enzymes of bacterial and fungal origin may be added as aids. Ale and lager are mashed in the same equipment, but they require different temperature programs and grist composition. Modern breweries often practice high-gravity brewing, in which highly concentrated worts are made, fermented, and then diluted, allowing more beer to be brewed on the same equipment.

Separating the wort. The mash tun used in infusion mashing is fitted with a false base containing precisely-

machined slots through which the husk, preserved during milling, cannot pass. The trapped husk thus forms a filter bed that removes solids from the wort as it is drained, leaving a residue of spent grains. Wort separation takes four to 16 hours. For thorough extraction, the solids are sprayed, or sparged, with water at 70° C.

The decoction brewer transfers the mash to a separation vessel called the lauter tun, where a shallow filter bed is formed, allowing a more rapid runoff time of about 2½ hours. Large modern breweries use either lauter tuns or special mash filters to speed up the runoff and conduct 10 or 12 mashes a day. As much as 97 percent of the soluble material is obtained, and 75 percent of this is fermentable. Wort is approximately 10 percent sugar (mainly maltose and maltotriose), and it contains amino acids, salts, vitamins, carbohydrate, and small amounts of protein.

Boiling. After separation, the wort is transferred to a vessel called the kettle or copper for boiling, which is necessary to arrest enzyme activity and to obtain the bitterness value of added hops.

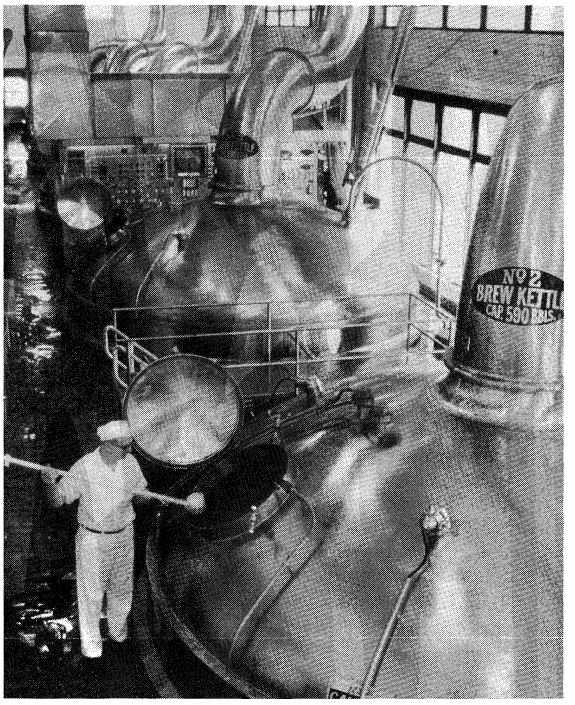
Flavouring value of hops

Hops. Several varieties of the hop (*Humulus lupulus*) are selected and bred for the bitter and aromatic qualities that they lend to brewing. The female flowers, or cones, produce tiny glands that contain the chemicals of value in brewing. Humulones are the chemical constituents extracted during wort boiling. One fraction of these, the α-acids, is isomerized by heat to form the related iso-α-acids, which are responsible for the characteristic bitter flavour of beer.

Traditionally the dried hop cones are added whole to the boiling wort, but powdered compressed hops are often used because they are more efficiently extracted. In addition, the hop components may be extracted by solvents such as liquid carbon dioxide and added in this form to the wort or, after isomerization, to the finished beer.

Heating and cooling. The kettle boil lasts 60 to 90 minutes, sterilizing the wort, evaporating undesirable aromas, and precipitating insoluble proteins (known as hot break, or trub). Trub and spent hops are then removed in a separator where the hop cones form the filter bed. In modern practice a more rapid whirlpool separator is also used. This device is a cylindrical vessel into which wort is pumped at a tangent, the circulating whirlpool movement causing solids to form a cone at the bottom. Clarified wort is cooled, formerly in shallow troughs or by trickling down an inclined cooled plate but now in a plate heat exchanger. This last is an enclosed, hygienic vessel in which hot wort runs along plates while cold water passes along the other side in the opposite direction. Oxygen is added at this stage, and the cooled wort passes to fermentation vessels.

By courtesy of the Miller Brewing Company, Wisconsin; photo by Scott J. Witte



Testing the wort before adding hops and boiling the kettle.

Fermentation. In this most important stage of the brewing process, the simple sugars in wort are converted to alcohol and carbon dioxide. Fermentation is carried out by yeast, which is added, or pitched, to the wort at three kilograms per hectolitre (about four ounces per gallon), yielding 10,000,000 cells per millilitre of wort.

Yeast. Yeasts are classified as fungi; those strains used for fermentation are of the genus *Saccharomyces* (meaning "sugar fungus"). In brewing it is traditional to refer to ale yeasts used predominantly in top fermentation as top strains of *S. cerevisiae* and to lager yeasts as bottom strains of *S. carlsbergensis.* Modern yeast systematics, however, classifies all brewing strains as *S. cerevisiae,* and many ales are made by bottom fermentation with what were originally top strains.

More than 400 simple organic compounds have been characterized in beer and many more identified, and the majority of these are produced by yeast. The bitter substances of hops, ethyl alcohol, and carbon dioxide have the greatest effects on the senses of taste and smell. Other compounds giving a beer its character include: esters such as isoamyl acetate (banana), ethyl hexanoate (apple), and ethyl acetate (solvent); higher alcohols such as isoamyl alcohol and 2-phenyl ethanol; acids such as octanoic, acetic, isovaleric, butyric malic, and citric; dialkyl sulfides such as dimethyl sulfide; and diketones such as diacetyl. The ester ethyl isovalerate and the aldehyde nonenal contribute to stale and oxidized flavours. The mechanisms of metabolism leading to the formation of these flavouring agents is neither well understood nor easily changed. Until new processes (perhaps genetic engineering) can produce changes in brewer's yeast, brewers will attach great value to known yeast strains and will maintain selected strains for brewing particular beers.

Formation of flavouring compounds

Fermenting methods. Brewing is unique among the fermentation industries in that yeast from one fermentation is used to pitch the next. This means that hygienic conditions and rigorous quality control are necessary. A high proportion of live cells and freedom from bacteria and other yeasts are important quality considerations.

Traditional open-topped earthenware fermentation vessels gave way to round, wooden and later square, copper-lined fermentors, and brewery fermentation systems evolved around the mechanism used to separate yeast from freshly fermented, or green, beer. Top fermentations, in which yeast rises to the surface, require the most elaborate systems, but most brewing operations now use more hygienically operated closed vessels and bottom fermentation. These vessels, erected outside the brewery, are several thousand hectolitres in capacity (one hectolitre = 26 gallons) and are made of stainless steel. Temperature control is achieved automatically by circulating cold liquid in jackets fitted to the wall of the vessel. Large ale breweries also use this system, removing ale yeast (*S. cerevisiae*) from the bottom of the vessel.

The temperature of the wort at pitching is 15° to 18° C (59° to 65° F) for ale and 7° to 12° C (50° to 63° F) for lager. As fermentation proceeds, the specific gravity falls as the sugars are converted by the yeast. The extent of fermentation is governed by the wort composition and by the amount of fermentable sugar to remain in maturing beer. During fermentation, yeast multiples five- to eightfold and generates heat. The temperature is allowed to rise until it reaches 20° to 23° C (68° to 74° F) for ale and 12° to 17° C (54° to 63° F) for lager. At that point the fermentation is cooled to 15° C (59° F) for ale and 4° C (39° F) for lager, considerably slowing yeast action. Yeast is then removed and the green beer, still containing about 500,000 yeast cells per millilitre, is transferred to a conditioning or maturation vessel, where a secondary fermentation may take place. In traditional brewing, the primary stage of fermentation took seven days for ale and three weeks or more for lager. These times have been shortened to two to four days and seven to 10 days by modern practices using more efficient fermentation vessels.

MATURATION AND PACKAGING

Priming and krausening

A slow secondary fermentation of residual or added sugar (called primings) or, in lager brewing, the addition of actively fermenting wort (called krausen) generates carbon dioxide, which is vented and purges the green beer of undesirable volatile compounds. Continued yeast activity also removes strong flavouring compounds such as diacetyl. Allowing pressure to build up in the sealed vessel then increases the level of carbonation, giving the beer its "condition." In traditional brewing, large volumes of ale were conditioned in tanks for seven days at 15° C, whereas lagers were matured at 0° C (32° F) for up to three months. These long maturation periods were caused by the precipitation of protein–tannin complexes, which at low temperature form "chill hazes" that are slow in settling out. Modern practice speeds up this process by adding excess tannin, clarifying with protein or tannin adsorbents, or using enzymes to degrade the proteins.

Traditional, or "real," ales are packaged into casks. Sugar primings, clarifying agents such as isinglass finings, and whole hops are added, and the beer is transferred to the point of sale, where it is carefully vented to the proper level of conditioning before being sold. Some British and Australian ales are packaged in bottles together with yeast to make "bottle-conditioned" beer.

Beer produced on a large scale in modern breweries is kept free of oxygen (which ultimately spoils beer), filtered through cellulose or diatomaceous earth to remove all yeast, and packaged at 0° C under pressure of carbon dioxide. Beer produced by high-gravity brewing is diluted to the desired alcohol concentration, immediately prior to packaging, with oxygen-free, carbonated water. Most beers packaged in bottles or metal cans are pasteurized in pack by heating to 60° C for five to 20 minutes. Beer is also packaged into metal kegs of 50-litre (in the United States, 15-gallon) capacity after pasteurization at 70° C for five to 20 seconds. Modern packaging machinery is designed to operate hygienically, exclude air, and run at rates of 2,000 cans or bottles per minute. (T.W.Y.)

Wine

Wine is the fermented juice of the grape. Of the grape genus *Vitis,* one species, *V. vinifera* (often erroneously called the European grape), is used almost exclusively. Beverages produced from *V. labrusca,* the native American grape, and from other grape species are also considered wines. When other fruits are fermented to produce a kind of wine, the name of the fruit is included, as in the terms peach wine and blackberry wine.

HISTORY

The spread of viticulture. *Vitis vinifera* was being cultivated in the Middle East by 4000 BC, and probably earlier. Egyptian records dating from 2500 BC refer to the use of grapes for wine making, and numerous Old Testament references to wine indicate the early origin and significance of the industry in the Middle East. The Greeks carried on an active wine trade and planted grapes in their colonies from the Black Sea to Spain. The Romans carried grape growing into the valleys of the Rhine and Moselle (which became the great regions of Germany and Alsace), the Danube (in modern-day Romania, Yugoslavia, Hungary, and Austria), and the Rhône, Saône, Garonne, Loire, and Marne (which define the great French regions of Rhône, Burgundy, Bordeaux, Loire, and Champagne, respectively). The role of wine in the Christian mass helped maintain the industry after the fall of the Roman Empire, and monastic orders preserved and developed many of the highly regarded wine-producing areas in Europe.

Greek and Roman wine trade

Following the voyages of Columbus, grape culture and wine making were transported from the Old World to the New. Spanish missionaries took viticulture to Chile and Argentina in the mid-16th century and to lower California in the 18th. With the flood of European immigration in the 19th and early 20th centuries, modern industries, based on imported *V. vinifera* grapes, were developed. The prime wine-growing regions of South America were established in the foothills of the Andes Mountains. In California, the centre of viticulture shifted from the southern missions to the Central Valley and the northern counties of Sonoma, Napa, and Mendocino.

British settlers planted European vines in Australia and New Zealand in the early 19th century, and Dutch settlers took grapes from the Rhine region to South Africa as early as 1654.

The introduction of the eastern American root louse, phylloxera, seriously threatened wine industries around the world between 1870 and 1900, destroying vineyards almost everywhere that *V. vinifera* was planted but especially in Europe and parts of Australia and California. To combat this parasite, *V. vinifera* scions (detached shoots including buds) were grafted to species native to the eastern United States, which proved almost completely resistant to phylloxera. After the vineyards recovered, European governments protected the reputations of the great regions by enacting laws that allotted regional names and quality rankings only to those wines produced in specific regions under strictly regulated procedures. Today, newer wine-producing countries have passed similar regulations.

Enology: scientific winemaking. Prior to the 19th century little was known about the process of fermentation or the causes of spoilage. The Greeks stored wine in earthenware amphorae, and the Romans somewhat extended the life of their wines with improved oaken cooperage, but both civilizations probably drank almost all of their wines within a year of vintage and disguised spoilage by adding such flavourers as honey, herbs, cheese, and salt water. Wooden barrels remained the principal aging vessels until the 17th century, when mass production of glass bottles and the invention of the cork stopper allowed wines to be aged for years in bottles.

Early storage

In the mid-19th century the French chemist Louis Pasteur and others explained the nature of fermentation and identified the yeasts responsible for it. Pasteur also identified the bacteria that spoil wine and devised a heating method (later called pasteurization) to kill the bacteria. Later in the century, methods were developed for growing pure strains of specific yeasts in culture. Advances in plant physiology and plant pathology also led to better vine training and less mildew damage to grapes.

Mechanized innovations in the 20th century have mainly contributed to quality control. Stainless steel fermentation and storage tanks are easily cleaned and can be refrigerated to precise temperatures. Automated, enclosed racking and filtration systems reduce contact with bacteria in the air. Beginning in the 1960s, the use of mechanical grape harvesters and field crushers allowed quick harvesting and immediate transfer to fermentation tanks.

THE WINE GRAPE

The thousands of grape varieties that have been developed, with 5,000 reported for *V. vinifera* alone, differ from one another in such characteristics as colour, size, and shape of berry; juice composition (including flavour); ripening time; and disease resistance. They are grown under widely varying climatic conditions, and many different processes are applied in producing wines from them. All of these possible variations contribute to the vast variety of wines available.

Species and varieties. *Vitis vinifera,* probably originating in the Caucasus Mountains, is the principal wine-producing plant, with most of the world's wine still made from varieties of this species. *V. labrusca* and *V. rotundifolia* have been domesticated in the eastern United States, the domestication of *V. amurensis* has been reported in Japan, and various interspecies hybrids have been used for wine production. The high sugar content of most *V. vinifera* varieties at maturity is the major factor in the selection of these varieties for use in much of the world's wine production. Their natural sugar content, providing necessary material for fermentation, is sufficient to produce a wine with alcohol content of 10 percent or higher; wines containing less alcohol are unstable because of their sensitivity to bacterial spoilage. The moderate acidity of ripe grapes of the *V. vinifera* varieties is also favourable to wine making; the fruit has an acidity of less than 1 percent (calculated as tartaric acid, the main acid in grapes) and a

Qualities of *Vitis vinifera*

pH of 3.1 to 3.7 (mildly acid). Malic acid is also an important acid; only small amounts of citric acid are present.

A third factor attracting wine makers to this grape is its tremendous range in composition. The pigment pattern of the skin varies from light greenish yellow to russet, to pink, red, reddish violet, or blue-black; the juice is generally colourless, although some varieties have a pink to red colour, and the flavour varies from quite neutral to strongly aromatic (Gewürztraminer, Cabernet Sauvignon, Zinfandel). Some varieties, such as Pinot Noir, having rather neutral flavoured juice, develop a characteristic flavour when fermented on the skins and aged.

The species *V. labrusca* and *V. rotundifolia* seldom contain sufficient natural sugar to produce a wine with alcohol content of 10 percent or higher, and additional sugar is usually required. Their acidity at maturity is often excessive, with a low pH. Varieties of these species usually have distinctive flavours. The flavours of *V. labrusca,* owing to methyl anthranilate and other compounds, are considered too pronounced by some consumers. This flavour, especially prevalent in wines made from the Concord-type varieties, is commonly called "foxy."

Cultivation. Grapes, although primarily a temperate-zone plant, can be grown under semitropical conditions. They are not adapted to the cooler parts of the temperate zone, where growing seasons may be too short to allow the fruit to reach maturity or where low winter temperatures (less than −7° C [20° F]) may kill the vine or its fruitful buds. *V. vinifera* is more susceptible to damage from winter conditions than is *V. labrusca.*

Climate strongly influences the composition of mature grapes. A major cause of the variation among grapes from different areas is the differing quantities of heat received by the vines during the growing season. Other important factors include differences in night and day temperature, hours of sun, and soil temperature.

Grapes begin their growth cycle in the spring when average daily temperature is about 10° C (50° F). To reach maturity, they require a certain amount of heat above 10° C during the growing season. This amount of heat, called the heat summation, is calculated by totaling the number of degrees of average daily temperature over 10° C for each day of the growing season. A heat summation of about 1,800° is required for successful growth. If the heat summation is less than required, the grapes will not ripen; they will reach the end of the growing season with insufficient sugar and too much acidity. This condition, frequently occurring in the eastern United States, Switzerland, and other cool regions, can be corrected by adding sugar to the crushed grapes. Where the heat summation is much greater than required, as in Algeria and parts of California, the grapes mature earlier and with less acidity and colour than those produced under cooler conditions.

The heat summation

Factors influencing the heat summation of a vineyard and, therefore, grape composition include: exposure (in Europe, best from the east); air drainage (preferably from the slopes to the valley); soil temperature (above 10° C during the growing season); and soil moisture content (not too dry at any time and not waterlogged for more than short periods).

Seasonal conditions also can be critical, especially in regions of low heat summation, as found in parts of France and Germany. When the growing season in such areas is warmer than usual, the fruit produced is riper and better balanced than is usual in cool seasons. In warm regions the sweeter dessert wines may benefit from somewhat low heat summation, resulting in less berry raisining (moisture loss) and giving the fruit better colour and acidity than is achieved when the growing season is excessively warm.

Such cultivation practices as weeding and pruning also may influence the mature fruit composition. Although the composition of the soil has an influence on soil temperature, root penetration, water-holding capacity, and vine nutrition, its effect on the quality of wine, varying from region to region, is poorly understood.

WINE REGIONS AND VARIETIES

Almost all wines are labeled by the region of production, maturity of the fruit, variety of grape or type of wine, and year of production, and they can be further distinguished by such characteristics as colour, sweetness, and varietal aroma. Specific characteristics are traditionally associated with certain wines, and in many cases these traditions are guaranteed by law.

Discussed below are the wines and viticultural laws of France, Italy, West Germany, the United States, Australia, and South Africa. Many other countries produce enormous quantities of table wines. In Europe there are Spain, Portugal, Switzerland, Hungary, Yugoslavia, Romania, Bulgaria, Greece, and the Soviet Union. In North Africa and the Middle East there are Algeria, Tunisia, and Israel. In South America there are Brazil, Peru, Chile, and Argentina. In Asia Japan is the largest producer.

Europe. In Europe wines are primarily distinguished by the region where they are produced.

France. Most French wines are everyday *vins ordinaires,* of no outstanding regional, varietal, or vintage characteristics. The finest wines are entitled to the *appellation d'origine contrôlée* (AOC; "controlled name of origin"), which is based on a hierarchy of specific geographic areas known to produce the best wines. The largest area in the hierarchy is the region; allowing for some variation, within the regions are districts, within the districts are communes, and within the communes are vineyards, or châteaus. To receive any of these successively more rigorous *appellations,* wines must be produced within specific areas and must meet standards of grape variety, alcoholic content, quantity of harvest, and techniques of vine growing and wine making. Of the smaller areas, some châteaus and communes receive rankings of quality such as *villages, supérieure,* and *grand cru* ("great vintage").

The French *appellation d'origine contrôlée*

The greatest regions of France are Bordeaux, Burgundy, Rhône, Loire, Champagne, and Alsace. Following the AOC hierarchy, Bordeaux contains such districts as Médoc, which contains the commune Pauillac, which in turn contains three *grand cru* châteaus. Bordeaux wines are mainly red and dry (except for those of the district of Sauternes, which are white and sweet). Primary varieties for the red wines are Cabernet Sauvignon, Cabernet Franc, and Merlot; for the white, Sauvignon Blanc and Sémillon.

Burgundy is smaller than the Bordeaux region. It comprises the districts of Chablis (dry white wines), Côte d'Or (red and white), Beaujolais (red), and Mâcon (white and red). The white wines are made from Chardonnay or Aligoté, the reds from Pinot Noir or (in Beaujolais) Gamay.

The Rhône region produces mostly strong, full-bodied red wines from the Syrah grape. The Loire is known for its white wines, the district of Pouilly-Fumé using Sauvignon Blanc grapes and Vouvray using Chenin Blanc. In the Champagne, legal definitions extend to the bottle-fermentation process by which the sparkling wine is produced; Pinot Noir and Chardonnay are the principal varieties. Alsace differs from other French regions by defining its mostly dry white wines primarily by grape variety, producing Alsatian Riesling, Gewürztraminer, Pinot Gris, and Sylvaner.

Wines receiving the classification *vins délimités de qualité supérieure* (VDQS; "delimited wines of superior quality"), must meet standards of region, variety, alcohol content, and sensory quality that result in good quality but are less severe than those of the AOC.

Italy. Known for its huge output of everyday red *vini da tavola* ("table wines"), Italy labels its best traditional wines as *denominazione di origine controllata* (DOC) or *denominazione di origine controllata e garantita* (DOCG). These wines must be produced in specific regions and must adhere to standards similar to the French AOC. Labels may indicate the grape variety—as in Barbera d'Alba, a red wine of the Barbera grape grown in the district of Alba in the Piedmont region.

Piedmont produces red Barolo and Barbaresco and the white, sparkling Asti Spumante. Vermouth, the flavoured dessert wine of Italy, originated in Turin, the principal Piedmontese city. From the district of Verona in the Veneto region come the red wines of Valpolicella and Bardolino and the whites of Soave. Tuscany is famous for the red wines of the various Chianti zones. Dry white Frascati wines come from the Latium region near Rome, while

Marsala, the fortified wine sweetened with concentrated grape juice, comes from Sicily.

Germany. The prime viticultural areas of West Germany fall into 11 regions, which are divided into districts, villages, and vineyards. A wine of better quality than the everyday *Tafelwein* and *Landwein* may receive the classification *Qualitätswein bestimmter Anbaugebiete* (QbA; "quality wine from a designated region") if it is produced in a specific region and meets standards of taste and alcohol content. Sugar may be added in the production of QbA wines to make up for Germany's short, cool growing season. Wines of the highest category, *Qualitätswein mit Prädikat* (QmP; "quality wine with special attributes"), must come from specific districts and be fermented from their natural sugar. The various *Prädikate* reflect the ripeness of the grape and, therefore, the sweetness of the wine. In order of increasing sugar content, they are: *Kabinett* (ripe harvest); *Spätlese* (late harvest); *Auslese* (selected late harvest); *Beerenauslese* (selected overripe); and *Trockenbeerenauslese* (from berries dried on the vine).

German *Qualitätswein*

About 90 percent of German wines are white. Riesling, Sylvaner, Müller-Thurgau, and Gewürztraminer grapes create the soft, fragrant, low-alcohol wines for which the country is famous.

Regions outside Europe. The newer wine-producing countries, lacking the centuries-old viticultural regions of Europe, emphasize the grape variety in their production of fine wines. Beginning in the 1960s, some of these countries enacted regulations guaranteeing the authenticity of these wines.

United States. Much American wine is mass-produced generic wine, often given such European-derived names as chablis, burgundy, and port. These brands must include an appellation of origin, such as California chablis, on the label.

American labeling laws

Varietal wines may be labeled after a *V. vinifera* grape if the designated variety makes up at least 75 percent of the product. It must then claim an appellation of origin. If the appellation is a county, state, or even the country, then no less than 75 percent of the wine's grapes must come from that area. If the appellation is one of the growing number of approved viticultural areas, then that area must account for 85 percent or more of the grapes. Wines may bear a vintage date if at least 95 percent of their grapes are harvested in that year.

California produces about 90 percent of American wines. The Napa Valley, Sonoma County, and other cooler areas of the north coast region produce the best wines. Cabernet Sauvignon and Chardonnay are the most prestigious, followed by Sauvignon Blanc and Pinot Noir. The Zinfandel, grown almost exclusively in California, produces a wine equal to those of the classic European grapes. California wines tend to be of higher alcoholic content and more pronounced varietal aroma and flavour than their European counterparts.

Australia. The main regions are found in an arc rimming the cooler southern states of New South Wales, Victoria, and South Australia. The Shiraz grape produces fine red wines, as does the Cabernet Sauvignon. Prominent white wines are Sémillon and Chardonnay. Sweet dessert wines are produced from Muscat and other grapes.

South Africa. Under the Wines of Origin laws, 75 percent of a varietal wine must come from the designated variety. The wine may claim one of many designated regions of origin only if all of the grapes come from that region (80 percent for fortified wines).

Long famous for sherry-type wines made from the Chenin Blanc (also called the Steen), South Africa also produces wines from several other noble varieties in areas along the cooler southwestern Cape.

THE WINE-MAKING PROCESS

Harvesting. Fresh and fully ripened wine grapes are preferred as raw material for wine making. In cool climates, as in northern Europe and the eastern United States, however, lack of sufficient heat to produce ripening may necessitate harvesting the grapes before they reach full maturity. The resulting sugar deficiency may be corrected by direct addition of sugar or by the addition of a grape juice concentrate. Grapes allowed to reach full maturity on the vine, or partially dried by exposure to sun after harvesting, are high in sugar content as a result of natural moisture loss (partial raisining as in the production of Málaga wines in Spain). A beneficent mold, *Botrytis cinera,* may also be employed to hasten moisture loss (as in the production of Sauternes in France). These grapes are used to produce sweet table wines. Special methods employed to produce these wines include the addition of sulfur dioxide, the use of small fermenting vessels during processing, or the use of cool temperatures—the objective being to stop the fermentation before all the sugar is fermented.

Because of the effect upon grape composition, proper timing of the harvest is of great importance. Premature harvesting results in thin, low-alcohol wines; very late harvesting may yield high-alcohol, low-acid wines.

Harvesting may be completed in one picking or in several. The grape cluster is cut from the vine with a special knife, or shears may be used for their convenience in removing rotten berries. The clusters, placed in buckets or boxes, are transferred to larger containers (large tubs in Europe, metal gondola trucks in California and elsewhere) for transportation to the winery. Mechanical harvesting systems, based on shaking the berries from the clusters or on breaking the stems, are widely used in California, Australia, France, and elsewhere.

Mechanical harvesting

At the winery the grapes may be dumped directly into the crusher or may be unloaded into a sump and carried to the crusher by a continuous conveyor system.

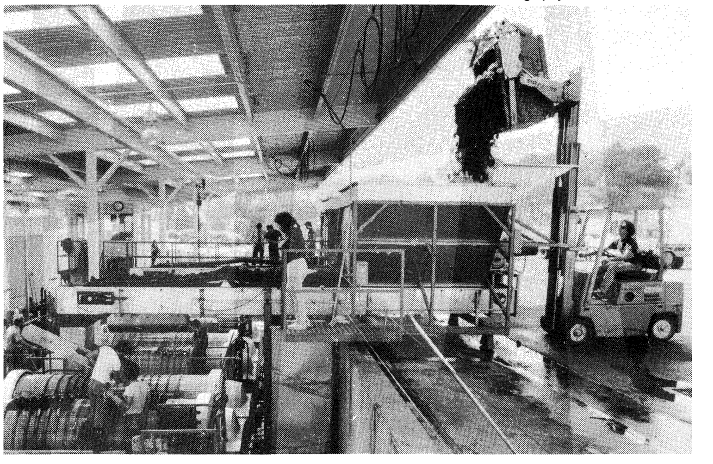
Crushing. In modern mechanized wine production, the grapes are normally crushed and stemmed at the same time by a crusher-stemmer, usually consisting of a perforated cylinder containing paddles revolving at 600 to 1,200 revolutions per minute. The grape berries are crushed and fall through the cylinder perforations; most of the stems pass out of the end of the cylinder. A roller-crusher may also be used. Ancient methods of crushing with the feet or treading with shoes are rare.

When red grapes are used to produce a white juice, as in the Champagne region of France, crushing is accomplished by pressing.

Red grapes are sometimes introduced whole into tanks, which are then closed. The resulting respiration in the fruit, consuming oxygen and producing carbon dioxide, kills the skin cells, which lose their semipermeability, allowing easy colour extraction. There is also some intracellular respiration of malic acid. This respiration process is slow and in warm regions may result in wines of low colour and acidity and distinctive odour.

Juice separation. When the juice of white grapes is processed or a white wine is desired, the juice is usually separated from the skins and seeds immediately after crushing. Occasionally, to increase flavour extraction, the white skins may be allowed to remain in contact with the juice for 12 to 24 hours, but this procedure also increases colour extraction, sometimes undesirably.

Alan Pitcairn/Grant Heilman Photography



Pouring Pinot Noir grapes into the press for the production of sparkling wine, Napa Valley, Calif.

Two main procedures are employed to separate the juice from the solids. Much of the juice may be drained off by placing the crushed grapes in a container having a false bottom and often false sides. This juice is called the free run juice, and the mass of crushed grapes is called the must, a term also used to refer to the unfermented grape juice, with or without skins.

Pressing the grapes

More commonly, the crushed grapes are placed in a press. The traditional basket press is gradually being supplanted by a horizontal basket press, applying pressure from both ends. Continuous screw-type presses are also employed, especially for drained pulp. The Willmes press, widely employed for white musts, consists of a perforated cylinder containing an inflatable tube. The crushed grapes are introduced into the cylinder, and the tube is inflated, pressing the grapes against the rotating cylinder sides and forcing the juice out through the perforations. Several pressings may be made without the extensive hand labour required for basket presses.

Continuous presses are practical for production of red wines, in which skins, seeds, and juice are all fermented together. Separation of the juice is simplified because fermentation makes the skins less slippery, and the amount of free run juice obtained is, therefore, much greater than for unfermented musts. Separation of the less slippery solids from the juice by pressing is also simplified.

The drained pomace (crushed mass remaining after extraction of the juice from the grapes), from white or red fermentations, may be used to provide distilling material for production of wine spirits. Water is usually added, the fermentation is completed, and the low-alcohol wine is drained off. The pomace may be further washed and pressed or may be distilled directly in special stills.

Must treatment. White musts are often turbid and cloudy, and settling is desirable to allow separation of the suspended materials. Such measures as prior addition of sulfur dioxide and lowering of the temperature during settling help prevent fermentation and allow the suspended material to settle normally. In many areas wineries centrifuge the white must to remove the solids. In this process a strong pulling force is created by circular motion. Musts are sometimes pasteurized, inactivating undesirable enzymes that cause browning. The addition of pectin-splitting enzymes to the musts to facilitate pressing is uncommon. Bentonite, a type of clay, may be added to musts to reduce total nitrogen content and facilitate clarification.

There is renewed interest in the prefermentation heat treatment of red musts to extract colour and deactivate enzymes. This process, when performed rapidly at moderate temperatures and without undue oxidation, may be particularly desirable in the production of red sweet wines, which employs short periods of fermentation on the skins, and for use with red grapes that have been attacked by the parasitic fungus *Botrytis cinera,* which contains high amounts of the polyphenol oxidase type of enzymes that cause browning.

Fermentation. The process of alcoholic fermentation requires careful control for the production of high quality wines. Requirements include suppression of the growth of undesirable microorganisms, presence of adequate numbers of desirable yeasts, proper nutrition for yeast growth, temperature control for prevention of excessive heat, prevention of oxidation, and proper management of the cap of skins floating in red musts.

Grape skins are normally covered with bacteria, molds, and yeast. The wild yeasts such as *Pichia, Kloeckera,* and *Torulopsis* are often more numerous than the wine yeast *Saccharomyces.* Although species of *Saccharomyces* are generally considered more desirable for efficient alcoholic fermentation, it is possible that other yeast genera may contribute to flavour, especially in the early stages of fermentation. *Saccharomyces* is preferred because of its efficiency in converting sugar to alcohol and because it is less sensitive to the inhibiting effect of alcohol. Under favourable conditions, strains of *Saccharomyces cerevisiae* have produced up to 18 percent (by volume) of alcohol, although 15 to 16 percent is the usual limit.

Wine yeast

Use of the yeast *Schizosaccharomyces pombe* has been proposed for the early stages of alcoholic fermentation. Because it metabolizes malic acid, this yeast would be useful in excessively acid musts, but commercial applications have not yielded consistently favourable results. The addition of lactic-acid bacteria to musts, using strains metabolizing malic acid, is now common.

The number of undesirable microorganisms is greatest in partially rotted or injured grapes. Such damage may occur in harvesting or during transportation, particularly in warm climates. Suppression of undesirable microorganism growth is required, and the most common method used is the addition of sulfur dioxide to the freshly crushed grapes at the rate of about 100 to 150 milligrams per litre. Sulfur dioxide is more toxic to undesirable microorganisms than to desirable microorganisms. When it is used in musts, an inoculum of the desired yeast strain, usually called a pure yeast culture, is added. Musts are rarely pasteurized, although this process may be applied when they contain undesirable amounts of oxidizing enzymes from moldy grapes.

Enologists, technicians in the science of wine making, do not agree on the most desirable yeast species and strain, but strains of *S. cerevisiae* are generally used. The chosen strain is allowed to multiply as much as possible in sterilized grape juice and is then transferred to larger containers of sterilized grape juice, where it continues to grow until the desired volume is reached. Suitable pressed yeasts of desirable strains are added directly, avoiding the troublesome practice of building up and maintaining a pure yeast culture. About 1 to 3 percent of a pure yeast culture, or sufficient pressed yeast to provide a population of 1,000,000 cells per millilitre, is used.

Temperature control during alcoholic fermentation is necessary to (1) facilitate yeast growth, (2) extract flavours and colours from the skins, (3) permit accumulation of desirable by-products, and (4) prevent undue rise in temperature, killing the yeast cells.

Optimum temperature for growth of common wine yeasts is about 25° C (77° F), and in many viticultural areas of the cooler temperate zone, grapes are crushed at about this temperature. Fermentation is seldom started at so high a temperature, however, because it is then difficult to prevent the temperature from exceeding 30° C during fermentation.

Extraction of flavours and colours is not a problem in white musts; the crushed grape mass is usually separated from the skins before fermentation. Fermentation of white musts at relatively cool temperature (about 10° to 15° C [50° to 60° F]) apparently results in greater formation and retention of desirable by-products. An undesirable feature of such relatively low-temperature fermentations is the longer period required for completion (six to 10 weeks compared to one to four weeks at higher temperatures) and the tendency for the fermentation to stop while residual sugar remains. (This is not always considered undesirable—*i.e.,* in German wine production.) In practice white table wines are usually fermented at about 20° C.

Optimum temperatures for fermentation

In red wine musts, the optimum colour extraction consistent with yeast growth occurs at about 22° to 28° C (72° to 82° F). Alcoholic fermentation produces heat, however, and careful temperature control is required to prevent the temperature from reaching a point (about 30° C) where yeast growth is seriously restricted. At still higher temperatures, growth will stop completely. Modern temperature control is accomplished by use of heat exchangers. Older methods include placing the fermenters in a cold room; using cold pipes in the fermenter; pumping the must through double-walled pipes, with cold water in the surrounding pipe; pumping the must through a sump containing cooling coils; and pumping the coolant through jackets surrounding the tank.

Contact with air must be restricted to prevent oxidation during fermentation. In very large containers, the volume of carbon dioxide given off is sufficient to prevent entry of air. In small fermenters, fermentation traps are inserted, preventing entry of air but permitting exit of carbon dioxide. These traps are particularly desirable during the final stage of fermentation, when carbon dioxide evolution is slow. Following fermentation, small amounts of sulfur

dioxide are added to help prevent oxidation. Ascorbic acid (50 to 100 milligrams per litre) is sometimes employed to decrease the oxidation and thus the amount of sulfur dioxide required as an antioxidant, but is not generally recommended.

The cap of skins and pulp floating on top of the juice in red-wine fermentation inhibits flavour and colour extraction, may rise to an undesirably high temperature, and may acetify if allowed to become dry. Such problems are avoided by submerging the floating cap at least twice daily during fermentation. This operation, comparatively easy with small fermenters, becomes difficult with large, tall fermenters of up to 100,000-gallon (380,000-litre) capacity. In large units the fermenting must is drawn off near the bottom and pumped back over the cap. The use of small fermentation vessels permits a greater percentage of heat loss to the surrounding atmosphere, simplifying temperature control.

Postfermentation treatment. With appropriate must composition, yeast strain, temperature, and other factors, alcoholic fermentation ceases when the amount of fermentable sugar available becomes very low (about 0.1 percent). Fermentation will not reach this stage when (1) musts of very high sugar content are fermented, (2) alcohol-intolerant strains of yeast are used, (3) fermentations are carried on at too low or high temperatures, and (4) fermentation under pressure is practiced. Fermentation of normal musts is usually completed in 10 to 30 days. In most cases, the major portion of the yeast cells will soon be found in the sediment, or lees. Separation of the supernatant wine from the lees is called racking. The containers are kept full from this time on by "topping," a process performed frequently, as the temperature of the wine, and hence its volume, decreases. During the early stages, topping is necessary every week or two. Later, monthly or bimonthly fillings are adequate.

Racking

Normally the first racking should be performed within one to two weeks after completion of fermentation, particularly in warm climatic regions or in warm cellars, as the yeasts in the thick deposit of lees may autolyze (digest themselves), forming off-odours.

Early racking is not required for wines of high total acidity—*i.e.,* those produced in cool climatic regions or from high-acid varieties. Such wines may remain in contact with at least a portion of the lees for as long as two to four months, permitting some yeast autolysis in order to release amino acids and other possible growth factors favouring growth of lactic-acid bacteria. These bacteria then induce the second, or malolactic, fermentation.

Malolactic fermentation. Enologists have known for some time that young wines frequently have a secondary evolution of carbon dioxide, occurring sometime after the completion of alcoholic fermentation. This results from malolactic fermentation, in which malic acid is broken down into lactic acid and carbon dioxide. The fermentation is caused by enzymes produced by certain lactic-acid bacteria.

Flavour by-products of unknown composition are also produced during this fermentation. Malolactic fermentation is desirable when new wines are too high in malic acid, as in Germany, or when particular nuances of taste and flavour are desired, as in the red wines of Burgundy and Bordeaux in France. In other regions, some producers may encourage malolactic fermentation, and others may discourage it, depending upon the particular character desired in the wine. In all regions, this second fermentation is somewhat capricious. One product, diacetyl (a flavour and aroma agent), is apparently beneficial at low levels and undesirable at higher levels.

At low temperatures, malolactic fermentation proceeds slowly, if at all. German cellars are often equipped with steam pipes, raising the temperature to encourage this fermentation. The bacteria may fail to grow because of a deficiency or complete absence of essential amino acids. Most lactic-acid bacteria growth can be inhibited by the presence of 70 to 100 milligrams per litre of sulfur dioxide.

Excessive malolactic fermentation may produce wines too low in acidity (flat tasting) or with undesirable odours (mousy, sauerkraut, or diacetyl). Such faults may be prevented by earlier racking, filtration, and addition of sulfur dioxide.

Clarification. Some wines deposit their suspended material (yeast cells, particles of skins, etc.) very quickly, and the supernatant wine remains nearly brilliant. This is particularly true when 50-gallon wooden barrels, which have greater surface-to-volume ratio than larger containers, are employed. The rough interior of wooden cooperage facilitates deposition of suspended material. Other wines, particularly in warm regions or when large tanks are used, may remain somewhat cloudy for long periods. Removal of the suspended material during aging is called clarification. The major procedures involved are fining, filtration, centrifugation, refrigeration, ion exchange, and heating.

Removal of suspended material

Fining. Fining is an ancient practice in which a material that aids clarification is added to the wine. The main processes involved are adsorption, chemical reaction and adsorption, and possibly physical movement. Proteins and yeast cells are adsorbed on fining agents such as bentonite (a type of clay formed mainly of montmorillonite) or gelatin. Chemical reactions occurring with tannins and gelatin may be followed by adsorption of suspended compounds. If an inert material, such as silica, is added to a cloudy wine, some clarification will occur simply by the movement of the particles of inert silica through the wine. This action probably occurs to a certain extent with the addition of any fining agent.

Bentonite has largely replaced all other fining agents. Such fining agents as gelatin, casein, isinglass, albumin, egg white, nylon, and PVPP (polyvinyl pyrrolidone) may be used for special purposes, including removal of excess tannin or colour.

Excessive amounts of metals, particularly iron and copper, may be present in the wine, usually from contact with iron or metal surfaces. These result in persistent cloudiness and require removal by such special fining materials as potassium ferrocyanide (blue fining), long recommended in Germany. Cufex, a proprietary product containing potassium ferrocyanide, may be used in the United States under strict control. Phytates have been used for removing iron. In modern winery operations excessive metal content is rare, mainly owing to the use of stainless steel equipment.

Filtration. Filtration is another ancient practice, and early filters consisted of rough cloth-covered screens through which the wine was poured. Modern filter pads are made of cellulose fibres of various porosities or consist of membrane filters, also in a range of porosities. The pore size of some filters is sufficiently small to remove yeast cells and most bacterial cells, but filters operate not only because of pore size but also by a certain amount of adsorption. Diatomaceous earth-filter aids, commonly added to the wine during filtration, increase the functional life of a filter by retarding pore clogging.

Centrifugation. Centrifugation, or high-speed spinning, used to clarify musts, is also applied to wines that are difficult to clarify by other means. This operation requires careful control to avoid undue oxidation and loss of alcohol during the process.

Refrigeration. Refrigeration aids wine clarification in several ways. Temperature reduction often prevents both yeast growth and the evolution of carbon dioxide, which tends to keep the yeast cells suspended. Carbon dioxide is more soluble at lower temperatures. A major cause of cloudiness is the slow precipitation of potassium acid tartrate (cream of tartar) as the wine ages. Rapid precipitation is induced by lowering the temperature to −7° to −5° C (19° to 23° F) for one or two weeks. If the resulting wine is filtered off the tartrate deposit, tartrate precipitation will not usually cause clouding later.

Ion exchange. Another method of tartrate stabilization is to pass a portion of wine through a device called an ion exchanger. If this ion exchanger is charged with sodium, it will replace the potassium in potassium acid tartrate with sodium, making a more soluble tartrate. Usually, if the potassium content of the blend of either treated or untreated wine is reduced to about 500 milligrams per litre, no further precipitation will occur. Exceptions may occur, however, and to be safe, tartrate and potassium contents

Comstock

and pH are included in the calculation. The use of ion exchange is illegal in several countries.

Heating. Many wines contain small amounts of proteins that may cause clouding either by precipitation or by reacting with copper or other metals to form aggregates that in turn form clouds. The use of bentonite removes some protein, and protein adsorption is increased if the wine is warm when fined. Pasteurization at 70° to 82° C (158° to 180° F) also can be used to precipitate proteins, but in modern practice this process is seldom employed to aid clarification.

AGING AND BOTTLING

Aging. Many wines improve in quality during barrel and bottle storage. Such wines eventually reach their peak and with further aging begin to decline. During the aging period, acidity decreases, additional clarification and stabilization occur as undesirable substances are precipitated, and the various components of the wine form complex compounds affecting flavour and aroma.

Wines are usually aged in wooden containers made of oak, allowing oxygen to enter and water and alcohol to escape. Extracts from the wood contribute to flavour. Humidity affects the kind of constituents that escape, with alcohol becoming more concentrated in wine stored under conditions of low humidity and weakening with high humidity. As the water and alcohol are released, volume decreases, leaving headspace, or ullage, that is made up by the addition of more of the same wine from another container.

Aging in wood

Some red table wines appreciate in quality, developing less astringency and colour, and a greater complexity of flavour with aging in oak cooperage of up to 500-gallon size for two to three years. In the best red wines, additional improvement may continue with two to 20 years of bottle aging (the rate of aging being lower in the bottle than in the barrel). Many dessert wines improve during cask aging, particularly sweet sherries, but extraction of excessive wood flavour must be avoided. Those rosé and dry red wines that will not improve with long cask and bottle aging are aged for a short period of time, clarified, and then bottled. More than 90 percent of all table wines are probably marketed and consumed before they are two years old. In dry white wines, a fresher flavour is considered desirable, and the chief benefit of aging is greater clarification as various undesirable substances are precipitated. These wines are rarely aged in the wood for long periods, and some are never kept in wood. This change is possible because of the efficiency of new clarification methods. Earlier bottling of white wines reduces costs for storage and for handling in wooden cooperage and produces fresher, fruitier flavour. Sweet white table wines profit by some aging in wood.

Bottling. Before bottling, wine may require blending, filtration, and use of antiseptics to combat microbe development. Often several casks containing the same wine will develop differences during aging, and blending is desirable to ensure uniformity. Wines that are slightly deficient in colour or acid may be blended with special wines as a means of correction. Blending frequently improves quality by adding to the complexity of the wine.

A final polishing filtration is required before bottling, and the amount of sulfur dioxide is adjusted, especially in sweet table wines. Sulfur dioxide is frequently used, but sorbic acid or sorbates are used in sweet table wines to inhibit yeasts, although they are not generally recommended because of the off-odour that may develop. Such operations as the addition of sulfur dioxide, heating (wherever beneficial), and polishing filtration are usually accomplished by a continuous in-line process. Equipment, usually semiautomatic or completely automatic, must be free of undesirable microorganisms and is made of resistant alloys to avoid undesirable metal pickup.

During the actual bottling operation, oxygen pickup must be kept to a minimum. Bottomfilling—that is, inserting a tube into the bottle and filling from the bottom—is often used. In some cases, the bottle may be flushed with carbon dioxide before filling, or the wine may be sparged (agitated) with nitrogen gas. Wines subject to oxidation require special care.

Sterile new bottles are used in the United States. Elsewhere, bottles may be reused after thorough cleaning and sterilization. The bottle shape and colour are dictated by custom and cost. Some white wines, subject to change when exposed to light, are preferably bottled in brown, brownish green, or greenish blue coloured bottles. Although brown glass is probably preferable for Sauternes, custom dictates the use of clear bottles. Glass is still the usual material, although experiments have been made with plastics.

Bottle shape and colour

After bottling, the closure is made. Screw caps are used for standard wines. Cork closures are preferred for wines that will be aged in the bottle. Red wines that may be aged in the bottle for many years are closed with corks two inches (five centimetres) long or longer. Occasionally a cork may communicate an off-odour, called "corked," to the wine, apparently resulting from a contaminant or from a defect that allows mold growth in or on the cork.

A capsule is placed over the closure, the label is applied, and the bottles are packaged in cases for shipment. Wines requiring bottle aging are often not capsuled, labeled, or cased until they have been aged.

Bottled table and dessert wines should be stored on their sides during aging, both at the winery and by the final customer pending consumption. Appropriate storage conditions include absence of light and low, even temperatures maintained at about 12° to 16° C (54° to 61° F). Diurnal fluctuations in temperature lead to rapid aging and early deterioration.

SPECIAL WINES

The procedures discussed above are primarily concerned with the production of still (non-sparkling) table wines. Sparkling, dessert, and flavoured wines require special techniques.

Sparkling wines. Wines containing excess carbon dioxide are called sparkling wines. They are always table wines, usually containing less than 4 percent sugar. The two basic techniques used for their production are a second sugar fermentation, often induced artificially, or direct carbonation, involving the addition of carbon dioxide.

Sparkling wine results when the escape of carbon dioxide from the fermenting liquid is prevented. The basic material is usually a dry white, rosé, or red table wine. Sufficient sugar is added to the basic wine to produce a pressure of about five or six atmospheres (units of pressure, each equal to 14.7 pounds per square inch) following fermentation, assuming there is no loss of carbon dioxide. The size of the fermentation container may vary from 0.1 to 25,000

gallons. Bottles or tanks used for this type of fermentation must be capable of withstanding pressures as high as 10 atmospheres. Use of tanks equipped with pressure gauges allows excess pressure to be let off as needed. The special bottles used for sparkling wines are thicker than normal in order to withstand pressure of seven to nine atmospheres. The neck of the bottle is shaped either for seating a crown cap or with a lip that catches a steel clamp to hold the cork in place.

Special bottles for sparkling wines

The basic wine is clarified before being placed in the fermentation container. Several wines are usually blended to secure a base wine of the proper composition and flavour balance. The original alcohol content should be only 10–11.5 percent; the secondary fermentation will result in an increase of about 1 percent. The pH should be 3.3 or slightly less, with 0.7 percent or more total acidity calculated as tartaric acid, and the wine should have a fresh fruity flavour. No single or pronounced varietal character should predominate in the base wine, except in muscat-flavoured sparkling wines. Special care is necessary to avoid wines with any off character in odour or taste, or any trace of undesirable bacterial activity.

The final clarified wine is placed in the fermentation vessel, and the requisite sugar for the fermentation, about 2.5 percent, is added, along with 1 to 2 percent of an actively growing yeast culture. The strain of yeast selected should be able to ferment adequately in wines of 10 to 11.5 percent alcohol and under pressure. A number of strains have proved satisfactory. The yeast cells should settle (agglutinate) rapidly and completely after fermentation.

The secondary fermentation is carried out at 10° to 12° C (50° to 54° F) for best absorption of the carbon dioxide produced and should be completed in four to eight weeks. To save time, both tank and bottle fermentations are often conducted at temperatures of 15° to 17° C (59° to 63° F) or even higher, and the secondary fermentation is frequently completed in 10 days to two weeks.

Tank fermentation. Additional differences between tank- and bottle-fermented wines may develop after secondary fermentation. Upon completion of fermentation, tank-fermented wines are filtered to remove the yeast deposit and then bottled. The filtration operation can introduce air, sometimes leading to oxidative changes affecting colour and taste. In addition, it is difficult to accomplish the necessary filtration, removing any viable yeast cells, without reducing the level of the pressure that has been built up within the wine. Because of such difficulties, sulfur dioxide may be added to tank-fermented wines in order to prevent refermentation. While still in the tank, the wine is sweetened to the desired level by the addition of inert sugar syrup.

Bottle fermentation. Bottle-fermented wines may also be clarified soon after fermentation. In the transfer process, the bottle-fermented wine is transferred, under pressure, to a second tank, from which it is filtered and bottled. In this case, as with tank-fermented wines, little aging of the wine takes place in contact with the yeast, and sulfur dioxide may be added. The transfer process is widely used in the United States, Germany, and elsewhere.

Classic champagne method

In contrast, in classic bottle fermentation, or *méthode champenoise* ("champagne method"), the wine remains in the bottle, in contact with the yeast, for one to three years. During this period of aging under pressure, a series of complex reactions occurs, involving compounds from autolyzed yeast and from the wine, resulting in a special flavour. Bottle-aged wine is rarely transferred, filtered, or rebottled because the addition of sulfur dioxide, required to prevent oxidation, would interfere with the delicate odour so carefully developed by aging. Aged bottle-fermented wines therefore are usually clarified in the bottle. In this process the bottles are placed neck down in special racks at a 45° angle. Each day the bottle is turned to the right and left, inducing the yeast debris within to move down the side of the bottle onto the cork. This process, riddling or *remuage,* may last from a few weeks to several months. When it is complete, all of the yeast is on the cork, and the bottle is gradually brought to an inverted position of 180°. Mechanical *remuage* in large containers is widely practiced.

Remuage, the turning of champagne bottles to force yeast sediment into the bottle necks, France.
G. Lienhard

In the traditional procedure, the cork is slowly pulled out, and the pressure within the bottle propels the sediment out of the bottle. In the modern procedure, to prevent undue pressure loss, the bottle temperature is lowered to 10° to 15° C (50° to 59° F). The neck of the bottle is placed in a freezing solution and frozen solid. When the crown cap, or cork, is removed and the yeast deposit is ejected, the process is called disgorging, or *dégorgement.* The bottle is quickly turned to an upright position. When performed properly, disgorging (which is usually mechanized), involves the loss of only 3 to 5 percent of the wine. The bottle is held under pressure while it is refilled.

The filling solution is a small amount of sweetening dosage, usually white wine containing 50 percent sugar. The amount added depends on the degree of sweetness the producer desires. Wines labeled brut, or sometimes nature (a term also applied to a still champagne), are extremely dry (very low in sugar content), usually containing 0 to 1.5 percent sugar; wines labeled extra dry or extra sec, or dry or sec, are sweeter, often containing 2 to 4 percent sugar; semi-dry or demi-sec wines may contain 5 percent or more sugar; and sweet or doux wines have about 8 percent sugar. In commercial practice, there is considerable variation in the exact degree of sweetness described by a specific term. If the dosage does not bring the contents to the desired level, more wine of a previously disgorged bottle is added. The closure, made of cork or plastic, is held in place with a wire netting.

If the wine has been aged for two or three years, the sugar in the final dosage does not ferment, as that in the original dosage did, because few viable yeast cells remain. Even in wines aged for shorter periods, skillful disgorging leaves few viable yeast cells on the sides of the neck of the bottle. Furthermore, the wine lacks oxygen to stimulate yeast growth and is lower in growth-promoting nitrogenous constituents and higher in alcohol than the original wine. The high carbon dioxide content also has a repressive effect on yeast growth. When bottle-fermented wines are fermented very rapidly and disgorged early, however, it is customary to add some sulfur dioxide with the final dosage to repress yeast growth.

American labeling laws

In the United States, tank-fermented wines must be labeled "fermented in bulk" or "bulk-fermented." Bottle-fermented wines may be labeled "bottle-fermented," but only wines handled by the classic method may be labeled "fermented in this bottle."

Carbonation. Carbonation is a less involved process but is used infrequently. Carbonated wines have many characteristics of fermented sparkling wines, and this simple physical process is much less expensive. The action of the second fermentation under pressure may produce es-

pecially desirable flavour by-products, however, and there is greater prestige value attached to fermented sparkling wines. In some cases, the wines used as a base for the carbonated sparkling wines may be overmature or otherwise inferior to those used for the fermented sparkling wines.

The base wine used for carbonation, like the base wine for fermented sparkling wines, must be well balanced, with no single varietal flavour predominating. Young fruity wines are preferred, and the wine should not contain any trace of off-odour. Since no secondary fermentation takes place, wines of 11.5 to 12.5 percent alcohol content are used. The wine should be tartrate-stable, metal-stable, and brilliant, and the sulfur-dioxide content should be low. For white wines, the colour should be a light yellow.

A variety of techniques have been used for carbonation. Production of carbonation by passing the wine from one bottle to another, under carbon-dioxide pressure, is now seldom employed because of its slowness. Carbonation has been produced in bottles after deaeration, and this technique could be adapted to multibottle operations. Direct carbonation is frequently practiced with cold wine in pressure tanks, and if the stream of gas is finely divided, good carbonation is obtained. Pinpoint carbonation, spraying the wine into a pressure chamber containing carbon dioxide, may also be employed. Following the carbonation procedure, the wine is bottled under pressure. A cork or plastic or crown-cap closure is applied, the label is affixed, and the wine is cased for distribution.

In many countries, there is a higher tax on fermentation-produced sparkling wines than on carbonated sparkling wines. The two types also have different labeling requirements, and the process of carbonation usually must be stated on the label.

There are a few low-level carbon dioxide wines on the market, produced either by fermentation or by carbonation. In Germany and other areas, tank-fermented wines, or "pearl" wines, of about one atmosphere pressure, are produced. In the United States, Portugal, and Switzerland, a number of wines are lightly carbonated at the time of bottling, adding piquancy.

There are a few wines in which the carbon dioxide comes not from alcoholic fermentation, but from malolactic fermentation of excess malic acid in the wine. The *vinhos verdes* wines of northern Portugal are examples of this type. This fermentation is sometimes responsible for undesirable gassiness in red wines.

Fortified wines. The addition of alcohol during or after alcoholic fermentation produces fortified wines of over 14 percent alcohol, generally called dessert wines in the United States. In most countries, these wines are taxed at higher rates than those of 14 percent or lower alcohol.

Why wines are fortified

Fortification has two purposes: (1) to raise the alcohol content sufficiently (usually 17 to 21 percent) to prevent fermentation of all of the sugar and (2) to produce types with a special alcohol character. The alcohol used for fortification is usually (legally required in most countries) distilled from wine. The distillation of the fortifying spirits is made to a high percent alcohol, usually 95 to 96 percent. Industrial alcohol has also been employed in a few countries.

The repressive effect of alcohol on alcoholic fermentation increases rapidly as the alcohol content is raised above 14 percent, particularly in the presence of sugar. To secure prompt cessation of fermentation, the added alcohol must be rapidly and uniformly mixed with the fermenting must, and this is accomplished by stirring or mixing with compressed air.

In the most simple type of fortification, the initial fermentation is allowed to proceed nearly to, or all the way to, completion. The resulting wine is usually subjected to a baking process, as in Madeiras and California sherries, lasting for one to four months, at 58° to 65° C (136° to 149° F). If the wine is low in sugar content, heating will change the flavour and colour of the wine only slightly; with greater sugar content, a more caramelized flavour, typical of sweet Madeiras and sweet California sherries, is produced.

When white must is fortified during fermentation, the resulting wine is sweet, the degree of sweetness depending on the original sugar content of the must and the time of fortification. Some types, fortified early, produce very sweet wines. Muscatels, produced in many countries, are often of this type.

Red sweet wines, such as port, are more difficult to produce. Although the grapes must be fermented on the skins to extract colour, the fermentation cannot be continued for long if the requisite sugar is to remain in the finished wine. One method of securing sufficient colour is to use grape varieties containing large amounts of pigments in their skins. The skins and juice are sometimes heated to about 65° C (149° F) to extract colour.

The *flor* sherries, such as the dry or fino-type sherry produced in Spain, are a special type of dessert wine. The base wine is fortified to about 15 percent alcohol, and a special alcohol-tolerant film yeast develops as a film on the wine surface. Acetaldehyde, an aldehyde, is one of the flavour products produced by this procedure. Following this process, the alcohol content may be further raised to 16–18 percent. By adjusting the oxygen content, the *flor* yeast may be induced to develop and produce acetaldehyde in a submerged culture, a process used commercially in California.

Marsala, a type of dessert wine produced in Sicily, has a dark amber colour and burnt sugar flavour, derived from the addition of grape juice that has been cooked and reduced to about one-third its original volume.

Aged dessert wines

Dessert wines aged for only short periods lack the complex flavour of those dessert wines aged in small oak cooperage for at least two to four years. During aging, white wines gradually darken in colour, while red wines become less red and more amber. Flavour becomes more complex and mellow as wood flavour is extracted from the container, various substances in the wine become oxidized, and complex compounds of acids and alcohol are formed. If the wood containers are stored in warm, dry rooms, more water than alcohol is lost, and the alcohol content of the wine increases. This effect is common in dessert wines of the south of Spain. At lower storage temperatures and normal humidity, there is little change and sometimes even a slight decrease in alcohol content.

In the production of certain wines, special character is achieved by blending wines of different ages, a technique often used for port blends. By varying the proportion of the various wines, a range of types varying in colour and flavour may be produced. The blending may be performed continuously, as in the solera system common in Spain. This process involves a series of casks graduated according to the age of the wine each contains. One or more times each year, a portion of wine, usually 10 to 25 percent, is taken out of the oldest cask. This is replenished from the next oldest containers, and these in turn from younger containers. After a number of years, depending on the portion withdrawn each year and the number of years since the start, the average age of wine in the oldest container no longer changes. This process is called a fractional-blending system.

Flavoured wines. Vermouth, a flavoured wine product, probably originated in Turin in the 18th century as a sweet dessert wine with various Mediterranean and other herbs and plant materials added. A similar product, lower in sugar content, was produced in the south of France. Although sweet vermouth is often considered an Italian type and dry vermouth usually refers to the French type, both countries now produce both types. Various producers have their own formulas, and the herbs and spices used as flavourings include bitter orange peel, cinnamon, clove, coriander, mace, marjoram, nutmeg, saffron, and wormwood.

French and Italian aperitifs

Aperitif wines, usually taken before meals, are made by adding quinine and other ingredients to sweet, heavy wines. In France they are marketed under such brand names as Byrrh, Dubonnet, Lillet, and Saint Raphaël; in Italy they include Campari and Punt e Mes.

There are various flavoured wine beverages, frequently mixed by the consumer and sometimes bottled by a manufacturer, in which flavouring materials are added after the manufacture of the wine. May wine, of German origin, is a type of punch made with Rhine wine or other light,

dry, white wines, flavoured with the herb woodruff and served chilled and garnished with strawberries or other fruit. Sangria, a popular punch in many Spanish-speaking countries, is made with red or white wine mixed with sugar and plain or sparkling water, flavoured with citrus fruit, and served chilled. Mulled wine is usually made with red wine diluted with water, sweetened with sugar, flavoured with such spices as cloves and cinnamon, and served hot. Glogg, a hot punch of Swedish origin, is frequently made with red wine and contains spices, almonds, and raisins. Wine coolers, popular in the United States, are wines of low alcohol flavoured with fruit juices.

Fruit wines. Fruit wines, derived from fruits other than grapes, include cider, made from apples; perry, produced from pears; plum wine and cherry wine; and wines made from various berries. They are frequently made by home wine makers and have some commercial importance in cold climates where wine grapes are not produced. Cider and perry are important products in England and northern France; fortified cherry and black currant wines are produced in Denmark; and important U.S. fruit wines, mainly produced on the eastern coast, include apple, cherry, blackberry, elderberry, and loganberry wines. Various kinds of fruit wines are exported from The Netherlands, Denmark, Poland, Czechoslovakia, Yugoslavia, and Israel.

Fruit wines usually have sweet flavour and should retain much of the flavour and colour of the original fruit. The musts are high in acid content and require dilution with water and the addition of sugar before fermentation. Many commercial fruit wines contain about 12 percent alcohol. When they are fortified with brandy, derived from the same fruit, alcoholic content is about 20 percent. The alcoholic content of cider and perry is usually 2–8 percent.

(M.A.A.)

Distilled spirits

The production of distilled spirits is based upon fermentation, the natural process of decomposition of organic materials containing carbohydrates. It occurs in nature whenever the two necessary ingredients, carbohydrate and yeast, are available. Yeast is a vegetative microorganism that lives and multiplies in media containing carbohydrates—particularly simple sugars. It has been found throughout the world, including frozen areas and deserts.

Natural occurrence of fermentation

Distilled spirits are all alcoholic beverages in which the concentration of ethyl alcohol has been increased above that of the original fermented mixture by a method called distillation. The principle of alcoholic distillation is based upon the different boiling points of alcohol (78.5° C, or 173.3° F) and water (100° C, or 212° F). If a liquid containing ethyl alcohol is heated to a temperature above 78.5° C but below 100° C, and the vapour coming off of the liquid is condensed, the condensate will have a higher alcohol concentration, or strength.

HISTORY OF DISTILLING

Because the two ingredients necessary to alcoholic fermentation are widely spread and always appear together, civilizations in almost every part of the world developed some form of alcoholic beverage very early in their history. The Chinese were distilling a beverage from rice beer by 800 BC, and arrack was distilled in the East Indies from sugarcane and rice. The Arabs developed a distillation method that was used to produce a distilled beverage from wine. Greek philosophers reported a crude distillation method. The Romans apparently produced distilled beverages, although no references concerning them are found in writings before AD 100. Production of distilled spirits was reported in Britain before the Roman conquest. Spain, France, and the rest of western Europe probably produced distilled spirits at an earlier date, but production was apparently limited until the 8th century, after contact with the Arabs.

The first distilled spirits were made from sugar-based materials, primarily grapes and honey to make grape brandy and distilled mead, respectively. The earliest use of starchy grains to produce distilled spirits is not known, but their use certainly dates from the Middle Ages. Some government control dates from the 17th century. As production methods improved and volume increased, the distilled spirits industry became an important source of revenue. Rigid controls were often imposed on both production and sale of the liquor.

The earliest stills were composed simply of a heated closed container, a condenser, and a receptacle to receive the condensate. These evolved into the pot still, which is still in use, particularly for making malt whiskeys and some gins. The next refinement was heating the alcohol-containing liquid in a column made up of a series of vaporization chambers stacked on top of one another. By the early 19th century large-scale continuous stills, very similar to those used in the industry today, were operating in France and England. In 1831 the Irishman Aeneas Coffey designed such a still, which consisted of two columns in series.

Since distillation requires that the liquid portion of a fermentation mixture be vaporized, considerable heat must be applied to the process. The fuel used in distilling spirits has always been that which has been most readily available at the particular time and place. Peat, coal, and wood were the fuels used historically, while the fuels of choice today are coal, natural gas, and oil. The high steam requirement for continuous-still operation inhibited the development of rectifying columns for production of spirits until after the Industrial Revolution.

Many of the minor components of distilled spirits, which are present only in parts per million, are detectable by the senses of taste and smell, but efforts to identify and quantify these compounds chemically have often been hampered by the lower limits of detection by analytical methods. Classes of compounds such as aldehydes, organic acids, esters, and alcohols were easily identified by conventional methods, but many of them could not be determined until after the development of chromatography. The Russian botanist Mikhail Tsvet was an early pioneer of this measurement technique, reporting his first work in 1903. Refinements in both technique and equipment, made during the first half of the 20th century, allowed numerous flavour components in distilled spirits to be identified by gas chromatography.

PRODUCTION

Raw materials. The raw materials used for making a distilled spirit are of two basic types: (1) those containing a high concentration of natural sugars or (2) those containing other carbohydrates that can easily be converted to sugars by enzymes. Enzymes are proteins that act as catalysts to promote chemical reactions. Very small amounts of an enzyme can cause a fundamental change in a large amount of material. Most enzymes are specific in their action, so that a system of several enzymes is necessary, for example, to convert starch into sugar and ultimately into ethyl alcohol. The amylases are enzymes that convert starches into sugars; sprouting grains—especially barley—are natural sources of these enzymes. Yeast has a complex enzyme system that converts sugar into carbon dioxide and a multiplicity of other products, including ethyl alcohol.

Reduced activity of any enzyme in the system distorts the results, often forming unwanted products. Enzymes are easily poisoned by certain compounds; they are also sensitive to temperature variations and to the degree of acidity of the medium.

Sugary materials. Grapes, cultivated in most of the subtropic and warm temperate zones of the world, are the major fruit employed as the raw material of distilled spirits, and the final product of their fermentation is brandy. Other natural fruits, such as apples and peaches, are used to a lesser extent, and many fruits are limited to local importance.

Sugary vegetables include sugarcane, sugar beets, and *Agave tequilana* (a type of cactus). Sugarcane and its products, including cane juices, molasses, and sugar, are the most important of the vegetable group. Grown throughout the tropics and semitropics, sugarcane is used in making rum and an alcohol derived from rum. Sugarcane juice can be pressed from the cane for use as the base raw ma-

terial for fermentation, or the juice may be concentrated for sugar production, with the molasses residue from the sugar crystalization used as a base for fermentation. This process is also applied to sugar beets.

Starchy materials. For many centuries, it was only feasible to employ local grain crops for liquor production, and, in this way, the basic characteristics of the local distilled beverage were established. Improved transportation removed this restriction, and today economic considerations frequently determine grain selection, with the principal grain used being the one available at the lowest price per unit of fermentable materials.

Cereal grains used for liquor production

Corn (maize) is the most important cereal grain employed; it is produced worldwide. Rye grain, though less efficient in fermentation than corn, is used extensively in whiskey production, primarily for the flavour characteristics it imparts to the final product. It is particularly employed in Canada and the United States. Rice, a widely grown cereal, has limited use in distilled spirits production outside of Asia from India to Japan. Barley grain, probably the first cereal employed for distillation in large quantities, was formerly a major crop throughout Britain, Scotland, Ireland, and western Europe. Wheat, because of its high cost, is used only where corn is in short supply and is then limited to production of grain alcohol for blending or in production of liqueurs. Potatoes have been used in distilled spirits production primarily in central Europe; in the tropics, other starchy roots are employed.

Preparing the mash. *Milling and pressing.* The purpose of milling and pressing operations is to make the starch or sugar more available for enzyme action. Crushing and pressing (grapes and other fruits), milling (cereal grains), or a combination of milling and pressing (sugarcane) are used.

In milling, grains are reduced to a meal to allow wetting of their starch cells. Various types of mills are used. Roller mills, where the grain passes through a series of corrugated rollers, was long the most common type. The grinding action of the rollers is mainly a shearing action. More efficient and economical impact-type mills (such as hammer mills) are now gaining in importance.

After the Industrial Revolution, steam replaced water as the power source for milling. Steam-powered mills were a maze of belts and pulleys. Since the mid-20th century, electricity has been almost the exclusive power source in milling.

Mashing. The purpose of the mashing operation is to (1) mix the proper proportions of grains, (2) increase the availability of the starch for enzyme action, and (3) convert the starches into fermentable sugars.

Mashing is done in a vessel called a mash tub, which is equipped with a means of agitation for mixing and is either jacketed or contains coils for heating and cooling. In mashing, the starch cells of the grain, enclosed in their own protective coatings, are broken to allow wetting and liquefaction of the entire starch mass. The process usually begins with the grain most difficult to treat. When corn is used, the ground meal is wetted at a temperature of approximately 66° C (150° F), and the temperature is then raised to boiling or sometimes higher while under pressure. Temperature is reduced when the starch cells are broken. The grain ranking second in cell resistance (usually rye) is added next. Other starchy substances, such as potatoes, are usually crushed and heated, exploding the starch cells. Temperature of the mash is reduced before ground malt meal, either in dry form or as a water slurry (insoluble mixture), is added. The amylase enzymes in the malt then produce a mixture in which the starches have been converted to fermentable sugars, suitable for utilization by the yeast. The sugars, principally dextrose and maltose, vary in concentration among producers but, generally, are sufficiently concentrated to make a final product ranging from 7 to 9 percent alcohol.

Use of malt

Any germinating cereal grain can be used for malt. In rare cases rye malt is used in making rye whiskey, but because the enzyme activity of malted barley is the highest, barley is used almost exclusively in the distilling industry. Barley malt contains sufficient enzymes to convert approximately 10 times its weight in other unmalted grains. Of the two enzymes—α-amylase and β-amylase—the former is the more important for conversion of other grains. In addition to converting starches from other carbohydrates to sugars, barley malt contains soluble proteins (amino acids), contributing flavour to the distillate secured from fermentation and distillation of grain-malt mixtures. (For a description of the production of malt from germinated barley, see above *Beer: The brewing process.*)

Fermentation. *Yeast and yeast culture.* As mentioned above, yeasts are found throughout the world; more than 8,000 strains of this vegetative microorganism have been classified. Approximately nine or 10 pure strains, with their subclassifications, are used for fermentation of grain mashes; these all belong to the type *Saccharomyces cerevisiae.* Each strain has its own characteristics, imparting its special properties to the distillate derived from its fermentation. A limited number of yeasts are used in the fermentation of wines, from which brandy is distilled. Strains used in the fermentation of grain mashes are also used in fermentation for rum, tequila, and beer production.

In grain-based products, yeast cells are grown in grain mixtures. The preparation of a cooked mash of rye and barley malt is most common. The mash is sterilized, then inoculated with lactic-acid bacteria to increase acidity. (Yeast is more tolerant of higher acidity than many commonly occurring bacteria.) When the desired acidity is reached, the mixture is again sterilized and a pure yeast culture is added. The yeast is grown under controlled conditions until it reaches the optimum point for mixing with the grain mash. In liquid fermentation, as from fruits and sugarcane, the yeast is generally grown in a mixture similar to the one it will be used to ferment; for example, a yeast culture to be used for molasses fermentation is usually grown in molasses.

Fermenting methods. In the fermentation process, simple sugars, including dextrose and maltose, are converted to ethyl alcohol by the action of yeast enzymes. Several intermediate compounds are formed during this complex chemical process before the final ethyl alcohol is obtained.

Yeast functions best in a slightly acid medium, and the prepared grain mash, fruit juice, molasses, or other mixture must be checked for adequate acidity (pH value). If acidity is insufficient, acid or acid-bearing material is added to achieve the necessary adjustment. The previously prepared yeast is then added, and final dilution of the mixture is made. The final concentration of sugars is adjusted so that the yeast fermentation will produce a finished fermented mixture containing between 7 and 9 percent alcohol.

Equipment for fermentation

Commercial fermentation is carried on in large vats. In the past these were open and made of wood, usually cypress. Most plants now use closed stainless steel vats for easier cleaning, and many are equipped with jackets or cooling coils for better temperature control. The time required for completion of fermentation is mainly dependent upon the temperature of the fermenting mash. Normal yeast is most effective in breaking down all of the fermentable sugars at temperatures ranging from 24° to 29° C (75° to 85° F), and, in this range, completion of fermentation requires from 48 to 96 hours. Fermentation at lower temperatures requires longer periods. The mash is ready for distillation upon completion of fermentation. If fermentation is allowed to continue past this period, it will be adversely affected by bacterial action. The ethyl alcohol content will be reduced, and the flavour and aroma of the finished product will be tainted.

Distillation. As mentioned above, the difference in the boiling points of alcohol and water is utilized in distillation to separate these liquids from each other. Basic distillation apparatus consists of three parts: the still or retort, for heating the liquid; the condenser, for cooling the vapours; and the receiver, for collecting the distillate.

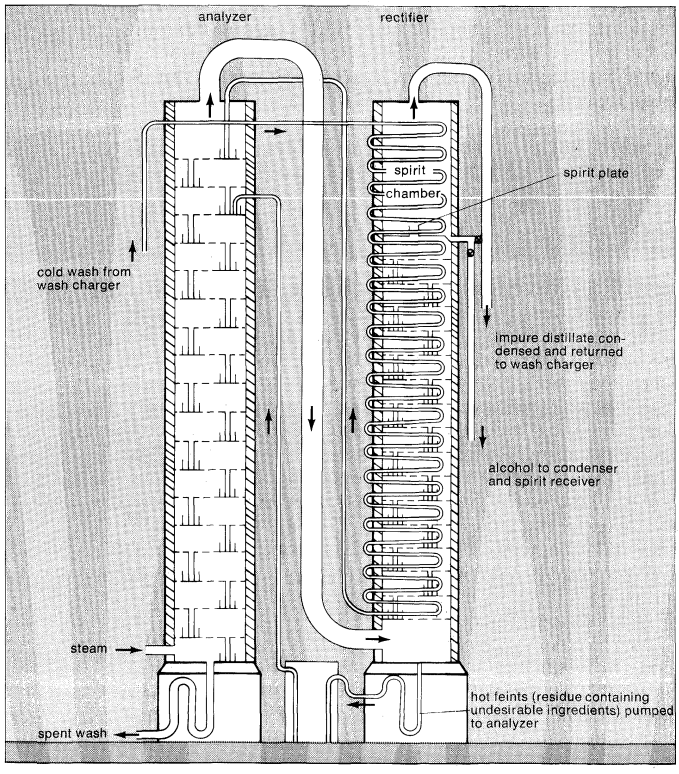
The pot still. The simple pot still is a large enclosed vessel, heated either by direct firing on the bottom or by steam coils within the vessel, with a cylindrical bulb at its top leading to a partially cooled vapour line. The bulb and vapour line separate entrained liquid particles from the vapour on its way to the final condenser. The usual pot-still operation involves a series of two or three pot

stills. Any vapour falling below a predetermined alcoholic content is fed into a second still, and condensed vapour from the second still falling below the required alcoholic content is fed to the third. The condensed vapours of the desired alcoholic content from all three stills are then commingled in a single receiving container.

The pot still, used primarily in Scotland and Ireland for whiskey production and in France for brandies, has had only brief use in distilled spirits production elsewhere and is gradually becoming obsolete. Even in countries in which the pot still has long been used, it has been replaced by continuous distillation for the major portion of alcoholic-liquor production, and its current use is limited to production of flavouring whiskeys and other flavouring ingredients.

The flavour profile of a pot-still product is more complex than that of a continuous-still product of the same alcohol content. This is a result of the different distillation methods. At a given temperature and pressure, vapours over a boiling mixture have a composition that is a function of the vapour pressures of the components of the mixture. In a pot still, the temperature of the fermentation mixture rises as the lower-boiling-temperature alcohol vaporizes. Meanwhile, the alcohol content of the distillate drops as the rising temperature vaporizes more water along with the alcohol. Distillation is allowed to continue until the alcohol content of the distillate falls to a predetemined level. Because of the rising temperature encountered in distilling a single batch, the composition of the first part of the condensate to leave the pot is different from that of the last part. The composition of the final product is the average of the composition of the vapours condensed during the entire run. By contrast, the temperature of the continuous still is held approximately constant throughout the run. This results in a flavour profile that is more uniform.

The continuous still. The continuous still, which came into use in the early 19th century, consists of a tall cylindrical column filled with perforated plates onto which water-rich vapours condense while alcohol-enriched vapours pass through. These plates thus serve as a series of small pot stills, one on top of the other. Live steam, used as the heat source, is fed into the bottom of the still, and the liquid to be distilled is fed near the top. Steam pressure holds the liquid on the plates, and, with any overflow caught by the plate below, the liquid level on each plate is maintained. Use of a sufficient number of plates assures that the concentration of alcohol in the vapour leaving the top of the still will be appropriate for the desired product and that the liquid leaving the bottom has been stripped of any alcohol.



Continuous still for preparing distilled liquors.

Many distillation operations combine column and pot stills. The condensed distillate from the column still is fed to the doubler, a type of pot still heated by closed steam coils, and redistilled.

The rectification still. Rectification is the process of purifying alcohol by repeatedly or fractionally distilling it to remove water and undesirable compounds. As mentioned above, a fermentation mixture primarily contains water and ethyl alcohol and distillation involves increasing the percentage of ethyl alcohol in the mixture. Water vaporizes very easily, however, and, unless care is taken, the distillate of a fermentation mixture will contain unacceptably large quantities of water. The fermentation mixture furthermore contains small quantities of complex constituents that can contribute to the flavour of the product even if they are present only in parts per million. It is important to retain those components that make a positive contribution to the product and to remove those that are unwanted, primarily some organic aldehydes, acids, esters, and higher alcohols. The ones that remain in the product are called congeners, and the congener level is controlled by the particular rectification system and by the system's method of operation.

The multicolumn rectifying system usually consists of three to five columns. The first column is always a preliminary separation column called the beer still, or analyzer. It usually consists of a series of metal plates with holes punched in them and baffles to control the liquid levels on the plates. The product coming from this column is between 55 and 80 percent ethyl alcohol. A 95-percent product can be produced on a two-column system consisting of a beer column and a rectifying column. The bulk of congener removal is accomplished in the rectifier—esters and higher alcohols, for example, being drawn off as side streams. However, a multicolumn system of several specialized rectifiers allows better control of the finished product. An aldehyde column, or purifier, is frequently used to separate these highly volatile low-boiling components, and sometimes ethyl alcohol is recovered in an extractive column and returned to the rectifier.

Three characteristics determine the elimination or retention of flavouring compounds: (1) their boiling points, (2) their solubilities in ethyl alcohol and water, and (3) their specific gravities. Some higher alcohols, for example, are removed on the basis of their solubility and specific gravity. These higher alcohols have limited solubility in water, and their specific gravities are less than that of water. Also, their boiling points are higher than that of ethyl alcohol and lower than that of water. Since they tend to accumulate in the rectifying column at the region where their boiling points cause them to condense, they can be drawn off as a liquid side stream. This side stream also contains a considerable amount of water. The limited solubility in water, plus the lower specific gravities, cause the higher alcohols to float to the top of the alcohol–water mixture, from which they can be removed.

MATURATION, BLENDING, AND PACKAGING

Aging. One method of classifying distilled liquors is as aged or unaged. Vodka, neutral spirits for use in a variety of products, most gins, and some rums and brandies are unaged. Aged products are predominantly whiskeys and most rums and brandies.

The term age refers to the actual duration of storage, while maturity expresses the degree to which chemical changes occur during storage. The maturation of whiskeys falls into two categories, according to whether storage is in new or reused cooperage. New charred, white-oak containers are required by law in the United States for the maturation of products to be called straight bourbon or rye whiskey. These containers, each containing 50 to 55 gallons, are stored in warehouses sometimes having controlled temperature and humidity. Older warehouses are called rick houses because the barrels are stored on sta-

tionary frames called ricks. In many newer houses, barrels are stacked on pallets.

White oak is one of the few woods that can hold liquids while allowing the process of breathing through the pores of the wood. The pore size of the wood is such that small molecules such as water move through the wood more easily than larger molecules such as alcohol. This breathing process is caused by temperature and humidity differences between the liquid in the barrel and the air in the warehouse. Charring the wood makes some of the wood compounds more soluble. As the liquid in the container moves back and forth through the wood, ingredients are extracted and carried back into the container's contents. Maturation also results from the contact of oxygen from the outside air with ingredients in the alcohol mixture. Therefore, maturation during aging consists of the interaction of the original compounds of the distillate, of oxidation reactions, and of the extraction of flavouring compounds from the wood. These factors must be well balanced in the properly matured product. The lower the level of the original congeners, the less wood extract required to achieve a good balance.

Outside the United States, reused cooperage is common. Since used containers have already yielded their initial oak extracts, the resulting product is low in extracted flavouring ingredients, which is desirable in some beverages. This maturation method, typified by Scotch and Irish whiskeys, can be carried on in casks holding up to 132 gallons. These casks have usually had previous use for storage or maturation of other whiskeys or wines and may be reused for many maturation cycles. Maturation in dry warehousing increases the alcoholic content of the liquid in the container, but the more common practice for Scotch and Irish whiskeys of maturation in high humidity warehouses reduces the alcoholic concentration.

The maturation procedure for brandies is similar to that of some whiskeys, but the brandies are usually matured in fairly large casks or oak containers. Most brandies are matured for three to five years, but some remain for as long as 20 to 40 years or even longer.

Rum is usually matured in reused oak containers; high concentrations of oak extracts are not considered desirable. Normal maturation time is two to three years, but rum, generally a blended product, may contain a percentage of older rums.

Most governments specify storage time for various products. The United States requires a two-year storage period for most whiskeys but has no requirement for any pure alcohol or neutral spirits (close to 100 percent alcohol) added to such whiskeys in the production of blended whiskey. Canada requires storage of two years for all distilled spirits. Scotland and England require a three-year storage and Ireland, five years for all products classified as whiskey; there are no requirements for vodka and gin.

Blending. Blending is another method of obtaining a balanced product with precise flavour characteristics. Blended products are composed of one or more highly flavoured components, a high-proof component with a low congener content, a colour adjustment ingredient, and perhaps an additional flavouring material. An example is a blended whiskey, which may contain several whiskeys, a grain spirit distilled at 90 to 95 percent alcohol, caramel colouring, and perhaps a small amount of a flavouring blender (part of which may be sherry or port wine). A blended Scotch consists of several highly flavoured malt whiskeys produced in pot stills and a base whiskey produced from grain in a continuous distillation system.

Packaging. *Bottling.* Distilled spirits react upon exposure to many substances, extracting materials from the container that tend to destroy the liquor aroma and flavour. For this reason, glass, being nonreactive, has been the universal container for packaging alcoholic liquors. (A few products are now packaged in plastic bottles, but these are primarily 50-millilitre miniatures, the light weight of which is particularly suited for use by airlines.) Packaging economics require containers that are standardized in size and shape and that lend themselves to automatic processes.

Early hand methods of filling, labeling, corking, and other operations have been replaced by highly mechanized bottling lines, with bottles cleaned, filled, capped, sealed, labeled, and placed in a shipping container at a rate as high as 400 bottles per minute. This progress became possible with the development of high-strength glass, plastic closures with inert liners, and high-speed machines. Even specialized packaging, long a hand operation, has been replaced by standardization of containers, allowing production on automatic lines.

Mechanized packaging

Designated proof. Spirit strength may be designated in several ways—weight per gallon, percentage by weight, or percentage by volume, all these having reference to absolute (*i.e.,* pure) alcohol and water. There are other standards in common use; *e.g.,* U.S. proof spirit, which is 50 percent by volume alcohol. Each degree of U.S. proof represents 0.5 percent alcohol, so that a liquor having 50 percent alcohol is termed 100 proof. British proof is based on a specific concentration of alcohol, a 50 percent alcoholic content being equivalent to 114.12 U.S. proof. British proof is expressed as degrees over or under proof (that is, over or under 50 percent alcohol), while U.S. proof is expressed in direct proof figures. The metric Gay-Lussac system simply states the percentage by volume of alcohol in a distilled liquor. (F.M.S./A.T.T.)

Soft drinks

Soft drinks are a class of nonalcoholic beverage, usually but not necessarily carbonated, normally containing a natural or artificial sweetening agent, edible acids, natural or artificial flavours, and sometimes juice. Natural flavours are derived from fruits, nuts, berries, roots, herbs, and other plant sources. Coffee, tea, milk, cocoa, and undiluted fruit and vegetable juices are not considered soft drinks.

The term was originated to distinguish the flavoured drinks from hard liquor, or spirits. Soft drinks were recommended as a substitute in the effort to change the hard-drinking habits of early Americans. Indeed, health concerns of modern consumers have led to new categories of soft drinks emphasizing low caloric and sodium content, no caffeine, and "all natural" ingredients.

There are many specialty soft drinks. Mineral waters are very popular in Europe and Latin America. Kava, made from roots of a bushy shrub, *Piper methysticum,* is consumed by the people of Fiji and other Pacific islands. In Cuba people enjoy a carbonated cane juice; its flavour comes from unrefined syrup. In tropical areas, where diets frequently lack sufficient protein, soft drinks containing soybean flour have been marketed. In Egypt carob or locust bean extract is used. In Brazil a soft drink is made using maté as a base. The whey obtained from making buffalo cheese is carbonated and consumed as a soft drink in North Africa. Some eastern Europeans enjoy a drink prepared from fermented stale bread. Honey and orange juice go into a popular drink of Israel.

HISTORY OF SOFT DRINKS

The first marketed soft drinks appeared in the 17th century as a mixture of water and lemon juice sweetened with honey. In 1676 the Compagnie de Limonadiers was formed in Paris and granted a monopoly for the sale of its products. Vendors carried tanks on their backs from which they dispensed cups of lemonade.

Carbonated beverages and waters were developed from European attempts in the 17th century to imitate the popular and naturally effervescent waters of famous springs, with primary interest in their reputed therapeutic values. The effervescent feature of the waters was recognized early as most important. Jan Baptist van Helmont (1577–1644) first used the term gas in his reference to the carbon dioxide content. Gabriel Venel referred to aerated water, confusing the gas with ordinary air. Joseph Black named the gaseous constituent fixed air.

Robert Boyle, the Anglo-Irish scientist who helped found modern chemistry, published his *Short Memoirs for the Natural Experimental History of Mineral Waters* in 1685. It included sections on examining mineral springs, on the properties of the water, on its effects upon human bodies, and, lastly, "of the imitation of natural medicinal waters by chymical and other artificial wayes."

Numerous reports of experiments and investigations were included in the *Philosophical Transactions* of the Royal Society of London in the late 1700s, including the studies of Stephen Hales, Joseph Black, David Macbride, William Brownrigg, Henry Cavendish, Thomas Lane, and others.

First carbonating apparatus

Joseph Priestley is nicknamed "the father of the soft drinks industry" for his experiments on gas obtained from the fermenting vats of a brewery. In 1772 he demonstrated a small carbonating apparatus to the College of Physicians in London, suggesting that, with the aid of a pump, water might be more highly impregnated with fixed air. Antoine Lavoisier in Paris made the same suggestion in 1773.

To Thomas Henry, an apothecary in Manchester, Eng., is attributed the first production of carbonated water, which he made in 12-gallon barrels using an apparatus based on Priestley's. Jacob Schweppe, a jeweler in Geneva, read the papers of Priestley and Lavoisier and determined to make a similar device. By 1794 he was selling his highly carbonated artificial mineral waters to his friends in Geneva; later he started a business in London.

At first, bottled waters were used medicinally, as evidenced in a letter written by English industrialist Matthew Boulton to the philosopher Erasmus Darwin in 1794: "J. Schweppe prepares his mineral waters of three sorts. No. 1 is for common drinking with your dinner. No. 2 is for nephritick patients and No. 3 contains the most alkali given only in more violent cases." By about 1820, improvements in manufacturing processes allowed a much greater output, and bottled water became popular. Mineral salts and flavours were added—ginger in about 1820, lemon in the 1830s, tonic in 1858. In 1886 John Pemberton, a pharmacist in Atlanta, Ga., invented Coca-Cola, the first cola drink.

PRODUCTION

All ingredients used in soft drinks must be of high purity and food grade to obtain a quality beverage. These include the water, carbon dioxide, sugar, acids, juices, and flavours.

Purification of water

Water. Although water is most often taken from a safe municipal supply, it usually is processed further to ensure uniformity of the finished product; the amount of impurities in the municipal supply may vary from time to time. In some bottling plants the water-treatment equipment may simply consist of a sand filter to remove minute solid matter and activated carbon purifier to remove colour, chlorine, and other tastes or odours. In most plants, however, water is treated by a process known as superchlorination and coagulation. There, the water is exposed for two hours to a high concentration of chlorine and to a flocculant, which removes such organisms as plankton (minute plants and animals); it then passes through a sand filter and activated carbon.

Carbon dioxide and carbonation. Carbon dioxide gas gives the beverage its sparkle and tangy taste and prevents spoilage. While it has not been conclusively proved that carbonation offers a direct medical benefit, carbonated beverages are used to alleviate postoperative nausea when no other food can be tolerated, as well as to ensure adequate liquid intake.

Carbon dioxide is supplied to the soft drink manufacturer in either solid form (Dry Ice) or liquid form maintained under approximately 1,200 pounds per square inch (84 kilograms per square centimetre) pressure in heavy steel containers. Lightweight steel containers are used when the liquid carbon dioxide is held under refrigeration. In that case, the internal pressure is about 325 pounds per square inch.

Carbonation (of either the water or the finished beverage mixture) is effected by chilling the liquid and cascading it in thin layers over a series of plates in an enclosure containing carbon dioxide gas under pressure. The amount of gas the water will absorb increases as the pressure is increased and the temperature is decreased.

Flavouring syrup. Flavouring syrup is normally a concentrated solution of a sweetener (sugar or artificial), an acidulant for tartness, flavouring, and a preservative when necessary. The flavouring syrup is made in two steps. First, a "simple syrup" is prepared by making a solution of water and sugar. This simple sugar solution can be treated with carbon and filtered if the sugar quality is poor. All of the other ingredients are then added in a precise order to make up what is called a "finished syrup."

Blending of syrup and water

Finishing. There are two methods for producing a finished product from the flavouring syrup. In the first, the syrup is diluted with water and the product then cooled, carbonated, and bottled. In the second, the maker measures a precise amount of syrup into each bottle, then fills it with carbonated water. In either case, the sugar content (51–60 percent in the syrup) is reduced to 8–13 percent in the finished beverage.

The blending of syrups and mixing with plain or carbonated water, the container washing, and container filling are all done almost entirely by automatic machinery. Returnable bottles are washed in hot alkali solutions for a minimum of five minutes, then rinsed thoroughly. Single-service or "one-trip" containers are generally air-rinsed or rinsed with potable water before filling. Automatic fillers service from 30 to 2,000 containers per minute.

Pasteurizing noncarbonated beverages. Noncarbonated beverages require ingredients and techniques similar to those for carbonated beverages. However, since they lack the protection against spoilage afforded by carbonation, these are usually pasteurized, either in bulk, by continuous flash pasteurization prior to filling, or in the bottle.

Powdered soft drinks. These are made by blending the flavouring material with dry acids, gums, artificial colour, etc. If the sweetener has been included, the consumer need only add the proper amount of plain or carbonated water.

Iced soft drinks. The first iced soft drink consisted of a cup of ice covered with a flavoured syrup. Sophisticated dispensing machines now blend measured quantities of syrup with carbonated or plain water to make the finished beverage. To obtain the soft ice, or slush, the machine reduces the beverage temperature to between −5° and −2° C (22° and 28° F).

PACKAGING AND VENDING

Soft drinks are packaged in glass or plastic bottles, tin-free steel, aluminum, or plastic cans, treated cardboard cartons, foil pouches, or in large stainless steel containers.

Vending of soft drinks had its modest beginning with the use of ice coolers in the early 20th century. Nowadays, most drinks are cooled by electric refrigeration for consumption on the premises. Vending machines dispense soft drinks in cups, cans, or bottles, and restaurants, bars, and hotels use dispensing guns to handle large volume. There are two methods of vending soft drinks in cups. In the "pre-mix" system, the finished beverage is prepared by the soft drink manufacturer and filled into five- or 10-gallon stainless steel tanks. The tanks of beverage are attached to the vending machine where the beverage is cooled and dispensed. In the "post-mix" system the vending machine has its own water and carbon dioxide supply. The water is carbonated as required and is mixed with flavoured syrup as it is dispensed into the cup. (H.E.K./M.J.Pi.)

BIBLIOGRAPHY

Tea: WILLIAM H. UKERS, *All About Tea,* 2 vol. (1935), deals with the historical, technological, scientific, commercial, social, and artistic aspects of tea production and includes extensive bibliographies. C.R. HARLER, *Tea Growing* (1966), *Tea Manufacture* (1963, reprinted 1970), and *The Culture and Marketing of Tea,* 3rd ed. (1964), discuss methods and problems of the tea industry. CLAUD BALD, *Indian Tea: A Textbook on the Culture and Manufacture of Tea,* 7th ed., rev. by C.J. HARRISON (1965), deals with the development of tea production in India, where the modern tea industry originated. T. EDEN, *Tea,* 3rd ed. (1976), discusses tea production in Sri Lanka and the newly developing African tea industry. See also J. WERKHOVEN (comp.), *Tea Processing* (1974), a survey prepared for the Food and Agriculture Organization of the United Nations. (S.Si.)

Coffee: On the history of coffee, see RALPH S. HATTOX, *Coffee and Coffeehouses: The Origins of a Social Beverage in the Medieval Near East* (1985). WILLIAM H. UKERS, *All About Coffee,* 2nd ed. (1935, reissued 1976), offers an excellent view of coffee technology and production. Later sources include M.N. CLIFFORD and K.C. WILLSON (eds.), *Coffee: Botany, Biochemistry, and Production of Beans and Beverage* (1985); R.J. CLARKE and

R. MACRAE (eds.), *Coffee,* 2 vol. (1985–87), on chemistry and technology; MICHAEL SIVETZ and NORMAN W. DESROSIER, *Coffee Technology* (1979), a comprehensive survey of roasted, soluble, and extracted coffees; and C.F. MARSHALL, *The World Coffee Trade: A Guide to the Production, Trading, and Consumption of Coffee* (1983).

(Ed.)

Beer: H.S. CORRAN, *A History of Brewing* (1975), is a well-researched work with references to brewing in Europe (mainly Britain) and in the United States. FRITZ SCHOELLHORN, *Bibliographie des Brauwesens* (1928), continued in F. KUTTER, *Bibliographie des Brauwesens* (1954), list technical references to Latin literature, from the 15th century onward to many German sources, and to similar scientific papers written in English, French, Swedish, Danish, Czech, Russian, Dutch, Norwegian, Italian, and Hungarian. Development of brewing materials and processes to the first quarter of the 20th century is covered in H. LLOYD HIND, *Brewing: Science and Practice,* 2 vol. (1938–40). Later sources include J. DE CLERCK, *A Textbook of Brewing,* 2 vol. (1957–58; originally published in French, 1948), a discussion of worldwide brewing practices and beer analysis; D.E. BRIGGS, *Barley* (1978); and ARTHUR H. COOK (ed.), *Barley and Malt* (1962), studies of the breeding of varieties of barley and of the technical and scientific aspects of malt and malting. A.H. BURGESS, *Hops* (1964), provides the same coverage of hop cultivation and the historical, scientific, and technical aspects of the use of hops in brewing. J.S. HOUGH, *The Biotechnology of Malting and Brewing* (1985), is an introductory account. D.E. BRIGGS *et al., Malting and Brewing Science,* 2nd ed., 2 vol. (1981–82), is a comprehensive text on brewing practice throughout the world and its underlying principles, with an extensive bibliography. J.R.A. POLLOCK (ed.), *Brewing Science,* 3 vol. (1979–87), is a collection of articles by practitioners of brewing, covering brewing science and related technology; and HAROLD M. BRODERICK (ed.), *The Practical Brewer: A Manual for the Brewing Industry,* 2nd ed. (1977), offers information on the American brewing industry and its history.

(T.W.Y.)

Wine: Encyclopaedias and dictionaries on wines and wine production include *Frank Schoonmaker's Encyclopedia of Wine,* rev. and expanded ed., rev. by JULIUS WILE (1978); HUGH JOHNSON, *The World Atlas of Wine: A Complete Guide to the Wines and Spirits of the World,* 3rd rev. ed. (1985), and *Hugh Johnson's Modern Encyclopedia of Wine,* 2nd ed. (1987); and TED GRUDZINSKI, *Winequest, the Wine Dictionary* (1985). Standard works on wine making include M.A. AMERINE *et al., The Technology of Wine Making,* 4th ed. (1980), a treatise on the making of all types of wine; and JEAN RIBERÉAU-GAYON *et al., Sciences et techniques du vin,* 4 vol. (1972–77). Viticulture is discussed in A.J. WINKLER, *General Viticulture,* rev. and enl. ed. (1974), a standard treatise on grape growing.

French wines are discussed in ALEXIS LICHINE and SAMUEL PERKINS, *Alexis Lichine's Guide to the Wines and Vineyards of France,* 3rd ed. (1986); STEVEN SPURRIER, *The Académie du vin Guide to French Wines* (1986); DAVID PEPPERCORN, *Bordeaux* (1982, reprinted 1986); and HUBRECHT DUIJKER, *The Wines of the Loire, Alsace, and Champagne* (1983). For German wines, see GERHARD TROOST, *Technologie des Weines,* 5th rev. ed. (1980); and FRANK SCHOONMAKER, *The Wines of Germany,* 2nd rev. ed., edited by PETER M.F. SICHEL (1983). Wines of other countries are discussed in BURTON ANDERSON, *The Simon and Schuster Pocket Guide to Italian Wines* (1987); JAN READ, MAITE MANJÓN, and HUGH JOHNSON, *The Wine and Food of Spain* (1987); ZOLTÁN HALÁSZ, *The Book of Hungarian Wines* (1981; originally published in Hungarian, 1981); LEN EVANS, *Complete Book of Australian Wine,* 3rd ed. (1978); ANTHONY DIAS BLUE, *American Wine: A Comprehensive Guide* (1985), on the United States; WILLIAM I. KAUFMAN, *Encyclopedia of American Wine, Including Mexico and Canada* (1984); and LEON D. ADAMS, *The Wines of America,* 3rd ed. (1985).

(M.A.A.)

Distilled spirits: Several comprehensive guides include a wealth of information on both wines and distilled spirits: HAROLD J. GROSSMAN, *Grossman's Guide to Wines, Beers, & Spirits,* 7th rev. ed., revised by HARRIET LEMBECK (1983), a popular work prepared for both the industry and the consumer, including an excellent section on both distilled spirits in general and on specific types; and ALEXIS LICHINE *et al., Alexis Lichine's New Encyclopedia of Wines & Spirits,* 5th rev. ed. (1987), a comprehensive encyclopaedia of alcoholic-beverage terminology, with introductory chapters treating the history of distilled spirits and their development and production. For the history of the process, see R.J. FORBES, *A Short History of the Art of Distillation: From the Beginnings Up to the Death of Cellier Blumenthal* (1970). G.G. BIRCH and M.G. LINDLEY (eds.), *Alcoholic Beverages* (1985), is a comprehensive book on production methods.

(F.M.S./A.T.T.)

Soft drinks: JOHN J. RILEY, *A History of the American Soft Drink Industry: Bottled Carbonated Beverages, 1807–1957* (1958, reprinted 1972), studies the evolution of the American flavoured soft drink, European development of simulated effervescent waters in the early 1800s, and early development of the flavoured carbonated beverage in the United States. Later developments can be traced through the history of specific companies: ANNE HOY, *Coca-Cola: The First Hundred Years* (1986); and DOUGLAS A. SIMMONS, *Schweppes, the First 200 Years* (1983). M.B. JACOBS, *Manufacture and Analysis of Carbonated Beverages* (1959), is a detailed treatment. See also L.F. GREEN and H.W. HOUGHTON, *Developments in Soft Drink Technology,* 3 vol. (1978–84).

Biblical Literature
and Its Critical Interpretation

Biblical literature, as it is treated in this article, consists of four bodies of written works: the Old Testament writings according to the Hebrew canon; intertestamental works, including the Old Testament Apocrypha; the New Testament writings; and the New Testament Apocrypha.

The Old Testament is a collection of writings that was first compiled and preserved as the sacred books of the ancient Hebrew people. As the Bible of the Hebrews and their Jewish descendants down to the present, these books have been perhaps the most decisive single factor in the preservation of the Jews as a cultural entity and Judaism as a religion. The Old Testament and the New Testament—a body of writings that chronicle the origin and early dissemination of Christianity—constitute the Bible of the Christians.

The literature of the Bible, encompassing the Old and New Testaments and various noncanonical works, has played a special role in the history and culture of the Western world and has itself become the subject of intensive critical study. This field of scholarship, including exegesis (critical interpretation) and hermeneutics (the science of interpretive principles), has assumed an important place in the theologies of Judaism and Christianity. The methods and purposes of exegesis and hermeneutics are treated below. For the cultural and historical contexts in which this literature developed, see JUDAISM; CHRISTIANITY.

The article is divided into the following sections:

Influence and significance

HISTORICAL AND CULTURAL IMPORTANCE

Expression of the Jewish religion in the Old Testament

In Judaism. After the kingdoms of Israel and Judah had fallen, in 722 BCE (before the Common Era, equivalent to BC) and 587/586 BCE, respectively, the Hebrew people outlived defeat, captivity, and the loss of their national independence, largely because they possessed writings that preserved their history and traditions. Many of them did not return to Palestine after their exile. Those who did return did so to rebuild a temple and reconstruct a society that was more nearly a religious community than an independent nation. The religion found expression in the books of the Old Testament: books of the Law (Torah), history, prophecy, and poetry. The survival of the Jewish religion and its subsequent incalculable influence in the history of Western culture are difficult to explain without acknowledgment of the importance of the biblical writings.

When the Temple in Jerusalem was destroyed in 70 CE (Common Era, equivalent to AD), the historical, priestly sacrificial worship centred in it came to an end and was never resumed. But the religion of the Jewish people had by then gone with them into many lands, where it retained its character and vitality because it still drew its nurture from biblical literature. The Bible was with them in their synagogues, where it was read, prayed, and taught. It preserved their identity as a people, inspired their worship, arranged their calendar, permeated their family lives; it shaped their ideals, sustained them in persecution, and touched their intellects. Whatever Jewish talent and genius have contributed to Western civilization is due in no small degree to the influence of the Bible.

In Christianity. The Hebrew Bible is as basic to Christianity as it is to Judaism. Without the Old Testament, the New Testament could not have been written and there could have been no man like Jesus; Christianity could not have been what it became. This has to do with cultural values, basic human values, as much as with religious beliefs. The Genesis stories of prehistoric events and people are a conspicuous example. The Hebrew myths of creation have superseded the racial mythologies of Latin, Germanic, Slavonic, and all other Western peoples. This is

not because they contain historically factual information or scientifically adequate accounts of the universe, the beginning of life, or any other subject of knowledge, but because they furnish a profoundly theological interpretation of the universe and human existence, an intellectual framework of reality large enough to make room for developing philosophies and sciences.

Centrality of the one and only God

This biblical structure of ideas is shared by Jews and Christians. It centres in the one and only God, the Creator of all that exists. All things have their place in this structure of ideas. All mankind is viewed as a unity, with no race existing for itself alone. The Covenant people (*i.e.*, the Hebrews in the Old Testament and Christians in the New Testament) are chosen not to enjoy special privileges but to serve God's will toward all nations. The individual's sacred rights condemn his abuse, exploitation, or neglect by the rich and powerful or by society itself. Widows, orphans, the stranger, the friendless, and the helpless have a special claim. God's will and purpose are viewed as just, loving, and ultimately prevailing. The future is God's, when his rule will be fully established.

The Bible went with the Christian Church into every land in Europe, bearing its witness to God. The church, driven in part by the power of biblical themes, called men to ethical and social responsibility, to a life answerable to God, to love for all men, to sonship in the family of God, and to citizenship in a kingdom yet to be revealed. The Bible thus points to a way of life never yet perfectly embodied in any society in history. Weighing every existing kingdom, government, church, party, and organization, it finds them wanting in that justice, mercy, and love for which they were intended.

MAJOR THEMES AND CHARACTERISTICS

The Bible is the literature of faith, not of scientific observation or historical demonstration. God's existence as a speculative problem has no interest for the biblical writers. What is problematical for them is the human condition and destiny before God.

The great biblical themes are about God, his revealed works of creation, provision, judgment, deliverance, his covenant, and his promises. The Bible sees what happens to mankind in the light of God's nature, righteousness, faithfulness, mercy, and love. The major themes about mankind relate to man's rebellion, his estrangement and perversion. Man's redemption, forgiveness, reconciliation, the gifts of grace, the new life, the coming kingdom, and the final consummation of man's hope are all viewed as the gracious works of God.

The Old Testament contains several types of literature: there are narratives combined with rules and instructions (Torah, or Pentateuch) and anecdotes of Hebrew persons, prophets, priests, kings, and their women (Former Prophets). There is an antiracist love story (Ruth), the story of a woman playing a dangerous game (Esther), and one of a preacher who succeeded too well (Jonah). There is a collection of epigrams and prudential wisdom (Proverbs) and a philosophic view of existence with pessimism and poise (Ecclesiastes). There is poetry of the first rank, devotional poetry in the Psalms, and erotic poetry in the Song of Songs. Lamentations is a poetic elegy, mourning over fallen Jerusalem. Job is dramatic theological dialogue. The books of the great prophets consist mainly of oral addresses in poetic form.

The New Testament also consists of different literary forms. Acts is historical narrative, actually a second volume following Luke. A Gospel is not a history in the ordinary sense but an arrangement of remembered acts and sayings of Jesus retold to win faith in him. There is one apocalypse, Revelation (a work describing the intervention of God in history). But the largest class of New Testament writings is epistolary, the letters of Paul and other Apostles. Originally written to local groups of Christians, they were preserved in the New Testament and given the status of doctrinal and ethical treatises.

INFLUENCES

On Western civilization. The Bible brought its view of God, the universe, and mankind into all the leading Western languages and thus into the intellectual processes of Western man. The Greek translation of the Old Testament made it accessible in the Hellenistic period (*c.* 300 BCE–*c.* 300 CE) and provided a language for the New Testament and for the Christian liturgy and theology of the first three centuries. The Bible in Latin shaped the thought and life of Western people for a thousand years. Bible translation led to the study and literary development of many languages. Luther's translation of the Bible in the 16th century has been called the beginning of modern German. The Authorized Version (English) of 1611 (King James Version) and the others that preceded it caught the English language at the blooming of its first maturity. Since the invention of printing (mid-15th century), the Bible has become more than the translation of an ancient Oriental literature. It has not seemed a foreign book, and it has been the most available, familiar, and dependable source and arbiter of intellectual, moral, and spiritual ideals in the West.

Influence on Western thought and language

Millions of modern people who do not think of themselves as religious live nevertheless with basic presuppositions that underlie the biblical literature. It would be impossible to calculate the effect of such presuppositions on the changing ideas and attitudes of Western people with regard to the nature and purpose of government, social institutions, and economic theories. Theories and ideals usually rest on prior moral assumptions—*i.e.*, on basic judgments of value. In theory, the West has moved from the divine right of kings to the divinely given rights of every citizen, from slavery through serfdom to the intrinsic worth of every person, from freedom to own property to freedom for everyone from the penalties of hopeless poverty. Though there is a wide difference between the ideal and the actual, biblical literature continues to pronounce its judgment and assert that what ought to be can still be.

On the modern secular age. The assumption of many people is that the Bible has lost much of its importance in a secularized world; that is implied whenever the modern period is called the post-Judeo-Christian era. In most ways the label fits. The modern period seems to be a time in which unprecedented numbers of people have discarded traditional beliefs and practices of both Judaism and Christianity. But the influence of biblical literature neither began nor ended with doctrinal propositions or codes of behaviour. Its importance lies not merely in its overtly religious influence but also, and perhaps more decisively, in its pervasive effect on the thinking and feeling processes, the attitudes and sense of values that, whether recognized as biblical or not, still help to make people what they are.

Influence on the arts

The deepest influence of biblical literature may be found in the arts of Western people, their music and, especially, in their best poetry, drama, and creative fiction. Many of the most moving and illuminating interpretations of biblical material—stories, themes, and characters—are made today by novelists, playwrights, and poets who write simply as human beings, not as adherents of any religion. There are two views of the human condition that scholars have attributed to biblical influence and that have become dominant in Western literature.

The first of these is the view that the mystery of existence and destiny is implicit in every man and woman. In contrast to the canons of classical tragedy, a person of any rank or station may experience the extremes of happiness or misery, exaltation or tragedy. An aged Jew of Rembrandt's paintings or an illiterate black woman of Faulkner's novels can reach the height of human dignity. The arts also put down the mighty from their seats and exalt those of low degree. Any man may be Everyman, the symbol of all human possibility.

The second view of the human condition is that the time of encountering all reality is now, and the place is here, in man's workaday activities and contingencies, whatever they may be. To be human is to know one short life in mortal flesh, in which the past and future are dimensions of the present. It is now or never that the choice is made, the offer of the gift of life accepted or declined. Any kingdom there is must be entered at once or lost forever. It is here in the actual situation of work and play, of love and need, and not in some far-off better time and place, that

the crisis is reached and passed, the issue settled, and the record closed.

These views, though here stated in language that has theological overtones, are not confined to adherents of Judaism or Christianity. They are characteristically Western views of the human condition. That they can be put in words reminiscent of the Bible indicates that the representation of man in Western literature is indeed conditioned by biblical literature. (H.G.D./Ed.)

Old Testament canon, texts, and versions

THE CANON

The term canon, from a Hebrew-Greek word meaning a cane or measuring rod, passed into Christian usage as a norm or a rule of faith. The Church Fathers of the 4th century CE first employed it in reference to the definitive, authoritative nature of the body of sacred Scripture.

The Hebrew canon. The Hebrew Bible is often known among Jews as TaNaKh, an acronym derived from the names of its three divisions: Torah (Instruction, or Law, also called the Pentateuch), Nevi'im (Prophets), and Ketuvim (Writings).

Divisions of the Hebrew Bible

The Torah contains five books: Genesis, Exodus, Leviticus, Numbers, and Deuteronomy. The Nevi'im comprise eight books subdivided into the Former Prophets, containing the four historical works, Joshua, Judges, Samuel, and Kings, and the Latter Prophets, the oracular discourses of Isaiah, Jeremiah, Ezekiel, and the Twelve (Minor—*i.e.,* smaller) Prophets—Hosea, Joel, Amos, Obadiah, Jonah, Micah, Nahum, Habakkuk, Zephaniah, Haggai, Zechariah, and Malachi. The Twelve were all formerly written on a single scroll and thus reckoned as one book. The Ketuvim consist of religious poetry and wisdom literature—Psalms, Proverbs, and Job, a collection known as the "Five Megillot" ("scrolls"; *i.e.,* Song of Songs, Ruth, Lamentations, Ecclesiastes, and Esther, which have been grouped together according to the annual cycle of their public reading in the synagogue)—and the books of Daniel, Ezra and Nehemiah, and Chronicles.

The number of books. The number of books in the Hebrew canon is thus 24, referring to the sum of the separate scrolls on which these works were traditionally written in ancient times. This figure is first cited in II Esdras in a passage usually dated *c.* 100 CE and is frequently mentioned in rabbinic (postbiblical) literature, but no authentic tradition exists to explain it. Josephus, a 1st century CE Jewish historian, and some of the Church Fathers, such as Origen (the great 3rd-century Alexandrian theologian), appear to have had a 22-book canon.

English Bibles list 39 books for the Old Testament because of the practice of bisecting Samuel, Kings, and Chronicles, and of counting Ezra, Nehemiah, and the 12 Minor Prophets as separate books.

The tripartite canon. The threefold nature of the Hebrew Bible (the Law, the Prophets, and the Writings) is reflected in the literature of the period of the Second Temple (6th–1st centuries BCE) and soon after it. The earliest reference is that of the Jewish wisdom writer Ben Sira (flourished 180–175 BCE), who speaks of "the law of the Most High . . . the wisdom of all the ancients and . . . prophecies." His grandson (*c.* 132 BCE) in the prologue to Ben Sira's work mentions "the law and the prophets and the others that followed them," the latter also called "the other books of our fathers." The same tripartite division finds expression in II Maccabees, the writings of Philo, a Hellenistic Jewish philosopher, and Josephus, a Hellenistic Jewish historian, as well as in the Gospel According to Luke. The tripartite canon represents the three historic stages in the growth of the canon.

The history of canonization. Because no explicit or reliable traditions concerning the criteria of canonicity, the canonizing authorities, the periods in which they lived, or the procedure adopted have been preserved, no more than a plausible reconstruction of the successive stages involved can be provided. First, it must be observed that sanctity and canonization are not synonymous terms. The first condition must have existed before the second could have been formally conferred. Next, the collection and organization of a number of sacred texts into a canonized corpus (body of writings) is quite a different problem from that of the growth and formation of the individual books themselves.

Criteria of canonicity

No longer are there compelling reasons to assume that the history of the canon must have commenced very late in Israel's history, as was once accepted. The emergence in Mesopotamia, already in the second half of the 2nd millennium BCE, of a standardized body of literature arranged in a more or less fixed order and with some kind of official text, expresses the notion of a canon in its secular sense. Because Babylonian and Assyrian patterns frequently served as the models for imitation throughout the Near East, sacred documents in Israel may well have been carefully stored in temples and palaces, particularly if they were used in connection with the cult or studied in the priestly or wisdom schools. The injunction to deposit the two tables of the Decalogue (Ten Commandments) inside the ark of the covenant and the book of the Torah beside it and the chance find of a book of the Torah in the Temple in 622 BCE tend to confirm the existence of such a practice in Israel.

The Torah. The history of the canonization of the Torah as a book must be distinguished from the process by which the heterogeneous components of the literature as such developed and were accepted as sacred.

The Book of the Chronicles, composed *c.* 400 BCE, frequently refers to the "Torah of Moses" and exhibits a familiarity with all the five books of the Pentateuch. The earliest record of the reading of a "Torah book" is provided by the narrative describing the reformation instituted by King Josiah of Judah in 622 BCE following the fortuitous discovery of a "book of the Torah" during the renovation of the Temple. The reading of the book (probably Deuteronomy), followed by a national covenant ceremony, is generally interpreted as having constituted a formal act of canonization.

Between this date and 400 BCE the only other ceremony of Torah reading is that described in Nehemiah as having taken place on the autumnal New Year festival. The "book of the Torah of Moses" is mentioned and the emphasis is on its instruction and exposition. The Samaritans, the descendants of Israelites intermarried with foreigners in the old northern kingdom that fell in 722 BCE, became hostile to the Judaeans in the time of Ezra and Nehemiah (6th–5th centuries BCE). They would not likely have accepted the Torah, which they did, along with the tradition of its Mosaic origin, if it had only recently been canonized under the authority of their arch-enemies. The final redaction and canonization of the Torah book, therefore, most likely took place during the Babylonian Exile (6th–5th centuries BCE).

The Nevi'im. The model of the Pentateuch probably encouraged the assemblage and ordering of the literature of the prophets. The Exile of the Jews to Bablylonia in 587/586 and the restoration half a century later enhanced the prestige of the prophets as national figures and aroused interest in the written records of their teachings. The canonization of the Nevi'im could not have taken place before the Samaritan schism that occurred during the time of Ezra and Nehemiah, since nothing of the prophetical literature was known to the Samaritans. On the other hand, the prophetic canon must have been closed by the time the Greeks had displaced the Persians as the rulers of Palestine in the late 4th century BCE. The exclusion of Daniel would otherwise be inexplicable, as would also the omission of Chronicles and Ezra–Nehemiah, even though they supplement and continue the narrative of the Former Prophets. Furthermore, the books of the Latter Prophets contain no hint of the downfall of the Persian Empire and the rise of the Greeks, even though the succession of great powers in the East plays a major role in their theological interpretation of history. Their language, too, is entirely free of Grecisms.

Canonization of prophetic writings

These phenomena accord with the traditions of Josephus and rabbinic sources limiting the activities of the literary prophets to the Persian era.

The Ketuvim. That the formation of the Ketuvim as a corpus was not completed until a very late date is ev-

idenced by the absence of a fixed name, or indeed any real name, for the third division of Scripture. Ben Sira refers to "the other books of our fathers," "the rest of the books"; Philo speaks simply of "other writings" and Josephus of "the remaining books." A widespread practice of entitling the entire Scriptures "the Torah and the Prophets" indicates a considerable hiatus between the canonization of the Prophets and the Ketuvim. Greek words are to be found in the Song of Songs and in Daniel, which also refers to the disintegration of the Greek Empire. Ben Sira omits mention of Daniel and Esther. No fragments of Esther have turned up among the biblical scrolls (*e.g.*, the Dead Sea Scrolls) from the Judaean Desert. Rabbinic sources betray some hesitation about Esther and a decided ambivalence about the book of Ben Sira. A third generation Babylonian *amora* (rabbinical interpretive scholar; pl. *amoraim*) actually cites it as "Ketuvim," as opposed to Torah and Prophets, and in the mid-2nd century CE, the need to deny its canonicity and prohibit its reading was still felt. Differences of opinion also are recorded among the *tannaim* (rabbinical scholars of tradition who compiled the Mishna, or Oral Law) and *amoraim* (who created the Talmud, or Gemara) about the canonical status of Proverbs, Song of Songs, Ecclesiastes, and Esther.

All this indicates a prolonged state of fluidity in respect of the canonization of the Ketuvim. A synod at Jabneh (*c.* 100 CE) seems to have ruled on the matter, but it took a generation or two before their decisions came to be unanimously accepted and the Ketuvim regarded as being definitively closed. The destruction of the Jewish state in 70 CE, the breakdown of central authority, and the ever widening Diaspora (collectively, Jews dispersed to foreign lands) all contributed to the urgent necessity of providing a closed and authoritative corpus of sacred Scriptures.

The Samaritan canon. As has been mentioned, the Samaritans accepted the Pentateuch from the Jews. They know of no other section of the Bible, however, and did not expand their Pentateuchal canon even by the inclusion of any strictly Samaritan compositions.

The Alexandrian canon. The Old Testament as it has come down in Greek translation from the Jews of Alexandria via the Christian Church differs in many respects from the Hebrew Scriptures. The books of the second and third divisions have been redistributed and arranged according to categories of literature—history, poetry, wisdom, and prophecy. Esther and Daniel contain supplementary materials, and many noncanonical books, whether of Hebrew or Greek origin, have been interspersed with the canonical works. These extracanonical writings comprise I Esdras, the Wisdom of Solomon, Ecclesiasticus (Ben Sira), Additions to Esther, Judith, Tobit, Baruch, the Epistle of Jeremiah, and additions to Daniel, as listed in the manuscript known as Codex Vaticanus (*c.* 350 CE). The sequence of the books varies, however, in the manuscripts and in the patristic and synodic lists of the Eastern and Western churches, some of which include other books as well, such as I and II Maccabees.

It should be noted that the contents and form of the inferred original Alexandrian Jewish canon cannot be ascertained with certainty because all extant Greek Bibles are of Christian origin. The Jews of Alexandria may themselves have extended the canon they received from Palestine, or they may have inherited their traditions from Palestinian circles in which the additional books had already been regarded as canonical. It is equally possible that the additions to the Hebrew Scriptures in the Greek Bible are of Christian origin.

The canon at Qumrān. In the collection of manuscripts from the Judaean Desert—discovered from the 1940s on—there are no lists of canonical works and no codices (manuscript volumes), only individual scrolls. For these reasons nothing can be known with certainty about the contents and sequence of the canon of the Qumrān sectarians. Since fragments of all the books of the Hebrew Bible (except Esther) have been found, it may be assumed that this reflects the minimum extent of its canon. The situation is complicated by the presence in Qumrān of extracanonical works—some already known from the Apocrypha (so-called hidden books not accepted as canonical by Judaism and the church) and pseudepigrapha (books falsely ascribed to biblical authors) or from the Cairo Geniza (synagogue storeroom), and others entirely new. Some or all of these additional works may have been considered canonical by the members of the sect. It is significant, however, that so far *pesharim* (interpretations) have been found only on books of the traditional Hebrew canon. Still, the great Psalms scroll departs from the received Hebrew text in both sequence and contents. If the Psalms scroll were a canonical Psalter and not a liturgy, then evidence would indeed be forthcoming for the existence of a rival canon at Qumrān.

Canonical and extracanonical writings

The Christian canon. The Christian Church received its Bible from Greek-speaking Jews and found the majority of its early converts in the Hellenistic world. The Greek Bible of Alexandria thus became the official Bible of the Christian community, and the overwhelming number of quotations from the Hebrew Scriptures in the New Testament are derived from it. Whatever the origin of the Apocryphal books in the canon of Alexandria, these became part of the Christian Scriptures, but there seems to have been no unanimity as to their exact canonical status. The New Testament itself does not cite the Apocryphal books directly, but occasional traces of a knowledge of them are to be found. The Apostolic Fathers (late 1st–early 2nd centuries) show extensive familiarity with this literature, but a list of the Old Testament books by Melito, bishop of Sardis in Asia Minor (2nd century), does not include the additional writings of the Greek Bible, and Origen (*c.* 185–*c.* 254) explicitly describes the Old Testament canon as comprising only 22 books.

From the time of Origen on, the Church Fathers who were familiar with Hebrew differentiated, theoretically at least, the Apocryphal books from those of the Old Testament, though they used them freely. In the Syrian East, until the 7th century the Church had only the books of the Hebrew canon with the addition of Ecclesiasticus, or the Wisdom of Jesus the son of Sira (but without Chronicles, Ezra, and Nehemiah). It also incorporated the Wisdom of Solomon, Baruch, the Letter of Jeremiah, and the additions to Daniel. The 6th-century manuscript of the Peshitta (Syriac version) known as Codex Ambrosianus also has III and IV Maccabees, II (sometimes IV) Esdras, and Josephus' *Wars* VII.

Early councils of the African Church held at Hippo (393) and Carthage (397, 419) affirmed the use of the Apocryphal books as Scripture. In the 4th century also, Athanasius, chief theologian of Christian orthodoxy, differentiated "canonical books" from both "those that are read" by Christians only and the "Apocryphal books" rejected alike by Jews and Christians. In the preparation of a standard Latin version, the biblical scholar Jerome (*c.* 347–419/420) separated "canonical books" from "ecclesiastical books" (*i.e.*, the Apocryphal writings), which he regarded as good for spiritual edification but not authoritative Scripture. A contrary view of Augustine (354–430), one of the greatest Western theologians, prevailed, however, and the works remained in the Latin Vulgate version. The *Decretum Gelasianum*, a Latin document of uncertain authorship but recognized as reflecting the views of the Roman Church at the beginning of the 6th century, includes Tobit, Judith, the Wisdom of Solomon, Ecclesiasticus, and I and II Maccabees as biblical.

Use of Apocryphal works in the Middle Ages

Throughout the Middle Ages, the Apocryphal books were generally regarded as Holy Scripture in the Roman and Greek churches, although theoretical doubts were raised from time to time. Thus, in 1333 Nicholas of Lyra, a French Franciscan theologian, had discussed the differences between the Latin Vulgate and the "Hebrew truth." Christian-Jewish polemics, the increasing attention to Hebrew studies, and, finally, the Reformation kept the issue of the Christian canon alive. Protestants denied canonical status to all books not in the Hebrew Bible. The first modern vernacular Bible to segregate the disputed writings was a Dutch version by Jacob van Liesveldt (Antwerp, 1526). Luther's German edition of 1534 did the same thing and entitled them "Apocrypha" for the first time, noting that while they were not in equal esteem with sacred Scriptures they were edifying.

In response to Protestant views, the Roman Catholic Church made its position clear at the Council of Trent (1546) when it dogmatically affirmed that the entire Latin Vulgate enjoyed equal canonical status. This doctrine was confirmed by the Vatican Council of 1870. In the Greek Church, the Synod of Jerusalem (1672) had expressly designated as canonical several Apocryphal works. In the 19th century, however, Russian Orthodox theologians agreed to exclude these works from the Holy Scriptures.

The history of the Old Testament canon in the English Church has generally reflected a more restrictive viewpoint. Even though the Wycliffite Bible (14th century) included the Apocrypha, its preface made it clear that it accepted Jerome's judgment. The translation made by the English bishop Miles Coverdale (1535) was the first English version to segregate these books, but it did place Baruch after Jeremiah. Article VI of the Thirty-nine Articles of religion of the Church of England (1562) explicitly denied their value for the establishment of doctrine, although it admitted that they should be read for their didactic worth. The first Bible in English to exclude the Apocrypha was the Geneva Bible of 1599. The King James Version of 1611 placed it between the Old and New Testaments. In 1615 Archbishop George Abbot forbade the issuance of Bibles without the Apocrypha, but editions of the King James Version from 1630 on often omitted it from the bound copies. The Geneva Bible edition of 1640 was probably the first to be intentionally printed in England without the Apocrypha, followed in 1642 by the King James Version. In 1644 the Long Parliament actually forbade the public reading of these books, and three years later the Westminster Confession of the Presbyterians decreed them to be no part of the canon. The British and Foreign Bible Society in 1827 resolved never to print or circulate copies containing the Apocrypha. Most English Protestant Bibles in the 20th century have omitted the disputed books or have them as a separate volume, except in library editions, in which they are included with the Old and New Testaments.

TEXTS AND VERSIONS

Textual criticism: manuscript problems. The text of the Hebrew printed Bible consists of consonants, vowel signs, and cantillation (musical or tonal) marks. The two latter components are the product of the school of Masoretes (Traditionalists) that flourished in Tiberias (in Palestine) between the 7th and 9th centuries CE. The history of the bare consonantal text stretches back into hoary antiquity and can be only partially traced.

Masoretic signs and marks

The earliest printed editions of the Hebrew Bible derive from the last quarter of the 15th century and the first quarter of the 16th century. The oldest Masoretic codices stem from the end of the 9th century and the beginning of the 10th. A comparison of the two shows that no textual developments took place during the intervening 600 years. A single standardized recension enjoyed an absolute monopoly and was transmitted by the scribes with amazing fidelity. Not one of the medieval Hebrew manuscripts and none of the thousands of fragments preserved in the Cairo Geniza (synagogue storeroom) contains departures of any real significance from the received text.

This situation, however, was a relatively late development; there is much evidence for the existence of a period when more than one Hebrew text-form of a given book was current. In fact, both the variety of witnesses and the degree of textual divergence between them increase in proportion to their antiquity.

No single explanation can satisfactorily account for this phenomenon. In the case of some biblical literature, there exists the real possibility, though it cannot be proven, that it must have endured a long period of oral transmission before its committal to writing. In the interval, the material might well have undergone abridgement, amplification, and alteration at the hands of transmitters so that not only would the original have been transformed, but the process of transmission would have engendered more than one recension from the very beginning of its written, literary career.

The problem is complicated further by the great difference in time between the autograph (original writing) of a biblical work, even when it assumed written form from its inception, and its oldest extant exemplars. In some instances, this may amount to well over a thousand years of scribal activity. Whatever the interval, the possibility of inadvertent and deliberate change, something that affects all manuscript copying, was always present.

The evidence that such, indeed, took place is rich and varied. First there are numerous divergences between the many passages duplicated within the Hebrew Bible itself—*e.g.*, the parallels between Samuel–Kings and Chronicles. Then there are the citations of the Old Testament to be found in the books of the Apocrypha and apocalyptic literature (works describing the intervention of God in history in cryptic terms), in the works of Philo and Josephus, in the New Testament, and in rabbinic and patristic (early Church Fathers) literature. There are also rabbinic traditions about the text-critical activities of the scribes (*soferim*) in Second Temple times. These tell of divergent readings in Temple scrolls of the Pentateuch, of official "book correctors" in Jerusalem, of textual emendations on the part of scribes, and of the utilization of sigla (signs or abbreviations) for marking suspect readings and disarranged verses. The Samaritan Pentateuch and the pre-Masoretic versions of the Old Testament made directly from Hebrew originals are all replete with divergences from current Masoretic Bibles. Finally, the scrolls from the Judaean Desert, especially those from the caves of Qumrān, have provided, at least, illustrations of many of the scribal processes by which deviant texts came into being. The variants and their respective causes may be classified as follows: aurally conditioned, visual in origin, exegetical, and deliberate.

Types and causes of variants

Problems resulting from aural conditioning. Aural conditioning would result from a mishearing of similar sounding consonants when a text is dictated to the copyist. A negative particle *lo'*, for example, could be confused with the prepositional *lo,* "to him," or a guttural *het* with spirant *kaf* so that *aḥ* "brother" might be written for *akh* "surely."

Problems visual in origin. The confusion of graphically similar letters, whether in the paleo-Hebrew or Aramaic script, is another cause for variations. Thus, the prepositions *bet* ("in") and *kaf* ("like") are interchanged in the Masoretic and Dead Sea Scroll texts of Isaiah.

The order of letters also might be inverted. Such metathesis, as it is called, appears in Psalms, in which *qirbam* ("their inward thoughts") stands for *qibram* ("their grave").

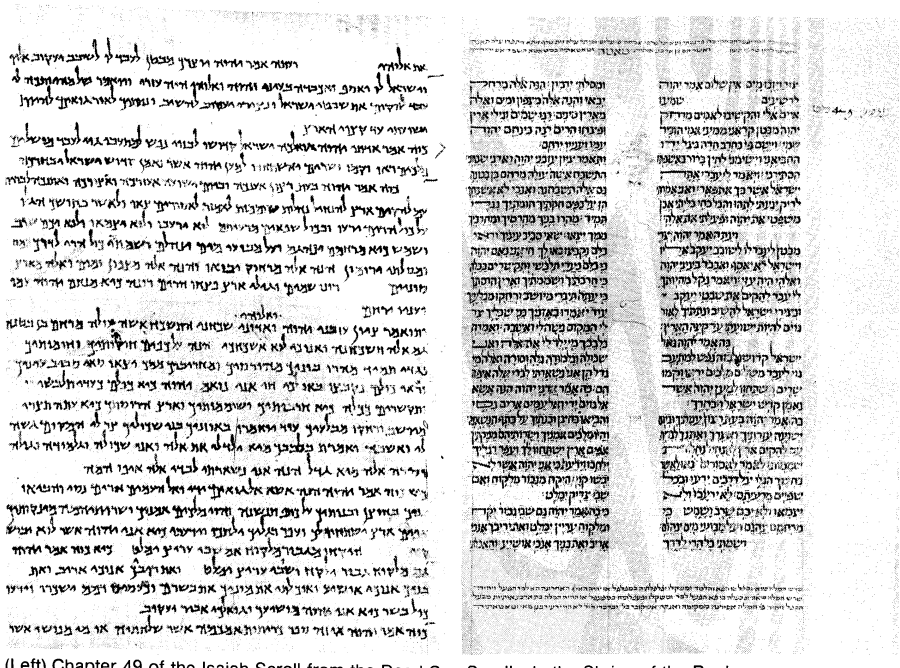
Dittography, or the inadvertent duplication of one or more letters or words, also occurs, as, for example, in the Dead Sea Scroll text of Isaiah and in the Masoretic text of Ezekiel.

Haplography, or the accidental omission of a letter or word that occurs twice in close proximity, can be found, for example, in the Dead Sea Scroll text of Isaiah.

Homoeoteleuton occurs when two separate phrases or lines have identical endings and the copyist's eye slips from one to the other and omits the intervening words. A comparison of the Masoretic text I Samuel, chapter 14 verse 41, with the Septuagint and the Vulgate versions clearly identifies such an aberration.

Exegetical problems. This third category does not involve any consonantal alteration but results solely from the different possibilities inherent in the consonantal spelling. Thus, the lack of vowel signs may permit the word *DBR* to be read as a verb *DiBeR* ("he spoke," as in the Masoretic text of Hosea) or as a noun *DeBaR* ("the word of," as in the Septuagint). The absence of word dividers could lead to different divisions of the consonants. Thus, *BBQRYM* in Amos could be understood as either *BaBeQaRYM* ("with oxen," as in the Masoretic text) or as *BaBaQaR YaM* ("the sea with an ox"). The incorrect solution by later copyists of abbreviations is another source of error. That such occurred is proved by a comparison of the Hebrew text with the Septuagint version in, for example, II Samuel, chapter 1 verse 12; Ezekiel, chapter 12 verse 23; and Amos, chapter 3 verse 9.

Deliberate changes. Apart from mechanical alterations of a text, many variants must have been consciously in-



(Left) Chapter 49 of the Isaiah Scroll from the Dead Sea Scrolls. In the Shrine of the Book, D. Samuel and Jeane H. Gottesman Centre for Biblical Manuscripts, the Israel Museum, Jerusalem. (Right) Hebrew Masoretic text of chapter 49 from the Book of Isaiah, 1341. In the Jewish National and University Library, Jerusalem.

troduced by scribes, some by way of glossing—*i.e.,* the insertion of a more common word to explain a rare one—and others by explanatory comments incorporated into the text. Furthermore, a scribe who had before him two manuscripts of a single work containing variant readings, and unable to decide between them, might incorporate both readings into his scroll and thus create a conflate text.

Textual criticism: scholarly problems. The situation so far described poses two major scholarly problems. The first involves the history of the Hebrew text, the second deals with attempts to reconstruct its "original" form.

As to when and how a single text type gained hegemony and then displaced all others, it is clear that the early and widespread public reading of the Scriptures in the synagogues of Palestine, Alexandria, and Babylon was bound to lead to a heightened sensitivity of the idea of a "correct" text and to give prestige to the particular text form selected for reading. Also, the natural conservatism of ritual would tend to perpetuate the form of such a text. The *Letter of Aristeas,* a document derived from the middle of the 2nd century BCE that describes the origin of the Septuagint, recognizes the distinction between carelessly copied scrolls of the Pentateuch and an authoritative Temple scroll in the hands of the high priest in Jerusalem. The Rabbinic traditions (see above) about the textual criticism of Temple-based scribes actually reflect a movement towards the final stabilization of the text in the Second Temple period. Josephus, writing not long after 70 CE, boasts of the existence of a long-standing fixed text of the Jewish Scriptures. The loss of national independence and the destruction of the spiritual centre of Jewry in 70, accompanied by an ever-widening Diaspora and the Christian schism within Judaism, all made the exclusive dissemination of a single authoritative text a vitally needed cohesive force. The text type later known as Masoretic is already well represented at pre-Christian Qumrān. Scrolls from Wādī al-Murabba'at, Naḥal Ze'elim, and Masada from the 2nd century CE are practically identical with the received text that by then had gained victory over all its rivals.

Reconstruction of an original text

In regard to an attempt to recover the original text of a biblical passage—especially an unintelligible one—in the light of variants among different versions and manuscripts and known causes of corruption, it should be understood that all reconstruction must necessarily be conjectural and perforce tentative because of the irretrievable loss of the original edition. But not all textual difficulties need presuppose underlying mutilation. The Hebrew Bible represents but a small portion of the literature of ancient Israel and, hence, a limited segment of the language. A textual problem may be the product of present limited knowledge of ancient Hebrew, because scholars might be dealing with dialectic phenomena or foreign loan-words. Comparative Semitic linguistic studies have yielded hitherto unrecognized features of grammar, syntax, and lexicography that have often eliminated the need for emendation. Furthermore, each version, indeed each biblical book within it, has its own history, and the translation techniques and stylistic characteristics must be examined and taken into account. Finally, the number of manuscripts that attest to a certain reading is of less importance than the weight given to a specific manuscript.

None of this means that a Hebrew manuscript, an ancient version, or a conjectural emendation cannot yield a reading superior to that in the received Hebrew text. It does mean, however, that these tools have to be employed with great caution and proper methodology.

Texts and manuscripts. *Sources of the Septuagint.* A Greek translation of the Old Testament, known as the Septuagint because there allegedly were 70 or 72 translators, six from each of the 12 tribes of Israel, and designated LXX, is a composite of the work of many translators labouring for well over 100 years. It was made directly from Hebrew originals that frequently differed considerably from the present Masoretic text. Apart from other limitations attendant upon the use of a translation for such purposes, the identification of the parent text used by the Greek translators is still an unsettled question. The Pentateuch of the Septuagint manifests a basic coincidence with the Masoretic text. The Qumrān scrolls have now proven that the Septuagint book of Samuel–Kings goes back to an old Palestinian text tradition that must be earlier than the 4th century BCE, and from the same source comes a short Hebrew recension of Jeremiah that probably underlies the Greek.

The Samaritan Pentateuch. The importance of the recension known as the Samaritan Pentateuch lies in the fact that it constitutes an independent Hebrew witness to the text written in a late and developed form of the paleo-Hebrew script. Some of the Exodus fragments from Qumrān demonstrate that it has close affinities with a pre-Christian Palestinian text type and testify to the faithfulness with which it has been preserved. It contains about

6,000 variants from the Masoretic text, of which nearly a third agree with the Septuagint. Only a minority, however, are genuine variants, most being dogmatic, exegetical, grammatical, or merely orthographic in character.

The Samaritan Pentateuch first became known in the West through a manuscript secured in Damascus in 1616 by Pietro della Valle, an Italian traveler. It was published in the Paris (1628–45) and London Polyglots (1654–57), written in several languages in comparative columns. Many manuscripts of the Samaritan Pentateuch are now available. The Avisha' Scroll, the sacred copy of the Samaritans, has recently been photographed and critically examined. Only Numbers chapter 35 to Deuteronomy chapter 34 appears to be very old, the rest stemming from the 14th century. A new, definitive edition of the Samaritan Pentateuch is being prepared in Madrid by F. Pérez Castro.

The Qumrān texts and other scrolls. Until the discovery of the Judaean Desert scrolls, the only pre-medieval fragment of the Hebrew Bible known to scholars was the Nash Papyrus (*c.* 150 BCE) from Egypt containing the Decalogue and Deuteronomy. Now, however, fragments of about 180 different manuscripts of biblical books are available. Their dates vary between the 3rd century BCE and the 2nd century CE, and all but 10 stem from the caves of Qumrān. All are written on either leather or papyrus in columns and on one side only.

Textual significance of the Qumrān scrolls

The most important manuscripts from what is now identified as Cave 1 of Qumrān are a practically complete Isaiah scroll (1QIsa[a]), dated *c.* 100–75 BCE, and another very fragmentary manuscript (1QIsa[b]) of the same book. The first contains many variants from the Masoretic text in both orthography and text; the second is very close to the Masoretic type and contains few genuine variants. The richest hoard comes from Cave 4 and includes fragments of five copies of Genesis, eight of Exodus, one of Leviticus, 14 of Deuteronomy, two of Joshua, three of Samuel, 12 of Isaiah, four of Jeremiah, eight of the Minor Prophets, one of Proverbs, and three of Daniel. Cave 11 yielded a Psalter containing the last third of the book in a form different from that of the Masoretic text, as well as a manuscript of Leviticus.

The importance of the Qumrān scrolls cannot be exaggerated. Their great antiquity brings them close to the Old Testament period itself—from as early as 250–200 BCE. For the first time, Hebrew variant texts are extant and all known major text types are present. Some are close to the Septuagint, others to the Samaritan. On the other hand, many of the scrolls are practically identical with the Masoretic text, which thus takes this recension back in history to pre-Christian times. Several texts in the paleo-Hebrew script show that this script continued to be used side by side with the Aramaic script for a long time.

Of quite a different order are scrolls from other areas of the Judaean Desert. All of these are practically identical with the received text. This applies to fragments of Leviticus, Deuteronomy, Ezekiel, and Psalms discovered at Masada (the Jewish fortress destroyed by the Romans in CE 73), as well as to the finds at Wādī al-Murabba'at, the latest date of which is CE 135. Here were found fragments of Genesis, Exodus, Leviticus, and Isaiah in addition to the substantially preserved Minor Prophets scroll. Variants from the Masoretic text are negligible. The same phenomenon characterizes the fragments of Numbers found at Naḥal Ḥever.

Masoretic texts. No biblical manuscripts have survived from the six centuries that separate the latest of the Judaean Desert scrolls from the earliest of the Masoretic period. A "Codex Mugah," frequently referred to as an authority in the early 10th century, and the "Codex Hilleli," said to have been written *c.* 600 by Rabbi Hillel ben Moses ben Hillel, have both vanished.

The earliest extant Hebrew Bible codex is the Cairo Prophets written and punctuated by Moses ben Asher in Tiberias (in Palestine) in 895. Next in age is the Leningrad Codex of the Latter Prophets dated to 916, which was not originally the work of Ben Asher, but its Babylonian pointing—*i.e.*, vowel signs used for pronunciation purposes—was brought into line with the Tiberian Masoretic system.

Production of the Aleppo Codex

The outstanding event in the history of that system was the production of the model so-called Aleppo Codex, now in Jerusalem. Written by Solomon ben Buya'a, it was corrected, punctuated, and furnished with a Masoretic apparatus by Aaron ben Moses ben Asher *c.* 930. Originally containing the entire Old Testament in about 380 folios, of which 294 are extant, the Aleppo Codex remains the only known true representative of Aaron ben Asher's text and the most important witness to that particular Masoretic tradition that achieved hegemony throughout Jewry.

Two other notable manuscripts based on Aaron's system are the manuscript designated as BM or. 4445, which contains most of the Pentateuch and which utilized a Masora (text tradition) *c.* 950, and the Leningrad complete Old Testament designated MSB 19a of 1008. Codex Reuchliana of the Prophets, written in 1105, now in Karlsruhe (Germany), represents the system of Moses ben David ben Naphtali, which was more faithful to that of Moses ben Asher.

Collations of the Masoretic materials. The earliest extant attempt at collating the differences between the Ben Asher and Ben Naphtali Masoretic traditions was made by Mishael ben Uzziel in his *Kitāb al-Ḥulaf* (before 1050). A vast amount of Masoretic information, drawn chiefly from Spanish manuscripts, is to be found in the text-critical commentary known as *Minhath Shai,* by Solomon Jedidiah Norzi, completed in 1626 and printed in the Mantua Bible of 1742. Benjamin Kennicott collected the variants of 615 manuscripts and 52 printed editions (2 vol., 1776–80, Oxford). Giovanni Bernado De Rossi published his additional collections of 731 manuscripts and 300 prints (4 vol., 1784–88, Parma), and C.D. Ginsburg did the same for 70 manuscripts, largely from the British Museum, and 17 early printed editions (3 vol. in 4, 1908–26, London).

Printed editions. Until 1488, only separate parts of the Hebrew Bible had been printed, all with rabbinic commentaries. The earliest was the Psalms (1477), followed by the Pentateuch (1482), the Prophets (1485/86), and the Hagiographa (1486/87), all printed in Italy.

The first edition of the entire Hebrew Bible was printed at Soncino (in Italy) in 1488 with punctuation and accents, but without any commentary. The second complete Bible was printed in Naples in 1491/93 and the third in Brescia in 1494. All these editions were the work of Jews. The first Christian production was a magnificent Complutensian Polyglot (under the direction of Cardinal Francisco Jiménez of Spain) in six volumes, four of which contained the Hebrew Bible and Greek and Latin translations together with the Aramaic rendering (Targum) of the Pentateuch that has been ascribed to Onkelos. Printed at Alcala (1514–17) and circulated about 1522, this Bible proved to be a turning point in the study of the Hebrew text in western Europe.

The first rabbinic Bible—*i.e.*, the Hebrew text furnished with full vowel points and accents, accompanied by the Aramaic Targums and the major medieval Jewish commentaries—was edited by Felix Pratensis and published by Daniel Bomberg (Venice, 1516/17). The second edition, edited by Jacob ben Hayyim ibn Adonijah and issued by Bomberg in four volumes (Venice, 1524/25), became the prototype of future Hebrew Bibles down to the 20th century. It contained a vast text-critical apparatus of Masoretic notes never since equalled in any edition. Unfortunately, Ben Hayyim had made use of late manuscripts and the text and notes are eclectic.

In London, Christian David Ginsburg, an emigrant Polish Jew and Christian convert, produced a critical edition of the complete Hebrew Bible (1894, 1908, 1926) revised according to the Masora and early prints with variant readings from manuscripts and ancient versions. It was soon displaced by the *Biblica Hebraica* (1906, 1912) by Rudolf Kittel and Paul Kahle, two German biblical scholars. The third edition of this work, completed by Albrecht Alt and Otto Eissfeldt (Stuttgart, 1937), finally abandoned Ben Hayyim's text, substituting that of the Leningrad Codex (B 19a). It has a dual critical apparatus with textual emendations separated from the manuscript and versional variants. Since 1957 variants from the so-called Judaean Desert scrolls have been included. In progress at the He-

brew University of Jerusalem in the early 1970s was the preparation of a new text of the entire Hebrew Bible based on the Aleppo Codex to include all its own Masoretic notes together with textual differences found in all pertinent sources. A sample edition of the Book of Isaiah appeared in 1965.

Early versions. *The Aramaic Targums.* In the course of the 5th and 6th centuries BCE, Aramaic became the official language of the Persian Empire. In the succeeding centuries it was used as the vernacular over a wide area and was increasingly spoken by the postexilic Jewish communities of Palestine and elsewhere in the Diaspora. In response to liturgical needs, the institution of a *turgeman* (or *meturgeman,* "translator"), arose in the synagogues. These men translated the Torah and prophetic lectionaries into Aramaic. The rendering remained for long solely an oral, impromptu exercise, but gradually, by dint of repetition, certain verbal forms and phrases became fixed and eventually committed to writing.

The Babylonian and Palestinian Targums

There are several Targums (translations) of the Pentateuch. The Babylonian Targum is known as "Onkelos," named after its reputed author. The Targum is Palestinian in origin, but it was early transferred to Babylon where it was revised and achieved great authority. At a later date, probably not before the 9th century CE, it was re-exported to Palestine to displace other, local, Targums. On the whole, Onkelos is quite literal, but it shows a tendency to obscure expressions attributing human form and feelings to God. It also usually faithfully reflects rabbinic exegesis.

The most famous of the Palestinian Targums is that popularly known as "Jonathan," a name derived from a 14th-century scribal mistake that solved a manuscript abbreviation "TJ" as "Targum Jonathan" instead of "Targum Jerusalem." In contrast with two other Targums, which are highly fragmentary (Jerusalem II and III), Pseudo-Jonathan (or Jerusalem I) is virtually complete. It is a composite of the Old Palestinian Targum and an early version of Onkelos with an admixture of material from diverse periods. It contains much rabbinic material as well as homiletic and didactic amplifications. There is evidence of great antiquity, but also much late material, indicating that Pseudo-Jonathan could not have received its present form before the Islāmic period.

Another extant Aramaic version is the Targum to the Samaritan Pentateuch. It is less literal than the Jewish Targums and its text was never officially fixed.

The Targum to the Prophets also originated in Palestine and received its final editing in Babylonia. It is ascribed to Jonathan ben Uzziel, a pupil of Hillel, the famous 1st century BCE–1st century CE rabbinic sage, though it is in fact a composite work of varying ages. In its present form it discloses a dependence on Onkelos, though it is less literal.

The Aramaic renderings of the Hagiographa are relatively late productions, none of them antedating the 5th century CE.

The Septuagint (LXX). The story of the Greek translation of the Pentateuch is told in the *Letter of Aristeas,* which purports to be a contemporary document written by Aristeas, a Greek official at the Egyptian court of Ptolemy II Philadelphus (285–246 BCE). It recounts how the law of the Jews was translated into Greek by Jewish scholars sent from Jerusalem at the request of the king.

This narrative, repeated in one form or another by Philo and rabbinic sources, is full of inaccuracies that prove that the author was an Alexandrian Jew writing well after the events he described had taken place. The Septuagint Pentateuch, which is all that is discussed, does, however, constitute an independent corpus within the Greek Bible, and it was probably first translated as a unit by a company of scholars in Alexandria about the middle of the 3rd century BCE.

Influence of the Septuagint

The Septuagint, as the entire Greek Bible came to be called, has a long and complex history and took well over a century to be completed. It is for this reason not a unified or consistent translation. The Septuagint became the instrument whereby the basic teachings of Judaism were mediated to the pagan world and it became an indispensable factor in the spread of Christianity.

The adoption of the Septuagint as the Bible of the Christians naturally engendered suspicion on the part of Jews. In addition, the emergence of a single authoritative text type after the destruction of the Temple made the great differences between it and the Septuagint increasingly intolerable, and the need for a Greek translation based upon the current Hebrew text in circulation was felt.

The version of Aquila. About 130 CE, Aquila, a convert to Judaism from Pontus in Asia Minor, translated the Hebrew Bible into Greek under the supervision of Rabbi Akiba. Executed with slavish literalness, it attempted to reproduce the most minute detail of the original, even to the extent of coining derivations from Greek roots to correspond to Hebrew usage. Little of it has survived, however, except in quotations, fragments of the Hexapla (see *Origen's Hexapla,* below), and palimpsests (parchments erased and used again) from the Cairo Geniza.

The revision of Theodotion. A second revision of the Greek text was made by Theodotion (of unknown origins) late in the 2nd century, though it is not entirely clear whether it was the Septuagint or some other Greek version that underlay his revision. The new rendering was characterized by a tendency toward verbal consistency and much transliteration of Hebrew words.

The translation of Symmachus. Still another Greek translation was made toward the end of the same century by Symmachus, an otherwise unknown scholar, who made use of his predecessors. His influence was small despite the superior elegance of his work. Jerome did utilize Symmachus for his Vulgate, but other than that, his translation is known largely through fragments of the Hexapla.

Purpose of the Hexapla

Origen's Hexapla. The multiplication of versions doubtless proved to be a source of increasing confusion in the 3rd century. This situation the Alexandrian theologian Origen, working at Caesarea between 230 and 240 CE, sought to remedy. In his Hexapla ("six-fold") he presented, in parallel vertical columns, the Hebrew text, the same in Greek letters, and the versions of Aquila, Symmachus, the Septuagint, and Theodotion, in that order. In the case of some books, Psalms for instance, three more columns were added. The Hexapla serves as an important guide to Palestinian pre-Masoretic pronunciation of the language. The main interest of Origen lay in the fifth column, the Septuagint, which he edited on the basis of the Hebrew. He used the obels (— or ÷) and asterisk (*) to mark respectively words found in the Greek text but not in the Hebrew and vice versa.

The Hexapla was a work of such magnitude that it is unlikely to have been copied as a whole. Origen himself produced an abbreviated edition, the Tetrapla, containing only the last four columns. The original manuscript of the Hexapla is known to have been extant as late as *c.* 600 CE. Today it survives only in fragments.

Manuscripts and printed editions of the Septuagint. The manuscripts are conveniently classified by papyri uncials (capital letters) and minuscules (cursive script). The papyri fragments run into the hundreds, of varying sizes and importance, ranging from the formative period of the Septuagint through the middle of the 7th century. Two pre-Christian fragments of Deuteronomy from Egypt are of outstanding significance. Although not written on papyrus but on parchment or leather, the fragments from Qumrān of Exodus, Leviticus, and Numbers, and the leather scroll of the Minor Prophets from Naḥal Ḥever from the first pre-Christian and post-Christian centuries, deserve special mention among the earliest extant. The most important papyri are those of the Chester Beatty collection, which contains parts of 11 codices preserving fragments of nine Old Testament books. Their dates vary between the 2nd and 4th centuries. During the next 300 years papyri texts multiplied rapidly, and remnants of about 200 are known.

Uncial and minuscule codices

The uncials are all codices written on vellum between the 4th and 10th centuries. The most outstanding are Vaticanus, which is an almost complete 4th-century Old Testament, Sinaiticus, of the same period but less complete, and the practically complete 5th-century Alexandrinus. These three originally contained both Testaments. Many others were partial manuscripts from the beginning. One of the most valuable of these is the Codex Marchalianus of the Prophets written in the 6th century.

The minuscule codices begin to appear in the 9th century. From the 11th to the 16th century they are the only ones found, and nearly 1,500 have been recorded.

The first printed Septuagint was that of the Complutensian Polyglot (1514–17). Since it was not released until 1522, however, the 1518 Aldine Venice edition actually was available first. The standard edition until modern times was that of Pope Sixtus V, 1587. In the 19th and 20th centuries several critical editions have been printed.

Coptic versions. The spread of Christianity among the non-Greek speaking peasant communities of Egypt necessitated the translation of the Scriptures into the native tongue (Coptic). These versions may be considered to be wholly Christian in origin and largely based on the Greek Bible. They also display certain affinities with the Old Latin. Nothing certain is known about the Coptic translations except that they probably antedate the earliest known manuscripts from the end of the 3rd and the beginning of the 4th centuries CE.

The Armenian version. The Armenian version is an expression of a nationalist movement that brought about a separation from the rest of the Church (mid-5th century), the discontinuance of Syriac in Greek worship, and the invention of a national alphabet by St. Mesrob, also called Mashtots (*c.* 361–439/440). According to tradition, St. Mesrob first translated Proverbs from the Syriac. Existing manuscripts of the official Armenian recension, however, are based on the Hexaplaric Septuagint, though they show some Peshitta (Syriac version) influence. The Armenian Bible is noted for its beauty and accuracy.

The Georgian version. According to Armenian tradition, the Georgian version was also the work of Mesrob, but the Psalter, the oldest part of the Georgian Old Testament, is probably not earlier than the 5th century. Some manuscripts were based upon Greek versions, others upon the Armenian.

The Ethiopic version. The Ethiopic version poses special problems. The earliest Bible probably was based on Greek versions, after Ethiopia had been converted to Christianity during the 4th and 5th centuries. The earliest existing manuscripts, however, belong to the 13th century. Most manuscripts from the 14th century on seem to reflect Arabic or Coptic influence, and it is not certain whether these represent the original translation or later ones. Many readings agree with the Hebrew against the Septuagint, which may have been caused by a Hexaplaric influence.

Special problems of the Ethiopic version

The Gothic version. The Gothic version was produced in the mid-4th century by Ulfilas, a Christian missionary who also invented the Gothic alphabet. It constitutes practically all that is left of Gothic literature. The translation of the Old Testament has entirely disappeared except for fragments of Ezra and Nehemiah. Though a Greek base is certain, some scholars deny the attribution of these remnants to Ulfilas.

The Old Latin version. The existence of a Latin translation can be attested in North Africa and southern Gaul as early as the second half of the 2nd century CE, and in Rome at the beginning of the following century. Its origins may possibly be attributed to a Christian adoption of biblical versions made by Jews in the Roman province of Africa, where the vernacular was exclusively Latin. Only portions or quotations from it, however, have been preserved, and from these it can be assumed that the translation was made not from Hebrew but from Greek. For this reason, the Old Latin version is especially valuable because it reflects the state of the Septuagint before Origen's revision. By the 3rd century, several Latin versions circulated, and African and European recensions can be differentiated. Whether they all diverged from an original single translation or existed from the beginning independently cannot be determined. The textual confusion and the vulgar and colloquial nature of the Old Latin recension had become intolerable to the church authorities by the last decade of the 4th century, and *c.* 382 Pope Damasus decided to remedy the situation.

The Vulgate. The task of revision fell to Eusebius Hieronymus, generally known as St. Jerome (died 419/420), whose knowledge of Latin, Greek, and Hebrew made him the outstanding Christian biblical scholar of his time.

Jerome produced three revisions of the Psalms, all extant. The first was based on the Septuagint and is known as the Roman Psalter because it was incorporated into the liturgy at Rome. The second, produced in Palestine from the Hexaplaric Septuagint, tended to bring the Latin closer to the Hebrew. Its popularity in Gaul was such that it came to be known as the Gallican Psalter. This version was later adopted into the Vulgate. The third revision, actually a fresh translation, was made directly from the Hebrew, but it never enjoyed wide circulation. In the course of preparing the latter, Jerome realized the futility of revising the Old Latin solely on the basis of the Greek and apparently left that task unfinished. By the end of 405 he had executed his own Latin translation of the entire Old Testament based on the "Hebrew truth" (*Hebraica veritas*).

Acceptance of the Vulgate within the Western Church

Because of the canonical status of the Greek version within the church, Jerome's version was received at first with much suspicion, for it seemed to cast doubt on the authenticity of the Septuagint and exhibited divergences from the Old Latin that sounded discordant to those familiar with the traditional renderings. Augustine feared a consequent split between the Greek and Latin churches. The innate superiority of Jerome's version, however, assured its ultimate victory, and by the 8th century it had become the Latin Vulgate ("the common version") throughout the churches of Western Christendom, where it remained the chief Bible until the Reformation.

In the course of centuries of rival coexistence, the Old Latin and Jerome's Vulgate tended to react upon each other so that the Vulgate text became a composite. Other corruptions—noted in over 8,000 surviving manuscripts—crept in as a result of scribal transmission. Several medieval attempts were made to purify the Vulgate, but with little success. In 1546 the reforming Council of Trent accorded this version "authentic" status, and the need for a corrected text became immediate, especially because printing (introduced in the mid-15th century) could ensure, at last, a stabilized text. Because the Sixtine edition of Pope Sixtus V (1590) did not receive widespread support, Pope Clement VIII produced a fresh revision in 1592. This Clementine text remained the official edition of the Roman Church. Since 1907, the Benedictine Order, on the initiative of Pope Pius X, has been preparing a comprehensive edition. By 1969 only the Prophets still awaited publication to complete the Old Testament. A year later, a papal commission under Cardinal Augustinus Bea of Germany was charged with the task of preparing a new "revision of the Vulgate," taking the Benedictine edition as its working base.

Syriac versions. The Bible of the Syriac Churches is known as the Peshitta ("simple" translation). Though neither the reason for the title nor the origins of the versions are known, the earliest translations most likely served the needs of the Jewish communities in the region of Adiabene (in Mesopotamia), which are known to have existed as early as the 1st century CE. This probably explains the archaic stratum unquestionably present in the Pentateuch, Prophets, and Psalms of the Peshitta, as well as the undoubtedly Jewish influences generally, though Jewish-Christians also may have been involved in the rendering.

The Peshitta displays great variety in its style and in the translation techniques adopted. The Pentateuch is closest to the Masoretic text, but elsewhere there is much affinity with the Septuagint. This latter phenomenon might have resulted from later Christian revision.

Following the split in the Syriac Church in the 5th century into Nestorian (East Syrian) and Jacobite (West Syrian) traditions, the textual history of the Peshitta became bifurcated. Because the Nestorian Church was relatively isolated, its manuscripts are considered to be superior.

A revision of the Syriac translation was made in the early 6th century by Philoxenos, bishop of Mabbug, based on the Lucianic recension of the Septuagint. Another (the Syro-Hexaplaric version) was made by Bishop Paul of Tella in 617 from the Hexaplaric text of the Septuagint. A Palestinian Syriac version, extant in fragments, is known to go back to at least 700, and a fresh recension was made by Jacob of Edessa (died 708).

There are many manuscripts of the Peshitta, of which the oldest bears the date 442. Only four complete codices are extant from between the 5th and 12th centuries. No critical edition yet exists, but one is being prepared by the Peshitta Commission of the International Organization for the Study of the Old Testament.

Arabic versions. There is no reliable evidence of any pre-Islāmic Arabic translation. Only when large Jewish and Christian communities found themselves under Muslim rule after the Arab conquests of the 7th century did the need for an Arabic vernacular Scripture arise. The first and most important was that of Sa'adia ben Joseph (892–942), made directly from Hebrew and written in Hebrew script, which became the standard version for all Jews in Muslim countries. The version also exercised its influence upon Egyptian Christians and its rendering of the Pentateuch was adapted by Abū al-Ḥasan to the Samaritan Torah in the 11th–12th centuries. Another Samaritan Arabic version of the Pentateuch was made by Abū Sa'īd (Abū al-Barakāt) in the 13th century. Among other translations from the Hebrew, that of the 10th-century Karaite Yāphith ibn 'Alī is the most noteworthy.

Influence of Arabic versions

In 946 a Spanish Christian of Córdova, Isaac son of Velásquez, made a version of the Gospels from Latin. Manuscripts of 16th-century Arabic translations of both testaments exist in Leningrad, and both the Paris and London polyglots of the 17th century included Arabic versions. In general, the Arabic manuscripts reveal a bewildering variety of renderings dependent on Hebrew, Greek, Samaritan, Syriac, Coptic, and Latin translations. As such they have no value for critical studies. Several modern Arabic translations by both Protestants and Catholics were made in the 19th and 20th centuries.

Later and modern versions: English. Knowledge of the pre-Wycliffite English renditions stems from the many actual manuscripts that have survived and from secondary literature, such as booklists, wills, citations by later authors, and references in polemical works that have preserved the memory of many a translation effort.

Anglo-Saxon versions. For about seven centuries after the conversion of England to Christianity (beginning in the 3rd century), the common man had no direct access to the text of the Scriptures. Ignorant of Latin, his knowledge was derived principally from sermons and metrical prose paraphrases and summaries. The earliest poetic rendering of any part of the Bible is credited to Caedmon (flourished 658–680), but only the opening lines of his poem on the Creation in the Northumbrian dialect have been preserved.

An actual translation of the Psalter into Anglo-Saxon is ascribed to Aldhelm, bishop of Sherborne (died 709), but nothing has survived by which its true character, if it actually existed, might be determined. Linguistic considerations alone rule out the possibility that the prose translation of Psalms 1–50 extant in the Bibliothèque Nationale at Paris is a 7th-century production. In the next century, Bede (died 735) is said to have translated parts of the Gospels, and, though he knew Greek and possibly even some Hebrew, he does not appear to have applied himself to the Old Testament.

The outstanding name of the 9th century is that of King Alfred the Great. He appended to his laws a free translation of the Ten Commandments and an abridgment of the enactments of Exodus 21–23. These actually constitute the earliest surviving examples of a portion of the Old Testament in Anglo-Saxon prose.

An important step towards the emergence of a true English translation was the development of the interlinear gloss, a valuable pedagogic device for the introduction of youthful members of monastic schools to the study of the Bible. The Vespasian Psalter is the outstanding surviving example of the technique from the 9th century. In the next century the Lindisfarne Gospels, written in Latin *c.* 700, were glossed in Anglo-Saxon *c.* 950.

The last significant figure associated with the vernacular

Bible before the Norman Conquest was the so-called Aelfric the Grammarian (*c.* 955–1020). Though he claimed to have rendered several books into English, his work is more a paraphrase and abridgment than a continuous translation.

Anglo-Norman versions. The displacement of the English upper class, with the consequent decline of the Anglo-Saxon tradition attendant upon the Norman invasion, arrested for a while the movement toward the production of the English Bible. Within about 50 years (*c.* 1120) of the Conquest, Eadwine's *Psalterium triplex,* which contained the Latin version accompanied by Anglo-Norman and Anglo-Saxon renderings, appeared. The contemporary Oxford Psalter achieved such influence that it became the basis of all subsequent Anglo-Norman versions. By 1361 a prose translation of most of Scripture in this dialect had been executed.

The Wycliffite versions. By the middle of the 13th century the English component in the Anglo-Norman amalgam had begun to assert itself and the close of the century witnessed a Northumbrian version of the Psalter made directly from Latin, which, because it survived in several manuscripts, must have achieved relatively wide circulation. By the next century, English had gradually superseded French among the upper classes. When the first complete translation of the Bible into English emerged, it became the object of violent controversy because it was inspired by the heretical teachings of John Wycliffe. Intended for the common man, it became the instrument of opposition to ecclesiastical authority.

Effect of the Wycliffite Bible

The exact degree of Wycliffe's personal involvement in the Scriptures that came to bear his name is not clear. Because a note containing the words "Here ends the translation of Nicholas of Hereford" is found in a manuscript copy of the original (and incomplete) translation, it may be presumed that, though there must have been other assistants, Hereford can be credited with overall responsibility for most of the translation and that his summons before a synod in London and his subsequent departure for Rome in 1382 terminated his participation in the work. Who completed it is uncertain.

The Wycliffite translations encountered increasing ecclesiastical opposition. In 1408 a synod of clergy summoned to Oxford by Archbishop Arundel forbade the translation and use of Scripture in the vernacular. The proscription was rigorously enforced, but remained ineffectual. In the course of the next century the Wycliffite Bible, the only existing English version, achieved wide popularity as is evidenced by the nearly 200 manuscripts extant, most of them copied between 1420 and 1450.

The translation of William Tyndale. Because of the influence of printing and a demand for scriptures in the vernacular, William Tyndale began working on a New Testament translation directly from the Greek in 1523. The work could not be continued in England because of political and ecclesiastical pressures, and the printing of his translation began in Cologne (in Germany) in 1525. Again under pressure, this time from the city authorities, Tyndale had to flee to Worms, where two complete editions were published in 1525. Copies were smuggled into England where they were at once proscribed. Of 18,000 copies printed (1525–28), two complete volumes and a fragment are all that remain.

When the New Testament was finished Tyndale began work on the Old Testament. The Pentateuch was issued in Marburg in 1530, each of the five books being separately published and circulated. Tyndale's greatest achievement was the ability to strike a felicitous balance between the needs of scholarship, simplicity of expression, and literary gracefulness, all in a uniform dialect. The effect was the creation of an English style of Bible translation, tinged with Hebraisms, that was to serve as the model for all future English versions for nearly 400 years.

Influence of Tyndale's Bible

The translation of Miles Coverdale. A change in atmosphere in England found expression in a translation that, for all its great significance, turned out to be a retrograde step in the manner of its execution, although it proved to be a vindication of Tyndale's work. On October 4, 1535, the first complete English Bible, the work of Miles Coverdale, came off the press either in Zürich or in Cologne. The edition was soon exhausted. A second impression appeared in the same year and a third in 1536. A new edition, "overseen and corrected," was published in England by James Nycholson in Southwark in 1537. Another edition of the same year bore the announcement, "set forth with the king's most gracious license." In 1538 a revised edition of Coverdale's New Testament printed with the Latin Vulgate in parallel columns issued in England was so full of errors that Coverdale promptly arranged for a rival corrected version to appear in Paris.

The Thomas Matthew version. In the same year that Coverdale's authorized version appeared, another English Bible was issued under royal license and with the encouragement of ecclesiastical and political power. It appeared (Antwerp?) under the name of Thomas Matthew, but it is certainly the work of John Rogers, a close friend of Tyndale. Although the version claimed to be "truly and purely translated into English," it was in reality a combination of the labours of Tyndale and Coverdale. Rogers used the former's Pentateuch and 1535 revision of the New Testament and the latter's translation from Ezra to Malachi and his Apocrypha. Rogers' own contribution was primarily editorial.

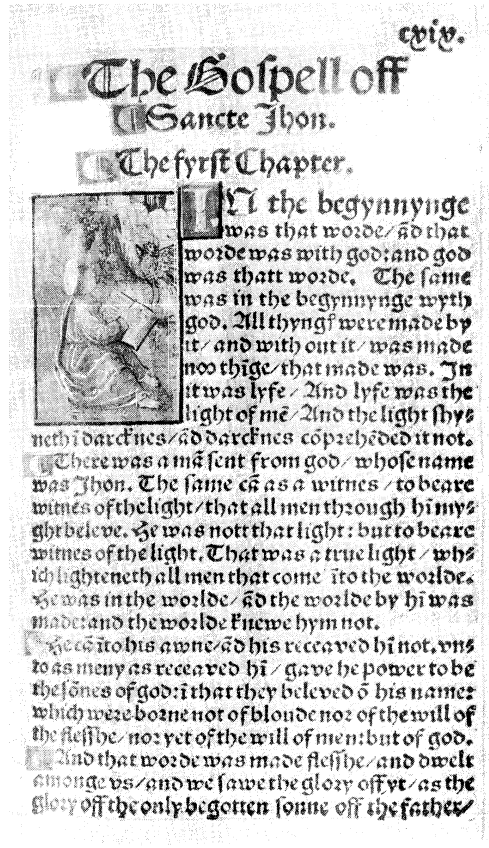
The Great Bible. In an injunction of 1538, Henry VIII commanded the clergy to install in a convenient place in every parish church, "one book of the whole Bible of the largest volume in English." The order seems to refer to an anticipated revision of the Matthew Bible. The first edition was printed in Paris and appeared in London in April 1539 in 2,500 copies. The huge page size earned it the sobriquet the Great Bible. It was received with immediate and wholehearted enthusiasm.

Henry VIII's support of the Great Bible

The first printing was exhausted within a short while, and it went through six subsequent editions between 1540 and 1541. "Editions" is preferred to "impressions" here since the six successive issues were not identical.

The Geneva Bible. The brief efflorescence of the Protestant movement during the short reign of Edward VI

By courtesy of the Baptist College, Bristol, England



cxiv.

The Gospell off Sancte Jhon.

The fyrſt Chapter.

IN the begynnynge was that worde/ & that worde was with god: and god was thatt worde. The ſame was in the begynnynge wyth god. All thyngſ were made by it/ and with out it/ was made noo thīge/ that made was. In it was lyfe/ And lyfe was the light of mē/ And the light ſhyneth i darcknes/ & darcknes cōprehēded it not.

There was a mā ſent from god/ whoſe name was Jhon. The ſame cā as a witnes/ to beare witnes of the light/ that all men thrōugh hī myght believe. He was nott that light: but to beare witnes of the light. That was a true light/ whych lightneth all men that come into the worlde. He was in the worlde/ & the worlde by hī was made: and the worlde knewe hym not.

He cā to his awne/ & his receaved hī not. Vnto as many as receaved hī/ gave he power to be the ſōnes of god: i that they believed ō his name: which were borne not of blonde nor of the will of the fleſſhe/ nor yet of the will of man: but of god.

And that worde was made fleſſhe/ and dwelt amonge vs/ and we ſawe the glory off yt/ as the glory off the only begotten ſonne off the father/

The opening page of chapter 1 of the Gospel According to John from Tyndale's Bible, 1525–26. In the library of the Baptist College, Bristol, England.

(1547–53) saw the reissue of the Scriptures, but no fresh attempts at revision. The repressive rule of Edward's successor, Mary, a Roman Catholic, put an end to the printing of Bibles in England for several years. Their public reading was proscribed and their presence in the churches discontinued.

The persecutions of Protestants caused the focus of English biblical scholarship to be shifted abroad where it flourished in greater freedom. A colony of Protestant exiles, led by Coverdale and John Knox (the Scottish Reformer), and under the influence of John Calvin, published the New Testament in 1557.

The editors of the Geneva Bible (or "Breeches Bible," so-named because of its rendering of the first garments made for Adam and Eve in chapter three, verse seven of Genesis)—published in 1560—may almost certainly be identified as William Whittingham, the brother-in-law of Calvin's wife, and his assistants Anthony Gilby and Thomas Sampson. The Geneva Bible was not printed in England until 1576, but it was allowed to be imported without hindrance. The accession of Elizabeth in 1558 put an end to the persecutions and the Great Bible was soon reinstated in the churches. The Geneva Bible, however, gained instantaneous and lasting popularity over against its rival, the Great Bible. Its technical innovations contributed not a little to its becoming for a long time the family Bible of England, which, next to Tyndale, exercised the greatest influence upon the King James Version.

The Bishops' Bible. The failure of the Great Bible to win popular acceptance against the obvious superiority of its Geneva rival and the objectionable partisan flavour of the latter's marginal annotations made a new revision a necessity. By about 1563–64 Archbishop Matthew Parker of Canterbury had determined upon its execution and the work was apportioned among many scholars, most of them bishops, from which the popular name was derived.

The Bishops' Bible came off the press in 1568 as a handsome folio volume, the most impressive of all 16th-century English Bibles in respect of the quality of paper, typography, and illustrations. A portrait of the Queen adorned the engraved title page, but it contained no dedication. For some reason Queen Elizabeth never officially authorized the work, but sanction for its public use came from the Convocation (church synod or assembly) of 1571 and it thereby became in effect the second authorized version.

Need for a Roman Catholic Version

The Douai–Reims Bible. The Roman Catholics addressed themselves affirmatively to the same problem faced by the Anglican Church: a Bible in the vernacular. The initiator of the first such attempt was Cardinal Allen of Reims (in France), although the burden of the work fell to Gregory Martin, professor of Hebrew at Douai. The New Testament appeared in 1582, but the Old Testament, delayed by lack of funds, did not appear until 1609, when it was finally published at Douai under the editorship of Thomas Worthington. In the intervening period it had been brought into line with the new text of the Vulgate authorized by Clement VIII in 1592.

The King James (Authorized) Version. Because of changing conditions, another official revision of the Protestant Bible in English was needed. The reign of Queen Elizabeth had succeeded in imposing a high degree of uniformity upon the church. The failure of the Bishops' Bible to supplant its Geneva rival made for a discordant note in the quest for unity.

A conference of churchmen in 1604 became noteworthy for its request that the English Bible be revised because existing translations "were corrupt and not answerable to the truth of the original." King James I was quick to appreciate the broader value of the proposal and at once made the project his own.

By June 30, 1604, King James had approved a list of 54 revisers, although extant records show that 47 scholars actually participated. They were organized into six companies, two each working separately at Westminster, Oxford, and Cambridge on sections of the Bible assigned to them. It was finally published in 1611.

Significance of the King James Version

Not since the Septuagint had a translation of the Bible been undertaken under royal sponsorship as a cooperative venture on so grandiose a scale. An elaborate set of rules was contrived to curb individual proclivities and to ensure its scholarly and nonpartisan character. In contrast to earlier practice, the new version was to preserve vulgarly used forms of proper names in keeping with its aim to make the Scriptures popular and familiar.

The impact of Jewish sources upon the King James Version is one of its noteworthy features. The wealth of scholarly tools available to the translators made their final choice of rendering an exercise in originality and independent judgment. For this reason, the new version was more faithful to the original languages of the Bible and more scholarly than any of its predecessors. The impact of the Hebrew upon the revisers was so pronounced that they seem to have made a conscious effort to imitate its rhythm and style in the Old Testament. The English of the New Testament actually turned out to be superior to its Greek original.

Two editions were actually printed in 1611, later distinguished as the "He" and "She" Bibles because of the variant reading "he" and "she" in the final clause of chapter 3, verse 15 of Ruth: "and he went into the city." Both printings contained errors. Some errors in subsequent editions have become famous: The so-called Wicked Bible (1631) derives from the omission of "not" in chapter 20 verse 14 of Exodus, "Thou shalt commit adultery," for which the printers were fined £300; the "Vinegar Bible" (1717) stems from a misprinting of "vineyard" in the heading of Luke, chapter 20.

The English Revised Version. The remarkable and total victory of the King James Version could not entirely obscure those inherent weaknesses that were independent of its typographical errors. The manner of its execution had resulted in a certain unequalness and lack of consistency. The translators' understanding of the Hebrew tense system was often limited so that their version contains inaccurate and infelicitous renderings. In particular, the Greek text of the New Testament, which they used as their base, was a poor one. The great early Greek codices were not then known or available, and Hellenistic papyri, which were to shed light on the common Greek dialect, had not yet been discovered.

A committee established by the Convocation of Canterbury in February 1870 reported favourably three months later on the idea of revising the King James Version: two companies were formed, one each for the Old and New Testaments. A novel development was the inclusion of scholars representative of the major Christian denominations, except the Roman Catholics (who declined the invitation to participate). Another innovation was the formation of parallel companies in the United States to whom the work of the English scholars was submitted and who, in turn, sent back their reactions. The instructions to the committees made clear that only a revision and not a new translation was contemplated.

Cooperation in the publication of the Revised Version

The New Testament was published in England on May 17, 1881, and three days later in the United States, after 11 years of labour. Over 30,000 changes were made, of which more than 5,000 represent differences in the Greek text from that used as the basis of the King James Version. Most of the others were made in the interests of consistency or modernization.

The publication of the Old Testament in 1885 stirred far less excitement, partly because it was less well known than the New Testament and partly because fewer changes were involved. The poetical and prophetical books, especially Job, Ecclesiastes, and Isaiah, benefitted greatly.

The revision of the Apocrypha, not originally contemplated, came to be included only because of copyright arrangements made with the university presses of Oxford and Cambridge and was first published in 1895.

The American Standard Version. According to the original agreement, the preferred readings and renderings of the American revisers, which their British counterparts had declined to accept, were published in an appendix to the Revised Version. In 1900 the American edition of the New Testament, which incorporated the American scholars' preferences into the body of the text, was produced. A year later the Old Testament was added, but not the Apocrypha. The alterations covered a large number of

obsolete words and expressions and replaced Anglicisms by the diction then in vogue in the United States.

The Revised Standard Version. The American Standard Version had been an expression of sensitivity to the needs of the American public. At the same time, several individual and unofficial translations into modern speech made from 1885 on had gained popularity, their appeal reinforced by the discovery that the Greek of the New Testament used the common nonliterary variety of the language spoken throughout the Roman Empire when Christianity was in its formative stage. The notion that a nonliterary modern rendering of the New Testament best expressed the form and spirit of the original was hard to refute. This, plus a new maturity of classical, Hebraic, and theological scholarship in the United States, led to a desire to produce a native American version of the English Bible.

In 1928 the copyright of the American Standard Version was acquired by the International Council of Religious Education and thereby passed into the ownership of churches representing 40 major denominations in the United States and Canada. A two-year study by a special committee recommended a thorough revision, and in 1937 the council gave its authorization to the proposal. Not until 1946, however, did the revision of the New Testament appear in print, and another six years elapsed before the complete Revised Standard Version (RSV) was published, the work of 32 scholars, one of them Jewish, drawn from the faculties of 20 universities and theological seminaries. A decision to translate the Apocrypha was not made until 1952 and the revision appeared in 1957. Insofar as the RSV was the first to make use of the Dead Sea Scroll of Isaiah, it was revolutionary.

Modernization in the Revised Standard Version

The Revised Standard Version was essentially not a new translation into modern speech, but a revision. It did engage in a good deal of modernization, however. It dispensed with archaic pronouns, retaining "thou" only for the Deity. But its basic conservatism was displayed in the retention of forms or expressions in passages that have special devotional or literary associations even where this practice makes for inconsistency. The primary aim was to produce a version for use in private and public worship.

Jewish versions. Though Jews in English-speaking lands generally utilized the King James Version and the Revised Version, the English versions have presented great difficulties. They contain departures from the traditional Hebrew text; they sometimes embody Christological interpretations; the headings were often doctrinally objectionable and the renderings in the legal portions of the Pentateuch frequently diverged from traditional Jewish exegesis. In addition, where the meaning of the original was obscure, Jewish readers preferred to use the well-known medieval Jewish commentators. Finally, the order of the Jewish canon differs from Christian practice and the liturgical needs of Jews make a version that does not mark the scriptural readings for Sabbaths and festivals inconvenient.

Until 1917 all Jewish translations were the efforts of individuals. Planned in 1892, the project of the Jewish Publication Society of America was the first translation for which a group representing Jewish learning among English-speaking Jews assumed joint responsibility.

This version essentially retained the Elizabethan diction. It stuck unswervingly to the received Hebrew text that it interpreted in accordance with Jewish tradition and the best scholarship of the day. For over half a century it remained authoritative, even though it laid no claim to any official ecclesiastical sanction.

With an increasingly felt need for modernization, a committee of translators was established composed of three professional biblical and Semitic scholars and three rabbis. It began its work in 1955 and the Pentateuch was issued in 1962. The Song of Songs, Ruth, Lamentations, Ecclesiastes, Esther, and Jonah, all in a single volume for the convenience of synagogue use, followed in 1969; and Isaiah and Psalms appeared in 1973. A second committee had been set up in 1955 to work separately on the rest of the Hagiographa (Ketuvim).

The New English Bible. The idea of a completely new translation into British English was first broached in 1946. Under a joint committee, representative of the major Protestant churches of the British Isles, with Roman Catholics appointed as observers, the New Testament was published in 1961 and a second edition appeared in 1970. The Old Testament and Apocrypha were also published in 1970.

Success of the New English Bible

The New English Bible proved to be an instant commercial success, selling at a rate of 33,000 copies a week in 1970. The translation differed from the English mainstream Bible in that it was not a revision but a completely fresh version from the original tongues. It abandoned the tradition of "biblical English" and, except for the retention of "thou" and "thy" in addressing God, freed itself of all archaisms. It endeavoured to render the original into the idiom of contemporary English and to avoid ephemeral modernisms.

Catholic versions. With the exception of a version by Irish-American archbishop Francis Patrick Kenrick (1849–60), all translations up to the 20th century were merely versions of the Douai–Reims Bible. A celebrated translation was that of Ronald Knox (New Testament, 1945; Old Testament, 1949; complete edition with Old Testament revised, 1955).

The most significant development in modern Catholic translations was initiated by the Confraternity of Christian Doctrine in 1936. A New Testament version of the Latin Clementine Vulgate (1941), intended as a revision, in effect was a new translation into clear and simple English. The Old Testament revision remained unfinished, the work having been interrupted by a decision inspired by the Pontifical Biblical Commission in 1943 to encourage modern vernacular translations from the original languages instead of from the Latin Vulgate. Accordingly, both the Old and New Testaments were respectively retranslated into modern English from the Hebrew and Greek originals. The resultant Confraternity Version (1952–61) was later issued as the New American Bible (1970). Another modern version, more colloquial, is the Jerusalem Bible (1966), translated from the French Catholic Bible de Jérusalem (one-volume edition, 1961).

Later and modern versions: continental. *Dutch versions.* Until the Reformation, Dutch Bible translations were largely free adaptations, paraphrases, or rhymed verse renderings of single books or parts thereof. A popular religious revival at the end of the 12th century accelerated the demand for the vernacular Scriptures, and one of the earliest extant examples is the Liège manuscript (*c.* 1270) translation of the *Diatessaron* (a composite rendering of the four Gospels) by Tatian, a 2nd century Syrian Christian heretical scholar; it is believed to derive from a lost Old Latin original. Best known of all the rhymed versions is the *Rijmbijbel* of Jacob van Maerlant (1271) based on Peter Comestar's *Historia scholastica.* Despite the poor quality of Johan Schutken's translation of the New Testament and Psalms (1384), it became the most widely used of medieval Dutch versions.

Early vernacular versions

With the Reformation came a renewed interest in the study of the Scriptures. Luther's Bible (see *German versions,* below) was repeatedly rendered into Dutch, the most important version being that of Jacob van Liesveldt (1526). It was mainly to counter the popularity of this edition that Roman Catholics produced their own Dutch Bible, executed by Nicolaas van Winghe (Louvain, 1548). A revision printed by Jan Moerentorf (Moretus, 1599) became the standard version until it was superseded by that of the Peter Canisius Association (1929–39), now in general use. A fresh translation of the New Testament in modern Dutch appeared in 1961.

French versions. The deep conflicts that characterized the history of Christianity in France made it difficult for one authoritative version to emerge.

The first complete Bible was produced in the 13th century at the University of Paris and toward the end of that century Guyart des Moulins executed his *Bible Historiale.* Both works served as the basis of future redactions of which the Bible printed in Paris (date given variously as 1487, 1496, 1498) by order of King Charles VIII, is a good example.

The real history of the French Bible began in Paris, in 1523, with the publication of the New Testament, almost certainly the work of the Reformer Jacques Lefèvre

d'Étaples (Faber Stapulensis). The Old Testament appeared in Antwerp in 1528 and the two together in 1530 as the Antwerp Bible. The first true Protestant version came out in Serrières, near Neuchâtel, five years later, the work of Pierre Robert, called Olivétan. This version was frequently revised throughout the 16th century, the most celebrated editions being Calvin's of 1546 and that of Robert Estienne (Stephanus) of 1553. The Roman Catholics produced a new version, the Louvain Bible of 1550, based on both Lefèvre and Olivétan. Modernizations of Olivétan appeared in succeeding centuries. The most important French version of the 20th century is the Jerusalem Bible prepared by professors at the Dominican École Biblique de Jérusalem (Paris, 1949–54, complete, 1956).

Gothic and pre-Reformation Bibles

German versions. The early Old Testament in Gothic has already been described. The New Testament remains are far more extensive and are preserved mainly in the Codex Argenteus (*c.* 525) and Codex Gissensis. The translation, essentially based on a Byzantine text, is exceedingly literal and not homogeneous. It is difficult to determine the degree of contamination that the original Gospels translation of Ulfilas had undergone by the time it appeared in these codices.

Nothing is known of the vernacular Scriptures in Germany prior to the 8th century when an idiomatic translation of Matthew from Latin into the Bavarian dialect was made. From Fulda (in Germany) *c.* 830 came a more literal East Franconian German translation of the Gospel story. In the same period was produced the *Heliand* ("Saviour"), a versified version of the Gospels. Such poetic renderings cannot, strictly speaking, be regarded as translations. There is evidence, however, for the existence of German Psalters from the 9th century on. By the 13th century, the different sects and movements that characterized the religious situation in Germany had stimulated a demand for popular Bible reading. Since all the early printed Bibles derived from a single family of late 14th-century manuscripts, German translations must have gained wide popularity. Another impetus towards the use of the German Scriptures in this period can be traced to mystics of the Upper Rhine. A complete New Testament, the Augsburg Bible, can be dated to 1350, and another from Bohemia, Codex Teplensis (*c.* 1400), has also survived.

The Wenzel Bible, an Old Testament made between 1389 and 1400, is said to have been ordered by King Wenceslas, and large numbers of 15th-century manuscripts have been preserved.

The first printed Bible (the Mentel Bible) appeared at Strassburg no later than 1466 and ran through 18 editions before 1522. Despite some evidence that ecclesiastical authority did not entirely look with favour upon this vernacular development, the printed Bible appeared in Germany earlier, and in more editions and in greater quantity than anywhere else.

A new era opened up with the work of Martin Luther, to whom a translation from the original languages was a necessary and logical conclusion of his doctrine of justification by faith—to which the Scriptures provided the only true key. His New Testament (Wittenberg, 1522) was made from the second edition of Erasmus' Greek Testament. The Old Testament followed in successive parts, based on the Brescia Hebrew Bible (1494). Luther's knowledge of Hebrew and Aramaic was limited, but his rendering shows much influence of Rashi, the great 11th–12th-century French rabbinical scholar and commentator, through the use of the notes of Nicholas of Lyra. The complete Lutheran Bible emerged from the press in 1534. Luther was constantly revising his work with the assistance of other scholars, and between 1534 and his death in 1546, 11 editions were printed, the last posthumously. His Bible truly fulfilled Luther's objective of serving the needs of the common man, and it, in turn, formed the basis of the first translations in those lands to which Lutheranism spread. It proved to be a landmark in German prose literature and contributed greatly to the development of the modern language.

Influence of Luther's Bible

The phenomenal success of Luther's Bible and the failure of attempts to repress it led to the creation of German Catholic versions, largely adaptations of Luther. Hieronymus Emser's edition simply brought the latter into line with the Vulgate. Johann Dietenberger issued a revision of Emser (Mainz, 1534) and used Luther's Old Testament in conjunction with an Anabaptist (radical Protestant group) version and the Zürich (Switzerland) version of 1529. It became the standard Catholic version. Of the 20th-century translations, the Grünewald Bible, which reached a seventh edition in 1956, is one of the most noteworthy.

Yiddish versions

German glosses in Hebrew script attached to Hebrew Bibles in the 12th and 13th centuries constitute the earliest Jewish attempts to render the Scriptures into that German dialect current among the Jews of middle Europe, the dialect that developed into Judeo-German, or Yiddish. The first translation proper has been partially preserved in a manuscript from Mantua dated 1421. The earliest printed translation is that of the Scriptural dictionaries prepared by a baptized Jew, Michael Adam (Constance, 1543–44; Basel, 1583, 1607). The version of Jacob ben Isaac Ashkenazi of Janów, known as the *Tz'enah u-Re'na* (Lublin, 1616), became one of the most popular and widely diffused works of its kind.

The first Jewish translation into pure High German, though in Hebrew characters (1780–83), made by Moses Mendelssohn, opened a new epoch in German-Jewish life. The first Jewish rendering of the entire Hebrew Bible in German characters was made by Gotthold Salomon (Altona, 1837). An attempt to preserve the quality of the Hebrew style in German garb was the joint translation of two Jewish religious philosophers, Martin Buber and Franz Rosenzweig (15 vol., Berlin, 1925–37; revised ed. Cologne, 4 vol., 1954–62).

Greek versions. A 13th-century manuscript of Jonah by a Jew is the earliest known post-Hellenistic Greek biblical work. A rendering of Psalms was published by a Cretan monk Agapiou in 1563. A version in Hebrew characters (a large part of the Old Testament) appeared in the Constantinople Polyglot Pentateuch in 1547.

The first New Testament was done by Maximus of Gallipoli in 1638 (at Geneva?). The British and Foreign Bible Society published the Old Testament in 1840 (London) and the New Testament in 1848 (Athens). Between 1900 and 1924, however, the use of a modern Greek version was prohibited. The theological faculty of the University of Athens is now preparing a fresh translation.

Hungarian versions. The spread of Lutheranism in the Reformation period gave rise to several vernacular versions. János Sylvester (Erdősi) produced the first New Testament made from the Greek (Sárvár, 1541). The Turkish occupation of much of Hungary and the measures of the Counter-Reformation arrested further printing of the vernacular Bible, except in the semi-independent principality of Transylvania. The first complete Hungarian Bible, issued at Vizsoly in 1590, became the Protestant Church Bible.

In the 20th century, a new standard edition for Protestants was published, the New Testament appearing in 1956 and the Old Testament (Genesis to Job) in 1951 and following. A new modernized Catholic edition of the New Testament from the Greek appeared in Rome in 1957.

Italian versions. The vernacular Scriptures made a relatively late appearance in Italy. Existing manuscripts of individual books derive from the 13th century and mainly consist of the Gospels and the Psalms.

These medieval versions were never made from the original languages. They were influenced by French and Provençal renderings as well as by the form of the Latin Vulgate current in the 12th and 13th centuries in southern France. There is evidence for a Jewish translation made directly from the Hebrew as early as the 13th century.

The first printed Italian Bible appeared in Venice in 1471, translated from the Latin Vulgate by Niccolò Malermi. In 1559 Paul IV proscribed all printing and reading of the vernacular Scriptures except by permission of the church. This move, reaffirmed by Pius IV in 1564, effectively stopped further Catholic translation work for the next 200 years.

The first Protestant Bible (Geneva, 1607, revised 1641) was the work of Giovanni Diodati, a Hebrew and Greek scholar. Frequently reprinted, it became the standard Prot-

estant version until the 20th century. Catholic activity was renewed after a modification of the ban by Pope Benedict XIV in 1757. A complete Bible in translation made directly from the Hebrew and Greek has been in progress under the sponsorship of the Pontifical Biblical Institute since the 1920s.

Portuguese versions. The first Portuguese New Testament (Amsterdam), the work of João Ferreira d'Almeida, did not appear until 1681. The first complete Bible (2 vol., 1748–53) was printed in Batavia (in Holland). Not until late in the 18th century did the first locally published vernacular Scriptures appear in Portugal. A revision of d'Almeida was issued in Rio de Janeiro (in Brazil), the New Testament in 1910 and the complete Bible in 1914 and 1926; an authorized edition in modernized orthography was published by the Bible Society of Brazil (New Testament, 1951; Old Testament, 1958). A new translation of the New Testament from Greek by José Falcão came out in Lisbon (1956–65).

Scandinavian versions. In pre-Reformation times, only partial translations were made, all on the basis of the Latin Vulgate and all somewhat free. The earliest and most celebrated is that of Genesis–Kings in the so-called *Stjórn* ("Guidance"; *i.e.,* of God) manuscript in the Old Norwegian language, probably to be dated about 1300. Swedish versions of the Pentateuch and of Acts have survived from the 14th century and a manuscript of Joshua–Judges by Nicholaus Ragnvaldi of Vadstena from *c.* 1500. The oldest Danish version covering Genesis–Kings derives from 1470.

Danish, Norwegian, Icelandic, and Swedish versions

Within two years of publication, Luther's New Testament had already influenced a Danish translation made at the request of the exiled king Christian II by Christiern Vinter and Hans Mikkelsen (Wittenberg, 1524). In 1550 Denmark received a complete Bible commissioned by royal command (the Christian III Bible, Copenhagen). A revision appeared in 1589 (the Frederick II Bible) and another in 1633 (the Christian IV Bible).

A rendering by Hans Paulsen Resen (1605–07) was distinguished by its accuracy and learning and was the first made directly from Hebrew and Greek, but its style was not felicitous and a revision was undertaken by Hans Svane (1647). Nearly 200 years later (1819), a combination of the Svaning Old Testament and the Resen–Svane New Testament was published. In 1931 a royal commission produced a new translation of the Old Testament with the New Testament following in 1948 and the Apocrypha in 1957.

The separation of Norway from Denmark in 1814 stimulated the revival of literature in the native language. The Old Testament of 1842–87 (revised, 1891) and New Testament of 1870–1904 were still intelligible to Danish readers, but the version of E. Blix (New Testament, 1889; complete Bible, 1921) is in New Norwegian. A revised Bible in this standardized form of the language, executed by R. Indrebö, was published by the Norwegian Bible Society in 1938.

The first Icelandic New Testament was the work of Oddur Gottskálksson (Roskilde, Denmark, 1540), based on the Latin Vulgate and Luther. It was not until 1584 that the complete Icelandic Scriptures were printed (at Hólar), mainly executed by Gudbrandur Thorláksson. It was very successful and became the Church Bible until displaced by the revision of Thorlákur Skúlason (1627–55), based apparently on Resen's Danish translation. In 1827 the Icelandic Bible Society published a new New Testament and a complete Bible in 1841 (Videyjar; 1859, Reykjavík), revised and reprinted at Oxford in 1866. A completely new edition (Reykjavík, 1912) became the official Church Bible.

Soon after Sweden achieved independence from Denmark in the early 16th century, it acquired its own version of the New Testament published by the royal press (Stockholm, 1526). Luther's New Testament of 1522 served as its foundation, but the Latin Vulgate and Erasmus' Greek were also consulted. The first official complete Bible and the first such in any Scandinavian country was the Gustav Vasa Bible (Uppsala; 1541), named for the Swedish king under whose reign it was printed. It utilized earlier Swedish translations as well as Luther's. A corrected version (the Gustavus Adolphus Bible, named for the reigning Swedish king) was issued in 1618, and another with minor alterations by Eric Benzelius in 1703. The altered Bible was called the Charles XII Bible, because it was printed during the reign of Charles XII. In 1917 the church diet of the Lutheran Church published a completely fresh translation directly from modern critical editions of the Hebrew and Greek originals and it received the authorization of Gustaf V to become the Swedish Church Bible.

South, East, and West Slavic versions

Slavic versions. The earliest Old Church Slavonic translations are connected with the arrival of the brothers Cyril and Methodius in Moravia in 863, and resulted from the desire to provide vernacular renderings of those parts of the Bible used liturgically. The oldest manuscripts derive from the 11th and 12th centuries. The earliest complete Bible manuscript, dated 1499, was used for the first printed edition (Ostrog, 1581). This was revised in Moscow in 1633 and again in 1712. The standard Slavonic edition is the St. Petersburg revision of 1751, known as the Bible of Elizabeth.

The printing of parts of the Bulgarian Bible did not begin until the mid-19th century. A fresh vernacular version of the whole Bible was published at Sofia in 1925, having been commissioned by the Synod of the Bulgarian Orthodox Church.

The Serbian and Croatian literary languages are identical; they differ only in the alphabet they use. To further the dissemination of Protestantism among the southern Slavs, Count Jan Ungnad set up a press in 1560 at Urach that issued a translation of the New Testament, in both Glagolitic (1562–63) and Cyrillic (1563) characters. The efforts of the Serbian leader Vuk Karadžić to establish the Serbo-Croatian vernacular on a literary basis resulted in a new translation of the New Testament (Vienna, 1847) that went through many revisions.

The spread of the Lutheran Reformation to the Slovene-speaking provinces of Austria stimulated the need for vernacular translations. The first complete Slovene Bible, translated from the original languages but with close reference to Luther's German, was made by Jurij Dalmatin (Wittenberg, 1584). Not until two centuries later did a Slovene Roman Catholic version, rendered from the Latin Vulgate, appear (Laibach, 1784–1802).

Between the 9th and 17th centuries the literary and ecclesiastical language of Russia was Old Slavonic. A vernacular Scriptures was thus late in developing. An incomplete translation into the Belorussian dialect was prepared by Franciscus Skorina (Prague, 1517–19) from the Latin Vulgate and Slavonic and Bohemian versions, but not until 1821 did the first New Testament appear in Russian, an official version printed together with the Slavonic. With the more liberal rule of Alexander II, the Holy Synod sponsored a fresh version of the Gospels in 1860. The Old Testament was issued at St. Petersburg in 1875. A Jewish rendering was undertaken by Leon Mandelstamm, who published the Pentateuch in 1862 (2nd ed., 1871) and the Psalter in 1864. Prohibited in Russia, it was first printed in Berlin. A complete Bible was published in Washington in 1952.

No manuscript in the Czech vernacular translation is known to predate the 14th century, but at least 50 complete or fragmentary Bibles have survived from the 15th. The first complete Bible was published in Prague in 1488 in a text based on earlier, unknown translations connected with the heretical Hussite movement. The most important production of the century, however, was that associated principally with Jan Blahoslav. Based on the original languages, it appeared at Kralice in six volumes (1579–93). The Kralice Bible is regarded as the finest extant specimen of classical Czech and became the standard Protestant version.

Closely allied to the Czech language, but not identical with it, Slovakian became a literary language only in the 18th century. A Roman Catholic Bible made from the Latin Vulgate by Jiří Palkovič was printed in the Gothic script (2 vol. Gran, 1829, 1832) and another, associated with Richard Osvald, appeared at Trnava in 1928. A Protestant New Testament version of Josef Rohaček was

published at Budapest in 1913 and his completed Bible at Prague in 1936. A new Slovakian version by Stefan Zlatoš and Anton Jan Surjanský was issued at Trnava in 1946.

A manuscript of a late 14th-century Psalter is the earliest extant example of the Polish vernacular Scriptures, and several books of the Old Testament have survived from the translation made from the Czech version for Queen Sofia (Sârospatak Bible, 1455). Otherwise, post-Reformation Poland supplied the stimulus for biblical scholarship. The New Testament first appeared in a two-volume rendering from the Greek by the Lutheran Jan Seklucjan (Königsberg, 1553). The "Brest Bible" of 1563, sponsored by Prince Radziwiłł, was a Protestant production made from the original languages. A version of this edition for the use of Socinians (Unitarians) was prepared by the Hebraist Szymon Budny (Nieswicz, 1570–82), and another revision, primarily executed by Daniel Mikołajewski and Jan Turnowski (the "Danzig Bible") in 1632, became the official version of all Evangelical churches in Poland. This edition was burnt by the Catholics and had to be subsequently printed in Germany. The standard Roman Catholic version (1593, 1599) was prepared by Jakób Wujek whose work, revised by the Jesuits, received the approval of the Synod of Piotrkow in 1607. A revised edition was put out in 1935.

Spanish versions. The history of the Spanish Scriptures is unusual in that many of the translations were based, not on the Latin Vulgate, but on the Hebrew, a phenomenon that is to be attributed to the unusual role played by Jews in the vernacular movement.

Nothing is known from earlier than the 13th century when James I of Aragon in 1233 proscribed the possession of the Bible in "romance" (the Spanish vernacular) and ordered such to be burnt. Several partial Old Testament translations by Jews as well as a New Testament from a Visigoth Latin text are known from this century. In 1417 the whole Bible was translated into Valencian Catalan, but the entire edition was destroyed by the Inquisition.

Between 1479 and 1504, royal enactments outlawed the vernacular Bible in Castile, Leon, and Aragon, and the expulsion of the Jews from Spain in 1492 transferred the centre of Spanish translation activity to other lands. In 1557, the first printed *Index of Forbidden Books* of the Spanish Inquisition prohibited the "Bible in Castilian romance or any other vulgar tongue," a ban that was repeated in 1559 and remained in force until the 18th century. In 1916 the Hispano-Americana New Testament appeared in Madrid as an attempt to achieve a common translation for the entire Spanish-speaking world. The first Roman Catholic vernacular Bible from the original languages was made under the direction of the Pontifical University of Salamanca (Madrid, 1944, 9th ed. 1959).

Swiss versions. Four parts of Luther's version were reprinted in the Swyzerdeutsch dialect in Zürich in 1524–25. The Prophets and Apocrypha appeared in 1529. A year later, the first Swiss Bible was issued with the Prophets and Apocrypha independently translated. The Swiss Bible underwent frequent revision between 1660 and 1882. A fresh translation from the original languages was made between 1907 and 1931.

Non-European versions. Translations of parts of the Bible are known to have existed in only seven Asian and four African languages before the 15th century. In the 17th century Dutch merchants began to interest themselves in the missionary enterprise among non-Europeans. A pioneer was Albert Cornelius Ruyl, who is credited with having translated Matthew into High Malay in 1629, with Mark following later. Jan van Hasel translated the two other Gospels in 1646 and added Psalms and Acts in 1652. Other traders began translations into Formosan Chinese (1661) and Sinhalese (1739).

A complete printed Japanese New Testament reputedly existed in Miyako in 1613, the work of Jesuits. The first known printed New Testament in Asia appeared in 1715 in the Tamil language done by Bartholomäus Ziegenbalg, a Lutheran missionary. A complete Bible followed in 1727. Six years later the first Bible in High Malay came out.

The distinction of having produced the first New Testament in any language of the Americas belongs to John Eliot, a Puritan missionary, who made it accessible to the Massachusetts Indians in 1661. Two years later he brought out the Massachusetts Indian Bible, the first Bible to be printed on the American continent.

By 1800 the number of non-European versions did not exceed 13 Asian, four African, three American, and one Oceanian. With the founding of missionary societies after 1800, however, new translations were viewed as essential to the evangelical effort. First came renderings in those languages that already possessed a written literature. A group at Serāmpore (in India) headed by William Carey, a Baptist missionary, produced 28 versions in Indian languages. Robert Morrison, the first Protestant missionary to China, translated the New Testament into Chinese in 1814 and completed the Bible by 1823. Adoniram Judson, an American missionary, rendered the Bible into Burmese in 1834.

With European exploration of the African continent often came the need to invent an alphabet, and in many instances the translated Scriptures constituted the first piece of written literature. In the 19th century the Bible was translated into Amharic, Malagasy, Tswana, Xosa, and Ga.

American Indian versions

In the Americas, James Evans invented a syllabary for the use of Cree Indians, in whose language the Bible was available in 1862, the work of W. Mason, also a Wesleyan missionary. The New Testament appeared in Ojibwa in 1833, and the whole Bible was translated for the Dakota Indians in 1879. The Labrador Eskimos had a New Testament in 1826 and a complete Bible in 1871.

In Oceania, the New Testament was rendered into Tahitian and Javanese in 1829 and into Hawaiian and Low Malay in 1835. By 1854 the whole Bible had appeared in all but the last of these languages as well as in Rarotonga (1851).

In the 20th century the trend toward the development of non-European Bible translations was characterized by an attempt to produce "union" or "standard" versions in the common language underlying different dialects. One such is the Swahili translation (1950) that makes the Scriptures accessible to most of East Africa. Within the realm of non-European translation there has also been a movement for the updating of versions to bring them in line with the spoken language, especially through the use of native Christian scholars. The first example of this was the colloquial Japanese version of 1955.

By 1970 some part, if not the entire Bible, had been translated into more than 100 languages or dialects spoken in India and over 300 in Africa. (N.M.Sa.)

Old Testament history

History is a central element of the Old Testament. It is the subject of narration in the specifically historical books and of celebration, commemoration, and remonstration in all of the books. History in the Old Testament is not history in the modern sense; it is the story of events seen as revealing the divine presence and power. Nevertheless, it is the account of an actual people in an actual geographical area at certain specified historical times and in contact with other particular peoples and empires known from other sources. Hence, far more than with other great religious scriptures, a knowledge of the historical background is conducive, if not essential, to an adequate understanding of a major portion of the Old Testament. Recent archaeological discoveries as well as comparative historical research and philological studies, collated with an analysis and interpretation of the Old Testament text (still the major source of information), have made possible a fuller and more reliable picture of biblical history than in previous eras. For another presentation of Old Testament history, see JUDAISM.

EARLY DEVELOPMENTS

Background and beginnings. The geographical theatre of the Old Testament is the ancient Near East, particularly the Fertile Crescent region, running from the Tigris and Euphrates rivers up to Syria and down through Palestine to the Nile Delta. In this area great civilizations and em-

pires developed and seminomadic ethnic groups, such as the Hebrews, were involved in the mixture of peoples and cultures. The exact origin of the Hebrews is not known with certainty, but the biblical tradition of their origin in a clan that migrated from Mesopotamia to Canaan (Palestine) early in the 2nd millennium BCE has analogues in what is known of the movements of other groups in that area and period. There are, moreover, obvious Mesopotamian motifs in biblical cosmogony and primeval history in the early part of the Bible, and Mesopotamian placenames are the obvious bases of some of the personal names of the clan's forebears. Canaanite influences are evident in the Hebrew alphabet, poetry, and certain mythological themes. Linguistic and other similarities with neighbouring Semitic peoples, such as the Amorites and Moabites, are also evident.

Exodus and conquest. According to biblical tradition, the clan migrated to Egypt because of a famine in the land of Canaan, were later enslaved and oppressed, and finally escaped from Egypt to the desert east of the Isthmus of Suez under a remarkable leader, Moses. The account—a proclamation, celebration, and commemoration of the event—is replete with legendary elements, but present-day scholars tend to believe that behind the legends there is a solid core of fact; namely, that Hebrew slaves who built the fortified cities of Pithom and Rameses somehow fled from Egypt, probably in the 13th century BCE, under a great leader (see also MOSES). A stele (inscribed stone pillar) of the pharaoh Merneptah of that time in which he claims to have destroyed Israel is the first known nonbiblical reference to the people by name. Whether the destruction was in the intervening desert or in Canaan (and whether a true or a false claim) is not clear. The tradition ascribes to Moses the basic features of Israel's faith: a single God, called YHWH, who cannot be represented iconically, bound in a covenant relationship with his special people Israel, to whom he has promised possession of (not, as with their forefathers, mere residence in) the land of Canaan. There is some dispute among scholars as to when such features as the Mosaic Covenant actually emerged and as to which of the traditional 12 tribes of Israel entered Canaan at the end of the period of wandering in the desert.

The work and faith of Moses

The biblical account of the conquest of Canaan is again, from the point of view of historical scholarship, full of legendary elements that express and commemorate the elation and wonder of the Israelites at these events. The conquest of Canaan—according to tradition, a united national undertaking led by Moses' successor, Joshua—was a rather drawn out and complicated matter. Archaeological evidence tends to refute some of the elements of the biblical account, confirm others, and leave some open. According to the tradition, after an initial unified assault that broke the main Canaanite resistance, the tribes engaged in individual mopping-up operations. Scholars believe that Hebrews who had remained resident in Canaan joined forces with the invading tribes, that the other Canaanite groups continued to exist, and that many of them later were assimilated by the Israelites.

The tribal league. The invading tribes who became masters of parts of Canaan, although effectively autonomous and lacking a central authority, considered themselves a league of 12 tribes, although the number 12 seems to have been more canonical or symbolical than historical. Some scholars, on the analogy of Greek leagues of six or 12 tribes or cities with a common sanctuary, speak of the Israelite league as an "amphictyony," the Greek term for such an association; but others hold that there is no evidence that the Israelites maintained a common shrine.

The period of the judges

Certain leaders arose, called judges, who might rule over several tribes, but this arrangement was usually of a local or regional character. However, the stories about such "judges" (who were frequently local champions or heroes, such as Gideon, Jephthah, and Samson), though encrusted with legend, are now thought to be substantially historical. The period from about 1200 to 1020 is called, after them, the period of the judges. It was during this period that Israelite assimilation of Canaanite cultural and religious ideas and practices began to be an acute problem and that other invaders and settlers became a threat to the security of Israel. One of the chief threats was from the Philistines, an Aegean people who settled (*c.* 12th century BCE) on the coast of what later came to be called, after them, Palestine. Organized in a league of five cities, or principalities, the Philistines, who possessed a monopoly of iron implements and weapons, pushed eastward into the Canaanite hinterland and subjugated Israelite tribes, such as the Judahites and Danites, that stood in their way, even capturing the sacred ark from the famous shrine of Shiloh when it was brought into battle against them. The Philistine threat was probably the decisive factor in the emergence of a permanent political (but at first primarily military) union of all Israel under a king—what historians call the united monarchy (or kingdom).

The united monarchy. The monarchy was initiated during the career of Samuel, a prophet of great influence and authority who was also recognized as a judge and is depicted in varying biblical accounts as either favouring or not favouring the reign of a human king over Israel. In any case, he anointed Saul, a courageous military leader of the tribe of Benjamin, as king (*c.* 1020 BCE). Saul won substantial victories over the Ammonites, Philistines, and Amalekites, leading the tribes in a "holy war," and for a time the Philistine advance was stopped; but Saul and his son Jonathan were killed in a disastrous battle with the Philistines in central Palestine. His successor, David, a former aide (and also his son-in-law) who had fallen out of favour with him, at first took over (*c.* 1010) the rule of Judah in the south and then of all Israel (*c.* 1000). Through his military and administrative abilities and his political acumen, David established a centralized rule in Israel, cleared the territory of foreign invaders, and, in the absence of any aggressive foreign empire in the area, created his own petty empire over neighbouring city-states and peoples. He established his capital in Jerusalem, which until then had maintained its independence as a Canaanite city-state wedged between the territories of Saul's tribe Benjamin and David's tribe Judah, and moved the ark there from the small Israelite town in which it had been stored by the Philistines, establishing it in a tent shrine. This felicitous combination of holy ark, political reign, and central city was to be hailed and proclaimed by future ages. Under David's successor, his son Solomon (reigned *c.* 961–922), Israel became a thriving commercial power; numerous impressive buildings were erected, including the magnificent Temple (a concrete symbol of the religio-political unity of Israel); a large harem of foreign princesses was acquired, sealing relations with other states; the country was divided into 12 districts for administrative, supply, and taxation purposes. Foreign cults set up to serve the King's foreign wives and foreign traders led to charges of idolatry and apostasy by religious conservatives. In the latter years of his reign, Solomon's unpopular policies, such as oppressive forced labour, led to internal discontent and rebellion, while externally the vassal nations of Damascus (Aram) and Edom staged successful revolts against his rule. The central and northern tribes, called Israel in the restricted sense, were especially galled by the oppressive policies, and soon after Solomon's death Israel split off to become a separate kingdom. The united monarchy thus became the divided monarchy of Israel (the northern kingdom) and Judah (the southern kingdom).

The centralization of state and religion in Jerusalem

FROM THE PERIOD OF THE DIVIDED MONARCHY THROUGH THE RESTORATION

The divided monarchy: from Jeroboam I to the Assyrian conquest. Jeroboam I, the first king of the new state of Israel, made his capital first at Shechem, then at Tirzah. Recognizing the need for religious independence from Jerusalem, he set up official sanctuaries at Dan and Bethel, at the two ends of his realm, installing in them golden calves (or bulls), for which he is castigated in the anti-northern account in the First Book of the Kings. Israel engaged in conflicts with Judah and, sometimes jointly with Judah, against foreign powers. At first there was great dynastic instability in the northern kingdom, until the accession of Omri (reigned *c.* 884–*c.* 872), one of its greatest kings, who founded a dynasty that lasted through the reign of his two grandsons (to 842). Under Omri an

impressive building program was initiated at the capital, Moab was subjugated (an event confirmed in an extrabiblical source, the Moabite Stone), and amicable relations were established with Judah. The Phoenician kingdom of Tyre was made an ally through the marriage of his son Ahab to the Tyrian princess Jezebel. Ahab (reigned *c.* 874–853 BCE)—unless the episode recounted in I Kings, chapter 20 actually took place four reigns later—fought off an attempt by Damascus, heading a coalition of kings, to take over Israel. Near the end of his reign, Ahab joined with Damascus and other neighbouring states to fight off the incursions of the great Assyrian Empire in their area. Peaceful relations were cemented with Judah through the marriage of Ahab's daughter (or sister) Athaliah to Jehoram, the son of the king of Judah (not to be confused with Ahab's son, Jehoram of Israel). But the establishment of a pagan Baal temple for Jezebel and her attempt to spread her cult aroused great opposition on the part of the zealous Yahwists among the common people. There was also resentment at the despotic Oriental manner of rule that Ahab, incited by Jezebel, exercised. She and her cult were challenged by Elijah, a prophet whose fierce and righteous character and acts, as illumined by legend, are dramatically depicted in the First Book of the Kings. In the reign of Ahab's son Jehoram, Elijah's disciple Elisha inspired the slaughter of Jezebel and the whole royal family, as well as of all the worshippers of Baal, thus putting a stop to the Baalist threat. Jehu, Jehoram's general who led this massacre, became king and established a dynasty that lasted almost a century (*c.* 842–745), the longest in the history of Israel.

Jezebel and the Baal cult: Elijah and Elisha

Meanwhile, in Judah, the Baal cult introduced by Athaliah, the queen mother and effective ruler for a time, was suppressed after a revolt, led by the chief priests, in which Athaliah was killed and her grandson Joash (Jehoash) was made king. In the ensuing period, down to the final fall of the northern kingdom, Judah and Israel had varying relations of conflict and amity and were involved in the alternative expansion and loss of power in their relations with neighbouring states. Damascus was the main immediate enemy, which annexed much of Israel's territory, exercised suzerainty over the rest, and exacted a heavy tribute from Judah. Under Jeroboam II (783–741) in Israel, and Uzziah (Azariah; 783–742) in Judah, both of whom had long reigns at the same time, the two kingdoms cooperated to achieve a period of prosperity, tranquillity, and imperial sway unequalled since Solomon's reign. The threat of the rising Assyrian Empire under Tiglath-Pileser III soon reversed this situation. When a coalition of anti-Assyrian states, including Israel, marched against Judah to force its participation, the Judahite king Ahaz (*c.* 735–720) called on Assyria for protection; the result was the defeat of Israel, which suffered heavily in captives, money tribute, and lost provinces, while Judah became a vassal state of Assyria. In about 721, after an abortive revolt under King Hoshea, the rump state of Israel was annexed outright by Assyria and became an Assyrian province; its elite cadre, amounting to nearly 30,000 according to Assyrian figures, was deported to Mesopotamia and Media, and settlers were imported from other lands. Thus, the northern kingdom of Israel ceased to exist. Its decline and fall were a major theme in the prophecies of Amos, Hosea, Isaiah, and Micah.

The final period of the kingdom of Judah. Meanwhile, the southern kingdom of Judah was to have another century and a half of existence before a similar and even grimmer fate befell it. Hezekiah (reigned *c.* 715–*c.* 686), who instituted a religious reform to return worship to a pure Yahwist form, also displayed political independence, joining a coalition of Palestinian states against Assyria. But the coalition was soon defeated, and Judah—with Jerusalem besieged—bought off the Assyrians, led by Sennacherib, with tribute. In the reign of Manasseh (692–638) there was a revival of pagan rites, including astral cults in the very forecourts of the temple of YHWH, child sacrifice, and temple prostitution; hence, he is usually portrayed as the most wicked of the kings of Judah. If he had any tendencies toward independence from Assyrian domination, they apparently were suppressed by his being taken in chains to Babylon, where he was molded into proper vassal behaviour, although one edifying and probably unhistorical biblical account reports his repentance and attempt at religious reform after his return to Judah. The great religious reform took place in the reign of his grandson Josiah (640–609) during a period when the Assyrian empire was in decline and was precipitated by the discovery of the Book of the Law during the restoration of the Temple. It was proclaimed by the king to be the Law of the realm, and the people pledged obedience to it. In accordance with its admonitions, the pagan altars and idols in the Temple were removed, rural sanctuaries ("high places") all the way into Samaria were destroyed, and the Jerusalem Temple was made the sole official place of worship. (For an identification of the law book with the legal portion of Deuteronomy, see below *Old Testament literature: Deuteronomy.*) Josiah also made an attempt at political independence and expansion but was defeated and killed in a battle with the Egyptians, the new allies of the fading Assyrian Empire. During the reigns of his sons Jehoiakim (*c.* 609–598) and Zedekiah (597–586), Judah's independence was gradually extinguished by the might of the new dominant Babylonian Empire under Nebuchadrezzar. The end came in 586 with the Babylonian capture of Jerusalem and the destruction of the principal buildings, including the Temple and the fortifications. The first deportation of Judahites to Babylon, during the brief reign of Josiah's grandson Jehoiachin in 597, was followed by the great deportation of 586, which was to be a theme of lament and remembrance for millennia to come. (Numerous Jews also migrated to Egypt during this troubled time.) Exhortations and prophecies on the decline and fall of Judah are to be found in Zephaniah, Nahum, Habakkuk, and Jeremiah (who played a significant role in the events), while the conditions and meaning of the exile are proclaimed by Ezekiel and Deutero-Isaiah (chapters 40–55 of Isaiah).

Josiah's reform and the Book of the Law

The Babylonian Exile and the restoration. The Babylonian Exile (586–538) marks an epochal dividing point in Old Testament history, standing between what were subsequently to be designated the pre-exilic and post-exilic eras. The Judahite community in Babylonia was, on the whole, more Yahwist in religion than ever, following the Mosaic Law, emphasizing and redefining such distinctive elements as circumcision and the sabbath and stressing personal and congregational prayer—the beginnings of synagogal worship. It is possible that they also reached an understanding of historical events (like that taught by the great pre-exilic and exilic prophets)—as the chastening acts of a universal God acting in history through Nebuchadrezzar and other conquerors. To this period is also ascribed the beginning of the compilation of significant portions of the Old Testament and of the organizing view behind it. In any event, it was from this community that the leadership and the cadres for the resurrection of the Judahite nation and faith were to come when Cyrus the Great (labelled "the Lord's anointed" in Deutero-Isaiah) conquered Babylon and made it possible for them to return (538). A contingent of about 50,000 persons, including about 4,000 priests and 7,000 slaves, returned under Sheshbazzar, a prince of Judah.

The first great aim was the rebuilding of the Temple as the centre of worship and thus also of national existence; this was completed in 515 under the administration of Zerubbabel and became the place of uninterrupted sacrificial worship for the next 350 years. The next task was to rebuild the walls of Jerusalem, which was undertaken by Nehemiah, a Babylonian Jew and court butler who was appointed governor of Judah and arrived in 444. Nehemiah also began religious reforms, emphasizing tithing, observance of the sabbath, and the prohibition against intermarriage with "foreign" women. This reform was carried through systematically and zealously by Ezra, a priest and scribe who came from Babylon about 400 BCE, called the people together, and read them the "book of the law of Moses" to bring them back to the strict and proper observance maintained in Babylon: circumcision, sabbath observance, keeping the feasts, and, to seal it all, avoiding intermarriage. (In this presentation, modern criti-

Rebuilding of the Temple and religious reform under Nehemiah and Ezra

cal scholarship is being followed, placing Nehemiah before Ezra instead of the traditional sequence, which reverses the positions.) Haggai, Zechariah, and Malachi are the prophets of this restoration period. Ezra and Nehemiah are its narrators.

It was in this period that enmity between the Jews, or Judaeans, as they came to be called, and the Samaritans, a term applied to the inhabitants of the former northern kingdom (Israel), was exacerbated. It has been surmised that this goes back to the old political rivalry between Israel and Judah or even further back to the conflict between the tribes of Joseph and Judah. Scholars ascribe the exacerbation of enmity in the restoration period variously to the Samaritans' being excluded from participating in the rebuilding of the Temple; to Nehemiah's rebuilding of the walls of Jerusalem (regarded as a threatening act by the Samaritan authorities); or to the proscriptions of intermarriage by Ezra. The animus of the Jews against the Samaritans is frequently expressed in the biblical books dealing with the restoration (expressions perhaps engendered by later events), but the attitude of the Samaritans and a good deal else about them is not evident. At some time they became a distinct religious community, with a temple of their own on Mt. Gerizim and a Scripture that was limited solely to the Pentateuch, excluding the Prophets and Writings.
